**Pear.** The pear is native to Afghanistan. The commercially important European pear is most successful in milder regions. The better pear varieties are susceptible to bacterial fireblight (*Erwinia amylovora*) in humid regions. Blight-resistant varieties such as Kieffer and Seckel can be grown successfully in humid areas, as can the blight-susceptible Bartlett, but special precautions must be taken with the latter. Pears are important on all continents, with Italy the leading producer, the U.S. second, and China, Japan, Turkey, Argentina, Australia, and South Africa also important.

In western Europe, Williams (Bartlett), Conference, Clapp's Favorite, Bonne Louise, and Doyenne du Comice are widely grown, with Passe Crassane important in Italy and Dr. J. Guyot in France. Leading U.S. varieties are Bartlett and Anjou. In the U.S.S.R., summer varieties are grown in the north, whereas in the south Williams, Clapp, Hardy, and Bosc are grown. Bulgaria has a favourable climate, with Bosc, Williams, Clapp, and Passe Crassane important. Many of the pear trees in Europe are grown in home gardens. In China pears have

walnut  
character-  
istics

been cultivated over 2,000 years. Oriental pears are grown on trees larger than European types, but the fruit is inferior in quality with more grit cells and less aroma, but sweet and juicy. There are four groups of these Oriental pears grown in different regions.

In the U.S., Canada, and Australia, the quantity of fresh fruit used by canners amounts to about half the total commercial crop; in South Africa, canning accounts for 30 percent. In Europe, canning is unimportant. In France, about one-third the total production is made into a fermented drink called perry, in Germany half, in Switzerland about four-fifths.

**Cherry.** The sweet cherry and tart (sour) cherry are found in the milder apple regions of the world and succeed in a somewhat shorter growing season. Because sweet cherries may crack if exposed to rain during ripening, they are grown mostly in semi-arid climates. Tart cherries are grown mainly in a humid climate.

Cherries are widely grown in Europe, in fact, the U.S.S.R. leads in cherries (tart), producing almost double the U.S. crop. After the U.S., in order, are West Germany, Italy, France, Switzerland, Yugoslavia, and East Germany.

The commercial sweet cherry tree is held to six to eight metres, is more susceptible to damage resulting from excessive water at the roots than the tart cherry, is less winter hardy ( $-26^{\circ}\text{C}$ ;  $-15^{\circ}\text{F}$ ), and cannot fertilize itself. The tart cherry is four to five metres high, withstands  $-32^{\circ}\text{C}$  ( $-25^{\circ}\text{F}$ ) winter temperature and can fertilize itself. Leaves are simple and medium size; the fruit is borne largely on spurs.

Sweet, tart  
cherries

In the U.S., sweet cherry production is about 41 percent that of the tart cherry. The principal sweet cherry varieties are Bing, Lambert, Windsor, and Napoleon (Royal Ann); all but the last, which is used mostly for canning and artificial maraschino cherries, are sold chiefly in the fresh-fruit markets. Montmorency is the key tart cherry. The frozen and hot-pack preservation for pie stock, with increasing amounts used in maraschino cherries, tends to stabilize this crop for year-round marketing.

Cherries are grown on Mazzard or Mahaleb stocks, mostly the former, and there is yet to come a satisfactory dwarfing stock. Mechanical tree shaking of tart cherries on portable canvas catching frames and hauling in tanks of chilled water has greatly facilitated harvesting, improved profits to the grower, and delivered a better product to the processor. Sweet cherries must be loosened from the tree with a chemical growth regulator spray to facilitate mechanical harvesting since they hang tight to the tree. Trees must be pruned to adapt them to trunk shakers and catching frames.

Cherry culture in England is concentrated mostly in Kent, where the summer rainfall conditions are reasonably favourable; some trees are over 100 years old. Practically all of the fruit is consumed fresh. Important varieties include Early Rivers, Napoleon, and Noir de Guben. Tart varieties in Europe are Schattenmorelle and the newer Kelleris 16 and Rexelle. In Oceania the sweet cherry varieties include St. Margaret, Bedford Prolific, Rons, and Napoleon.

**Strawberry.** The cultivated strawberry, probably the most cosmopolitan of all perennial fruit plants, is grown from the cool tropics to the Arctic zone. Two factors account for its great climatic range: (1) it is evergreen and grows so close to the ground that mulch or snow can protect it from the coldest winter temperatures; (2) different varieties exhibit special adaptation to environmental conditions in this broad area.

This herbaceous plant has compound leaves with three leaflets arising from a fleshy crown that is anchored by a fibrous root system. Flowers, usually white, arise from the leaf axils. The edible portion of the fruit is largely receptacle with tiny seeds covering the outside of the berry. Runners, sent out from the "mother" crown, take root starting with the second node and form "daughter" plants that spread the planting in all directions.

While it is impossible to assert that one climate or another is the best for strawberries, the fact that annual

yields of more than ten metric tons per acre are obtained from planting of the variety Lassen in some areas of California suggests that this may be one of the better climates for the species. On the other hand, strawberry growing is a sound business, yielding up to 10,000–15,000 quarts per acre in the cooler parts of the U.S., the United Kingdom, Denmark, Sweden, and Norway.

Objectives of modern strawberry breeders are to develop: (1) a series of early, midseason, and late-ripening varieties that look and taste alike, (2) a large berry that tends to have a peak ripening for mechanical harvesting and has an easy-to-remove calyx, (3) low chilling requirement for the mild climatic areas, (4) a firmer high-quality berry that withstands field rots, that ships well, and that looks appealing on the counter, and (5) varieties resistant to major pests and diseases. In the 1960s the leading North American varieties were Northwest (18 percent of total production), grown mainly in Washington and Oregon; Blakemore and Tennessee Beauty, from Arkansas to Tennessee; Tioga, Fresno, Gresno, and Shasta in California; Florida 90 in Florida and Texas; Headliner in Louisiana and Alabama; Surecrop in Illinois and Maryland; Albritton in North Carolina; Jerseybelle, Robinson and Midway in the northeast; Klondike in northern Mexico; and Redcoat in Canada. Varieties in Poland are Purpuratka, Senga Sengana, and Surprise des Halles, in Bulgaria the Madame Moutat and Senga Sengana, in Australia and New Zealand the Redgauntlet, in England the Royal Sovereign and the Cambridge numbered varieties. Strawberries are sold fresh, frozen, or preserved. The perishability of the fresh fruit and the excellence of the frozen pack has caused freezing to gain preference as the industry has perfected procedures. In addition, strawberries are preserved as jams, used in ice cream, and canned.

The U.S. leads all countries in world production followed by Poland, Yugoslavia, East Germany, and Italy. Other countries in order are Bulgaria, France, United Kingdom, Mexico, The Netherlands, Czechoslovakia, West Germany, Hungary, Australia, Canada, and others. No data are available from U.S.S.R., but it is known that plantings on some government farms may total 250 acres.

Since hand harvest is an expensive operation, several promising strawberry-harvesting machines are being tested.

**Raspberry, blackberry.** Commercial raspberries and blackberries, known as brambles, are of a number of species of the genus *Rubus*. They are termed biennial because the canes fruit (on leafy shoots) in their second growing season, then die. These canes may be erect or require support by trellis or stakes. The different species vary in climatic requirements, but the most important thrive in temperate regions that have neither very hot summers nor very cold winters. The blackberry withstands more summer heat and dryness than raspberries and hence is found farther south. These brambles do well in the south of England.

Some species also are cultivated in Europe as far north as Denmark, Sweden, the U.S.S.R., and in similar climates. Red raspberry varieties of importance in the United Kingdom are Lloyd George, Norfolk Giant, Malling Promise, and Malling Enterprise; in the U.S., Latham, Willamette, Ranere, Washington, and Newburgh; in the U.S.S.R., Usanka, Novost Kuzmina, and Russkaya. The blackcap and purplecap raspberries are less common; their culture is mostly confined to the eastern U.S. Plum Farmer and Cumberland are well-known blackcaps, and Sodus is a purple variety. All these fruits are marketed fresh locally or processed frozen or in jams, preserves, or in ice cream. Blackberry wine or brandy is common on store shelves. Several trailing and semitrailing blackberry species are commercially grown in the U.S. and in Europe; hybrids among them or with raspberry have produced large fruited juicy berries that taste good in preserves or canned. Among the most popular of these are the Himalaya berry, the Oregon evergreen blackberry, boysenberry, and youngberry.

Breeders'  
objectives

Virus diseases

From the 1930s to 1960s virus diseases were so prevalent in raspberries that it was difficult to obtain profitable yields. Few berries at very high prices were seen on the fresh markets. By treating the canes with water so hot it almost kills the tissue, it is now possible to obtain virus-free propagation stocks that yield well. Hence, the future looks much brighter for this delicious fruit.

Mechanical harvesters are being used on cane fruits in the northwest U.S. for harvesting berries. The canes are machine slapped near the base with rubber fingers, jarring the ripe berries onto belts; trash is blown off, and the fruit carried to shallow crates for grading and packing. The machine, about 3.5 metres high by 3.5 metres wide, straddles the row.

**Blueberry.** Several species of this delicious berry are indigenous to North America. The wild fruit, now largely processed, was enjoyed by Indians and early settlers. Blueberry production in the U.S., mainly the highbush type, has increased more rapidly than any other fruit industry over the past half century. This is due to the skill and imagination of breeders and growers who began domesticating and crossing wild species of the highbush type early in the 20th century, and in recent years have improved the lowbush and rabbiteye types. The breeding and selection were mainly for flavour, larger berry, light blue colour, hardiness, and resistance to diseases and insects. This plant varies in height from 300–900 millimetres (one to three feet) for the lowbush blueberry, two to four metres for the highbush and five to six metres for the rabbiteye highbush. The highbush types are grown from Quebec and Michigan south to southern Georgia, whereas the lowbush types are found in mountainous areas from Newfoundland to Saskatchewan, south to Virginia. The rabbiteye highbush type is grown in the South from southern Georgia and northern Florida to Louisiana. Propagated from cuttings of main varieties, the nursery-grown plants are set according to ultimate size from 900 to 1,200 millimetres in rows 2.5 metres apart to 3–4.5 metres on the square for the rabbiteye type. Most blueberry soils are largely unsuitable for other types of agriculture. They are sandy loams high in organic matter and acid (pH 4.3–5.5); successful highbush plantings, however, have been fruited on upland medium loam soils neutral or slightly alkaline in humid areas.

Large mechanical harvesters that straddle the row are used on large highbush plantings mainly for harvesting blueberries for processing. Some growers pick the better first-over harvest berries by hand and then finish off the crop with harvesters for processing.

Blueberries freeze exceptionally well without any special preparation except washing. Most people can eat blueberries, which are mildly acidic, without side effects (as sometimes occur with other fruits, such as strawberries). Markets in the U.S. and throughout the world have not been fully exploited. It is probable that the blueberry industry will continue to grow in acreage and production.

**Currant and gooseberry.** Currants and gooseberries, closely related, are hardy deciduous bushes, well adapted to fruit growing in the cool temperate zone. Plants are of the bush type, mostly one to two metres in height, that spread and bear on leafy shoots from canes two years or older that arise from the crown area. Old, weak, bearing wood is pruned out as new wood develops. The largest U.S. red currant region extends from southern Michigan to the Hudson River Valley of New York; others lie around San Francisco, in the Willamette Valley, Oregon, and in the Puget Sound area of Washington. Gooseberries can be grown farther south than currants owing to their greater heat and drought tolerance. Black currants (most important), red currants, gooseberries, and white currants are grown in Great Britain, Germany, Poland, The Netherlands, France, Belgium, Australia, and New Zealand. Plantings in the U.S.S.R. are mostly in home gardens, with some commercial acreage near large cities.

These fruits are used primarily in preserves and jellies. Gooseberry also is an important culinary fruit in Britain and on the European continent; black currant juice has

special dietary uses. Among the important red-currant varieties are Wilder and Red Lake; black currant: Mendip Gross, Seabrooks' Black, and Baldwin; gooseberry: Poorman, Careless, and Lancashire Lad.

**Cranberry.** The cranberry is a trailing woody plant consisting of a cover of runners and flowering and fruiting upright, forming a mat over the ground surface about one foot deep. The cranberry grows best on an acid, high-organic-matter, bog type of soil. The cranberry of North America is found wild from Newfoundland to Minnesota and south to Arkansas and the Carolinas. Commercially, it is grown on bog areas that have been levelled and ditched for drainage and for flooding during the winter season for protection against cold and frost in early spring. U.S. cranberry production totalled about 1,800,000 barrels (144 Imperial quarts per barrel) in the late 1960s. The vines are pruned by hand or a machine with comblike blades to reduce the matted condition and thin the fruiting uprights. The U.S. average yield is about 70 barrels per acre, but some bogs may exceed this figure by 25 or more barrels.

A recent harvesting development that has cut labour cost and increased the amount of berries retrieved is "water harvesting." The bog is flooded just above the uprights. A hand-guided, motor-driven, two-wheeled, bicycle-like machine with rotating wheels barred together whips the berries loose from the uprights. The berries float to the surface and are wind driven to an elevated road around the bog where they are guided into a motor-driven belt and bulk-loaded into a truck. This method has cut losses of berries by more than 20 percent. Labour costs also have been lowered markedly.

Cranberry juice is prepared from frozen berries the year around, diluted one-to-ten and sold by quarts and pints in glass jars, alone or mixed with apple juice. Many new products are being tested and sold.

**Chestnut.** The European or Spanish chestnut is the species comprising most of the world's commercial chestnuts exported from the Mediterranean area, mainly Italy. Large importers are the U.S., France, United Kingdom, Hungary, Switzerland, and West Germany. The other three main species of chestnut are the Japanese, common in the Japanese diet, Chinese, and the American. The Japanese chestnut tree is an abundant producer, but the nuts are poorer in texture and flavour than the European. The Chinese chestnut tree is more resistant to the blight that destroyed the European and American species in the U.S. While the Chinese chestnut is not as large as the European, it is well formed and flavourful. The American chestnut was largely destroyed by a blight in the early 1900s; it is valued both for its nuts and timber.

The important European chestnut is found in elevations up to 1,220 metres in the Mediterranean area, southern Asia, and east to the Caucasus. Trees may attain a 20-metre spread, with a 600-millimetre-diameter trunk, and be quite long-lived. Leaves are deciduous, simple, alternate, serrated, and with or without hairs. The burrlike fruits contain two to three nuts. The chinquapin, a close relative, has a similar fruit that contains only one nut. The horse-chestnut, unrelated, belongs to another genus and is not eaten.

Young trees are hard to establish, particularly during droughts, but once established they persist. Grafted scion varieties among chestnuts are not as common as with other tree fruits and nuts. A few orchards of scion varieties have been started. Selected Chinese varieties and hybrids that are being tested in the United States are Abundance, Crane, Kuling, Meiling, Nanking, Orrin, Colby, Conard, and Hemming.

Chestnuts contain 40–45 percent carbohydrates, 5 percent oil, and about 50 percent moisture. The nuts dry rapidly if not stored under controlled humidity. They must be protected against molds. Most nuts are picked by hand, although they could be mechanically harvested. Chestnuts are served boiled, roasted, steamed, pureed, and as dressing for poultry and meats. In Korea the chestnut is almost as important an item of diet as the potato is in the U.S.

**Hickory nut.** Native to North America and a close relative of the pecan, the hickory has undergone relatively little domestication and improvement. The widely spread shagbark hickory probably bears the best nuts. It prefers a humid climate and is found on the upland slopes and lowlands near streams and wet places. Trees grow to 30 metres or more, upright, rectangular in form, with loose plates of bark on the trunk. Nuts are borne in twos and threes with a green hull that splits in quarters upon drying and releases the nut. Nuts are 25–40 millimetres long, oblong, pointed at one end and about 25 millimetres thick, with a relatively thin but hard shell averaging 100 seeds per pound. The kernel has aromatic properties typical only of the hickory and probably no other has as high flavour in cookery.

Scion varieties sold by nurseries include Curtis, Dover, Eliot, Hale, paper shell, and others. Nuts are permitted to fall to the ground and in competition with wildlife, mainly squirrels, they are picked up, hulled, and stored in a cool dry place throughout the winter and are edible until spring. Nuts last up to two years when stored at 0–1° C (32–34° F) and 65 percent relative humidity.

The greatest obstacles to the culture and improvement of hickories are the difficulty of successful transplanting and their delayed bearing. Other hickory nuts include shellbark, Carolina, mockernut, bitternut, many hybrids, and others. The hican is a hybrid between hickory and pecan. Hickory nuts are used in ice cream, cookies, candies, fruit cakes, and pie toppings, in addition to being eaten out of hand. The wood is valuable for tool handles.

## II. Basic practices in fruit farming and marketing

Although fruit- and nut-growing enterprises cover great ranges of climates and plant materials, their technologies have many common problems and practices. The most significant of these are discussed below.

### THE VARIETY: ITS PROPAGATION AND IMPROVEMENT

The first step in establishing a fruit- or nut-growing industry is the selection of individual plants with high productivity and a superior product. Such an individual is a horticultural variety. If it is multiplied vegetatively from rooted cuttings, from root pieces that throw shoots, or by graftage, each plant in the group (called a clone) that results is identical with the others. Nearly all commer-

cially important perennial fruit and nut crops are clonally propagated; *i.e.*, their varieties are multiplied vegetatively by one means or another. Some nut crops, such as the wild pecan, cashew, black walnut, hickory, and chestnut still come from trees that grow at random from seed; hence, character and quality tend to vary.

Many important varieties of fruit plants were selected generations ago. The Sultanina (Thompson Seedless) grape, the Lob Injir (Calimyrna) fig, and the Gros Michel banana have obscure origins; planted by the millions since selection, each specimen is actually a vegetative continuation of the selected individual growing on an independent root system. But regardless of the age of a fruit-growing industry, or the perfection of some of the selected varieties, a continuing search for new varieties is essential. There is always room for improvement in climatic adaptability, in insect and disease resistance, and in the solution of special horticultural or marketing problems. In fact, government experiment stations over the world now stress scientific breeding for improvement of market quality and yield of key fruit and nut crops.

Not only are varietal selection and improvement a continuing need but so also is the maintenance of existing varieties. Although an improved vegetative mutation of a variety is exceptional, the opportunities for accidental multiplication of degenerate (low quality) mutants increase in proportion to the number of specimens of the variety. As a result, care is taken to propagate a clone only from superior individuals, and in the case of citrus, where mutation is especially common, further precautions are necessary. There are, of course, occasional mutations that may greatly improve a variety and these are sought, selected, and propagated.

Vegetative propagation technique varies with the individual fruit plant. Date, banana, and pineapple are multiplied by use of offshoots or suckers. Grape, fig, olive, currant, and blueberry are usually propagated from cuttings. Strawberry and black raspberry reproduce vegetatively by special organs—the former by stolons or runners, the latter by cane tip rooting or layering. Many kinds of fruit trees must be grafted or budded on especially grown rootstocks because the species to be multiplied does not root itself easily; apple, pear, peach, mango, and citrus are examples of this group. Many nut trees have a single tap root with but few branching roots,

Vegetative propagation technique

Selection of plants

necessitating a deep hole and special care in transplanting.

Today's trend is toward a smaller tree in most fruit crops, particularly the apple and pear, and toward closer planting in hedgerow style, with carefully regulated fertilization and irrigation (Figure 1). This increases production per acre, lowers labour cost, increases early yields, and facilitates access in maintenance and harvesting. This approach, in fact, has been used for decades in Europe. Labour is the largest element of cost in fruit and nut production. Every means is exploited to reduce, facilitate, or eliminate hand labour.

With most fruit species a period of one to two years intervenes between the time a cutting is rooted and the plant is ready for setting in the field, or between graftage or budding and field planting. During this interval the plants remain in a nursery where they can be given intensive culture in rows. Pineapple and banana planting materials, however, do not require nursery care before field planting.

In choosing fruit varieties, the grower must: (1) recognize the relative adaptabilities of available varieties to the climatic and soil conditions of his farm and (2) select a group that satisfies both his management needs and the market demands from those best adapted to his conditions. For instance, an apple producer in the northeastern U.S. may raise four varieties: Milton, McIntosh Red, Red Delicious, and Rome Beauty. The main harvest seasons for these succeed each other at two-week intervals; this helps him extend the harvest period and make efficient use of his labour. The first two varieties cross-fertilize satisfactorily, as do the last two. The first of these varieties is usually marketed without storage, while the storage seasons of the others are of increasing length. This helps the grower to extend his marketing period.

#### THE SITE

The site of a fruit-growing enterprise is as significant in determining its success as the varieties grown. In fact, variety and site together set a ceiling on the productivity and profit that can be realized under the best management. In most developed fruit regions microclimatic conditions (climate at plant height, as influenced by slight differences in soil, soil covering, and elevation) and soil conditions are the two components of a site that determine its desirability for a fruit-growing enterprise. Sometimes (particularly with highly perishable fruits) transportation to market must also be considered.

Local conditions at a site that expose it to unusual frost hazard are as detrimental to citrus in Florida as they are to peach trees in New Zealand and apple trees in the south of England. In regions and sites where temperatures during the season may drop no more than a few degrees below freezing, artificial frost protection is sometimes used. This is accomplished by open-flame burning (petroleum bricks, logs, etc.) or heating of metal objects with oil, gas, propane, electricity, etc. (stones or stacks that radiate heat). Another technique is the spraying of water on plants, (e.g., strawberries) as long as the temperature is below freezing.

For highest productivity, most fruit trees must root extensively to a depth of one metre or more. Heavy subsoil or other conditions causing imperfect internal drainage may result in shallow, weak root systems that do not take water and nutrients efficiently from the soil. In semi-arid and arid regions, accumulation of saline soils in a sub-surface layer sometimes limits rooting of fruit trees, causes abnormal foliar symptoms, and reduces yields. Tiling and surface ditching help decrease water accumulation in poorly drained subsoils and reduce wet spots in otherwise satisfactory sites. Special control of irrigation procedures and periodic leaching may alleviate the worst salt effects in saline soils. Choice of tolerant species, varieties, and rootstocks may make fruit growing economical on imperfectly drained or mildly saline sites, though plants rarely perform as well as they do on sites free from these difficulties. Coconuts, however, tolerate saline soil conditions near tropical saltwater coasts.

Once selected, a site is cleared, levelled (if needed), and cultivated. Then drainage, irrigation, and road systems are installed as required. In rolling or sloping terrain, where contour planting is needed to control erosion and conserve moisture, the locations of the plant or row positions are determined by the contour terraces and waterways established. In old lands, nematode or other pest populations make fumigation necessary before planting. In some problem California soils, giant plows and treaded tractors turn the soil to depths of one to two metres. In very infertile sites, or sites where the physical condition of the surface soil is poor, it may be helpful to grow a succession of leguminous cover crops for a year or more before planting and/or apply a fertilizer containing major fertilizer elements (nitrogen, potassium, phosphorus, calcium, sulfur) and all or certain trace elements (iron, manganese, boron, zinc, copper, molybdenum) and lime, based on a soil test.

#### PLANTING AND SPACING SYSTEMS

Growth, flowering habits, and light requirements on the one hand, and management problems on the other, determine the most satisfactory planting plan for a fruit- and nut-growing enterprise. There is a trend toward use of dwarfing stocks, growth control chemicals, or closer planting and training, or all of them to get the highest yields and best operation efficiency possible on a unit of ground.

Low-growing crops such as strawberry and pineapple are usually managed in beds containing several rows, or in less formal matted rows. In an acre of strawberries, 200,000 or more plants may occupy the matted rows. A pineapple plantation with two-row beds, having plants 300 millimetres (one foot) apart in rows 600 millimetres (two feet) apart totals 15,000 to 18,000 plants per acre. With such dense populations, intense competition for light, water, and nutrients causes smaller average fruit size. Nevertheless, the total yield per unit of land is usually greater than it would be with lower plant numbers.

The spacing of grapevines along a trellis row and of trees planted in hedgerows involves the same group of problems. Maximum vineyard production frequently results with vine distances of 2.4 to 2.7 metres (600  $\pm$  per acre). The trend for peach trees and spurtype apple strains is hedgerows 4.2 metres apart or closer, in rows 5.4 to 6 metres apart.

With those species and varieties that require cross-pollination by insects, the planting plan must take those special needs into account. This is a problem with apple, pear, plum, and sweet cherry orchards. At least two varieties that cross-fertilize successfully must be planted in association with each other.

#### TRAINING AND PRUNING

Pruning is the removal of parts of a plant to influence growth and fruitfulness. It is an important fruit-growing practice. Primary attention is given to form in the first few years after fruit trees or vines are planted. Form influences strength and longevity of the mature plant as well as efficiency of other fruit-growing practices; pruning for form is called training. As the plant approaches maximum fruitfulness and fills its allotted space, maintenance pruning for various purposes becomes increasingly important.

The grape may be trained following one of two systems: (1) spur system, cutting growth of the previous season (canes) to short spurs, (2) long-cane system, permitting canes to remain relatively long. Whether a spur or long-cane system is followed depends on the flowering habit of the variety. Relatively small trees that respond favourably to severe annual pruning (e.g., the peach and Kadota fig) are usually trained to create an open-centred tree with a scaffold of four or five main branches that originate on a short trunk and branch a number of times to provide fruiting wood. Annual renewal pruning can be reasonably efficient under these circumstances. Larger trees that do not respond favourably to heavy annual pruning are trained best to a system that encourages

Climate,  
soil  
conditions

the main leader branch to grow erect to a height of 2.4–3.0 metres, with four or five main lateral branches at intervals on its sides forming the scaffold that carries fruiting wood up and out; this is called a modified leader system. The central leader type of tree, with one main leader up through the centre and many side branches, is common for pear and apple planted in hedgerows, and possibly for other fruits and nuts as the close-planted hedgerow system is more widely adopted.

Maintenance  
pruning

The principal reasons for maintenance pruning are: (1) to permit efficient spraying and harvesting operations, (2) to maintain satisfactory light exposure for most of the leaves, and (3) to create a satisfactory balance between flowering and leaf surface.

To reduce hand labour costs, larger commercial fruit growers use machine pruning (Figure 1) on many types of fruits. Peach, apple, pear, and other fruits usually planted in hedgerows are mowed across the top and sides by machine, then thinned out as needed by a follow-up crew using pneumatic clippers and hand-powered saws, operating from hydraulically manipulated scaffolds or lifts of various types.

#### SOIL MANAGEMENT, IRRIGATION, AND FERTILIZATION

**Soil management.** Two soil management practices, (1) clean cultivation and chemical weed control or both and (2) permanent sod culture, illustrate contrasting purposes and effects. In clean cultivation or chemical weed control, the surface soil is stirred periodically throughout the year or a herbicide is used to kill vegetation that competes for nutrients, water, and light. Stirring increases the decomposition rate of soil organic matter and thereby releases nitrogen and other nutrients for use by the fruit crop. It may also provide some improvement in water penetration. On the other hand, laying bare the soil surface exposes it to erosion; destruction of organic matter eventually lowers fertility and causes soil structure to change from loose and friable to tight and compacted. Though sod culture minimizes the destructive processes and may permit a modest increase in fertility, the sod itself competes with fruit plants for water and nutrients and may even compete for light. As a result, permanent sod culture is practical only with tree crops that are normally rather low in vegetation, such as apple, pear, sweet cherry, nuts, and mango. Competition from established sod may be detrimental to vigorously growing fruit plants like grape, peach, and raspberry unless adequate fertilizer and water are supplied.

Sprinklers,  
cultivation,  
mulching

Because each of these soil management systems has advantages and disadvantages, modifying or complementary practices are often used; for example, cover cropping, mulching, and chemical control of vegetation with or without strip sod in the row middles. In fact, the trend is toward mowed sod middles with strip chemical control under the trees and with overhead sprinklers during hot dry weather (Figure 1). Sprinklers not only provide water but tend to cool the plants and give fruit of better market quality without aggravating diseases. Cultivation combined with winter cover cropping has been used widely in grape, peach, cherry, bush fruit, and citrus plantings, as well as with other species. Mulching is the addition of undecomposed plant materials such as straw, hay, or processors' refuse to the soil under the plants. In orchards, mulching materials are most often applied under trees maintained in permanent sod. Strip in-row chemical control of vegetation in commercial fruit plantings has almost taken over as an economical and sound practice.

**Irrigation.** In semi-arid and arid regions, irrigation is necessary. Probably the maximum demand occurs in date gardens, because they expose a large leaf surface the year around under conditions of high evaporation and practically no rainfall. Irrigation in humid climates is generally being provided increasingly during extended dry periods that occur at one time or another during most growing seasons. For example, large acreages of banana are irrigated on coastal lowlands of the torrid tropics where annual rainfall exceeds 1,500 millimetres (see IRRIGATION AND DRAINAGE).

**Fertilization.** Needs of perennial fruit plants for fertilizers depend on the natural fertility of the soil supporting them and on their individual requirements. Of the essential elements, supplemental nitrogen is almost always needed; potassium supplements may be needed, even in some desert areas. Although strawberry, grape, peach, and a few other fruits have responded favourably to phosphorus, and although its application has been recommended, the phosphorus requirement of woody plants is low and deficiency is rather rare. Calcium deficiency may be more common than realized; lime is often desirable to reduce soil acidity and because of other indirect benefits. Inadequate magnesium in the soil has been noted by workers studying a wide range of fruit species. Of the trace elements, zinc, iron, and boron are most likely to be deficient, but copper, manganese, and molybdenum deficiencies also are being reported for some fruits in some regions. Iron deficiency is difficult to control in orchards where soils have high alkalinity. Granulated fertilizers in modern close-planted commercial orchards are usually broadcast by machine a month or two before growth starts. Additional nitrogen sometimes is applied in heavy crop years to apple, pear, and citrus.

#### POLLINATION

The stimulus of pollination, fertilization, and seed formation is needed to get good size, shape, and flavour of most of the fruits. (Banana, pineapple, and some citrus and fig varieties are exceptions.) Transfer of pollen from the anthers (male) to the stigmas (female) is accomplished in nature either by insects or by movement in air. It is common practice to bring beehives into the orchard during bloom. Rainy cold weather during bloom with little or no sunshine can deter activity of the honey bee (the key insect pollinator) and reduce fruit set appreciably. This is one of the main problems not fully solved by fruit researchers. Hand-pollination by daubing collected and preserved pollen onto the stigmas, (as is done with date palms) sometimes is practiced for other fruits, but this approach is not widespread.

#### THINNING

Removal of flowers or young fruit (thinning) is done to permit the remaining fruits to grow more rapidly and to prevent development of such a large crop that the plant is unable to flower and set a commercial crop the following year. Thinning is done by hand, mechanically, or chemically. With the date, the pistillate flower cluster is reduced in size at the time of hand-pollination. In the case of certain table grape varieties, some clusters are cut off. With Thompson seedless grape, a combination of girdling the trunk bark and judicious application of gibberellin (growth regulating) sprays at blossoming gives excellent full bunches.

Young peach fruits are thinned by striking the branches with a padded pole or by shaking the entire tree for a few seconds with a well-padded motor-driven shaker arm grasping the trunk. Hand thinning of young apple and peach fruits once was also a common practice, but because of the expense and difficulty, there has been increasing use of chemical sprays as a substitute. Two kinds of sprays are used: (1) mildly caustic sprays applied during bloom, such as Elgetol in arid regions, or (2) sprays of growth-regulating substances such as 3-CPA (2,3-chlorophenoxy propionamide) applied within a few weeks after bloom in areas with late frosts.

#### PEST CONTROL AND PRESERVATION

In many fruit enterprises, pest control is the most expensive and time-consuming growing practice. Where the concentration of fruit farms in an area warrants it, individual efforts are complemented by legislative measures including quarantine regulations to force removal of pest-laden, unattended orchards. Sometimes the most economical control procedure is biological in nature. There is increased research today to find and multiply parasites that kill fruit crop pests. Such biological methods are necessary as political pressures increase for ban-

Biological  
pest  
control

ning DDT and other chemicals. Selection of varieties that are immune, resistant to attack, or tolerant to specific pests, is a biological control procedure also widely used. Chemical control procedures, however, are relied on most heavily. Air-blast spray or mist-application machinery covering 70 acres of trees or more in a day is now in common use (Figure 2).

HARVESTING AND PACKING

The proper time to remove a fruit from the tree or plant varies with each fruit and is governed by whether the product will be sold and consumed within hours, or stored for weeks, months, or even a year. Most fruits are harvested as close as possible to the time they are eaten. A few, of which banana and pear are outstanding examples, may be harvested immature and still ripen satisfactorily. Orange, grapefruit, and some varieties of avocado may be "stored" on the tree for several months after

Figure 2: Air-concentrate mist blower used to spray bush fruits, grapes, and compact high-density tree fruits.

they attain good quality; this cuts costs in handling and marketing. Many fruits, including apple, pear, orange, lemon, and grapefruit, may drop from the tree during the last part of the maturation period. Preharvest drop of these fruits can be delayed by application of dilute sprays of growth-regulating substances like naphthaleneacetic acid (NAA). The chemical spray Alar [N-(dimethylamino) succinamic acid] applied four to six weeks after bloom on apple not only reduces fruit drop at harvest but increases red colour, firmness, and return bloom the next year, in addition to other advantages. For the fresh market, most tree and bush fruits are still harvested by hand. For processing, drying, and occasionally for fresh market, mechanical motor-driven tree and bush shakers with appropriate catching belts, bins, pallets, and electric lifts reduce harvesting and handling labour. In years to come, machinery may make it possible to machine-harvest most fruits, with no more, and possibly less, damage than with hand picking (Figure 3). The public is becoming increasingly particular about the appearance and quality of the product it buys. Hence, store managers seek the best grades of fruits and nuts available, and growers make every effort to produce crops with attractive colour and smooth finish. Fruits are packed by government-controlled grades such as Fancy

or Extra Fancy within given size limits and are so labelled on the carton or box, together with the source. Most fruits and nuts not meeting this quality demand are processed or sent through channels using the lower grades and off sizes. Small packages of plastic foam or wood pulp base holding four to six fruits covered and heat sealed with polyethylene plastic film are popular. These are delivered to stores in corrugated cartons holding a few dozen packages. Citrus, apples, and whole nuts or kernels also are packaged in polyethylene bags and delivered in cartons. Loose fruit may be sold in cell cartons and tray packs consisting of stacked form-fitting pulp trays in a "bushel size" box. Every effort is made to eliminate bruising. Large truck-pulled containers with individually motor-driven refrigeration units, with or without controlled atmosphere (CO<sub>2</sub>-O<sub>2</sub>, to retard ripening), are loaded at the fruit source and trucked to destination or loaded on ships by derrick for overseas shipment. These sealed containers are also being used increasingly for bananas to reduce labour and handling and to deliver a better product. Air shipment of "vine- and tree-ripe" fruit (strawberries, figs, sweet cherries, pineapples, avocados) to distances as far as from California to Europe in a day or less is becoming increasingly common with the much larger and faster cargo planes and reduced air-freight prices.

Shipment in controlled atmosphere

Table 4: Major Compositional Changes in the Edible Fraction of Several Selected Fruits		
constituent	content at maturity* (percent of fresh weight)	content upon ripening† (percent of content at maturity)
<b>Apple</b>

<b>Pineapple</b>		
Sugars	15.0	103
Acid	0.8	88

\* "Content at maturity" means content when the fruit is normally harvested in mature but not necessarily ripe stage. † "Content upon ripening" refers to content at edible stage.

POSTHARVEST PHYSIOLOGY OF FRUITS

Fruit ripening is a form of senescence and signifies the final stage in fruit development. A fleshy fruit is the enlarged ovary of a flower (avocado) or additional floral parts such as in apple, pear, and pineapple. Usually fertilization, and sometimes pollination alone, stimulate the floral parts causing a rapid cell division that leads to differentiation and the formation of the fruit structure. During this stage fruits consist of small, young cells filled with protoplasm. When the young fruit has been stimulated, presumably by plant hormones that originate from the embryonic seeds, rapid cell expansion takes place. During this stage fruits gain rapidly in size and weight. The cells develop small cavities or spaces in their tissue (become vacuolated) and begin the process of foodstuff accumulation, which lends fruits their compositional diversity. Banana, apple, and date accumulate mainly carbohydrates. Avocado and olive store fatty materials. Important constituents of most fruits are organic acids such as malic acid, found in apple and pear; citric acid, in cit-

Figure 3: Mechanical fruit harvesting.

(Top) Fruit harvester operating under a cherry tree. The limb shaker (at left of tree) removes the cherries which are caught on decelerator strips and carried to the bulk bin at left. (Bottom left) Cranberry harvester used on a bog to loosen and float berries. (Bottom right) Grape harvester straddling a row of *Vinifera* or *Labrusca* grapes. The berries fall on belts and are carried on escalators to the top of the harvester where they enter the arm to be deposited (at right) in a tractor-pulled bulk bin for processing.

#### Stages of ripening

rus and pineapple; and tartaric acid, in grapes. Fruits are usually low in protein.

After cell expansion has slowed and become nominal, fruits enter the stage of maturity and undergo preparation for ripening. Some crops, such as pear and avocado, are harvested at the so-called mature-green state and allowed to ripen afterward. Most fruits are at a stage of incipient ripening before they are picked. Ripening is marked by rapid and dramatic changes that give fruits their attractive and edible character. Some of the familiar changes are softening, which results from degradation of cell wall substances; disappearance of a green background, because of chlorophyll degradation (as in pear, apple, and banana); appearance of coloured pigments such as the carotenoids—orange-yellow—and anthocyanins—red (as in orange, mango, and strawberry); a decrease in acidity and increase in the sugar content (orange, apple); and emission of the volatile substances that give many fruits their distinct aroma (as in banana, pear, and apple). In climacteric fruits (*e.g.*, banana, pear, apple), ripening is accompanied by increased respiration. In nonclimacteric fruit (*e.g.*, strawberry, cherry) this phe-

nomenon does not occur. It is thought that the transition from the mature to the ripe stage is brought about by certain "ripening" enzymes. Protein molecules act as catalysts. The activity of these enzymes leads first to various ripening reactions, and then to gradual deterioration of the fruit tissue. Table 4 lists the major compositional changes in the edible fraction of several selected fruits. Table 5 lists the composition of various fruits and nuts.

Because ripening leads to tissue breakdown, fruits are considered a highly perishable commodity. Different fruits have varying degrees of postharvest longevity. While strawberries last only a week to ten days, apples or lemons can be stored successfully for several months. Postharvest life of fruits can be extended by refrigeration with or without a modified oxygen-carbon dioxide atmosphere. Most temperate-zone fruits can be held safely at 0° to 5° C (32° to 41° F), but many subtropical and tropical fruits, including lemon, avocado, banana, and mango, show chilling injury in prolonged cold storage and consequently fail to ripen properly. Bananas do not tolerate temperatures below 12° C (about 53° F), while several avocado varieties can be stored at 7° to 8° C

(about 46° F). Fruit life can be extended further by both refrigeration and controlled atmosphere (CA) storage in which oxygen is kept at about 5 percent and carbon dioxide at 1 to 3 percent, while temperature is held at a level best suited to the particular fruit. So-called CA storage is common today for apples and pears and is being adapted to other fruits. Controlled atmosphere and refrigeration in conjunction with the removal of ethylene gas (which emanates from fruits and speeds ripening) helps slow the ripening process considerably. Golden Delicious apples and some pears are shipped in polyethylene containers in which a desirable, modified atmosphere is created by the respiring fruit.

Drying,  
canning,  
freezing

Drying is a standard practice for stabilizing the market movement of dates, figs, raisin grapes, prunes, and apricots. Canning is of paramount importance to the pineapple, peach, and pear industries, and freezing is a means of stabilizing some of the most perishable fruits, including strawberry, raspberry, and blueberry.

Nuts are susceptible to mold, souring, staleness, discoloration, and rancidity. Cured and dried nuts are kept in prolonged cold storage under controlled temperature and humidity levels. Nuts also are stored and sold in vacuum packs of carbon dioxide-enriched atmosphere.

#### WASTE MATERIALS, OTHER USES

Apple wood is excellent for fireplace use, and cherry and certain other fruit woods are used for the finest household furniture. The dried residue from processing apples and citrus is made into feed for conditioning livestock for market, as are waste materials from many processed fruits. Apple pumice (waste material) is spread on the orchard floor with a manure spreader to help in soil conditioning and as a source of minerals.

Nutshells have many uses. Filbert shells are made into plywood, artificial wood, and linoleum; a mixture of shells with powdered coal and lignite makes cinder blocks; shells are used in making poisonous gases and gas masks, and as fuel and mulch. Cashew shell liquid, a skin irritant, is made into resins for varnishes; kills mosquito larvae; can be impregnated in wood as a varnish to preserve against insect attack; is used in automotive brake linings and clutch facings; is used as a laminating agent for paper, cloth, and glass fibres; and is used to treat cement floors and synthetic rubber to retard deterioration. Finely ground black-walnut-shell flour is used in plastic molding powder; as a glue extender; to prevent overheating of drills; to "sand" blast jet engines; for polishing, burnishing, and deburring metal parts; for cleaning foundry molds; and to spray on tires for better traction. Pecan shells are used in place of gravel in cement walks and driveways; as fuel; as mulch and as a soil conditioner; in livestock bedding; as filler for fertilizers, feeds, etc.; in the manufacture of tanning agents, with charcoal and abrasives in hand soap; as a filler in plastic and veneer wood; and many of the same uses as black walnut shells. Some nutshells are made into beads, marbles, buttons, carving tools, ink, and ornaments. The India clearing nut is cut open and rubbed on the inside of earthenware that will contain drinking water; the juice coagulates the water impurities which sink to the bottom. The nuts of the betel palm in the Far East and of the kola tree in West Africa are chewed for their stimulatory effects.

The United States Department of Agriculture and State Agricultural Experiment Stations publish bulletins on the culture of fruits, on insect and disease problems, and on economic and marketing problems. Similar information is published by the British Ministry of Agriculture for fruit crops important in Great Britain.

(N.F.C.)

## Fugger Family

The Fuggers were a German family who founded in the imperial city of Augsburg a textile business that grew into the biggest trading, mining, and banking concern of 15th- and 16th-century Europe. By granting huge loans to the emperors Maximilian I and Charles V, the Fuggers were able to influence the policies of these rulers.

By courtesy of the Herzog Anton Ulrich-Museum, Braunschweig

Jakob II Fugger the Rich (right), and his chief accountant, Matthäus Schwarz, miniature, 1519. In the Herzog Anton Ulrich-Museum, Braunschweig, West Germany.

**The founding fathers.** Hans Fugger, a weaver born in the village of Graben in Swabia, established the family in Augsburg in 1367. By twice marrying the daughters of masters of the weavers' guild, the industrious Fugger acquired civic rights and the freedom of the company. He also became a member of the guild's committee of 12 and of the city's great council and conducted a successful textile trade. After his death in 1408, his sons Andreas and Jakob I, both of whom had learned the goldsmith's trade, jointly carried on the family business until they dissolved their partnership in 1454. Although Andreas, the more enterprising of the two, and his descendants quickly attained great wealth, they went bankrupt in 1499, as a result of an overextension of business activity and the loss of a lawsuit. These Fugger vom Reh (Fuggers of the Doe, from their coat of arms) spread over southern, central, and eastern Germany; as late as 1944, there were Fugger (descendants of the Fuggers) residing in Warsaw.

In 1441 Jakob had married the daughter of a mint master who went bankrupt three years later. Warned by this event, Jakob proceeded carefully in his business; yet by perseverance and industry he succeeded in substantially increasing his profits, and in 1463 he was made a member of the more highly respected merchants' guild. After his death in 1469, two of his seven sons,

Jakob the  
Rich

Ulrich and Georg, began by profitably expanding the firm's international trade. In 1473 they were granted a coat of arms with a lily, causing this branch of the family to be called Fugger von der Lilie. With the help of their brother Markus in Rome, they handled remittances to the papal court of monies for the sale of indulgences and the procuring of church benefices. From 1508 to 1515 they leased the Roman mint. Ulrich and Georg established an agency of their own in the German merchants' building in Venice, where their youngest brother, Jakob II the Rich, who had originally been destined for an ecclesiastical career, studied modern book-keeping from 1478 on. Taking charge of the Fugger agency in Innsbruck in 1485, he showed sound business acumen in making the firm a partner in the Tirolean mines by granting permanent loans, secured by deliveries of copper and silver, to Archduke Sigismund and King (later Emperor) Maximilian. The large profits realized from this venture encouraged the Fuggers to participate also in mining operations in Silesia. There Jakob, a shrewd and sober yet enterprising merchant, met a mining expert with whom he leased the copper mines in Neusohl (modern Banská Bystrica, Czechoslovakia) in 1495, eventually building them up into the greatest mining centre of the time.

In 1494 the Fuggers established their first public company with a capital of 54,385 guilders, a sum that was to be doubled two years later when Jakob persuaded the Prince Bishop of Brixen to join the company as a silent partner. Jakob's aim was to establish a copper monopoly by opening foundries in Hohenkirchen and Fuggerau (named for the family, in Carinthia, now Austria) and by expanding the sales organization in Europe, especially the Antwerp agency. True to his motto, "I want to gain while I can," Jakob, unhappily married since 1498 and without an heir, engaged in all manner of commerce, including the lucrative spice trade. The taciturn and hard-driving merchant had long ago assumed the direction of the firm. The death of his chief creditor, the Prince Bishop of Brixen, whose inheritance was claimed by the Pope, brought about a serious crisis that Jakob managed to solve through shrewd negotiations. Prudently, he divided the company's assets equally into cash holdings, production plants and merchandise, landed properties, and precious stones. In 1504 he thus secretly purchased from the city of Basel a portion of the captured crown jewels of Charles the Bold, duke of Burgundy. Laying the foundation for the family's widely distributed landholdings, he acquired the countships of Kirchberg and Weissenhorn from Maximilian I in 1507. In 1514, the Emperor made him a count.

Financier  
of  
emperors  
and enemy  
of Protes-  
tantism

The chief financial supporter of Maximilian I's policies since 1490, Fugger was identified with these policies for better or for worse, even though he refused to support Maximilian's bid for the papacy. His greatest achievement was the financing of the election of Charles V, Maximilian's successor, as emperor. Of the total election expenses of 852,000 guilders, Jakob Fugger alone raised almost 544,000 in order to eliminate Francis I of France. By skillful negotiations he arranged to have this debt repaid out of the Maestrazgo—the lease of the revenues paid to the Spanish crown by the three great knightly orders. A part of the sum came from the mercury mines of Almadén and the silver mines of Guadalcanal. In 1516 he also made an ally of King Henry VIII of England by granting him various loans.

At the height of his power Jakob Fugger was sharply criticized by his contemporaries, especially by the German Humanist and reformer Ulrich von Hutten and by Martin Luther, for his stand on interest charges (the Fuggers were among the merchant dynasties that urged the Pope to rescind or amend the medieval prohibition on the levying of interest) and the sale of indulgences and benefices, as well as for his loan policies. The imperial fiscal and governmental authorities in Nürnberg brought action against him and other merchants to halt their monopolistic tendencies. Fugger's position was furthermore threatened by social unrest among the miners in the Tirol and at Neusohl in Hungary, by attempts of the

Hungarian nobles to nationalize his mines, and by the Peasants' Revolt. At the Augsburg headquarters he was threatened by an uprising of artisans. Fugger mastered these crises through sheer tenacity and fixity of purpose. Albrecht Dürer has immortalized the severe, taciturn countenance of the master merchant. As head of the company, Fugger, who was himself a man of few wants, created monuments to his time that have survived for centuries—in the Fugger buildings and the splendid memorial chapel and above all in the Fuggerei, the world's oldest social settlement, which he endowed as a peaceful haven for his impoverished old servants and fellow citizens. In his last years, seeing his work and his church threatened by the Reformation, he fought the new movement.

**Decline of the House.** At his death in 1525, Jakob the Rich bequeathed to his nephew Anton Fugger, who had been destined for the succession since 1517, company assets totalling 2,032,652 guilders. The new chief, an ambitious and very talented businessman, guided the firm with a firm hand. In 1527 he married Anna Rehlinger, a patrician's daughter who bore him four sons. Most of Anton's time was taken up with the securing of permanent loans for the emperors Charles V and Ferdinand I, and for King Philip II of Spain. In accordance with his credo that money is the sinews of war—*pecunia nervus bellorum*—Fugger, a strict Roman Catholic, granted the Emperor credits that proved to be decisive in the struggle against the Protestants and particularly in the war against the Schmalkaldic League of Protestant princes and cities. While large sales of fustian cloth to England and loans extended to its kings proved to be profitable, the formerly rich yield of the Tirolean and Hungarian mines decreased until Anton gave up Neusohl altogether in 1547. With dogged resolution but indifferent success, he tried to make up for these losses by establishing new trade ties with Peru and Chile and by engaging in mining ventures in Sweden and Norway, as well as in the slave trade from Africa to America. He was, however, more successful in the spice trade and the importation of Hungarian cattle. National resentments in Spain forced him to renounce the Maestrazgo lease after 1542 and to give up the silver mines of Guadalcanal. Nonetheless, Anton Fugger had, by 1546, amassed 5,100,000 guilders—the highest capital in the company's history.

His health weakened in 1540, Anton Fugger reacted more acutely to the shifts in his fortunes; since his sons and nephews showed little interest in business, he even considered dissolving the firm. When that proved impossible, he stubbornly tried to carry on, although he could satisfy the demand for credit only by increased borrowing. An inventory taken after his death in 1560 showed assets of 5,600,000 and liabilities of 5,400,000 guilders (2,900,000 in Spain alone). Anton had, however, safeguarded part of his fortune through the timely purchase of Babenhausen and other landed estates. After the personal bankruptcy of his nephew Hans Jakob Fugger, who had become a partner in 1543 and who eventually became Bavarian chancellor, Anton's oldest son, Markus, carried on the business successfully, if on a reduced scale. During the period 1563–1641 the company, which was not completely dissolved until after the Thirty Years' War, earned some 50,000,000 ducats from the production of mercury at Almadén alone.

While Jakob and Anton Fugger had hardly made use of their title as counts, their descendants, showing little mercantile inclination, acquired a Humanistic education at European universities. Marrying within their class, they spent most of their lives on their estates, where they established valuable libraries and built magnificent residences. It is to Jakob and Anton Fugger's land purchases that the three surviving lines of the family (all dating from the mid-16th century)—the counts Fugger-Kirchberg of Oberkirchberg, the prince Fugger-Glött of Kirchheim, and the prince Fugger-Babenhausen of Babenhausen—owe the preservation of a part of the great wealth once held by the family firm.

The Fugger family may be considered a prototype of

Shoring  
up of the  
Fugger  
fortune

the trading company of the early capitalistic era. In overcoming the economic concepts of the Middle Ages, they used methods that have evoked, both in their time and in the present, admiration as well as violent criticism.

**BIBLIOGRAPHY.** G. VON POLNITZ' comprehensive presentation *Die Fugger*, 3rd ed. (1970), offers the best survey of the Fugger family and contains an extensive bibliography. The same author's biographies *Jakob Fugger*, 2 vol. (1949–51), and *Anton Fugger*, 4 vol. (1958–71; vol. 5 in prep.), are instructive source-books based on research in major European archives. L.L. SCHICK, *Un Grand homme d'affaires au début du XVI<sup>e</sup> siècle: Jacob Fugger* (1957), is a biography written from a professional banker's viewpoint. R. EHRENBURG, *Das Zeitalter der Fugger*, 2 vol. (1896; Eng. trans., with some sections omitted, *Capital and Finance in the Age of the Renaissance: A Study of the Fuggers and Their Connections*, 1928), is a pioneering study of money and credit circulation in the 16th century. WILHELM MASSEN, *Hans Jakob Fugger (1516–1575) ein Beitrag zur Geschichte des XVI. Jahrhunderts* (1922); REINHARD HILDEBRANDT, *Die "Georg Fuggerischen Erben"* (1966); and ROBERT MANDROU, *Les Fugger, propriétaires fonciers en Souabe, 1560–1618* (1969), are all exemplary studies of the company's later development. H. KELLENBENZ, *Die Fuggersche Maestrazgopacht (1525–1542)* (1967), describes the history of the Maestrazgo lease and its development while administered by the Fuggers.

## Fugue

Although the statement is debatable, it is often said that the fugue is the most complex and highly developed type of composition in Western music. The term fugue, derived from *fuga*, the Latin word for "flight," was first used about 1330 by Jacques de Liège, the author of *Speculum musicae*, an important medieval treatise. At that time it referred to a technique of musical writing based on strict imitation. Later, after its emergence as an independent musical form in the 17th century, the fugue became a composition in counterpoint based on a generating theme, in which different parts, or voices, enter successively in imitation, as if in pursuit of each other. The heir of all the compositional techniques that had developed earlier, it differs from its ancestors (the motet, the ricercar, the canzona) in having a more specifically tonal character, unity of form, and a greater economy.

### DESCRIPTION OF THE FUGUE

The fugue is written in counterpoint, two or more lines that sound simultaneously. Counterpoint's laws and techniques have developed from the 10th century to the Renaissance, a period during which Western music was essentially polyphonic. One of the main problems was the harmonic aspect of the meeting of the voices, and the rules of counterpoint are always precise regarding the use of consonance and dissonance. Counterpoint deals also with movement between the parts. It includes various techniques of development, among which imitation is probably the most remarkable feature of polyphonic music. There are many kinds of imitations. The strictest is the canon, in which the melody stated by the first voice is later reproduced by the second voice. A good example is the song "Frère Jacques." Other common types of imitation include inversion of all the intervals, augmentation (in which the rhythmic values are doubled), diminution (in which they are reduced), or even retrograde imitation, in which the last note of one voice becomes the first note of the next. All these techniques are used in fugal composition, which is characterized more by its "language" than by its form.

**Elements.** The fugue is written for a certain number of voices, or instrumental parts. The most frequent are fugues for three or four voices, but there are also fugues for two, five, or more voices. Although the fugal form varies from composer to composer, there are certain common elements.

**Subject.** The subject is the theme of the fugue. It is stated alone by the first voice before being taken up by the others. In the course of the fugue, it will be stated in different keys, and it will be sometimes slightly modified or inverted. Some of its elements may be developed separately.

**Answer.** The second voice brings in the answer, generally stated in the key of the dominant (the fifth degree of the major or minor scale). If it reproduces the subject exactly, it is called a real answer. But in most cases, in order to preserve the tonal unity of the fugue, the answer has to undergo a "mutation" that alters some of its melodic intervals and makes the modulation to the dominant key smoother. This is called the tonal answer.

**Countersubject.** The countersubject accompanies the answer. If it is maintained throughout the fugue, it is called sustained or obbligato countersubject and will follow the subject like its shadow for each new statement. Subject and countersubject are the two principal "actors" of the fugue, and theoretically all the musical substance must be derived from them.

**Exposition.** The first part of the fugue, which includes the successive entrance of the voices, in subject-answer alternation, is called exposition. This progressive enrichment of the polyphonic web is one of the most striking traits of the fugue. In some fugues, after the exposition, the composer brings in the answer followed by the subject. This is called counterexposition.

**Episode.** An episode is any passage, developed or not, that links two statements of the subject. It is characteristically written in imitative style. Generally it uses a motive from the subject or the countersubject, but sometimes a new element is introduced. There is a great variety of episodes.

**Stretto.** When the subject overlaps the answer (or the answer the subject), it is called a stretto. This device, whereby the entries are drawn more closely together, is often used at the end of the fugue, where it achieves spectacular effects.

**Plan of the fugue.** Once past the exposition, the plan of the fugue depends on the will of the composer and the resources of its thematic elements. For instance, the Danish composer Dietrich Buxtehude (died 1707) often presents the subject and the answer only in the principal and in the dominant keys, in short expositions linked by small episodes. With J.S. Bach, the tonal plan becomes more elaborate and includes a journey to the principal neighbouring keys. Since the composer adapts his plan to the character and to the potential of his themes, the itinerary is always different. That is why in his hands the fugue becomes the most versatile of musical forms; each fugue of Bach brings a new solution to the problem of the relation between form and content.

**The "school fugue."** Theorists created an ideal plan of the fugue and gradually perfected it, in the 19th century, as fewer and fewer real fugues were being written. They devised a tripartite form consisting of the exposition, the development, and the stretto.

### VARIETIES OF FUGUE

**Simple fugue.** This is monothematic, without a maintained countersubject (such as the *Fugue in D Major* of Bach's work *The Well-Tempered Clavier*, Book I, No. 5). More elaborate fugues use one or more countersubjects. In a counterfugue, the answer imitates the subject by inversion. There are beautiful examples of this technique in Bach's work *The Art of the Fugue*, numbers 5 to 7.

**Double fugue.** There are two ways of writing a double fugue; either the two subjects may be presented simultaneously, in which case the fugue is not very different from a fugue with countersubject (Bach, *Fugue in B Minor on a Theme of Corelli*, BWV 579), or else the second subject has a special exposition. The latter yields, in general, a tripartite scheme: exposition and development of the first subject, exposition and development of the second subject, and finally combination of the two elements, which are devised so that they can be superimposed. A splendid example is given by Bach's *Toccata and Fugue in F Major* for organ, BWV 540. The same principles apply to a triple or quadruple fugue.

**Fughetta.** This is a miniature fugue but strictly written, whereas the fugato starts like a fugue but gives up its discipline once past the exposition.

**Choral fugues.** The fugue plays a considerable role in works for chorus and orchestra. Generally the chorus

Versatility  
of the  
fugue

Types of  
imitation

sings in strict counterpoint, while the instruments play an expressive or decorative accompaniment. The composition techniques of the fugue can also be used in forms as universal as the prelude, the aria, the chorus, the overture, the concerto, and others.

#### LITERATURE OF THE FUGUE

Since vocal polyphony was based on a text that had to be sung by each of the parts (either simultaneously or, more frequently, in imitation), it was not very much concerned with the problem of form. That is why theorists and musicians concentrated on questions of texture.

At first the term *fuga* applied to strict imitations (which would now be called canons); the concept evolved in a more general sense when it was realized that a freer use of all kinds of imitations offered much more stimulating opportunities. Besides the purely vocal polyphony, the first independent forms of keyboard music (the *ricercar*, the *canzona*, the *capriccio*, the *fantasia*) testify to the remarkable development of what can be called the fugal style of the 16th and 17th centuries. In this evolution, the role of the Italian composer Andrea Gabrieli and of the English virginalists was preponderant. The two great precursors of the fugue proper were the Dutch composer J.P. Sweelinck (died 1621) and the Italian Girolamo Frescobaldi (died 1643). Both greatly influenced the keyboard music of the 17th century, in particular through their students Samuel Scheidt and Johann Jakob Froberger. In Germany, a generation of musicians dominated by Buxtehude gave the fugue its modern form by putting it in a tonal perspective and abandoning the fragmentary style of their predecessors. Almost all the composers of the 17th century contributed to the history of the fugue.

**J.S. Bach.** The genius of Bach found particular expression in the fugue, perhaps because it allies the strictest economy of language to a relative freedom of form. Each of his fugues amazes by the freshness of its inspiration, the wonders of its writing, or by its gigantic proportions, all marvellously represented in the two volumes of *The Well-Tempered Clavier* (1722–44), two sets of 24 preludes and fugues going through the cycle of the 24 major and minor keys. Some of his organ fugues tend toward development, some toward symmetry, and some toward virtuosity; others take the form of double fugues.

His last work, *The Art of the Fugue*, is a collection of 14 fugues and four canons, all based on a theme in D minor and its inversion. All the resources and procedures of the fugue are demonstrated in what constitutes the most inspiring treatise on fugue, a treatise without words, in which music speaks alone. After being long slighted as a purely theoretical work, *The Art of the Fugue* has won a high place in the hearts of music lovers, who see it as Bach's musical testament. Bach's cantatas, passions, and oratorios abound in admirable fugues.

**Handel and after.** Handel's fugues are less erudite than those of Bach and sometimes employ looser counterpoint, but they touch the listener by their vitality and their harmonious proportions. The great fugal sections of his oratorios are more important than his keyboard fugues.

After Bach the fugue lost much of its importance. With the appearance of the sonata, the musical taste changed, and composers tended to consider counterpoint as an archaic discipline. Nonetheless, the fugue retained a place in choral works, and fugal methods were kept in the sonata form, particularly in the development section.

A great passion for Bach led Mozart (died 1791) to a more contrapuntal style. This influence is obvious in the *Fugue in C Minor*, for two pianos, K. 426, which, though pure Mozart, is nonetheless a homage to Bach. In ingenuity and mastery, Mozart rivalled the greatest contrapuntists in, for instance, the great choruses of the *Mass in C Minor*, K. 427, or in the final development of the *Jupiter Symphony*.

**Beethoven.** Beethoven resorted more and more to fugal technique in his last works. He confessed that he wrote his fugues with the greatest difficulty, and it is true that his counterpoint gives an impression of effort.

Most of the fugal passages integrated into his last sonatas and quartets create a dramatic tension. Far from being a scholastic technique, the fugue was for Beethoven a means to reach the expressive limits of an idea. He used this language in particular circumstances. The strange and desolate atmosphere of the opening fugue of the *String Quartet in C Sharp Minor*, Opus 131, brings to mind the 20th-century fugue in the first section of the *Music for Strings, Percussion and Celesta* of Béla Bartók. The Promethean side of Beethoven asserts itself particularly in the *Great Fugue* from the *String Quartet in B Flat Major*, Opus 130, and the noble fugal section of the *Missa Solemnis*. Unlike Mozart's classical fugues, Beethoven's are rather irrational in form but are justified by their creative power alone.

**The Romantic era.** Compared with the fugues of Beethoven, those of Felix Mendelssohn defer to traditional rules. Critics sense in them a nostalgia for Bach, sometimes weakened by a touch of sentimentalism. A more authentic romantic breath animates the fugues of Robert Schumann on B.A.C.H. (the German letters for the notes B $\flat$ –A–C–B $\natural$ ), but the fugue is not his natural language. The genre is more suited to César Franck, as may be seen in his *Prélude, fugue et variation*, or in his *Prélude, chorale et fugue*. His harmonic sensitivity enriches a contrapuntal technique while not breaking with tradition. The fugues of Franz Liszt are entirely different: once past the exposition, he cannot renounce symphonic developments. There is an original use of the *fugato* before the re-exposition in his *Piano Sonata in B Minor*. The fugal style was used to varying degree by the major composers of the 19th century, including Brahms in his *German Requiem*, Richard Wagner in his opera *Die Meistersinger*, and Verdi in his *Requiem* and at the end of his last opera, *Falstaff*.

Among the post-Romantics, who cultivated their own exaggerated form of counterpoint, mention must be made of Max Reger, whose admirers took him as the heir of J.S. Bach. Though that appears to be going too far, his counterpoint does possess vitality in works such as the *Variations and Fugue on a Theme by Mozart*, for orchestra, or the fugue on the chorale melody "Wachet auf, ruft uns die Stimme," for organ.

**The 20th century.** As an autonomous form, the fugue played only a modest role in the first half of the 20th century. The most beautiful example is the already mentioned fugue of the *Music for Strings, Percussion and Celesta* of Béla Bartók, a born contrapuntist. This is a true model of fugal treatment in a post-tonal style. The methods of the fugue are also found in his *Sonata for Two Pianos and Percussion* and in his admirable quartets.

Stravinsky, though influenced by the composers of the 17th and 18th centuries, showed no particular interest in the fugue. Although the second part of his *Symphony of Psalms* can be considered a double fugue, it does not strike the listener as such.

In his collection of interludes and fugues, called *Ludus Tonalis*, Paul Hindemith seems to have drawn his inspiration from Bach's *Well-Tempered Clavier*. Although an interesting work, it did not herald a rebirth of the fugue. A new conception of counterpoint appeared in the works of Arnold Schoenberg and Anton von Webern. The serial techniques of composers like Pierre Boulez can, to a certain extent, claim some kind of kinship with fugal language, and a work such as the *Passion According to St. Luke* of Krzysztof Penderecki testifies to the permanence of a musical form the history of which is probably unfinished.

**BIBLIOGRAPHY.** Major historical treatises on the study of the fugal style include: N. VINCENTINO, *L'Antica Musica ridotta alla moderna pratica* (1555); GIOSEFFO ZARLINO, *Istitutioni harmoniche* (1558; Eng. trans. of pt. 3, *The Art of Counterpoint*, 1968); THOMAS MORLEY, *A Plaine and Easie Introduction to Practicall Musicke* (1597; new ed. by R.A. HARMAN, 1952); JAN PIETERSZON SWEELINCK, *Kompositionslehre* (1670, reissued 1891); JOHANN JOSEPH FUX, *Gradus ad parnassum*, 2 vol. (1725; Eng. trans., *Steps to Parnassus*, 1943), part of this work ed. and trans. by ALFRED MANN as "The Study of Fugue," in *Musical Quarterly*, vol. 36–37 (1950–

Bach's Art  
of the  
Fugue

## Fujiwara Family

The Fujiwara was one of the more remarkable families in Japanese history. For 300 years following the transfer of the capital from Nara to Heian (the present Kyōto), late in the 8th century AD, this family so dominated the government and court life of the Japanese and exerted such great influence that the Heian period (794–1185) is sometimes called the Fujiwara period.

No less remarkable was the fact that Fujiwara power and authority rested not on military prowess but on political strategy and on the Fujiwara's special relationship to the Imperial family, which it carefully cultivated and exploited. This relationship stemmed from the Fujiwara policy of attaching itself to the Imperial family through the marriage of Fujiwara daughters to emperors. It meant that the Fujiwara's daughters were empresses, that their grandsons and nephews were emperors, and that members of their family, including its lesser branches, received all the patronage. Thus, the Fujiwara clan chieftain, whether he held office or not, could manipulate the reins of government.

The Fujiwara also took care to combine with the Buddhist church to increase its influence. A precedent set earlier, of pious emperors shaving their heads and retiring to monasteries, was used by the Fujiwara to persuade independent-minded emperors to retire from worldly affairs. Nor did the family neglect laying a firm economic foundation for its political power. It encouraged the landed gentry in the provinces to commend land to the Fujiwara, which greatly reduced or completely eliminated the tax obligations of the landowners and permitted the Fujiwara to divert public revenues to its private coffers.

Although the Fujiwara rise to power was gradual, its founding in the 7th century foretold its future role and importance. Its founder, Nakatomi Kamatari (614–669), was already in his day the de facto ruler of the country, for it was he, together with the heir apparent, who had earlier plotted and successfully carried out the overthrow of a powerful rival of the Imperial house. It was to Kamatari, therefore, that a grateful prince, who consequently was able to ascend the throne as Emperor Tenchi, entrusted the affairs of government. In the year of Kamatari's death, the Emperor conferred on him the new family name of Fujiwara (Wisteria Arbour), in commemoration of the place where the two had conspired to oust their common rival.

Fuhito (659–720), Kamatari's son, was the first to use the new name. And it was he who, by arranging the marriage of a daughter to Emperor Shōmu, began the policy of attaching his own family to the Imperial family. Fuhito's four sons each established a branch of the family, of which the Hokke, or Northern Branch, was to become the most influential.

But it was not until the latter half of the 9th century that Fujiwara power began to be felt. Yoshifusa (804–872), who was father-in-law to the reigning monarch and

grandfather of the heir apparent, at the Emperor's death succeeded in having the heir elevated to the throne as Emperor Seiwa at the age of nine. Yoshifusa, thereupon, had himself appointed regent—the first instance in Japanese history of a person not of royal blood being named to this position. This led to the practice of the Fujiwara persuading emperors to retire at a comparatively early age and of placing on the throne child emperors, for whom the Fujiwara acted as regents. During the next two centuries there were eight such abdications and seven child emperors.

With a firm grip on the regency, the Fujiwara had seemingly gone as far as they could to become the de facto rulers without actually destroying or displacing the Imperial family. The only drawback to the regency was that it ended when the emperor reached his majority. This was remedied by Yoshifusa's nephew Mototsune (836–891), who established a new position more prestigious and powerful than that of regent or prime minister—the office of *kampaku*, whose function was to serve as the emperor's spokesman and intermediary between the throne and the officialdom. In practice it was a civil dictatorship and the highest office in the land, second only to the emperor and sought by all subsequent leaders.

The Fujiwara monopoly of government in the 9th century was interrupted only briefly when Emperor Uda, who did not have a Fujiwara mother, ascended the throne in 887. Uda, moreover, managed to reign without a Fujiwara regent and, in the last six years of his reign, without a Fujiwara *kampaku*, because of the death of Mototsune.

Mototsune's son, Tokihira (871–909), only 21 years old at his father's death, quickly re-established Fujiwara domination. Tokihira never advanced to the office of *kampaku*, yet he effectively removed or neutralized opposition to the family. Among his rivals was a celebrated and beloved scholar-statesman, Sugawara Michizane, who was falsely accused of conspiring to place his own grandson on the throne and was banished to distant Kyushu. Other rivals were given sinecures to monasteries and lectureships in Chinese history by the resourceful Tokihira and were thus effectively removed from politics. That he was able to accomplish these moves from a relatively low position demonstrated that the Fujiwara, whether in high office or not, were the real rulers of the country.

But it was Michinaga (966–1027) who epitomized Fujiwara power and glory. He gave three daughters to emperors and a fourth to an heir apparent who later became emperor. Four grandsons were emperors, and a son was a regent. For 30 years he basked in the splendour and sophistication of court life. His mansions, more magnificent than the palaces of the emperors, were the scene of frequent banquets, concerts, poetry contests, and picnics. It is this brilliant if effete and frivolous court life that Murasaki Shikibu, a contemporary, described in her great novel *Genji monogatari* (*The Tale of Genji*). Michinaga also inspired still another contemporary romance, the *Eiga monogatari* (*Tales of Power and Glory*), by an unknown author.

But, in the midst of Michinaga's glory at the capital, Fujiwara power was rapidly declining in the provinces. As early as the 940s there were two serious rebellions in the provinces, which were suppressed for the government by warrior families allied with the Fujiwara. But the victories served only to increase the power and popularity of the military families, to whom the landed gentry tended to commend more and more of their lands rather than to the Fujiwara. The failure of the Fujiwara to check this practice brought the rapid erosion of the economic basis of Fujiwara power and the strengthening of the military families of the outlying provinces.

The passing of Michinaga in 1027 hastened the decline of the family, which could neither prevent Sanjo II, who did not have a Fujiwara mother, from taking throne in 1068 nor stop the establishment of a unique scheme of administration aimed at weakening Fujiwara control of the government. Known as *insei*, or "cloistered rule," this scheme called for the emperor to abdicate, leaving an

Fujiwara  
power and  
glory

infant on the throne, and to establish a separate administration in a monastery, from where, as a lay priest and free of Fujiwara overlordship, he would attempt to rule.

The *insei* definitely weakened Fujiwara influence in the 11th century, and the Fujiwara was eliminated as a power at the court in the 12th century. In the Hōgen Disturbance of 1156 the contender supported by the Minamoto, a warrior family allied with the Fujiwara, lost to Shirakawa, supported by the warrior family of the Taira. In the Heiji War of 1159, the Minamoto-Fujiwara forces, who attempted to wrest back control of the court from the Taira, were ignominiously defeated. And thus, ironically, the Fujiwara, who for three centuries had eschewed violence and who had looked down contemptuously on the crude, unlettered warrior, were vanquished by violence and replaced as rulers by the very objects of their contempt. If there was any consolation for the Fujiwara, it was the knowledge that the House of Taira promptly adopted and helped to perpetuate the life-style and the political and social institutions that the Fujiwara had established.

**BIBLIOGRAPHY.** A complete translation of the *Ōkagami* ("Great Mirror"), written by an unknown author in the 11th century and covering the period from 850 to 1025, the period of Fujiwara domination, is now available. See JOSEPH K. YAMAGIWA (trans.), *The Ōkagami: A Japanese Historical Tale* (1967). A more recent general history that gives considerable attention to the subject is GEORGE SANSOM, "The Fujiwara Regents," in *A History of Japan*, vol. 1 (1958). Two indispensable reference works in Japanese are: OTA AKIRA, *Seishi kakei dai-jiten* (Dictionary of Families and Genealogies), rev. ed., 3 vol. (1963), and *Dai Nihon jimmei jisho* (Biographical Dictionary of Japan), rev. ed., 5 vol. (1937).

(M.Sh.)

## Fukien

Fukien (Fu-jian in Pin-yin romanization), one of the provinces of the People's Republic of China, is located on the southeast coast of China to the northwest of the island of Taiwan. It is bordered by the provinces of Chekiang to the north, Kiangsi to the west, and Kwangtung to the southwest; and by the East China Sea to the northeast, the Formosa Strait to the east, and the South China Sea to the southeast. It occupies a strategic maritime position linking the two sections of the China Sea. One of the smaller Chinese provinces, Fukien has an area of 47,500 square miles (123,000 square kilometres). In 1970 its population was estimated to number 18,000,000. Its capital and largest city is Foochow (Happy City).

The name of the province, Fukien, means Happy Establishment. The province is also known as Min Sheng (Min Province), after the "seven Min tribes" that inhabited the area during the Chou dynasty (12th to 3rd century BC). The area became Min-chung Chün (Min-chung Province) in the Ch'in dynasty (221–206 BC). It was, however, during the Sung dynasty (AD 960–1279) that the name Fu-chien was adopted and the basic geographical boundaries of the province established. The region is one of the most picturesque in Asia, with wooded hills and winding streams, orchards, tea gardens, and terraced rice fields on the gentler slopes.

**History.** The area now called Fukien was first referred to in the *Chou Li*, a classic that may date to the 12th century BC, although modern scholars believe it to have been written at a much later date. In this classic the seven Min tribes are mentioned together with "eight barbarian peoples" in the south.

During the latter part of the Ch'un Ch'iu period (722–481 BC) one of the feudal states within the China area was the kingdom of Yüeh, located south of Hangchow Bay; it included what is now Fukien Province. The lord of Yüeh was nominally a vassal (viscount) of the Chinese king. The Yüeh and their culture are considered by some to have constituted one of the principal elements that merged to form the contemporary Chinese ethnic and cultural complex.

During the last quarter of the 5th century BC, Yüeh became a powerful kingdom after its conquest of the state of Wu (473 BC) to its north. During the era known as the Warring States Period, Yüeh was, in turn, con-

quered by the kingdom of Ch'u (c. 334 BC) to the northwest. Wu-chu, one of the sons of the vanquished Yüeh king, fled by sea and landed near Foochow to establish himself as the king of Min-yüeh. When the first emperor of the Ch'in dynasty conquered the kingdom of Ch'u in 223 BC, the Chinese domain was finally unified within the bounds of a monolithic state. Li Ssu, the famous prime minister of Ch'in, deposed the king of Min-yüeh, establishing instead a paramilitary province there called Min-chung Chün. The collapse of the Ch'in dynasty (206 BC) was followed by the war between the famous general Hsiang Yü and the crafty Han Kao Tsu, the founder of the Han dynasty. Wu-chu, the deposed king of Min-yüeh, sided with Han Kao Tsu, who defeated his rival and became emperor of China; he re-established Wu-chu as the king of Min-yüeh, which consisted roughly of the present area of Fukien. During the reign of the emperor Han Wu Ti (140–87 BC) a rebellion by the Min-yüeh tribes was put down, and the tribes were resettled in the inland region far to the north between the Huai Ho and the Yangtze.

During the Six Dynasties period (from the 3rd to the 6th centuries AD) the region remained in the Chinese domain, but true Sinicization did not really come about until the coming of the T'ang dynasty (from the 7th to the 10th centuries AD), when intermarriage between the T'ang settlers from the north and the local people became common.

Fukienese have settled in Southeast Asia in great numbers since the end of the Sung dynasty. Today overseas Fukienese (Min-ch'iao) constitute three-eighths of all overseas Chinese. The Taiwanese, who make up the bulk of the population of Taiwan, all came from Fukien during the last three centuries and still speak what is essentially the southern Fukienese dialect.

In 1842, by the Treaty of Nanking following the Opium War with Britain, Foochow and Amoy were opened to international trade, and Foochow became a major seaport. During World War II, Foochow and Amoy were occupied by the Japanese. Fukien was taken by the People's Liberation Army in 1949, but the Nationalists have retained several offshore islands.

**The natural environment.** *Relief.* About 95 percent of Fukien is mountainous. The province is crossed by several ranges of moderate elevation that run roughly parallel to the coast. They constitute a part of a system of ancient blocks of mountains trending from southwest to northeast. The Fukien-Chekiang section forms a part of a raised massif (mountainous mass) that has been subjected to folding and refolding. A sharp natural boundary exists to the west and northwest between this uplifted block, on the one hand, and the low-lying Kiangsi Basin and the southwest part of Chekiang Province, on the other. Along this boundary runs the Wu-i Shan (Wu-i Mountains), which, in the extreme north, include the Hsien-hsia Ling (Hsien-hsia Mountains) on the Chekiang-Fukien border.

The Wu-i Shan, which form a formidable natural barrier between Fukien and the interior of China, reach a height of about 6,000 feet in western Fukien and in adjacent parts of southwest Chekiang. The range forms the watershed between the Min Chiang system to the southeast and the Kan Chiang system—tributary to the Yangtze—to the northwest. The few passes across the Wu-i Shan are high and difficult.

The mountain ranges tend to be more compressed in the interior and to broaden out toward the coast. Faults occur both along the axes of the mountains and across them, thus causing an extreme fragmentation of the land surface, so that local relief forms a complicated pattern.

The general slope of the land descends from the northwest to the southeast. As a result, the main rivers cut across the intermediate ranges in deep gorges; their tributaries, however, drain broader intermontane valleys that follow the grain of the relief. The result is an almost perfect example of the trellis pattern of stream drainage, which is particularly well illustrated in the Min Chiang system.

The drainage area of the Min of Fukien (to be distin-

Emigra-  
tion of  
Fukienese

Early  
history

## The Min Chiang system

guished from the Min Chiang of Szechwan Province) occupies about half of the province. It is formed by the confluence upstream of three rivers, the largest of which is the Chieng Ch'i (Establishment Stream), which flows from the north, where its source is located near the Fukien-Chekiang border. It has its own subsystem of tributary streams that drain the famous Wu-i tea district. The second source stream of the Min—Fu-t'un Ch'i (Rich Colony Stream)—also called Shao-wu Ch'i—is named after the chief city of the region; it flows down the eastern slopes of Wu-i Shan. The third source, Sha Ch'i (Sandy Stream), flows from the south and southwest, arising on the eastern slopes of another section of the Wu-i range. The three streams, converging from the north, south, and west, meet at Nan-p'ing (Southern Peace), their waters uniting to form the Min Chiang, which flows southeast past the city of Foochow to the sea.

To the south of the Min are the Chiu-lung Chiang (the River of Chang-chou), which has its outlet to the sea at Amoy, and the Ch'in Chiang (Promotion River), with its outlet at the city of the same name. To the southwest of the Min is the Han Chiang, which crosses the southwestern border of Fukien Province to empty into the sea at Swatow, the main port of eastern Kwangtung.

Rivers are of great importance in Fukien, having for centuries provided the only means of transport. They flow into estuaries that form natural harbours, and their abundant water supplies are used for domestic consumption as well as for the irrigation of the myriad rice fields in the alluvial plains along their courses.

## The coast and coastal islands

Fukien has a submerged rocky coast that abounds in islands and islets, capes and peninsulas, bays and havens. The shoreline is extremely irregular, with a total length estimated to be 1,680 miles in length. The chief islands offshore are Quemoy (Chin-men Tao [Golden Gate Island], under Chinese Nationalist control), Hsia-men Tao (Mansion Gate Island) and Tung-shan Tao (Eastern Hills Island) in the south, and Hai-t'an Tao and Ma-tsu Tao (like Quemoy, under Nationalist control) in the north.

**Climate.** Fukien lies just north of the Tropic of Cancer. The climate along the coastal area of the province is semitropical—very hot in summer but cool in winter. The mean temperatures in Foochow are about 84° F (29° C) in July and about 53° F (12° C) in January. There are three seasons in the year. November through February is the cool season; March through May, the warm season; and June through October, the hot season. The growing period lasts throughout the year. The northwestern mountains have a temperate climate but can become very cold in winter.

Summer is dominated by a monsoonal (rain-bearing) tropical airflow from the sea. Rainfall increases from the coast to the western mountains and averages between 50 and 80 inches a year. Some precipitation occurs in winter, occasionally in the form of snow in the northwest. The coast is visited by typhoons during late summer and early autumn.

**Soils and vegetation.** The province has an extremely varied vegetation, ranging from tropical species to forest and plant types associated with a cold temperate climate. The vegetation pattern depends upon altitude, as well as upon local topographical, edaphic (soil), and ecological conditions. Commercial forests are located upstream in the mountainous and rainier interior, away from rural settlements. After centuries of rice cultivation, soils in the valley plains have been greatly modified. Well-developed gray-brown forest soils are widely distributed in the forest areas of the interior mountains, whereas mature red soils are common in the low hills and on high terraces. White saline soils and salt swamps are found in the coastal flatlands. Their parent rocks are marine saline deposits, penetrated by seawater. Attempts at desalination appear to have been successful, and some soils that were formerly saline are reported to be used for rice cultivation.

Fukien has a unique vegetation that abounds in endemic species, genera, and even families. The province has subtropical, laurel-leaved forests, as well as many kinds of

conifers. In western Fukien the lower elevations support tropical mountain forests. The lianas are purely tropical. Tree ferns grow in the ravines. Higher up, where altitude modifies the climate, deciduous trees, conifers, and rhododendrons occur.

**Animal life.** Animal life in Fukien is of the subtropical forest variety and is characterized by great diversity. There are many kinds of birds, such as sparrows, pigeons, crows, ducks, and pheasants; amphibians, such as various frogs, toads, and salamanders; and reptiles, including the black python. Among the province's mammals, the tiger still survives in the interior mountains.

**People and population.** *Ethnic composition and distribution.* The Chinese (Han) make up 99 percent of the population. In 1957 ethnic minorities totalled only about 120,000; the largest group consisted of She tribesmen (She Min), numbering 110,000 and representing about one-half of all the She in China. About 95 percent of those in Fukien live in the hilly hinterland of the northern coast, of whom 82 percent were distributed in the four counties (*hsien*) of Fu-an, Hsia-p'u, Fu-ting, and Ning-te; all of them were engaged in farming.

Other ethnic groups included the Miao, Hui, and Manchu, together numbering no more than 10,000. The Miao are distributed in the mountainous interior of northern Fukien; the Hui (Muslims) are distributed in the cities of Foochow, Amoy, and Ch'üan-chou; and the Manchus live principally in Foochow, being descendants of Manchu soldiers who garrisoned Chinese cities during the Ch'ing (Manchu) dynasty. As these groups are small and widely dispersed among the Han people, there is no ethnic-minority autonomous district (*tzu-chih-chou*) in the province. They are, however, said to be represented at all levels of local government. The She people, culturally affiliated with the Miao and the Yao, are not officially recognized as an ethnic group. They are distributed in the northern mountains, from the coast to the interior, and are even found beyond the Fukien border in Kiangsi and southern Chekiang. Nor are the "boat people" (Tanka or Tang-chia), who live on boats in the streams and estuaries, recognized as a separate group. All discriminatory restrictions against ethnic and cultural minorities in the province were removed in 1912.

**Linguistic patterns.** There are four principal local dialects in Fukien. Hokchiu (the Foochow dialect) is spoken principally in Foochow and in the Min-hou Special District (*chuan-ch'ü*) area, corresponding roughly to the area of the former Foochow Fu (prefecture). Hookien, the Amoy dialect, is spoken in southern Fukien (thus, it is also known as the Min-nan, or south Fukien, dialect). The Hokchia, or Hakka, dialect of Fukien is spoken in the upper Han Chiang Valley of southwestern Fukien. Lastly, the Henghua dialect is spoken in the Henghua district between Foochow and Amoy. These four dialects are as different from the standard *kuo yü* (northern Mandarin) and from each other as English, for example, is from German or Dutch. The usage of *kuo yü* (the national tongue) in compulsory elementary education and by the mass media has, however, established a lingua franca among the literate younger generation. Yet, even before this, the same Chinese written script (*Han-wen*) had been generally in use in Fukien, as elsewhere in China, irrespective of local dialects, since 221 BC.

**Demography.** A Sung dynasty census of AD 1080 counted about 2,000,000 persons in Fukien—a number about five times greater than 400 years earlier. By the late 18th century the population numbered about 12,000,000. In the 1953 census there were 13,100,000 inhabitants, and by 1970, as mentioned, the population was estimated at 18,000,000. Almost 20 percent of the population is urban. There are four large cities: Foochow (which had about 700,000 inhabitants in 1970), Amoy (350,000), Ch'üan-chou (100,000), and Chang-chou (100,000). Foochow and Amoy are important seaports.

**Administration and social conditions.** *Government.* The province is subdivided into nine subprovincial levels, or secondary administrative units; two municipalities (*shih*), Fu-chou and Hsia-men; and seven special districts (*chuan-ch'ü*). These subprovincial areas are again

## Minority groups

## The four principal dialects

subdivided into 62 counties (*hsien*) and four county-level municipalities (*shih*).

Since 1958 the new sub-*hsien* administrative unit has been the commune. In practice, the production brigades into which a commune is subdivided own the land, as well as the means of production, and provide political and economic guidance to the rural inhabitants. The brigade is again subdivided into production teams, which are generally quite small, averaging 20 to 40 households.

**Social conditions.** *Health and welfare.* Public health has improved considerably since the establishment of the people's republic, and malnutrition has not been reported since the early 1960s. Social welfare services are provided by the rural communes.

*Education.* One of the most notable institutions of higher learning in Fukien is Amoy University. Foochow, famous since the Sung dynasty as a cultural centre, hosts Foochow University, Fukien Medical College, Fukien Agricultural Institute, Fukien Normal College, and the Fukien Institute of Epidemiology of the Chinese Academy of Medical Sciences.

Illiteracy has generally been eliminated among those persons born since 1950. Primary and secondary education is offered by rural communes and by factories.

**The economy.** *Agriculture.* Fukien claims to have achieved self-sufficiency in staple food production since 1952, although nutrition standards remain low by comparison with some Western countries. The basic limitation is the unfavourable man-to-land ratio. The arable land per capita available amounts to only one-fifth of an acre. As about 80 percent of the population is engaged in agriculture, each person among the agricultural population has only one-quarter of an acre to support himself and the state. (F.Hu.)

Two crops of rice are harvested each year, the first in June, the second in September. The forests are of great importance as a source of timber. The most important woods are fir, pine, and rosewood, mostly floated in the form of big rafts down to Foochow, a great timber emporium. The export of tea from Foochow to the European market has become insignificant, but Fukien remains a great tea-growing province with a large home market. A special feature is its production of flower-scented teas, for the manufacture of which there are nearly 50 factories in Foochow. There are also factories for the manufacture of paper from bamboo pulp.

In addition to its agricultural and timber resources, Fukien also has considerable mineral wealth, including coal, iron, copper, gold, graphite, and Kaolin (China clay) for making porcelain. Mines are widely scattered over the province. (Jo.E.S.)

*Transportation.* Since the Korean War and the partial blockade of the Fukien coast by the United States and by Chinese Nationalist forces based on Taiwan, overseas trade has been virtually halted until such time as peaceful relations, both national and international, are restored in the Formosa Strait. Fukien's trade patterns have consequently turned inland, especially since the completion, in 1955, of the Amoy-Ying-t'an (Kiangsi) railway, a 430-mile trunk line that crosses the Wu-i Shan to link the province with the Chinese national rail network. In 1958 the railway from Foochow to Nan-p'ing was completed, also linking the capital of the province to this network. Fukien's traditional isolation has also been breached in recent years by the construction of modern highways, linking it to neighbouring Kiangsi and Chekiang provinces. Air services centre on the chief airport at Foochow.

Fukien's rivers are still in use for transportation. The headwaters of the Chien Chi are navigable for small boats right up to the Wu-i Shan, despite the river's rocky channel and many rapids; boats bring downstream the tea grown on the slopes of the mountains. Below Chienning, larger boats of special construction are employed for the tea trade.

**Cultural traditions.** Traditional Chinese culture reached a high level in Fukien during the Sung period (from the 10th to the 13th centuries AD). Certain unique traditional customs evolved that gave women a stronger

social position than that of the women in North China. The province's long literary tradition centres about local history recorded during the last thousand years. Modernization, however, has been slow by comparison with neighbouring provinces—e.g., Chekiang and Kwangtung.

Radio programs are broadcast in several dialects, including the standard *kuo yü*, Hokchia, and Hookien. Newspapers are published in Foochow and Amoy.

(F.Hu.)

**BIBLIOGRAPHY.** The most comprehensive contemporary regional monograph is SUN CHING-CHIH (ed.), *Economic Geography of South China* (Kwangtung, Kwangsi, Fukien) (Eng. trans. 1959). The best atlas available on the Chinese People's Republic is *Kung-fei ch'ieh-chü-hsia ti Chung-kuo ta-lu fen-sheng ti t'u* (1966), a reproduction of the maps and geographical description of the provinces in *Chung-kuo fen sheng ti t'u* (Eng. trans., *Provincial Atlas of China*, 1964), with critical commentaries and supplementary data. Recent observations of a team of French modern sinologists are reported in *Nagel's Encyclopedia-Guide to China* (1968). The best account available on rural conditions under the Communists is found in the *Rural People's Communes in Lien-chiang: Documents Concerning Communes in Lien-chiang Country, Fukien Province, 1962-63*, ed. by C.S. CHEN, trans. by C.P. RIDLEY (1969).

(F.Hu./Jo.E.S.)

## Fuller, R. Buckminster

Architect, engineer, inventor, philosopher, and poet, Richard Buckminster Fuller established a reputation as one of the most original thinkers of the second half of the 20th century. He was perhaps the first to attempt to develop, on a global basis, comprehensive, long-range, technological and economic plans designed "to make man a success in Universe."

R. Buckminster Fuller

Fuller shown with a geodesic dome constructed as the U.S. pavilion at the American Exchange Exhibit, Moscow, 1959.

He conceives of man as a passenger in a cosmic spaceship—a passenger whose only wealth consists in energy and information. Energy has two phases, associative (as atomic and molecule structures) and dissociative (as radiation); and according to the first law of thermodynamics, the energy of the universe cannot be decreased. Information, on the other hand, is negatively entropic; as knowledge, technology, "know-how," it constantly increases. Research engenders research; and each technological advance multiplies the productive wealth of the world community. Consequently, "Spaceship Earth" is a regenerative system whose energy is progressively turned to human advantage and whose wealth increases by geometric increments.

Fuller was born in Milton, Massachusetts, July 12, 1895. He is descended from a long line of New England Non-conformists, the most famous of whom was his great-aunt, Margaret Fuller, the friend of Emerson and Thoreau, and co-founder of *The Dial*, the organ of the Transcendentalist movement. Fuller was twice expelled from Harvard University and never completed his formal education. He saw service in the U.S. Navy during World

Tea  
growing

War I as commander of a crash-boat flotilla. In recognition of his invention of special life-saving equipment, he was awarded an appointment to the U.S. Naval Academy at Annapolis. In 1917 he married Anne Hewlett, daughter of James Monroe Hewlett, a well-known architect and muralist, later a director of the American Academy in Rome. Hewlett had invented a modular construction system using a compressed fibre block; and after the war Fuller and Hewlett formed a construction company, using this material (later known as Soundex, a Celotex product), in modules, for house construction. In this operation, Fuller himself supervised the erection of several hundred houses; the experience taught him that construction with craft labour is disastrously wasteful: "The experience made me realize that craft building—in which each house is a pilot model for a design which never has any runs—is an art which belongs to the middle ages."

In 1922, soon after the founding of the construction organization, The Stockade Building System, his first daughter, Alexandra, died at the age of four. She had suffered, in succession, influenza, polio, and spinal meningitis—illnesses epidemic at the time, and whose spread Fuller blamed partially on inadequacies of the environment. He concluded that the inadequacies were unnecessary, and that the environment can be controlled; it can be "valved" to human advantage. Fuller's key to controlling the environment is comprehensive anticipatory design.

The Stockade Building System encountered financial difficulties in 1927. Fuller, a minority stockholder, was forced out. He found himself stranded in Chicago, without income, alienated, dismayed, confused.

At this point in his life, Fuller made what he called a "blind date with principle." He resolved to devote his remaining years to a nonprofit search for design patterns that could maximize the social uses of the world's energy resources and evolving industrial complex. The inventions, discoveries, and economic strategies that followed have been interim factors related to this end.

In 1927, in the course of the development of his comprehensive strategy, he invented and demonstrated a factory-assembled, air-deliverable house, later called the Dymaxion house, which had its own utilities. Regarding air-land-water transportation as a necessary adjunct to his totally autonomous house, he designed in 1928, and manufactured in 1933, the first limited, land-taxiing prototype of his omnidirectional vehicle, the Dymaxion car. This automobile, the first streamlined car, could cross open fields like a jeep, accelerate to 120 miles per hour (190 kilometres per hour), make a 180° turn in its own length, carry 12 passengers, and average 28 miles per gallon of gasoline. Equipped with all-around bumpers, it provided maximum protection to its occupants in event of collision. In 1943, at the request of the industrialist Henry Kaiser, Fuller developed a new version of the Dymaxion car embodying advantages of the improved technology. The new version was planned to be powered by three separate air-cooled engines, each coupled to its own wheel by a variable fluid drive. The coupling system provided maximum torque with minimum engine size. Once starting inertia was overcome, only a single engine was required to maintain cruising speed. Thus the car could average 40 to 50 miles per gallon of gas, and could operate with a minimum of pollution. All wheels were steerable; the car consequently could move sideways like a crab, parking in a space no greater than its own length. The projected 1943 Dymaxion, like its predecessor, was never put into commercial production, possibly because of the resistance of the automotive industry to radical innovations.

Assuming that there is in nature a vectorial, or directionally oriented, system of forces that provide maximum strength with minimum structures, as is the case in the nested tetrahedron lattices of organic compounds and of metals, Fuller developed a vectorial system of geometry that he called "Energetic-Synergetic geometry." The basic unit of this system is the tetrahedron (a pyramid shape with four sides, including the base), which, in combination with octahedrons (eight-sided shapes), forms the

most economic space-filling structures. The architectural consequence of the use of this geometry by Fuller was the geodesic dome, a frame the total strength of which increases in logarithmic ratio to its size. Because geodesic domes have no limiting dimensions, they can be used, as Fuller has proposed, as "sky breaks" over entire cities, making possible comprehensive environment control, including the economic use of hostile terrain, as in the Arctic Circle or Antarctica.

Many thousands of geodesic domes have been erected in various parts of the world, the most publicized of which was the United States exhibition dome at Expo 67 in Montreal. One houses the tropical exhibit area of a St. Louis botanical garden; another, the Union Tank Car Company's dome, was built in 1958 in Baton Rouge, Louisiana. This dome, at the time of its construction the largest clear span structure in existence, is 384 feet (117 metres) in diameter and 116 feet (35 metres) in height. A geodesic dome for the shopping centre of East St. Louis, Illinois, has a planned diameter of a half mile (about 0.8 kilometre).

Other inventions and developments by Fuller include a system of cartography that presents all the land areas of the world without significant distortion; die-stamped prefabricated bathrooms; tetrahedronal, floating cities; underwater geodesic-domed farms; and expendable paper domes. But Fuller does not regard himself as an inventor or an architect. All of his developments, in his view, are accidental or interim incidents in the growth of world strategy, which aims at a radical solution of world problems by finding means to do more with less.

He once wrote:

I did not set out to design a house that hung from a pole, or to manufacture a new type of automobile, invent a new system of map projection, develop geodesic domes or Energetic-Synergetic geometry. I started with the universe—as an organization of energy systems of which all our experiences and possible experiences are only local instances. I could have ended up with a pair of flying slippers.

Comprehensive and anticipatory design initiative alone, he holds—exclusive of politics and political theory—can solve the problems of human shelter, nutrition, transportation, and pollution; and it can solve these with a fraction of the materials now inefficiently used. Moreover, energy, ever more available, directed by cumulative information stored in computers, is capable of synthesizing raw materials, of machining and packaging commodities, and of supplying the physical needs of the total global population.

Fuller has been research professor at Southern Illinois University (Carbondale) since 1959. In 1968, the board of trustees named him university professor, the second faculty member so distinguished in the university's history. On recommendation of the Royal Institute of British Architects, Queen Elizabeth II awarded Fuller the Royal Gold Medal for Architecture. He also received the 1968 Gold Medal Award of the National Institute of Arts and Letters.

#### BIBLIOGRAPHY

*Critical appraisals of Fuller's life and work:* ROBERT W. MARKS, *The Dymaxion World of Buckminster Fuller* (1960), which contains a detailed explanation of Fuller's energetic-synergetic geometry and technical descriptions of Fuller's inventions and structures prior to 1960; JOHN MCHALE, *R. Buckminster Fuller* (1962), a critical evaluation of Fuller's architectural achievements.

*Basic writings of Fuller:* *Nine Chains to the Moon* (1938, reprinted 1963), an outline of his general technological strategy for maximizing social applications of energy resources. Developments of this central theme, with additional technical data, may be found in *Education Automation: Freeing the Scholar to Return to His Studies* (1962); *Ideas and Integrity: A Spontaneous Autobiographical Disclosure* (1963); *No More Secondhand God, and Other Writings* (1962); *Utopia or Oblivion: The Prospects for Humanity* (1969); and *Operating Manual for Spaceship Earth* (1969).

#### Fulton, Robert

Robert Fulton, U.S. inventor and artist who led in the development of the steamboat, employed his talents as a

The  
geodesic  
dome

The  
Dymaxion  
house and  
Dymaxion  
automobile

portrait and landscape painter to finance the building of his first models. He brought steamboating from the experimental stage to its successful commercial status by the synthesis and extension of the most practical engineering ideas of the United States and Europe.

Fulton, oil painting by Benjamin West, 1806. In the collection of the New York State Historical Association, Cooperstown.

Fulton was born on a farm in Lancaster County, Pennsylvania, on November 14, 1765. When the unproductive farm was lost by mortgage foreclosure in 1771, the family moved to Lancaster, where Fulton's father died in 1774 (not 1786 as is generally written). Having learned to read and write at home, Fulton was sent at age eight to a Quaker school; later he became an apprentice in a Philadelphia jewelry shop, where he specialized in the painting of miniature portraits on ivory for locket and rings.

Early training

After settling his mother on a small farm in western Pennsylvania in 1786, Fulton went to Bath, Virginia, to recover from a severe cough. There the paintings of the young man—tall, graceful, and an engaging conversationalist—were admired by people who advised him to study in Europe. On returning to Philadelphia, Fulton applied himself to painting and the search for a sponsor. Local merchants, eager to raise the city's cultural level, financed his passage to London in 1787.

Although Fulton's reception in London was cordial, his paintings made little impression; they showed neither the style nor the promise required to provide him more than a precarious living. Meanwhile, he became acquainted with new inventions for propelling boats: a water jet ejected by a steam pump and a single, mechanical paddle. His own experiments led him to conclude that several revolving paddles at the stern would be most effective.

Beginning in 1794, however, having admitted defeat as a painter, Fulton turned his principal efforts toward canal engineering. His *Treatise on the Improvement of Canal Navigation*, in 1796, dealt with a complete system of inland water transportation based on small canals extending throughout the countryside. He included details on inclined planes for raising boats—he did not favour locks—aqueducts for valley crossings, boats for specialized cargo, and bridge designs featuring bowstring beams to transmit only vertical loads to the piers. A few bridges were built to his design in the British Isles, but his canal ideas were nowhere accepted.

Undaunted, he travelled in 1797 to Paris, where he proposed the idea of a submarine, the "Nautilus," to be used in France's war with Britain; it would creep under the hulls of British warships and leave a powder charge to be exploded later. The French government rejected the idea, however, as an atrocious and dishonourable way to fight. In 1800 he was able to build the "Nautilus" at his own expense; he conducted trials on the Seine and

finally obtained government sanction for an attack, but wind and tide enabled two British ships to elude his slow vessel.

In 1801 Fulton met Robert R. Livingston, a member of the committee that drafted the U.S. Declaration of Independence. Before becoming minister to France, Livingston had obtained a 20-year monopoly of steamboat navigation within the state of New York. The two men decided to share the expense of building a steamboat in Paris using Fulton's design—a side paddlewheel, 66-foot- (20-metre-) long boat, with an eight-horsepower engine of French design. Although the engine broke the hull, they were encouraged by success with another hull. Fulton ordered parts for a 24-horsepower engine from Boulton and Watt for a boat on the Hudson, and Livingston obtained an extension on his monopoly of steamboat navigation.

Returning to London in 1804, Fulton advanced his ideas with the British government for submersible and low-lying craft that would carry explosives in an attack. Two raids against the French using his novel craft, however, were unsuccessful. In 1805, after Nelson's victory at Trafalgar, it was apparent that Britain was in control of the seas without the aid of Fulton's temperamental weapons. In the same year, the parts for his projected steamboat were ready for shipment to the United States, but Fulton spent a desperate year attempting to collect money he felt the British owed him.

Arriving in New York in December 1806, Fulton at once set to work supervising the construction of the steamboat that had been planned in Paris with Livingston. He also attempted to interest the United States government in a submarine, but his demonstration of it was a fiasco. By early August 1807 a 150-foot- (45-metre-) long "Steamboat," as Fulton called it, was ready for trials. Its single-cylinder condensing steam engine (24-inch bore and four-foot stroke) drove two 15-foot-diameter side paddlewheels; it consumed oak and pine fuel, which produced steam at a pressure of two to three pounds per square inch. The 150-mile (240-kilometre) trial run from New York to Albany required 32 hours (an average of almost 4.7 miles [7.6 kilometres] per hour), considerably better time than the four miles per hour required by the monopoly. The passage was epic because sailing sloops required four days for the same trip.

The "Steamboat"

After building an enginehouse, raising the bulwark, and installing berths in the cabins of the now-renamed "North River Steamboat," Fulton began commercial trips in September. He made three round trips fortnightly between New York and Albany, carrying passengers and light freight. Problems, however, still remained: the inevitable mechanical difficulties, for example, and the jealous sloopboatmen, who through "inadvertence" would ram the unprotected paddlewheels of their new rivals. During the first winter season he stiffened and widened the hull, replaced the cast-iron crankshaft with a forging, fitted guards over the wheels, and installed larger and quite lush passenger accommodations. These modifications made it essentially a different boat, which was registered in 1808 as "The New North River Steamboat of Clermont," soon reduced to "Clermont" by the press.

In 1808 Fulton married his partner's niece, Harriet Livingston, by whom he had a son and three daughters.

In 1811 the Fulton-designed, Pittsburgh-built "New Orleans" was sent south to validate the Livingston-Fulton steamboat monopoly of the New Orleans Territory. The trip was slow and perilous, river conditions being desperate because of America's first recorded, and also largest, earthquake, which had destroyed New Madrid just below the confluence of the Ohio and Mississippi rivers. Fulton's low-powered vessel remained at New Orleans, for it could go no farther upstream than Natchez. He built three boats for Western rivers that were based at New Orleans, but none could conquer the passage to Pittsburgh.

Fulton was a member of the 1812 commission that recommended building the Erie Canal. With the English blockade the same year, he insisted that a mobile float-

Commer-  
cial devel-  
opment

ing gun platform be built—the world's first steam warship—to protect New York harbour against the British fleet. The "Demologos" incorporated new and novel ideas: two parallel hulls, with paddlewheel between; the steam engine in one hull, and boilers and stacks in the other. Launched in 1814, the heavily gunned and armoured steamship underwent successful sea trials; when peace came in December, it was transferred to the Brooklyn Navy Yard, where it was destroyed by an accidental explosion in 1829. By 1810 three of Fulton's boats served the Hudson and Raritan rivers. His steamboats also replaced the horse ferries that were used for heavily travelled river crossings in New York, Boston, and Philadelphia. He retained the typical broad double-ended hulls that needed no turning for the return passage. Manhattan's crosstown Fulton Street, named in 1816, was the principal thoroughfare connecting the two river terminals.

Fulton spent much of his wealth in litigations involving the pirating of patents relating to steamboats and in trying to suppress rival steamboat builders who found loopholes in the state-granted monopoly. His wealth was further depleted by his unsuccessful submarine projects, investments in paintings, and financial assistance to farmer kin and young artists. After testifying at a legal hearing in Trenton, early in 1815, he became chilled en route home to New York, where he died on February 24. His family made claims on the United States government for services rendered. A bill of \$100,000 for the relief of the heirs finally passed the Congress in 1846 but was reduced to \$76,300, with no interest.

A Hudson-Fulton Celebration in 1909 commemorated the success of "The North River Steamboat of Clermont" and the discovery in 1609 of the North River by the English navigator who was the first to sail upstream to Albany. A "Robert Fulton" commemorative stamp was issued in 1965, the bicentenary of his birth; and the two-story farmhouse, his birthplace, has been acquired and restored by the Pennsylvania Historical and Museum Commission.

**BIBLIOGRAPHY.** J.T. FLEXNER, *Steamboats Come True* (1944), a scholarly study of the principal American steamboat protagonists—Fitch, Rumsey, Livingston, Stevens, and Fulton—is a sober evaluation that presents much material untouched by earlier biographers such as Fulton's close friend, C.D. COLDEN, *The Life of Robert Fulton* (1817); an admirer, J.F. REIGART, *The Life of Robert Fulton* (1856); and his great-granddaughter A.C. SUTCLIFFE, *Robert Fulton and the "Clermont"* (1909), among others. H.W. DICKINSON, *Robert Fulton, Engineer and Artist* (1913), deals with technical matters in an exemplary way. For a phase, there is W.B. PARSONS, *Robert Fulton and the Submarine* (1922).

(R.S.H.)

## Fundamentalist and Evangelical Churches

Fundamentalist and Evangelical churches comprise a mixed group of theologically conservative communions that stress the full, and often verbal, inspiration of the Bible and its complete authority over faith and practice. They preach that a felicitous eternal life is won only as the gift of God's grace through a radical conversion and commitment to Christ as Saviour.

### NATURE AND SIGNIFICANCE

This group of churches arose in the United States in the 1920s out of the dissension and potential schism that existed within several Protestant denominations. They are derived from one group of dissenters who called themselves Fundamentalists and who claimed to defend the standards of orthodox Christianity. An opposing group, referred to either as Liberals or Modernists, attempted to assimilate the work of 19th-century biblical criticism and to make the church relevant to the social dilemmas of that era. Fundamentalists charged that Modernism was betraying Christianity and abandoning the Gospel in favour of the new science. Modernists claimed that there could be no hope for a church that wrapped itself in an outworn theology and ignored modern thought. During the same decade the anti-evolution

crusade broke out, and Fundamentalists became involved, especially in the famous 1925 "monkey" trial (concerning the state law prohibiting the teaching of Charles Darwin's theory of evolution in public schools) of John T. Scopes in Dayton, Tennessee.

Fifty years later, Modernism and Liberalism had practically disappeared, and the theologies that succeeded them had only a historical relationship to the thought of such Modernists as Shailer Mathews, Charles Briggs, and A.C. McGiffert, Sr. But Fundamentalism has survived and is flourishing. After World War II, due to the pejorative associations clinging to the older name, Fundamentalists began to call themselves Evangelicals. No religious census exists that reveals their numbers, and only a few denominations, such as the Conservative Baptist Association of America, or more loosely organized bodies, such as the Independent Fundamental Churches of America, can be definitely categorized as Fundamentalist. The National Association of Evangelicals, a cooperative, ecumenical agency founded largely by Fundamentalists, claimed a membership of approximately 3,000,000 in 1971. The numerical strength of these churches does not indicate the impressive influence of Fundamentalist views found in many major Protestant denominations, as demonstrated in the popular adage "Scratch a Protestant and you will find a Fundamentalist."

### HISTORY

**Origins.** The roots of Fundamentalism are found in the history of the American millenarian movement. In the 1830s and 1840s, a great deal of excitement was generated in the United States by expectations of the Second Advent of Christ and an ensuing thousand years of peace ("the millennium"). For the most part this excitement was related to the preaching of a group of ministers who had been converted to the proclamation then being made by a New York farmer, William Miller, that the second coming might be expected in or before 1843. These adventists were effective in winning the support of 50,000 to 100,000 adherents, but the failure of the prediction virtually destroyed the movement and brought the millenarian cause into disrepute. Critics of millenarianism during the next few decades used adventism as a reproach with which to destroy the credibility of anyone maintaining the doctrine of Christ's imminent advent. In Great Britain, where the Millerites were known but not influential, the millenarian movement, beginning about 1825, made rapid progress among the evangelical party within the Church of England and contributed to the formation of new dissenting groups, such as the Catholic Apostolic Church and the Plymouth Brethren. English influence made a significant impact in America at the time of Miller's prominence and sustained interest in the Second Coming where it might otherwise have disappeared.

By the 1870s millenarian interest increased in those churches associated with the Reformed tradition, particularly among American Episcopalians, Presbyterians, and Dutch Reformed. The greatest impact of these views was felt in the East and Northeast and in urban centres, such as St. Louis and Chicago, where ministers kept abreast of current theological literature.

Scattered interest in the subject of the imminent return of Christ was concentrated and built into a movement largely through the Niagara Bible Conference. Initiated by James Inglis, a New York City Baptist minister, shortly before his death in 1872, the conference continued under James H. Brookes (1830–97), a St. Louis Presbyterian minister and editor of the influential millenarian periodical *The Truth*. Other early millenarian leaders included George C. Needham, a Baptist Evangelist (1840–1902); William J. Erdman (1834–1923), a Presbyterian minister noted for his skill as a biblical expositor; and William R. Nicholson (1822–1901), who left the Episcopal Church in 1873 and became a bishop in the small Reformed Episcopal denomination. Toward the close of the century, the movement attracted leaders such as the prominent Boston Baptist minister Adoniram J.

Millenar-  
ianism

Fundamen-  
talism and  
Liberalism  
(Modern-  
ism)

Gordon (1836–95); and Maurice Baldwin (1836–1904), bishop of Huron in the Church of Canada. The group held annual summer conferences, which generally met at Niagara-on-the-Lake, Ontario, until 1899. The millenarians associated with the Niagara Conference also sponsored a series of public conferences in major cities beginning in 1878, such as the Bible and Prophetic Conference in New York City.

**Development of Fundamentalist views.** Beliefs that the condition of the church and society generally were deteriorating to the point of alarm, that nothing could save the Christian or improve the lot of this earth except the coming of Christ, and that the return of Christ was indeed promised in the Scriptures and might be expected at any moment placed them squarely within the apocalyptic tradition. Critics called them Millerites, but the millenarians pointed out that they carefully refrained from any date setting. These premillennialists (another name often applied to them) found their views opposed by progressive millennialists, or postmillennialists. Premillennialists were less optimistic than progressive millennialists. Traditionally, postmillennialists were confident that the churches were succeeding with the task of evangelism; that social, moral, and economic progress was being made in the world with God's help (especially in America); and that Christ would return at that point in the not too distant future when the world was fitted for such a king. The millenarian movement began to grow within America when confidence in America's destiny first began to wane among some Protestant leaders, faced as they were with labour unrest, social discontent, and the rising tide of Roman Catholic immigration.

The appeal of the millenarian movement was not simply due to a loss of confidence in the American dream. A serious concern with the interpretation of the Bible also won many converts to the millenarian movement. In the early 19th century, most of the Protestant churches defended the Bible as the inspired Word of God, but biblical authority meant something special to the millenarians. They believed that the Scriptures predicted an apostasy in Christendom and a degeneracy within society during the last days and that the only remedy foretold by biblical authors was the return of Christ at a time that 19th-century millenarians were convinced could be no later than their own generation.

Millenarian theology was articulated before biblical criticism raised doubts about the meaning of the biblical text. Many American Protestants found it possible to accept the results of 19th-century biblical criticism and to support their faith upon a new understanding of the authority of the Bible, but millenarians could not.

During the late 1880s and 1890s the challenge to the prevailing assumptions about the Bible began to create a serious problem for the millenarians, but the Fundamentalist controversy did not break out then; it was instead postponed for a generation. Concerned by the progress of biblical criticism, millenarian leaders did not despair. Their apocalyptic theology taught them not to expect any improvement in the world. While much of the church seemed about to be swept into infidelity, the millenarian movement entered the period of its greatest prominence and national influence. As the century drew to a close, the Protestant evangelist Dwight L. Moody (1837–99) lent support to their movement, providing in his Northfield conferences an influential platform for millenarian expression. Millenarians supported foreign missions work and influenced the surge of missionary zeal that was eventually institutionalized as the Student Volunteer Movement. Also, they found within the Princeton Theological Seminary at Princeton, New Jersey, a group of scholars interested in defending the authority and inspiration of the Bible.

Millenarians invited the Princeton professors to their conferences and adopted their arguments in defense of the Bible. Virtually none of the Princeton faculty adopted millenarianism and some opposed it strongly, but both parties appreciated each other's support on the issue of biblical authority.

The high point of millenarian influence upon the conservative tradition within evangelical Protestantism occurred when millenarians cooperated with other defenders of the inerrant Bible in founding the American Bible League in 1902 and in writing a series of 12 pamphlets entitled *The Fundamentals*. Over 250,000 of each of these pamphlets were distributed free to ministers and laymen from 1909 to 1915 through the philanthropy of Lyman and Milton Stewart, brothers whose fortune was made in the California oil industry and whose theology was millenarian. Without rancour or hysteria, *The Fundamentals* attacked the current theories of biblical criticism and reasserted the authority of the Bible, using the arguments developed at Princeton Seminary. The series was a summary of the previous generation's attempt to defeat biblical criticism and Modernism through argument.

Almost all of the leaders who had founded the Niagara Conference had died by 1914. The new generation of leaders were not as firmly attached to their denominations as were their predecessors. And their defense of the millenarian cause was more militant and uncompromising. During the last years of the 19th century, disagreements over prophetic interpretation were expressed, but James H. Brookes held the dissident factions together. Within a few years of his death, however, the Niagara Conference was abandoned, and shortly thereafter a paper war broke out between the two leading millenarian periodicals, *Watchword and Truth* and *Our Hope*, that deeply divided the movement.

**The Fundamentalist-Modernist controversy.** At the end of World War I, the millenarians, alarmed by the growth of Liberalism and disturbed over more general symptoms of social degeneracy, held a number of conferences in New York City and Philadelphia, which were successful enough to encourage the formation of a larger and more comprehensive organization in 1919, the World's Christian Fundamentals Association. As a result of this conference, the millenarian movement changed its name without changing its basic character. Furthermore, the 1919 conference placed planks in a platform on which the millenarian-Fundamentalist movement would stand for the next 30 years. The leaders reiterated the creedal basis of the movement, with its characteristic biblical and millenarian articles, called for the exorcism of Modernism and all its associated demons (especially evolution), practically abandoned the universities and placed their faith in the more recently founded Bible institutes, denounced the unitive and cooperative spirit exemplified in the Federal Council of the Churches of Christ in America, and threatened schism if this type of spiritual decline persisted. In spite of vigorous leadership from men like W.B. Riley (pastor of First Baptist Church in Minneapolis), A.C. Dixon (Baptist pastor and evangelist), and R.A. Torrey (evangelist and superintendent of Moody Bible Institute), however, the association never prospered. Dozens of conferences were held in which evolution was hotly condemned and the educational institutions of the country were denounced for abandoning biblical teaching, but even these gatherings could not be sustained after 1928.

During the late 19th century, the liberal faction in the church had numbered only a few men, most of them professors in seminaries or universities. Their acceptance of higher criticism was generally viewed with apprehension by parishioners, the clergy, and officials of their denominations. Where legal machinery existed to examine the new teachings, as it did in the Presbyterian denomination, the verdict was given against the innovations of Liberals such as the biblical theologian Charles A. Briggs (1841–1913). Within a few decades, however, such protests were abandoned as the evidence for the new understanding of the Bible mounted and a new generation of seminarians joined the Liberal cause. By 1914, among the Episcopal, Methodist, Baptist, and Presbyterian denominations in the North, Liberalism had gained many adherents. The battle to prevent the reception and spread of these new views had been lost. During the 1920s it only

Cooperation of millenarians and defenders of biblical inerrancy

Authority of the Bible

Rising tide of Liberalism

remained to be decided whether the Liberals could be forced out of the denominations.

The decade of the '20s was marked by intemperate behaviour on the part of many Americans. The war created tensions and frustrations within America that the Armistice of 1918 did little to reduce. Fears of the menace of Communism, labour unrest, and violence appeared in sermons immediately after the war. The American rejection of the League of Nations indicated that many Americans found the new world of international politics not to their liking. The Fundamentalists of the 1920s shared these fears and a mood of intellectual isolationism.

Not every Protestant denomination was affected by controversy during the 1920s. In some, such as the Southern Baptist denomination, Modernism had not yet become prominent. In others, such as the Methodist and Episcopal churches, Modernism had gained many adherents; but the opposition did not become well enough organized and the governmental structures of the denominations did not lend themselves to the kind of campaign necessary to bring the issue to a focus. Serious controversy did erupt, however, among the Northern Baptists and the Presbyterians in the Northern states. Within the Presbyterian Church, conservatives reflecting the theological position of Princeton Seminary had, with the help of the millenarians, imposed a set of essential doctrines upon the denomination in 1910, declaring the inerrant inspiration of the Bible, the virgin birth of Christ, and the Atonement (redemptive activity), Resurrection, and miracle-working power of Christ necessary to the Christian faith. In 1922, when a New York minister, Harry Emerson Fosdick, soon to become a leading Modernist spokesman, protested the activities of millenarians in foreign mission fields in a sermon entitled "Shall the Fundamentalists Win?" the conservatives and millenarians in the denomination were able to force Fosdick, who was a Baptist, out of his position as pastor of the First Presbyterian Church of New York City.

A withdrawal of the Liberals had been the solution desired by millenarians such as James H. Brookes and conservatives such as the Princeton professor J. Gresham Machen. To avoid a schism within the Presbyterian Church in the U.S., a Commission of Fifteen was appointed to work out a compromise. The report of the commission took the position that the Presbyterian denomination had traditionally tolerated a diversity of opinion and rejected the right of the general assembly to determine which were the essential doctrines of the Christian faith. The report virtually destroyed the conservatives' position. Within the Presbyterian denomination, the Fundamentalist-Modernist controversy meant not the victory of the Modernists but the defeat of the Fundamentalists.

The focus of discord within the Northern Baptist denomination was in their annual convention, which functioned much like the convention of a political party. Beginning in 1920, a group of Baptists calling themselves the National Federation of Fundamentalists began holding annual pre-convention conferences on Baptist fundamentals. Thus organized, they attempted to carry their views into the convention. When the tactics of the National Federation failed to make immediate progress, some of the more militant Baptist Fundamentalists founded the Baptist Bible Union. Among the Baptists, however, as among the Presbyterians, divisions among the Fundamentalists caused their defeat.

Displeasure with the teaching of evolution, as well as anxiety over the spread of biblical criticism, gained momentum in the 1920s. Fundamentalists, believing that the Bible could not be reconciled with the view of the origin of life taught by Charles Darwin, opposed evolution; but not every opponent of evolution was a Fundamentalist. Anti-evolution crusaders lobbied for legislation to prevent the teaching of evolution in the public schools. Tennessee passed such a statute, which was challenged in the courts in 1925 at the instigation of the American Civil Liberties Union. John T. Scopes, a science teacher in the small town of Dayton, offered to serve as the defendant

against the charge of having taught evolution. Two of the foremost public figures of that decade, William Jennings Bryan, a conservative Presbyterian Fundamentalist, and Clarence Darrow, a defense counsel in notable criminal trials, made headlines as the assistant prosecuting attorney and the defense attorney, respectively.

By the end of the 1920s the Fundamentalist controversy was nearly over, but the Fundamentalist movement was not dead. The history of Fundamentalism had begun in the 1870s with the establishment of the millenarian movement, not in the 1920s. The Fundamentalist controversy was an episode in the history of Fundamentalism that contributed little more to the movement than its new name. Although the decade of the 1920s marked the period of Fundamentalism's greatest national attention, it was not a time of strength for the cause. The years that followed were a period of rebuilding.

**Institutional development.** During the 1930s and 1940s, Fundamentalists gradually withdrew from conflict and from the national spotlight. During this period the institutional structure of modern Fundamentalism developed. Some Fundamentalists broke away from their denominations to form new churches, such as the Presbyterians, led by J. Gresham Machen, who in 1936 formed the Presbyterian Church in America, or the Baptists, who left the Northern Baptist Convention to establish the General Association of Regular Baptists. Some remained within congregations of the larger denominations. But most Fundamentalists joined a congregation of one of the smaller sects that had remained faithful to the creed of biblical literalism and premillennialism, such as the Christian and Missionary Alliance, the Plymouth Brethren, and the Evangelical Free Church, or one of the many independent Bible churches and tabernacles that arose during that period.

Much of the structure of modern Fundamentalism is provided by Bible institutes and Bible colleges. Many of these schools, such as the Moody Bible Institute in Chicago or the Bible Institute of Los Angeles, in addition to teaching their students, publish periodicals, broadcast from their own radio stations, hold conferences, and maintain a staff of extension speakers. They operate very much like denominational headquarters, providing a bond between otherwise isolated congregations. In the arts and sciences the strongest bastion has long been Wheaton College, a scholarly college in a suburb of Chicago. There is also a series of organizations for Fundamentalists paralleling the professional and business organizations of American society. Doctors, scientists, athletes, social workers, historians, businessmen, nurses, students, and others may join groups designed especially for their interest or vocational area. Chapters of the Inter-Varsity Christian Fellowship, or Campus Crusade for Christ, exist on hundreds of university and college campuses to provide religious support similar to that provided by organizations of the major Protestant denominations and Roman Catholics. The American Scientific Affiliation, which in 1970 numbered 1,437 practicing scientists of Evangelical belief, holds meetings and publishes a journal in which the compatibility of science with the Bible and with a Christian world view is emphasized.

Paralleling the ecumenical bodies of Protestantism are the American Council of Christian Churches founded in 1941 and the National Association of Evangelicals founded in 1942. The ACCC was (until 1969) virtually the voice of one man, Carl McIntire, who spoke against larger ecumenical bodies, such as the National Council of Churches, and against the danger of the Communist conspiracy to destroy America. The NAE operates as a coordinating body for its members but implements no programs of its own.

The most significant influences upon the Fundamentalist and Evangelical churches in America since World War II have been the prosperity of the postwar decades, the religious revival of the 1950s, and the alleged threat of Communist subversion. Evangelicals as a group should not be categorized among the socially or economically

disadvantaged. In an era in which a typical Evangelical might be found living in a suburban community, worshipping in a new and attractive church building, driving a late model automobile, and even travelling to Europe or Palestine for a vacation, there is little relevance to the stereotyped view that Fundamentalism is a religion of the dispossessed or economically disinherited.

Analysis of the revival of the 1950s supports this argument. Periods of religious concern have occurred with great regularity in American history since the time of Jonathan Edwards and have often reflected the dominant values of the generation that experienced them. During the 1950s an example of these values was Billy Graham, the Fundamentalist revivalist. Dressing like a junior executive, Graham utilized the new technology of television to urge upon America the need to repent of its wickedness and "make a decision for Christ." Graham's sermons made it clear that Fundamentalism had largely dropped its warfare with science, had come to terms with industrial-urban society, and willingly accepted the prosperity brought by science. Graham still warned that America would suffer judgment if it did not repent its immorality, and immorality was categorized most often as individual guilt for individual sins. The examples cited were usually drawn from areas related to domestic problems or the increasing crime rate. Graham's continued prominence and popularity among Fundamentalists reflect a transformation in the public image of the Fundamentalist in comparison to the decade of the 1920s. He has become widely accepted as a part of the mainstream of American society.

Anti-Communism and the Fundamentalists

Anxiety over the threat of Communist subversion has also played an important role in modern Fundamentalist history. The threat of Communism closely resembled the traditional foes of Fundamentalism, biblical criticism and evolution: it came from abroad, seemed to spread uncontrollably and subversively, and tended to undermine Christianity. And in an era in which American Evangelicals were prospering in a burgeoning economy, it provided a good place in which to locate the Satanic activities that no believer doubted were operating in the world. Anti-Communism during the 1950s and 1960s virtually duplicated the history of the anti-evolution crusade of the 1920s.

#### DOCTRINES AND PRACTICES

Traditionally Fundamentalist belief has been defined in terms of five doctrines (inerrant inspiration of the Bible, and the virgin birth, Atonement, Resurrection, and miracle-working power of Christ) usually referred to as the five points of Fundamentalism. Fundamentalists often define their faith in creedal statements, but they have never adopted any particular group of five doctrines as essential. An early historian of the movement, S.G. Cole, erroneously described the 14-point creed of the Niagara Conference as a 5-point declaration. The Presbyterian Church affirmed five points as essential to orthodoxy in their denomination in 1910, 1916, and 1923, but this statement contained nothing about the Second Coming of Christ.

Most Fundamentalists would subscribe to the creed written in 1878 for the Niagara Conference by James H. Brookes, which includes the following affirmations: the verbal inspiration of the Bible, preserving it completely from error in the original manuscripts; the Trinity; the total depravity of man; the necessity of a "new birth" for salvation; substitutionary atonement; assurance of salvation to the believer; and the premillennial Second Coming of Christ. The Scofield Reference Bible, with its detailed footnotes and cross-references that encourage premillennial Bible study, has had a formative influence upon Fundamentalist thought.

Fundamentalist beliefs have not changed significantly since 1878. The greatest theological excitement in the history of modern Fundamentalism has been caused by the theology of Karl Barth. Although Barth began to achieve a reputation in Europe soon after World War I, it was not until the late 1940s that he began to influence

Fundamentalist theologians. Intrigued by Barth's emphasis upon the Bible as the Word of God, they hoped that they might find in his theology a sign of Liberalism's return to the Fundamentalists' biblical positions. A number of Fundamentalist scholars travelled to Basle (Switzerland) to study with Barth, but it became clear that, though Barth placed great stress upon biblical authority, he accepted the findings of the biblical critics and, thus, was unacceptable to Fundamentalists.

Though Fundamentalists are not notably ascetic, they do observe certain taboos. Most Fundamentalists do not smoke or drink alcoholic beverages and usually do not dance or attend movies and plays. At most Bible institutes and Fundamentalist colleges, these practices are strictly forbidden. Worship practices may vary from denomination to denomination but are usually nonliturgical and heavily influenced by revivalism. A sermon with congregational singing and prayer are common elements of Fundamentalist services.

Fundamentalism, though stereotyped in the public mind as a Southern rural phenomenon, was founded in the Northeast. The National Association of Evangelicals, the present organization of churches upholding Fundamentalist principles in varying degrees, has its headquarters in Wheaton, Illinois. *Christianity Today*, a conservative periodical published in Washington, D.C., is the major voice of Fundamentalism today.

**BIBLIOGRAPHY.** E.R. SANDEEN, *The Roots of Fundamentalism* (1970), is a recent attempt to define the character of the Fundamentalist movement and to describe its origins in the millenarianism of the 19th century (extensive bibliography). S.G. COLE, *The History of Fundamentalism* (1931), accurately describes the events of the 1920s. L. GASPER, *The Fundamentalist Movement* (1963), provides some description of the movement since 1930.

## Fundy, Bay of

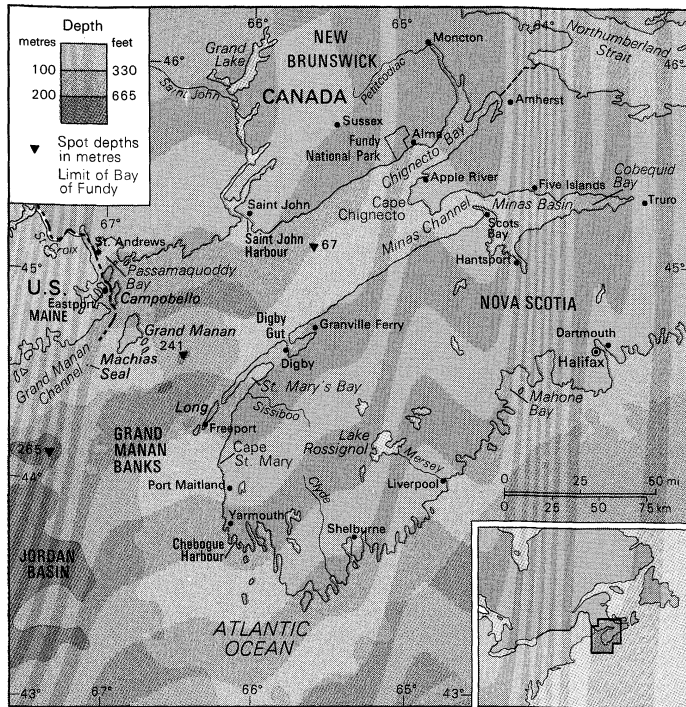

An inlet of the Atlantic Ocean between the Canadian provinces of Nova Scotia on the south and east and New Brunswick on the north and west, the Bay of Fundy is famous for its fast-running tides that, with the aid of its peculiar coastal physiography, produce rises as great as 70 feet (21 metres), the highest in the world. Aside from the spectacular rock formations and forests of its shorelines and the fine agricultural lands created by dikes from its on-land marshes, the bay has come into prominence as a major potential source of hydroelectricity, but one that continues to present great engineering difficulties and other problems of feasibility.

The bay, 32 miles (51 kilometres) across at its entrance and 94 miles (151 kilometres) long, covers some 3,600 square miles (9,300 square kilometres). Its shores are indented by numerous coves and several large deepwater harbours, the main ones at Saint John and St. Andrews in New Brunswick and Digby and Hantsport in Nova Scotia, all harbour towns that burgeoned during the great lumbering, shipping, and shipbuilding activity of the 19th and early 20th centuries. In 1948 an 80-square-mile section of shore and stream-riven hills in New Brunswick was set aside as Fundy National Park.

Steep bedrock cliffs up to 200 feet high bound the bay and channel its waters until they separate into two narrow niches, Chignecto Bay on the north and Minas Basin on the south. In these, the tide range is magnified by the narrowness and shape of the bay, a rise of 46 feet (14 metres) being common in Chignecto Bay and 53 feet (16 metres) in Minas Basin. When the tide runs out the channels become veins of red mud, reflecting the erosion of the outcrops of red sandstone and shale along the coast. The rising tide produces a "reversing falls" at the mouth of the Saint John River, and the tidal surge up the Petitcodiac River toward Moncton has a bore, or tidal wave, that is three to six feet high at its crest, with the tide rising a phenomenal eight to 11 feet (2.4 to 3.4 metres) per hour.

Passamaquoddy Bay, astride the Maine-New Brunswick border, over several decades has been the focus of investigations into the feasibility of harnessing the hydro

Location and unique character

The Bay of Fundy.

Plans and problems of hydro-electric projects

potentiality. This bay's tidal flow is immense—some 70,000,000,000 cubic feet (2,000,000,000 cubic metres) entering and leaving on the twice-daily turn of the tide—more than ten times the flow of the Rance River Estuary in Bretagne (Brittany), site of the only existing tidal-power plant. The possibilities of Passamaquoddy, whose tides average an 18-foot rise and reach 25 feet during the spring, were studied first in the 1920s, and a large-scale damming project was recommended. It was, however, too ambitious for its time, and economic support collapsed during the Depression of the 1930s. A Work Projects Administration (WPA) plan was blocked by the United States Congress in 1937.

After World War II, a joint United States–Canadian commission again attacked the problem, and, in the 1960s, an engineering report reconsidered the plans that had been made and the drawbacks that had been brought to light in the previous studies. In addition to the continuing engineering difficulties and the immense costs involved, other factors impeding development include the extensive navigation on Fundy, the tidal currents running as much as 20 feet per second, the increasing concern over possible environmental damage resulting from such development, and the opposition of private power interests to a public power program.

It would appear that the Fundy project eventually will be judged against the background of the emerging energy crisis both in the U.S. and Canada and the limitations in power technology that these nations must eventually face. With developmental programs for energy tied so closely to environmental concerns, the Bay of Fundy may yet realize its potentiality not only as a natural phenomenon of interest to tourists, oceanographers, and scientists but also for the possible effective blending of long-range conservation and management policies concerning the use of national and international resources.

## Furniture and Accessory Furnishings

The word furniture comes from the French *fourniture*, which means equipment. In most other European languages, however, the corresponding word (German *Möbel*; French *meuble*; Spanish *mueble*; Italian *mobile*) is derived from the Latin adjective *mobilis*, meaning movable. The continental terms describe the intrinsic character of furniture better than the English word. To be furniture, it must be movable.

In general, furniture produced in the last 5,000 years has not undergone innovative development in any profound sense. An Egyptian folding stool dating from about 1500 BC fulfills the same functional requirements and possesses the same basic features as a modern one. Only in the mid-20th century, with entirely new, unnatural, and artificial materials such as plastic and completely new fabrication techniques such as casting have there been signs of a radical revision of the concept of furniture.

Since furniture presupposes some degree of residential permanency, it is understandable that no independent furniture types seem to have been developed among the Africans, the Melanesians, the Eskimos in Greenland, the American Indians, or the Mongolian nomads in Asia.

This article deals with the materials, processes and techniques, ornamentation, kinds of furniture, and, finally, with the history of furniture.

This article is divided into the following sections:

### I. General considerations

#### Materials

- Wood
- Metal
- Other materials

#### Stylistic and decorative processes and techniques

### I. General considerations

#### MATERIALS

**Wood.** Wood is the most used and possibly the best suited material for making furniture. Although there are over a hundred different kinds that can be used for furniture, some woods have natural properties that make them superior to the others.

A relatively cheap material, wood lends itself to various kinds of treatment; for example, it can be stained, painted, gilded, and glued. It can be shaped by means of hand- or power-operated cutting and drilling tools. Heated, it can be bent to a certain extent into a predetermined shape and thereafter will retain the shape. The an-

Advantages of wood

nual rings in wood create a structure with varying character, which in itself provides a natural ornamental surface, in which patterns can be formed by means of pre-calculated juxtapositions. Colours range from white, yellow, green, red, brown, grey to black through countless

Carved wood chairs (1600s) and wood-panelled room (1682–85) from the *Schlössli* at Flims, Switzerland, and through the door an English carved oak bed (late 1500s) from Cumnor Palace, Berkshire. In the Metropolitan Museum of Art, New York City.

intermediary tones. By juxtaposing wood of different colours, extremely rich effects have been achieved, especially in the 17th and 18th centuries. Wood, if stored under favourable conditions, is durable, and pieces of furniture from the oldest civilizations—Egypt, for example—are still extant. Last, most wood has an aromatic scent.

Developments in the sphere of craftsmanship and mechanical techniques, during the past two hundred years or so, have made furniture production both cheaper and quicker. Using timber as a basis and applying techniques such as shredding, heating and glueing, it has been possible to evolve new materials. To an increasing extent, cabinetmakers and furniture factories are using semi-manufactured wood such as veneer, carcass wood, plywood, laminated board, and hardboard (fibreboard).

Veneer is a very thin layer of particularly fine wood that has been glued on to inferior wood in order to produce a smooth and beautiful surface. It would hardly be possible to achieve such a surface by using solid wood, partly because of the expense, partly because of its brittleness, and partly because the grain can never be shown off to its best advantage when the timber is cut into solid boards.

The practice of veneering furniture has been known since the time of pharaonic Egypt, but it was not fully exploited until the beginning of the 18th century. During the Rococo period, especially, great virtuosity was displayed by the craftsman in the veneering of curving, concave, and convex surfaces; for instance, as found on chests of drawers.

Veneer is made by sawing, machine-cutting, and peeling. Saw-cut veneer is best, but because of the relatively large loss of wood in the form of sawdust, it is also the most expensive. Therefore, furniture veneer, as a rule, is machine-cut.

Veneering is done on carcass wood, either in the form of a solid surface or a surface composed of several layers glued together. Old furniture is nearly always veneered on solid wood of an inferior quality to the veneer, such as beech, oak, or deal. High-quality English mahogany furniture made in the 18th century, however, was veneered with mahogany on mahogany. In the 20th century, machine-made laminated board of various thicknesses is generally used. The advantage of ready-made laminated board is that it does not shrink. Wood expands and contracts in various ways, and its strength can vary axially, radially, or tangentially; by blocking the wood—i.e., glueing pieces of wood together in different directions—such differences are eliminated and equal strength is obtained both longitudinally and laterally. The characteristic feature of laminated board is that the veneer on both sides encloses a wooden board composed of narrow strips of wood glued together on edge. The board is therefore thick enough to be suitable for table tops or doors.

If laminated board consists only of single sheets of veneer glued together, it is known as plywood. Plywood is widely used in the manufacture of furniture, particularly as backing for chests and other storage pieces, for the bottoms of drawers, and for shelves.

**Metal.** Metals have been used since antiquity for making furniture or ornaments for furniture. Splendid Egyptian pieces, such as the thrones and stool that were found in the tomb of the youthful Tutankhamen (14th century BC), were rich in gold mounts (decorative details). In ancient Greece, bronze, iron, and silver were used for making furniture. Finds that were buried in the ashes of Pompeii and Herculaneum in Italy included tables with folding underframes and beds made partly or entirely of metal.

Throughout the Middle Ages the metal chair—for example, the 7th-century throne belonging to Dagobert I, king of the Franks—was used for special ceremonies.

Various examples of silver furniture have been preserved; not solid metal, they consist of embossed (decorated with relief) or chased (hammered) plates of silver fastened to a wooden core. Silver furniture was made for palaces in the days when monarchs amassed enormous wealth. In times of war, the silver mountings were melted down and turned into silver coins; it was thus that all the silver furniture disappeared from the royal palaces of France.

During the 18th and 19th centuries, iron furniture became a typical industrial product. Iron beds in particular became popular. Because they could be easily folded up, they were much in demand as camp beds; one used by Napoleon at St. Helena is a famous example. As ordinary beds in private homes or hotels, they could be decorated with brass ornaments such as big knobs screwed onto their posts. Iron has also been used for chairs; for instance, rocking chairs or, perhaps more frequently, garden chairs that can stand out in the rain, protected only by a coat of paint.

The possibilities of steel for furniture were explored in Germany during the 1920s, notably by architects associated with the Bauhaus, where architects, designers, and artists experimented with modern materials. Experiments were made with steel springs and chromium-plated steel tubing. The genre was soon imitated, and tubular steel furniture became a symbol of functionalism. Since then, thinner tubing and plaited wire, with a resiliency similar to that found in wickerwork chairs have been used. Because of its lightness, aluminum became a furniture material.

Metal, however, is still employed primarily for locks, mounts, and hinges used on furniture or for purely ornamental purposes. In the Middle Ages, simply constructed chests demanded extensive use of iron bands to provide extra strength, and the ends of these bands were cut to form decorative shapes. Cabinets of the Renaissance and Baroque periods were decorated with mounts of pewter or bronze. Inlaid objects, decorated with material such as wood or ivory, set into the surface of the veneer furniture made at royal furniture workshops in France, es-

pecially so-called *bouffe* furniture, were marked by an elaborate style of *marquetry* (patterns formed by the insertion of pieces of wood, shell, ivory, or metal into a wood veneer) influenced by Oriental traditions, in which blue-tempered steel, brass, and copper were customarily used.

In the 17th and 18th centuries, especially in England and the American colonies, a refined style for furniture mounts, keyhole escutcheons (an ornamental shield around a keyhole), hinges, and the like, all based largely on Chinese models, was developed. The design of these mounts was dictated by a clear functional purpose, in contrast to contemporary French Rococo mounts, the majority of which were ornamental, often at the expense of utility. French bronze founders displayed great skill in making purely decorative mounts for the bodies of chests of drawers and protective mounts for corners and legs. No essentially new, independent forms of furniture mounts seem to have been developed since the 18th century.

**Other materials.** Among other secondary materials in furniture making, glass has been used in the form of mirrorglass or as a purely decorative, illusionistic element in cabinets and writing desks. Italian craftsmen have made glass furniture; that is, wooden furniture covered with silvered glass in various colours. Ivory and other forms of bone were used as inlay material in Egyptian furniture. During the 17th and 18th centuries, ivory was widely used for inlay work in cupboard doors and table tops.

Tortoiseshell was also used, as a costly inlay on a silvered ground, in furniture made during the Renaissance and Baroque periods. Mother-of-pearl has been used, particularly as inlay material and for keyhole escutcheons. Marble and, to a certain extent, plaster of paris have been used, especially in the 18th century, for the tops of chests of drawers and console tables, and in the 19th century for the tops of washstands and dressing tables.

Papier-  
mâché and  
plastics

In Victorian England, papier-mâché (a molding material made of paper pulped with glue and other additives) was used to make such items of furniture as fire screens, small tables and chairs, and clock cases. Finally, since World War II, various plastic materials have been used quite extensively in the construction of chairs with seats and backs molded in one piece and provided with a metal base.

#### STYLISTIC AND DECORATIVE PROCESSES AND TECHNIQUES

**Constructional style and stylization.** In general, furniture can be designed in two styles, one of which is constructional in that the appearance of the piece reflects the way it is put together, and the other of which is stylized in that the appearance of the piece conceals the way it is put together, the principle being to make the joints flush with adjoining members so as to give the impression that the object is made in one piece.

Examples of furniture made in a purely constructive style are forms employing wickerwork or bamboo, in which even the greatest display of imaginativeness in design and pattern serves to make the construction stronger and more resilient.

Constructional details and joints are not normally visible and are, therefore, seldom of aesthetic importance to the external appearance, but joints can be emphasized artistically. The Greek form of chair known as the *klimos* demonstrates its joints boldly in the form of solid junctions holding the legs, seat, and stiles together. The curvature of the legs and of the backrest suggests elasticity. Extremely delicate joinery with invisible joints can be deliberately indicated by means of inlay work, examples of which can be seen in ancient Egyptian furniture.

Stick-back and tubular steel chairs are also examples of constructional styles. The stick-back chair consists of a solid seat into which the legs, back staves, and possibly the armrests are directly mortised (joined by a tenon or projecting part of one piece of wood and mortise or groove in the other piece). Furniture of bent steel tubing, particularly tables, chairs, and stools, was manufactured

on an industrial basis in Germany in the 1920s. In this fashion a new constructional style arose, for the steel tube, which makes smaller dimensions possible, was so strong that it opened up the possibility of completely new, untraditional designs. Bent steel tubes form a resilient structure.

In contrast to the constructional style is stylization, in which there is no internal conformity between the motifs and the strength of the joints. There have been any number of examples of stylization throughout the history of furniture. In both Egyptian and Chinese furniture the joints might be deliberately concealed by painting or lacquer. Chinese furniture can also appear stylized in the sense that it gives an impression of having been put to-

Stylization

gether in a more constructive manner than is actually the case. (In other words, stylization attempts to make joints flush with adjoining members so as to give the impression of an uninterrupted, harmonious, or sensitive contour. When two pieces of wood are joined together with a modern, strong glue, the resulting joint will be so rigid that, in the event of a severe shock to the piece, the wood itself will be more likely to break than will the actual joint.)

A good example of stylization is to be found in French furniture made around the middle of the 18th century. In French Rococo commodes, only the back is straight. The serpentine front and sides meet in sharp corners, at which the joints are covered by brass mounts. The number and position of the drawers is concealed by an overall pattern of veneer and bronze ornament that disregards the edges of the drawers. (In a number of cases the bronze mounts on the front consist of fanciful handles and keyhole escutcheons, but are never emphasized the way they are in corresponding English commodes, even in the case of false drawer fronts or drawers provided with moulding that serves to protect the veneer.) The fully developed French Rococo chair with armrests has no visible joints. The back, arms, and frame form a continuous whole; the difference between supported and supporting members is concealed. There are no stretchers (horizontal rods) between the legs to strengthen the con-

struction, which is solid enough by reason of the thick dimensions of the members that meet in the seat frame. To counteract the impression of heaviness in these essentially thick dimensions, the wood is molded to give a sensation of lightness without in any way weakening the construction. A chair of this type when painted or gilded looks as if it had been made in one piece, which is precisely the intention.

**Decorative processes and techniques.** Whether constructional principles are exploited as a motif or elegance of overall shape is stressed through stylization, every piece of furniture can be embellished in one way or another. A piece of furniture may be embellished by effects produced in the structural wood itself or in another kind of wood added to the first; that is, by carving and turning or by inlay work. Alternatively, the piece can be decorated by the addition of materials other than wood, such as bronze, ivory, or marble. Finally, in the case of furniture meant for sitting or lying on, there is the possibility of textile enrichment in such forms as upholstery, loose covers, and cushions.

**Carving.** There are examples of furniture carving in Egypt at the time of the pyramids: animal legs of cedar-wood on biers, beds, and chairs; and ducks' heads terminating the legs of folding stools. A more constructionally determined type of carving resulted in the creation of elegant headrests that took the place of pillows in a hot climate.

Whereas carving does not appear to have played a significant part in Greek and Roman furniture, it was a dominant feature of European furniture of the Middle Ages. The fronts of chests bear Gothic perpendicular tracery (decorative interlacing of lines) in imitation of the decorative stonework found in ecclesiastical architecture.

Another source of inspiration for carved ornaments in bourgeois furniture was the ecclesiastical wood carving found in choir stalls and altarpieces. The art of the wood-carver also flourished in Islām during the Middle Ages, especially in kiosks (open pavilions), oriel (large bay win-

dred years dominated the figure-carving repertoires of European cabinetmakers.

During the 17th century the fashion for carved work at first receded but came to the fore again in the console tables (tables designed to fit against the wall), mirror frames, and high-backed chairs of Court Baroque. In striking contrast to lacquer cabinets of Japan, sumptuous, gilded carved work became popular on the stands invariably made for them in Europe.

In the 18th century, wood-carvers enjoyed a final splendid period of prosperity when the Rococo style of ornamentation called for the plastic effects obtainable through carving. Whole panels of woodwork, doors, mirror frames, chairs, and settees were adorned with the finest wood carving, featuring combinations of mussel-shell patterns and naturalistic vines and plant tendrils. Even in English furniture of more sober design there were ample opportunities for carved work; for example, in the many chairback variations in the Chippendale manner.

American cabinetmakers were particularly skillful at carving block fronts (the sides curving forward and the middle receding) on the drawers of chests of drawers, and the English at framing tea tables with piecrust (scalloped) tops.

**Turned work.** Turning is a process by which parts of furniture, such as legs and posts, are shaped while turning on a lathe. Turned work is found on Greco-Roman furniture. It is not certain whether the technique was actually employed in Egyptian furniture, though some members look as though they might have been turned. It was particularly in the shaping of wooden chair legs that Greek joiners used the lathe; the same sharp edges and deep molding seem to be repeated in the legs of bronze furniture. It is possibly ancient turned work traditions upheld in Byzantium that are reflected in certain chairs of medieval form found, for example, in Norway; made of pinewood, the construction consists principally of turned staves (thin bars), some with appendant loose rings, some of them fluted (grooved). Similar turned chairs were made in Wales in the 16th century. In the 17th century, turned work was concentrated on pillars for cupboards and on ball feet, but is also seen on chair and table legs, on which rich variations involving twisted and intertwining forms occur. Turned work in ivory also flourished in the 17th century. Except for the Windsor chair, or stick-back, however, the craft of the turner played no significant role in English furniture of the 18th century; it is similarly alien to French Rococo furniture.

**Inlay and marquetry.** Inlaid woodwork, in which decorative material such as wood or ivory is set into the surface of the veneer, has accompanied the art of furniture making for thousands of years. Ivory inlay can be seen in Egyptian furniture, particularly in small, meticulously executed toilet caskets, but it is difficult to locate in Greek and Roman furniture, today known almost exclusively from pictorial representations.

In medieval Europe, inlay work gave way to wood carving and then experienced a rich period of development during the Renaissance in Italy. Italian intarsia (mosaic of wood) work found particular favour in panels over the backs of choir stalls and in the private studies and chapels, or oratories, of princes. An intarsia study of the Duke of Urbino, an Italian nobleman and patron of the arts, is still preserved in the palace of Urbino, and a corresponding room, originally at Gubbio, is now in the Metropolitan Museum of Art in New York. Together with illusionism, linear perspective (the technique of representing on a plane or curved surface the spatial relation of objects as they might appear to the eye), which had just been discovered, achieved triumphs in Italian intarsia work.

Ivory was used on both Renaissance and Baroque cupboards, sparingly to begin with, lavishly later on. Inlay work was especially used in the many splendid German and French cabinets of the period. In Holland and England an extremely rich form of marquetry (patterns formed by the insertion of pieces of wood, shell, ivory,

dows projecting from the wall and supported by brackets) windows, and Qur'an lecterns. The most original and remarkable form of medieval carved ornamentation was the linenfold, which resembled folded sheets of linen laid on the surface of the wood. Although the motif was widely known, its origins are obscure.

During the Renaissance, wood-carvers changed motifs: new ornamental riches, partly inspired by the forms of classical antiquity, began to adorn cupboards and chests. Acanthus leaf designs, strapwork (narrow bands folded, crossed, and sometimes interlaced), Moresque designs, the auricular (resembling a flowered Alpine primrose) style, bunches of fruit, and scrollwork for over a hun-

Italian  
intarsia  
work

or metal into the wood veneer) was developed, incorporating floral motifs in various kinds of exotic wood on walnut. English grandfather clocks made around 1700 often had richly inlaid cases. It was in France, however, during the Rococo period especially that inlay work reached unprecedented levels of quality. The serpentine sides and fronts of commodes were veneered with costly woods whose often relatively simple grain patterns formed an effective background for richly ornamented mounts of gilded bronze.

**Upholstery and covers.** Upholstery and covers belong to the sphere of furniture designed for sitting or lying on. From the Orient, Europeans learned the use of wickerwork, which provided a ventilated and resilient background for loose cushions. The upholstered chair is a genuinely European phenomenon that achieved its most distinguished and logical form in England during the 18th century. Poor heating systems in houses, general prosperity, and a desire for comfort were the conditions that gave rise to a number of imaginatively varied types of upholstered armchairs in which the only wood visible is in the legs, with the back closing right up against the sitter and side wings affording protection from possible drafts.

The upholstered chair created a new effect that depended almost entirely upon the craftsmanship of the upholsterer. The upholstered chair or sofa has remained a specialty of the Anglo-Saxon world; club life in particular contributed to its popularity and resulted in heavily stuffed forms including that of the so-called chesterfield.

By mid-20th century, new materials such as foam rubber and various types of plastic composition had inspired independent methods that dispensed entirely with traditional upholstery techniques. Upholstery was succeeded by molded plastic forms and by sacks filled with plastic balls that are able to conform to the changing positions of the body.

**Imagery and ornamentation.** Painted and plastic images, or ornamental decoration, on furniture are secondary processes compared with construction and design. Some of the best and most expressive furniture forms, such as the Greek klismos chair and the English Windsor chair, are quite independent of imagery or ornamentation. On the other hand, no period in the history of furniture is entirely devoid of these secondary processes.

All furniture decoration is normally concentrated where it will not be in the way; for example, on the legs, arms, and backs of chairs; on the ends and canopies of beds; on the legs and stretchers of tables; and on all vertical surfaces of cupboards and chests of drawers. The superfluous nature of furniture decoration is particularly pronounced in forms that express rank or prestige. The thrones of kings and bishops, the seats of guild masters, beds of state, the writing desks of chief executives, and the like have all lent themselves to imagery and ornamentation; and as the functional aspect of the piece has declined, it has seemed that the amount of ornamentation has increased. Purely functional milk stools and typewriting tables are devoid of ornamentation. This division can be noted with varying clarity throughout the history of furniture.

At times the ornamentation itself has, in a sense, been functional. The decoration of the earliest examples of furniture from Mesopotamia and Egypt, for example, had a symbolic or magical function. The legs of Sumerian stools are shaped like those of an ox, which was the guardian animal of the city of Ur. Egyptian furniture shows a much wider development of furniture legs based on animal models. Three-footed stools ending in dogs' paws, folding stools with legs in the shape of ducks' heads, and bed legs in the form of lions' feet are known from a thousand years of Egyptian furniture history. Tables with lions' legs can be seen on Assyrian reliefs. Similar animal symbols are known from representations of Greek furniture. Sometimes the arms as well as the legs of Greek chairs had animal shapes—terminating, for example, in the head of a lion or a

ram. It is thought likely that ceremonial seats and thrones featured animal motifs partly as a magical expression of the transference of power. This ancient tradition lived on in European furniture; for example, in thrones, where griffons, lions, and eagles played a prominent part in the decoration.

Even in the furniture of antiquity it is difficult to differentiate between the symbolic and the aesthetic in decorative features. It is clear, however, that the animal world has always been one of the primary sources of ornamental motifs in furniture. Animal legs and heads are found, for example, as terminal decorations in the French Rococo chair and imitations thereof. The animal leg played a prominent part in English furniture of the 18th century and later passed into American furniture. English cabinetmakers and chair makers devised a naturalistically carved lion's foot and a characteristic claw-and-ball foot, a motif that may stem from Chinese forms of ornamentation (not, however, on furniture) such as the dragon's claw holding a ball or a pearl. Richly carved English mahogany chairs sometimes also feature the heads of birds, lions, or dogs as terminal decorations on the arms. Although the majority of Chinese chairs and tables are supported by straight legs of rounded wood, Chinese thrones and seats for dignitaries have curved legs that, for some unknown reason, may be imitations of elephant trunks.

Next to the animal world—and of more recent origin—architecture is the most important source of decorative motifs in furniture. In the late Middle Ages, the perpendicular tracery of Gothic architecture was transferred through the craft of the wood-carver to the fronts of chests. Italian chests and walnut cupboards of the same period were modelled on the marble sarcophagi of classical antiquity, which are entirely architectonic in form. During the Renaissance and Baroque periods the column was introduced as a strikingly decorative frontal feature in the form of table legs and on cupboards. The fronts of very big, heavy cupboards particularly lent themselves to architectonic composition corresponding to the portals and gables of houses. At the same time, the ornamental wealth of the Renaissance broke through in rosettes, cupids, and fruits on panelling and frames.

During the Court Baroque period under Louis XIV in France, the royal official style left its mark not only on ornate pieces of furniture but also on panels, doors, mirror frames, and, indeed, even on the facades of palaces and châteaux and the layout of formal gardens. The coherence between interior and furniture was even more pronounced during the Rococo period and under Louis XVI, culminating temporarily in the furniture and rooms of the French Empire style.

The 19th century often seems to have offered nothing more than a breathless repetition of this coherence between the ornamental design of furniture and the architecture of the interior—both revivals of the styles of the past. A new style did not arise until the close of the century. French Art Nouveau furniture, with its gliding vegetable forms, must be seen in conjunction with the houses and rooms for which it was executed. The furniture of Antonio Gaudí, a Spanish architect and designer, for example, had a profound coherence with his own buildings; and the strangely expressive and stylized furniture of a Scottish architect, Charles Rennie Mackintosh, forms an integral part of his buildings and interiors in Glasgow.

The influence of architecture on furniture can also manifest itself in a lack of ornament. There is a relationship, for example, between functionalistic architecture as it was first manifested in the 1920s at the Bauhaus in Germany and steel furniture designed by the German architect Mies van der Rohe.

#### KINDS OF FURNITURE

**Chair.** Of all furniture forms, the chair may be the most interesting. While most other forms (except the bed) are intended to support objects, the chair supports man. The term chair is used here in the widest sense, from stool to throne to derivative forms such as the

bench and sofa, which may be regarded as extended or connected chairs, and whose character (*i.e.*, whether they are intended for sitting or reclining) is not clearly defined.

The social history of the chair is as interesting as its history as an art and craft. The chair is not merely a physical support and an aesthetic object; it is also an indicator of human worthiness. One is offered a chair; one does not just sit down anywhere at all without being asked to do so. Chair forms may also involve an indication of rank. At the old royal courts there were social distinctions between sitting on a chair with arms, on a chair with a back but no arms, and having to make do with a stool. In the 20th century, the director's or manager's chair has been an indicator of superior dignity, and even in democratic parliaments the speaker sits on a raised level.

As a furniture form, the chair encompasses a wealth of variations. There are chairs designed to match man's age and physical condition (the high chair, the wheel-chair) and for his position in society (the executive chair, the throne). In the olden days there were chairs to be born in (birth chairs); in the 20th century, there have been chairs to die in (the electric chair). There are chairs with one, two, three, and four legs, chairs with or without arms, and chairs with or without backs. There are chairs that can be folded up, chairs on wheels, and chairs on runners.

Modern living has developed special chairs for automobiles and aircraft. All of these chair forms have been evolved to conform to changing human needs. Because of its close association with man, the chair appears to its full advantage only when in use. Whereas it makes no difference to one's appreciation of a cupboard or a chest of drawers whether there is anything inside or not, a chair is best seen and evaluated with a person sitting on it, for chair and sitter complement one another. Thus the various parts of a chair have been given names corresponding to the parts of the human body: arms, legs, feet, back, and seat.

Because the basic function of the chair is to support man, its value is judged primarily on how well it fulfills this practical role. In the construction of a chair, the designer is bound by certain static laws and principal measurements. Within these limits, however, he has great freedom.

The history of the chair covers a period of several thousand years. There are civilizations that have created distinctive chair forms, expressive of the highest en-

deavour in the spheres of technique and aesthetics. Among such cultures, special mention must be made of ancient Egypt and Greece; China; Spain and Holland in the 17th century; England in the 18th century; and France in the 18th century during the reigns of Louis XV and Louis XVI.

*Egypt.* Two ancient Egyptian chair forms, both the result of careful design, are known from discoveries made in tombs. One of these is a four-legged chair with a back, the other a folding stool. The classical Egyptian chair has four legs shaped like those of an animal, a curved seat, and a sloping back supported by vertical stretchers. In this way a strong triangular construction was obtained. There was apparently no marked difference between the construction of Egyptian thrones and chairs for ordinary citizens. The main difference lies in the decorative ornamentation, in the choice of costly inlays. The Egyptian folding stool probably was developed as an easily portable seat for officers. As a camp stool the form persisted until much later times. But the stool also took on the character of a ceremonial seat, its mechanical function as a folding stool being forgotten. This can already be observed, from as early as 1366–57 BC in two stools, executed in ebony with ivory inlay work and gold mounts, from the tomb of Tutankhamen. They are in the form of folding stools but cannot be folded as the seats are of wood. The simple construction of the folding stool, consisting of two frames that turn on metal bolts and support a seat of leather or fabric fastened between them, reappears somewhat later in the Bronze Age folding chairs of Scandinavia and northern Germany. The best known of these is the folding stool, made of ashwood, found at Guldthj (National Museum in Copenhagen).

*Greece and Rome.* The typical Greek chair, the *klismos*, is known not from any ancient specimen still extant, but from a wealth of pictorial material. The best known is the *klismos* depicted on the Hegeso Stele at the Dipylon burial place outside Athens (c. 410 BC). It is a chair with a backward-sloping, curved backboard and four curving legs, only two of which are shown. These unusual legs were presumably executed in bent wood and were therefore subjected to great pressure from the weight of the sitter. The joints fastening the legs to the frame of the seat are therefore very strong and clearly indicated.

The Romans adopted the Greek chair; a number of statues of seated Romans show several examples of a heavier and apparently somewhat more crudely con-

The classical Egyptian chair

structed klismos. Both types, the light and the heavy, were revived during the Classicist period. The klismos chair is found in French Empire furniture, in English Regency, and in special forms of considerable originality in Denmark and Sweden around 1800.

**China.** The ancestry of the chair in China cannot be traced as far back as in Egypt and Greece. Since the T'ang dynasty (AD 618–907) an unbroken series of drawings and paintings has been preserved showing the interiors and exteriors of Chinese houses and their furniture. Also preserved since the 16th century are a number of chairs of wood or lacquered wood that bear an astonishing resemblance to representations of older chairs.

Two major  
Chinese  
chair  
forms

As was the case in Egypt, there were two major chair forms in China: a chair with four legs and a folding stool. The four-legged chair is found both with and without arms but always with a square seat and straight stiles (upright side supports) to support the back. In one form, however, the stiles are slightly curved above the arms so as to conform to the rhythm of the S-shaped back splat (the central upright of a chairback). All three parts are mortised into the yoke-like top rail. While the design of the back splat exercised an influence on English chairs of the Queen Anne period, wooden members that only to a limited extent reinforce corner joints (and are loose into the bargain) represent a feature exclusive to Chinese chairs. The four legs pass through the seat frame, which closes about the rounded staves. All members are round in section or have rounded edges—it is as though one can just discern a bamboo tradition hovering in the background. The seat is uncomfortable and may have a plaited bottom. These chairs must have required the sitter to remain stiff and upright; for if too much pressure is exerted on the back, the chair has a tendency to topple over. In patriarchal Chinese homes of this period armchairs presumably were reserved for the senior members of the family, for they were held in great esteem.

The Chinese folding stool is presumed to have travelled to China from the West. It does not differ so very much

from the Egyptian or Scandinavian folding stools, but it has a variation in that the top rail is elegantly joined to the two legs of the stool by means of a curved member, which is often provided with metal mounts. From a Western viewpoint the overall effect of both these furniture forms is stylized. The constructive and decorative elements are combined in a manner that is simultaneously naïve and refined. The pieced-together appearance is a result of the fact that the individual members do not appear to have been joined together with either glue or screws, but have been mortised into one another and locked into position in the manner of a Chinese puzzle.

**Spain: 17th century.** The Golden Age of Spain during the 17th century also left its mark on the chair. Paintings show a type of chair with a relatively crude wooden frame; a back and seat, nailed on, consist of two layers of leather, with horsehair stuffing in between, stitched to produce a pattern of small pads. The front board and a corresponding board at the back could be folded after loosening some small iron hooks. Thus the chair was an easily portable piece of furniture for travelling which, at the same time, had the dignity of a four-legged, high-backed armchair.

**Holland: 17th century.** A low, square, upholstered type of chair can be seen in engravings of interiors of affluent Dutch homes by Abraham Bosse, a French artist, and in paintings by the Dutch artists Jan Vermeer and Gerard Terborch. Although this kind of chair is also found in countries where Dutch styles of interior decoration and Dutch furniture won favour, it is not certain that the form actually originated in Holland. Normally, the legs of the chair are smooth, round in section, and of slender dimensions; they are sometimes baluster-shaped (vase-shaped) or twisted. It is clearly a bourgeois piece of furniture and was made in considerable numbers, as can be seen from one of Abraham Bosse's engravings, in which a whole row of such chairs has been lined up against a wall. The form asserts itself by virtue of its harmonious proportions and fine upholstery in gilt leather or fabric bordered with fringes.

**France and England: 17th and 18th centuries.** The French Rococo chair in its most mature form—that is, as developed in Paris around 1750—spread over most of Europe and has been imitated or copied into the mid-20th century. The model owes its popularity to a combination of comfort and elegance. The seat conforms to the human body and permits a relaxed sitting position. The back is bow-shaped, the legs curved. Normally the seat and back are upholstered, and there are small upholstered pads on the armrests. Smooth transitions achieved between seat frame, legs, and back disguise all the joints, which are solidly constructed on craftsman-like principles despite the absence of stretchers between the legs.

French  
Rococo  
chair

French Rococo chairs and imitations thereof employ wood of fairly thick dimensions; but all members are deeply molded, all superfluous wood has been cut away, and finer examples may be further embellished with very delicate and decorative carving. The wood may be left in its natural state, painted, or gilded. Silk damask or tapestry is used for the upholstery on the seat, back, and armrests; canework is sometimes used in place of upholstery.

English chairs of the 18th century are more differentiated in design than the French. The French taste for stylistic uniformity, which spread from the most distinguished circles in Paris and Versailles over most of France and won favour in several parts of the Continent, had no parallel in England. Prior to 1740, the most commonly used wood was walnut; thereafter, and for the rest of the century, it was mahogany. Walnut, though beautiful in hue, was soft and therefore less suited to wood carving than to rounded, curving forms. Outer surfaces, such as the back and seat frame, were usually veneered. During the walnut period, highly overstuffed armchairs, covered with leather or embroidered material, were also developed. The best upholstery of this period is precisely and firmly modelled and accentuated

Low, square, upholstered chairs typical of 17th-century Dutch homes shown in "Recreation," engraving by Abraham Bosse, 1635.

by braiding or tacks. When imports of mahogany became common, no specifically new chair designs appeared, but the character of the woodwork changed. Mahogany, having a firmer, closer grain, could be cut thinner, which meant that individual parts of the chair could be more slender in shape. Mahogany also lent itself better to carving than walnut. Carving was concentrated more on the arms and back than on the legs, which as a rule were straight and smooth with chamfered (bevelled) edges and molding. There was a wealth of variety in chairback designs, featuring elegant, pierced, vase-shaped splats or two upright posts connected by horizontal slats (ladder-back).

Alongside the French Rococo chair and the best English chairs in walnut and mahogany, the more country stick-back chair was relatively unaffected by the stylistic changes of the day. Originally a medieval form, known, for example, from paintings by Pieter Bruegel the Elder and still found in mid-20th century in the churches and inns of southern Europe, the stick-back chair (in all of its variations) consists basically of a solid, saddle-shaped seat into which the legs, back staves, and possibly the armrests are directly mortised. This typically peasant form underwent a renewal and a process of refinement in England and America during the 18th century. Under the name Windsor chair (a term that seems to have been used for the first time in 1731) or Philadelphia chair, it became well-known and was widely distributed throughout the world. Related in form to the Windsor chair is an American chair made by members of the Shaker sect in the workshops they set up in their small, closed religious communities. Some of the best examples of these were executed around the middle of the 19th century at the Shaker headquarters in Pennsylvania.

**Late 18th to 20th century.** During the Neoclassical period, no basic changes took place in chair forms, but legs became straight and dimensions lighter. Backs in the shape of classical vases replaced the fanciful outlines of the Rococo period. Around 1800, freely executed imitations of Greek and Roman chairs of the klismos type, with curved legs and backrest, appeared. French chairs of the Empire period, executed in dark mahogany and embellished with ornate bronze mounts, created a ponderous effect.

In cheaper versions of inferior workmanship, bourgeois chairs of the 19th century carried on the traditions of the 17th and 18th centuries. The only real innovations were the bentwood (wood that has been bent and shaped)

chairs in beech that became popular all over the world and are still made in the 20th century. Around 1900 the continental Art Nouveau and *Jugendstil* styles (French and German styles characterized by organic foliate forms, sinuous lines, and non-geometric forms), and the Arts and Crafts movement in England (established by the English poet and decorator William Morris to reintroduce standards of medieval craftsmanship), gave rise to original chair designs by Eugène Gaillard in France, Henry van de Velde in Belgium, Josef Hoffman in Austria, Antonio Gaudí in Spain, and Charles Rennie Mackintosh in Scotland. These new furniture styles did not exercise wide, let alone decisive influence. The Art Nouveau chairs designed by the French architect Hector Guimard, for example, are collector's pieces, but his name is known to a broader public only because of his fanciful entrances to the Paris Métro.

**Modern.** After World War I, the Bauhaus school in Germany became a creative centre for entirely revolutionary thinking, resulting, for example, in tubular steel chairs designed by the architects Marcel Breuer, Ludwig

Mies van der Rohe, and others. During World War II, the aircraft industry accelerated the development of laminated wood and molded plastic furniture. The dominant chair forms of this period go back to designs by a Finn, Alvar Aalto, Brun Mathsson, and an American, Charles Eames. Rapid technical developments, in conjunction with a severance from all tradition, suggest that completely new chair forms will probably be evolved in the future.

**Table.** *Fixed and mechanical tables.* In general, tables can be divided into fixed and mechanical types. The fixed table, consisting of a square or round top supported by one or more legs, is the least complicated from the viewpoint of craftsmanship. It is a form that requires wood of thick dimensions in order to make the joints by which the top is fastened to the legs strong enough to resist lateral pressure. Old Spanish or Italian tables are

ings, in which the extension leaves, when pulled, slide out on sloping runners. When the leaves have been fully extended, the top is lifted and then dropped into place. The table height remains the same. The construction demands great accuracy and skill on the part of the craftsman. There are also more complicated forms of extension tables with runners enabling the legs as well as the leaves to be drawn out; extra leaves can then be inserted.

Tables with flaps also are constructed to take up less space when folded away and can be variously made, either with flaps that are supported by brackets that swing out on hinges or on so-called gate legs. During the 18th century, England was a leader in the design of ingenious folding tables, especially card tables. In the gateleg card table, the top can be folded so as to occupy half the space, and when opened is supported by a leg that swings out like a gate. In another system, the square underframe can be extended to form a rectangular top, the two sides being divided by hinges. On modern card tables, all four legs can be folded up within the frame surrounding the top; when not in use, the tables can therefore be stored easily.

Gateleg table

*Historical forms and styles.* Round stone tables on low pedestal legs are known in Egypt from the time of the pyramids (c. 2700 BC). Egyptian limestone reliefs also show tables of normal height. Dating from the later dynasties, crude wooden tables with architectonic molding have been preserved. No tables have survived from ancient Greece. From the Roman ruins of Pompeii and Herculaneum, however, there are examples of monumental table supports or side members made of marble decorated with relief work and metal tables, many of them of the folding type. All wooden furniture has been lost, however.

Several wooden-topped communion tables dating from the early Middle Ages still stand in churches, hidden by altar cloths or built into boxes. Usually, such tables rest either on solid masonry or on a stone socle (a projecting member beneath the base of a superstructure), but they are sometimes elegantly supported by several columns. Generally, communion tables are made of stone, and since one stands before them, they are higher than the usual table. Examples of wooden tables preserved from the late Middle Ages are, as a rule, long narrow tops fastened to side members.

The interesting feature about the tables of the Renaissance and Baroque periods is their constructive and aesthetic design. Their thick and heavy tops rest on an underframe; the legs are baluster-shaped or turned, with deeply carved bulbous decoration. In the 17th century and later, table forms were widely differentiated and made for a great variety of purposes; i.e., dining tables, library tables, drawing-room tables, card tables, tea tables, small candlestick tables, sideboards, and console tables.

often constructed with sloping stretchers to counteract this pressure. The simplest way to make a table steady without exaggerating the dimensions of the individual parts is to fasten the legs to an underframe. Fixed table-tops can also make do with a single leg; for example, the so-called pedestal table, terminating in a tripod or quadripod. Pedestal tables topple over easily, however, unless both top and pedestal are particularly heavy. Three-legged tables with a fixed top provide a more reliable support than a single-legged type but are unstable when subjected to uneven pressure from above.

The term mechanical refers to all tables whose tops can be enlarged or reduced according to need. Such tables may require pivotable or collapsible legs to augment the strength of the top. A familiar solution to the extension of a tabletop is the so-called Dutch system, known since the 17th century from Dutch engravings and paint-

Pedestal table

From the Ming dynasty and the 18th century, several interesting Chinese fixed-top table forms have been preserved, in which the constructive elements are in some cases emphasized and in others deliberately disguised. Like other Chinese furniture forms, the tables create a stylized effect, with a naïve, calculated character. Chinese tables may be completely covered with lacquer and gilt ornamentation, but sometimes the wood is left in its natural colour.

**Bed.** In Homer's *Odyssey* there is a description of how Odysseus made his own bed: the trunk of an olive tree was cut to the exact shape and planed smooth; after holes had been drilled in the framework, oxhide thongs, dyed crimson, were threaded back and forth to make a pliant web; finally, the wood was embellished with inlay work in gold, silver, and ivory.

As a furniture form, the bed is as old as the chair. In principle the construction of the bed is extraordinarily simple: it consists merely of a rectangular platform raised in some way or other slightly above floor level. A considerable number of bed forms cannot be classed as furniture at all. Alcoves and bunks in ships, railway carriages, and airplanes belong more to the sphere of building trade joinery than to cabinetmaking.

That a number of beautiful and original bed forms of fine artistic execution have been created since antiquity is attributable to the fact that the bed gives the furniture designer rich possibilities in terms of framing and presentation, particularly in conjunction with textiles. Apart from the actual bedclothes, which will always be of greater importance than the actual platform and the surrounding framework, imaginative experiments combining the practical and the impressive—in four-poster beds and tentlike canopies, for example—have been made for centuries.

An Egyptian bier dating from the 1st dynasty (c. 3100–2890 BC) shows the original form of the bed: a rectangular framework of staves, round in section and mortised into one another so as to leave the ends free lengthwise, supported on four small legs carved to represent stylized lions' feet. Amusingly, the feet face in the same direction—as if they were walking with the dead person. This is characteristic of all Egyptian beds. Made of cedarwood, the light framework is higher at the head than at the foot; and whereas the foot is always terminated by a footboard, there is no board at the head. The beds were so constructed because the Egyptians when sleeping or resting used a stool-like support for the head. Essential to the Egyptian bed, countless examples of this piece of equipment—made usually of wood but sometimes of ivory and faience—have been found in Egyptian tombs. The actual framework of the bed was often covered with plaited leather thongs.

In China, a bed in the form of a complete little house, with an anteroom in the form of a veranda, was placed in the middle of the room.

Before central heating and a knowledge of hygiene became common, the closed bed was the generally accepted form in cold climates. The simplest way to avoid drafts was to place the bed in an alcove—as was the practice in farmhouses right up to the 19th century. The most frequently encountered form of bed in European civilization, however, was the four-poster. Throughout the Middle Ages and later, the four-poster was developed in a variety of forms. Already during the Middle Ages, beds were designed for clearly ceremonial effect. The four posts supported an expanse of cloth that extended from the head like a canopy, just as the most distinguished row of choir stalls in a church was crowned by a baldachin (an ornamental structure resembling a canopy). Miniatures in illuminated manuscripts of the same period show tentlike beds entirely closed by drapery and curtains.

In the time of the absolute monarchies in the 17th and 18th centuries, pompous four-posters were developed in which the surrounding textile drapery completely concealed the wooden construction of the bed, thereby achieving a synthesis of practical and ceremonial considerations. Every palace or mansion had a chamber of

state among its official reception rooms. Contemporary memoirs describe the complicated ceremony that took place at Louis XIV's daily awakening. Where his royal highness spent the night was his own concern, but his awakening was an act of state, in the conduct of which princes of the blood, dukes, and distinguished courtiers all had their respective duties: one would draw aside the bed-curtain, another would have the royal dressing gown ready, another the royal slippers. It was the first audience of the day, the king's levee. A large number of 17th- and 18th-century four-poster beds are still preserved in palaces, country houses, and museums; and most of them have a clearly dramatic, almost theatrical effect. The four-poster beds of the Baroque and Rococo periods, moreover, reflect great artistic refinement, especially in the rare instances in which they can still be seen in their original interiors complete with their entire textile adornment. Such beds of state are typical of continental Europe. In England and America, particularly toward the end of the 18th century, greater interest was taken in showing off the bedposts and the upper framework connecting them. Many English four-posters have slender, finely carved mahogany posts, whereas on the Continent the corresponding parts may be entirely covered with the same silken material as that used for the curtains, canopy, and bedspread.

During the Empire period in France an entirely new form of bed was developed and won favour throughout most of Europe. The design was inspired by the Roman couch as known from reliefs and from excavations in Pompeii and Herculaneum. The frame was very high, and the bed ends consisted of volutes (spiral or scroll-shaped forms) of equal height. The bed was crowned by a tentlike superstructure, and the martial aspect was further emphasized by the use of spears to support the draperies and curtains; the whole bedroom, in fact, might well be draped like a tent. In these surroundings, the army commanders of Napoleon's time could feel like the caesars and consuls of ancient Rome. During a campaign, however, collapsible iron camp beds were more practical. Napoleon owned several and died in one on St. Helena in 1821. As a furniture form, the iron bed was a neutral framework built to support bedclothes and equipped with stanchions (upright supports) for curtains; it was light, transportable, and spartan.

Among plantation owners in the West Indies and the southern United States, a type of four-poster popular at the beginning of the 19th century was dominated by wood, rather than textile hangings. The posts supported very light, roughly made wooden frames, to which thin, white mosquito netting was fastened to protect the sleeper. The monumental and dignified effect was obtained by the quality of the woodwork. Of thick dimensions, the wood is solid mahogany polished to a high gloss. The four bedposts are not necessarily identical at the head and foot of the bed, but all have bulbous and turned sections, exaggerated almost to the point of crudeness. The headboards and footboards are imaginatively designed with voluted gables (triangular decoration) and galleries (ornamental railings) supported on pillars. Besides the practical function of these West Indian beds, they also served to indicate the importance of their owner; like the royal four-poster of the days of absolute monarchy, they clearly showed the difference between master and slave.

In the 20th century, the bed has belonged exclusively to one's private life; and compared with those of the past, modern beds are simple. Four-posters are still "modern," possibly because they appeal to something primitive, namely the sensation of sleeping in a tent. In general, development has been concentrated on improving the quality of bedclothes and increasing the amount of comfort by attention to springs, spring mattresses, eiderdowns, and pillows. The actual woodwork of the bed is usually restricted to joined veneered sections of laminated board, canework sometimes being used for the headboards and footboards.

**Storage furniture.** *Chest.* The chest, including the coffin (and sarcophagus), is an ancient primitive furniture form that has survived into the 20th century. The design

of a clothes chest is optional; its size depends on changing demands. The construction of a coffin, on the other hand, is a set task. The format is determined by certain principal dimensions, and the human figure has at all times exercised an influence on the shape of the coffin; the Egyptian mummy case, which takes on the form of the swathed corpse, is an example. Traditional features of ancient Roman sarcophagi, and simplified versions of the monumental style of the Baroque and Renaissance periods continue to thrive.

Early  
medieval  
chests

The principal constructional features of early medieval chests lasted until the Renaissance. The so-called Oseberg ship, dating from the Viking era (9th century AD) and discovered in 1904 in Vestfold, Norway, included among the furniture on board a chest made of oak planks secured by iron bands. The planks are not mortised together, and the end sections stand vertical, thereby forming feet, wider at the bottom than above. The lid is formed by a single curved oak plank that has been rough-hewn into shape. The bottom of the chest rests in a groove cut into the end sections. The wooden construction, a primitive form of carpentry, is held together by broad iron bands, the nails are tin-plated. In this Oseberg chest, the iron mounts essential to the construction constitute the decorative element as well. All medieval chests are developments of the same principle: a piece of carpentry with decorative iron mounts, but the principle found freer application in medieval church doors than in the chests of the period.

"Nun's  
chest"

The chest often appears in portable form as a traveller's trunk that can also serve as a stationary piece of furniture. A number of painted, parchment-covered Florentine chests dating from the middle of the 15th century have been preserved. These were used as trunks by young girls on their way to enter a convent and later stood in their cells as pieces of storage furniture for clothes and other personal belongings. A "nun's chest" of this type is in principle quite different from the sumptuous cassoni of the Italian Renaissance that were adorned with gilded stucco work and painted panels.

Cassoni were stationary pieces of palace furniture. Specifically designed for travelling, however, were Javanese camphorwood chests that made the long voyage round the Cape of Good Hope full of stuffs and spices and eventually came to rest in an English manor house or in a gabled Dutch mansion in Amsterdam. The plank construction with metal mounts is of primitive craftsmanship. The large, smooth expanses of reddish-brown wood, with their elaborate openwork brass mounts and big, chased bolt heads to take the brunt of rough handling, have a kind of sophisticated crudeness about them. On later camphorwood chests the brass mounts are sunk flush with the surface of the wood, just as on portable writing desks and toilet cases of the French Empire period. Veneered wood was not suitable for chests intended for travel purposes, but it was possible to cover the entire chest with leather fastened with metal nails, possibly to form a pattern. Several beautiful, leather-covered chests made in Italy and Spain in the 17th century are known, and the form persisted in the large wardrobe trunks of succeeding centuries.

When furniture-making techniques demanding the skill of the cabinetmaker evolved during the Renaissance, frames, panels, and carving appeared on chests. In southern Europe, walnut lent itself admirably to carving; in northern Europe, oak. While the Italians were inspired by the molding and decorative plant ornamentation of the stone sarcophagi of ancient Rome, in northern Europe late medieval wood carving traditions were continued. As a rule the carved woodwork was picked out (trimmed) with paint and gilded. In the 18th century, the chest was largely supplanted for storage purposes by the chest of drawers and the commode (low chest of drawers), but it never entirely disappeared. Particularly in the big country houses of England and America, chests of mahogany or walnut were used for a long time, often having drawers in the bottom and finely fashioned brass mounts that revealed Chinese influence.

*Cupboard.* Strictly speaking, the cupboard is a derivative form of the chest. Early Renaissance cupboards re-

Renaissance cassone, painted and gilded wood, Florence, 15th century. In the Victoria and Albert Museum, London.

sembled two chests placed one on top of the other, but they were opened from the front by means of doors. The design and construction of the cupboard's pronounced front have always provided ample scope for artistic composition, and it is no mere coincidence that the cupboard more than any other furniture form should have closer links with architecture. It literally invited an architectonic composition: socle, columns, cornice. This development can be traced from the close of the Middle Ages in a large number of southern German and Tirolean cupboards bearing late Gothic perpendicular tracery and smooth surfaces veneered with ashwood. Very large cupboards took on their most striking form, however, during the Renaissance in 17th-century Holland and northern Germany. In molding and composition, they have much in common with architectural facades, but their picturesque and textural effects are the result of refined craftsmanship. The use of veneer was almost essential if these large expanses of wood were to be infused with life. A carcass of wood was given a veneer of fine walnut; socle, frames, columns, and cornice were decorated with veneered black ebony. The doors were furnished with strong locks, and the keyhole was concealed behind a sliding middle column. The cornice was often decoratively crowned with a set of Dutch faience or Chinese porcelain vases. These heavy cupboards were made to appear lighter by placing them on big, turned ball feet. In marked contrast to the European Baroque cupboards, Chinese cupboards of the same period were simple, smooth-surfaced, and boxlike. Their construction was based on a simple system of uprights and frames, and as a rule they were made in pairs. If painted, a large decorative painting was spread across the entire surface, including the doors. Inside, Chinese cupboards are finished with great care and painted in a different colour from the outside. The mounts are of various white and yellow metal alloys, smooth, either round or square; and the locks are secured with prismatically designed padlocks. Japanese and Siamese cupboards, apart from certain independent features, follow the old Chinese traditions.

The clothes cupboard of the 19th and 20th centuries, an indispensable piece of bedroom furniture wherever there are no built-in cupboards, is based on traditional features of the 18th-century English clothespress but equipped to meet the changing fashions of modern times.

**Bookcases.** Bookcases or bookshelves are a less interesting form of storage furniture from the viewpoint of furniture history. Perhaps the most significant innovation appeared in 18th-century England in the bookcase with adjustable shelves and a closed-off lower section for folio files. The shelves were protected by glass doors consisting of an ingenious trelliswork of carved wood. Bookcases and shelves become interesting only when they form part of specially designed library interiors and when several shelves full of books create an intimate, compact whole.

**Mixed forms.** Apart from the kinds of storage furniture already mentioned, there are numerous combination

forms. An ordinary table can be used as a writing desk, and the only differences between the typical French Rococo writing desk of the 18th century and other tables are the drawers in the underframe and the leather-covered top. The novelty of Louis XV's writing desk consists of a rolltop device for closing the writing flap. In England a special type of writing desk was developed which, besides drawers in the underframe, has a side cupboard fitted with additional drawers and, occasionally, sliding trays. Some have a false drawer front that can be pulled out to form a writing surface. When a writing desk has a cupboard built on the top of it and is placed on a chest of drawers, the result is a cabinet or secretary. There are also bookcases with lower sections equipped with a flap, either hinged or sliding, for writing. All of these combinations, frequently of ingenious design, were made anonymously in England during the 18th century, apparently having arisen from a desire on the part of the well-to-do middle classes to develop a sophisticated and differentiated pattern of life.

A special group of storage furniture embraces the various forms of corner furniture, low or high cupboards that were made in pairs (just as in the case of several other old furniture forms) particularly for small rooms, in which they became fixed components of the interior scheme.

**Kitchen furniture and furnishings.** Kitchen furniture and furnishings go back to antiquity. In the Middle Ages, the kitchen, because of its fireplace, was the most centrally placed room in the home. Later, closed fireplaces were constructed in the form of stoves; and cupboards, sinks, and plate racks were as a rule fixed to the wall. The kitchen in a modern home, if not combined with a dining area, is a small room filled with concentrated and complicated equipment. On the other hand, institutional kitchens have expanded enormously. Outdoor cooking equipment, such as various forms of open-air grills, also forms part of the kitchen furniture of the 20th century.

**Bathroom furniture and fixtures.** Bathrooms in large private homes were not unknown in the 18th century, and splendidly equipped marble bathrooms are still preserved in several European palaces and mansions. It was, however, not until the 19th century that bathrooms in private homes became more commonplace. Fixtures generally include a toilet, bidet, washbasin, bath, mirror, and shelves. It was only in the 20th century that the equipping of bathrooms became a separate industry with a wide variety of special forms of bathroom furniture and fixtures. The materials used are porcelain, enamel, plastic, wood, and stainless steel.

**Specialized furniture.** Office furniture in the widest sense of the term has undergone rapid developments since mid-19th century. Such pieces as the high desks used by clerks in old offices and the big American rolltop desks have been replaced by carefully designed standard forms of writing desks with side cupboards, typewriting tables, filing cabinets, and office chairs with adjustable

English  
writing  
desks

Chinese  
cupboards

Office  
furniture

backs and swivel seats. From office furniture one passes naturally to the vast sphere of institutional furniture: theatre furnishings in the form of rows of connected seats, restaurant furniture, furniture for conference rooms, laboratories, workshops, and factories. Several of these specialized furnishings reflect past traditions. The way in which the British House of Commons is furnished, for example, derives without doubt from the pattern in which choir stalls were grouped in medieval churches; whereas the semicircular, often amphitheatrically designed assembly halls of the United States Congress and the parliaments of many European countries are developed forms of academies of surgery or other university auditoriums. Similarly, museums, libraries, and archives have their special furniture in the form of showcases, desks, special tables, and socles.

There are also furnishings for movable premises, primarily railway carriages equipped for sleeping or dining, passenger ocean liners with cabins, airplanes, buses, coaches, and private cars.

Finally, there is the large, highly heterogeneous group comprising outdoor or open-air furniture; for example, furniture for gardens, balconies, terraces, and solaria.

#### KINDS OF ACCESSORY FURNISHINGS

Besides the aforementioned kinds of furniture and all the many special forms (which it would be almost impossible to list), there is an extensive group of accessory furnishings that is not furniture in the strict sense but, nevertheless, constitutes an important element in the furnishing of interiors. Included here are clocks and other mechanical works, mirrors, textiles, screens, stoves, and fireplaces; and a number of smaller articles made by cabinetmakers, such as boxes, caskets, sewing tables, wastepaper baskets, lighting fixtures, frames, panelling, and floor surfaces.

**Clocks.** Clocks are considered furnishings if the movement is enclosed within a case, which need not necessarily be of wood. Clocks can be divided into table clocks and long-case clocks. There were two creative centres for table clocks, namely England and France. In 17th- and 18th-century France, the table clock became an object of monumental design, the best examples of which are minor works of sculpture. The actual movement is framed by a marble socle, and the clockface by a sculptural frame of solid bronze incorporating freely molded figures and ornamentation. Some of France's best sculptors and bronze casters were engaged in the creation of decorative frames for clock movements. A French speciality, imitated elsewhere on the Continent, was the wall clock, or so-called cartel clock, the earliest examples of which were designed by a goldsmith and ornamentalist, Juste Meissonnier. The clockface is the centre of an ornament, or *rocaille-cartouche*, cast in bronze, sometimes garnished with figures of symbolic significance; for example, Time, a man with a scythe, or a crowing cock. In England, where tastes were more bourgeois, the fine movements made by skillful London clockmakers were built into wooden cases, architectonic in composition and featuring pilasters (partly recessed columns) and cornices. Simple walnut cases could be adorned with metal ornaments and brass balls. The more expensive table clocks were concealed in cases embellished with inlaid wood or tortoiseshell.

Long-case clocks were also made in France and England. French long-case clocks are monumental and richly designed. In the reign of Louis XIV there were long-case clocks of the *bouffe* type with metal and tortoiseshell inlay work. Later, in the 18th century and especially during the Rococo period, the case that concealed the weights acquired more dramatic form: richly inlaid wooden surfaces were framed and adorned by magnificently gilded Rococo ornaments in bronze. The English long-case clock was to a greater extent a piece of furniture, and the main features of its construction remained unaltered throughout the 18th century. The long-case clock stands on a base, or socle, from which the somewhat narrower case for the weights rises up, crowned by the framework of the actual movement and

clockface. The last-named section is in reality a table clock mounted on a weight case. Each individual section of the long-case clock is thus clearly separate; each has its distinct function; and no attempt was made, as in France, to veil the independence of the individual parts. The weight case is provided with a door in which there may be a window through which the position of the weights can be observed.

During the 18th century, barometers became increasingly popular. The mechanism was provided with a decorative wooden framework intended to harmonize with the other furniture in a room.

**Mirrors.** The use of mirror glass in furnishings arose during the 17th century. The discoloration of the melted glass because of silvering and, not least, the prohibitive cost and difficulty of manufacturing mirror glass of considerable size restricted the possibilities of large-scale application. The mirror gallery at Versailles was thus an outstanding technical achievement for its time. When Louis XIV strode through the gallery at the head of his court, the glass walls reflected the diamonds in his crown. This effect was imitated to a greater or lesser degree in all the courts of Europe. In the 18th century the wall mirror found its way into most interiors. The popularity and wide distribution of mirror glass was stimulated by the need for an increased amount of artificial light. During the 16th and 17th centuries, this need had been satisfied by placing candles in front of highly polished concave metal plates. By using silvered mirror glass, the light effect was multiplied. From then on, large mirrors hung over console tables were a necessary and functional part of rooms illumined by artificial light.

**Fabrics.** The use of fabrics in furnishing rooms is closely bound up with the need for heating. In the primitively heated rooms of the Middle Ages, textiles were used to keep out cold and drafts. In 12th- and 13th-century churches, painted textile drapery can still be discerned beneath the picture friezes. In rather cold churches, just as in poorly heated homes, loosely hung textile wall coverings were of the greatest importance. They were hung loosely because of the practice of taking them down and moving them, together with the relatively few items of furniture, according to need. It was not until the end of the 17th century and during the 18th century that tapestries and other forms of textile wall hanging became fixtures; that is, fastened to the wall within frames. Wall pictures made of paper and, subsequently, patterned wallpaper became a cheaper substitute for textile wall hangings during the 19th century. Screens or room dividers were often covered with textiles, partly to afford protection against direct radiant heat and partly to create cozy corners in large rooms. Framed screens were often covered with pieces of tapestry, with other woven materials, or with gilt leather.

**Fireplaces.** The heating of rooms and large halls remained a major problem until the advent of modern central heating systems. The open hearth was replaced during the late Middle Ages by the fireplace, which is merely an architectonic way of framing the burning logs. During the period when it was important as a source of heat, the fireplace became the object of design work by significant artists. A Scottish architect, Robert Adam, and his brothers and an Italian architect and engraver, Giambattista Piranesi, made considerable artistic contributions to the design and construction of fireplaces.

**Other accessory furnishings.** Small utility objects constitute an important part of the furnishing of interiors. Several of them are the work of cabinetmakers; for example, boxes for writing paper and playing cards, caskets for letters and documents, trays for serving or presentation. Accessory furnishings include the various articles, large and small, that are employed in the course of domestic work—from small looms to lace pillows, spinning wheels, embroidery frames, and sewing tables. Women's chattels, partly in the form of equipment for domestic needs and partly in the form of items of storage furniture for such small items as pins, scissors, wool, and materials, all had their place in the home.

Finally, the structure and decoration of the walls, ceil-

clocks

ings, and floors—for example, panelling, stucco work, parquet flooring, carpets—also come under the heading of accessory furnishings. (Er.L.)

## II. History

### WESTERN

**Egypt.** Beds, stools, throne chairs, and boxes were the chief forms of furniture in ancient Egypt. Although only a few important examples of actual furniture survive, stone carvings, fresco paintings, and models made as funerary offerings present rich documentary evidence.

Reconstructed bed canopy with bed, chair, and curtain box from the tomb of Queen Hetepheres at Giza, wood overlaid with gold foil, Egypt, 4th dynasty, c. 2600 BC. A bed, with detachable footboard of inlaid falence and silvered headrest, and a low armchair stand beneath a canopy designed to take hangings. In the Museum of Fine Arts, Boston. Original in the Egyptian Museum.

Construction of the Egyptian bed

The bed may have been the earliest form; it was constructed of wood and consisted of a simple framework supported on four legs. A flax cord, plaited, was lashed to the sides of the framework. The cords were woven together from opposite sides of the framework to form a springy surface for the sleeper. In the 18th dynasty (c. 1567–1320 BC) beds sloped up toward the head, and a painted or carved wooden footboard prevented the sleeper from slipping down.

The great beds found in the tomb of Tutankhamen were put together with bronze hooks and staples so that they could be dismantled or folded to facilitate storage and transportation; furniture existed in small quantities and when the pharaohs toured their lands, they took their beds with them. In the same tomb was a folding wooden bed with bronze hinges.

Instead of pillows, wooden or ivory headrests were used. These were so essentially individual, being made to the measure of the owner, that they were often placed in tombs to be used by the dead man on his arrival in the land of eternity. Folding headrests were probably for the use of travellers.

Early stools for ceremonial purposes were merely squared blocks of stone. When made of wood, the stool had a flint seat (later shaped concavely) covered with a soft cushion. In time the stool developed into the chair by the addition of a back and arms. Such throne chairs were reserved for use by personages of great importance.

Footstools were of wood. The royal footstool was painted with the figures of traditional enemies of Egypt so that the pharaoh might symbolically tread his enemies under his feet. Carvings of animal feet on straight chair legs were common, as were legs shaped like those of animals. Boxes, often elaborately painted, or baskets were used for keeping clothes or other objects. Tables were almost unknown; a pottery or wooden stand supporting a flat basketwork tray held dishes for a meal, and wooden stands held great pottery jars containing water, wine, or beer.

The Egyptians used thin veneers of wood glued together for coffin cases; this gave great durability. Egyptian furniture in general was light and easily transportable; its decoration was usually derived from religious symbols, and stylistic change was very slow.

**Mesopotamia.** The furniture of Mesopotamia and neighbouring ancient civilizations of the Middle East had beds, stools, chairs, and boxes as principal forms. Documentary evidence is provided chiefly by relief carvings. The forms were constructed in the same manner as Egyptian furniture except that members were heavier, curves were less frequent, and joints were more abrupt. Ornament was richly applied in the form of cast-bronze and carved-bone finials (crowning ornaments, usually foliated) and studs, many of which survive in museums. Mesopotamia originated three features that were to persist in classical furniture in Greece and Italy and thus were transmitted to other western civilizations. First was the decoration of furniture legs with sharply profiled metal rings, one above another, like many bracelets on an arm; this was the origin of the turned wooden legs so frequent in later styles. Second was the use of heavy fringes on furniture covers, blending the design of frame and cushion into one effect; this was much lightened by classical taste but was revived in Neoclassicism. Third was the typical furniture grouping that survived intact into the Dark Ages of Europe: the couch on which the main personage or personages reclined for eating or conversation; the small table to hold refreshments, which could be moved up to the couch; and the chair, on which sat an entertainer—wife, hetaera (courtesan), musician, or the like—who looked after the desires of the reclining superior personages. From this old hierarchy of furniture derive the cumbersome court regulations concerning who may sit and on what, persisting in the palaces and ceremonies of 20th-century monarchs.

Mesopotamian ornamentation

**Greece.** Principal furniture forms were couches, chairs (with and without arms), stools, tables, chests, and boxes. From extant examples, the depiction of furniture on vases and in relief carvings, and literary descriptions, much more is known about Greek furniture than about Egyptian. At Knossos, a built-in throne of stucco, much restored, is often considered to represent pre-Hellenic furniture in the Aegean area. Primitive Aegean pottery shows rounded chair forms, perhaps indicating basketry models, and Bronze Age sculpture shows complex-membered chair frames.

In ancient Greek homes, the couch, used for reclining by day and as a bed by night, held an important place. The earliest couches probably resembled Egyptian beds in structure and possibly in style. The legs occasionally imitated those of animals with claw feet or hoofs, but usually they were either turned on the lathe and ornamented with moldings or cut from a flat slab of wood sharply silhouetted and decorated in various ways—with incised designs or with volutes, rosettes, and other patterns in high relief. From about the 6th century BC, the legs projected above the couch frame; these projections became headboards and footboards, the latter eventually made lower than the headboards. In Hellenistic times headrests and footrests were carved and decorated with bronze medallions carrying busts of children, satyrs, or heads of birds and animals in high relief. Turned legs largely replaced rectangular ones. Although a bronze bed of the 2nd century BC has been found at Priene and marble couches sometimes occur in tombs, the usual material was wood. The legs often terminated in metal feet and sometimes were encased in bronze moldings, and

The Greek couch

By courtesy of the Staatliche Antikensammlungen und Glyptothek, Munich

the rails also were sometimes covered with bronze sheathing.

From the Greek Archaic period onward many varieties of individual seats are known, the most imposing, perhaps, being elaborately adorned, high-backed ceremonial chairs of wood or marble. Like the couches, they were supported on turned legs, legs cut from a rectangular piece of wood, or legs with animal feet; they frequently had arm rails. Another type of boxlike seat with no feet and with or without a back is also found. The klismos chair was lighter and had a curved back and plain, sharply curved legs, indicating a great mastery of wood-working. The *diphros* was a stool standing on four crossed, turned legs, sometimes connected by stretcher bars and sometimes terminating in hoofs or claw feet. The convenience of folding stools was realized at an early date, and the *diphros* was popular.

Greek tables were usually small and easily portable. An interesting type had an oblong top supported by three legs, two at one end and one at the other. These legs usually tapered from the top and terminated in claw feet, and the bronze and stone examples which are occasionally found show carved flutings on the front of the legs and scroll ornament at the side below the table tops. Rectangular tables with four legs were also used, as were round tops.

**Rome.** Principal furniture forms were couches, chairs with and without arms, stools, tables, chests, and boxes. Excellent documentary evidence is found in mural paintings, relief carvings, and literary descriptions. Extant examples are more common than those of the ancient Near East: a wealth of bronze furniture was recovered at Pompeii; at Herculaneum even wood pieces were partly preserved.

As in Greece, the couch was a principal furniture form. At Pompeii couches with bronze frames closely resembled Greek examples. Gold, silver, tortoiseshell, bone, and ivory were used for decoration, with veneer of rare woods. Later couches, found in Italy and in distant parts of the empire, were characterized by the high back and sides.

Roman chairs developed from Greek models. The Greek throne chair evolved into a small armchair with solid rounded back made in one piece with sides set on a rectangular or semicircular base. This armchair was often of wickerwork, wood, or stone. The Greek klismos chair was given heavier structural members by the Romans and was called the cathedra.

The Romans developed a decorative type of stool, often made in bronze. This was supported by four curved legs,

ornamented with scrolls. The folding stool, with cross legs sometimes connected by stretcher bars, was used both by Roman officials and in households. Remains of folding stools are known from sites such as those at Ostia, Italy, and barrows in Britain—on the Essex-Cambridgeshire border, and in Kent. This developed into a stool that had more solid double curved legs; examples were found at Pompeii. An example in iron with bronze decorations, even heavier in form, was found at Nijmegen, in The Netherlands.

Tables with round and rectangular tops and three and four legs were common. Tables with round tops and

Roman tables

SCALA, New York

Roman table or stand with circular top from the Temple of Isis at Pompeii, bronze, before AD 79. The clawed legs, connected with elegantly scrolled braces, are surmounted by winged sphinxes. In the Museo Archeologico Nazionale, Naples.

three legs of animal form became increasingly popular from the 4th century BC onward. A nearly complete wooden table, found in Egypt and now in the Palais du Cinquantenaire, Brussels, is decorated with swans' heads with graceful necks rising out of a band of acanthus foliage, below which are very realistic antelope legs, with hoofs instead of claw feet. This type of table seems to

Klismos and *diphros* chairs

The Roman couch

have been popular throughout the Roman empire, as it often appears on tombstones depicting funerary banquets. It is known that citrus wood and Kimeridgian shale were favourite materials. Several complete tables found at Pompeii and Herculaneum, usually in gardens or open courts, are made of marble and decorated with beautifully carved heads of lions and panthers. Another type of smaller table is round or rectangular with only one central leg. Also found are pairs of solid slabs ornamented in high relief, carrying carved tops of marble or wood.

Storage  
chests

Pompeian wall paintings show that plain, undecorated wooden tables and benches were used in kitchens and workshops, and some household possessions were kept in cupboards with panelled doors. Rectangular footstools, sometimes with claw feet, were used with the high chairs and couches. Small bronze tripods and stands were also items of Roman furniture. Clothes and money were stored in large wooden chests with panelled sides, standing on square or claw feet. Roman treasure chests were covered with bronze plates or bound with iron and provided with strong locks. Jewelry and personal belongings were kept in caskets, in small round or square boxes, or even in baskets.

**Middle Ages.** *Early Middle Ages.* With the collapse of the Roman Empire during the 4th–5th centuries, Europe sank into a period in which little furniture, except the most basic, was used: chairs, stools, benches, and primitive chests were the most common items. Several centuries were to pass before the invading Teutonic peoples evolved forms of furniture that approached the Roman standard of domestic equipment.

Comparatively little furniture of the medieval period in Europe has survived, and only a handful of these pieces date from before the end of the 13th century. One reason for this is the perishable nature of wood, but more important is the fact that furniture was made in relatively small quantities until the Renaissance. Much of the earlier history of furniture has to be drawn from contemporary literature, illuminated manuscripts, Romanesque and Gothic sculpture, and later inventory descriptions.

There is evidence that certain ancient traditions of furniture making, particularly that of turnery, influenced early medieval craftsmen. Turnery was used in making chairs, stools, and couches in Byzantium, and it seems that this technique was known across Europe as far north as Scandinavia. The Anglo-Saxon epic poem *Beowulf*, which gives some glimpses of the domestic economy of western Europe in about the 7th century, mentions no furniture other than benches and some kind of seat or throne for the overlord.

The need  
for easily  
trans-  
ported  
furniture

*Later Middle Ages.* In the 14th and 15th centuries there were many developments both in construction and design of furniture throughout Europe; a range of new types, among them cupboards, boxes with compartments, and various sorts of desks, evolved slowly. Most of the furniture produced was such that it could be easily transported. Noblemen who owned more than one dwelling place usually had only one set of furnishings that he carried with him from house to house. Anything that could be moved, and this frequently included the locks on the doors and the window fittings, was carried away and used to furnish the next house en route. Furniture was so scarce that it was quite usual for a visitor to bring his own bed and other necessities with him. These conditions had a double effect on medieval furniture, not only making it difficult for men to possess more than the basic types of furniture but also affecting the design of the furniture itself. Folding chairs and stools, trestle tables with removable tops, and beds with collapsible frameworks were usual.

The religious houses were an exception to this in that they enjoyed a certain security denied to the outside world. Much of the best furniture of this period was therefore made for use in churches and monasteries, and many of the ideas and developments that were later to add to the domestic comfort of Europe originated in the cloister. An example can be seen in the early develop-

ment for ecclesiastical use of the various types of reading and writing furniture, such as lecterns and desks, that show ingenuity in construction. Throughout the Middle Ages and well on into the 16th and 17th centuries, all types of furniture remained scarce, and any reasonably good furniture belonged to the nobility and the wealthy merchants. The household equipment of the peasantry throughout Europe, even as late as the 18th century, was frequently crude in design and roughly constructed.

Framed panelling had been used in ancient times, as examples found at Herculaneum testify; its reintroduction in the Burgundian Netherlands at the beginning of the 15th century was an improvement that soon spread throughout western Europe. Panelled construction solved the problem of building large surface areas, as on the front of a chest or cupboard, which before this time had been limited by the size of individual planks. These planks, usually hewn with an adz, were heavy and liable to warp and split. Panels could be cut thinner, the main strain being taken by the framework, and the furniture was therefore lighter; moreover, if the panels were not fitted too tightly in their stiles, the wood was less likely to split if it did warp. Now that it was possible to construct larger surface areas, a new range of storage furniture, cupboards and chests in particular, was developed. Panelled construction was also used for chairs.

Framed  
panelling

Other constructional improvements of the 15th century included the introduction of drawers into cupboards and similar storage furniture, and neater and more efficient joints, such as the mitre and the mortise and tenon. Panelling was frequently decorated with a flat form of ornament called linenfold, or parchment. Linenfold was widely used in the north of France, Flanders, Low Germany north to the Baltic, Scandinavia, and England. The linenfold of France, the Low Countries, and Germany is carved with a sharper definition and greater delicacy than was usual in England and elsewhere. Both panelled furniture and room panelling were decorated with linenfold. Other forms of carved decoration on furniture became more common during the 15th century, when surfaces were carved with tracery and other Gothic motifs. During the Middle Ages a great many pieces of furniture, including those with carved decoration, were painted and sometimes gilded, a practice that continued well on into the Renaissance (the present state of existing pieces, with their plain wooden surfaces, is misleading). Chairs, tables, and various types of cupboards were also frequently draped with bright fabrics, while chairs, settles, and other seat furniture were provided with cushions.

The chest was the basic type of medieval furniture, serving as cupboard, trunk, seat, and, if necessary, as a simple form of table and desk. It was from this versatile piece of furniture that several other types, such as the cupboard and the box chair, were evolved. Chests were made of six planks, crudely pegged or nailed together and frequently strengthened with iron banding. Examples of this sort, dating from the 13th century and in many instances found in churches, are among the earliest pieces of extant European furniture. The chest remained one of the most important pieces of furniture until the end of the 15th century, when on the Continent the cupboard began to compete with it in usefulness.

The  
medieval  
chest

Chairs remained scarce throughout the Middle Ages, and occupation of a chair long symbolized authority or a mark of honour, and even a large house might possess only chairs for the lord and his wife and perhaps another for a distinguished visitor; the use of the word chairman is a modern reflection of this medieval custom. Early chairs constructed of turned spindles, seen in Romanesque sculpture, have already been mentioned. Later there were two main types. One was a variety of folding chair, with X-shaped frame, made of both wood and metal, the seat and back consisting of rectangular strips of some strong fabric or leather. Eventually there evolved a heavier type of chair. This was basically a development of the chest, and in many cases the seat was hinged, allowing the base to be used for storage. Panelling, often carved with linenfold and sometimes with other Gothic motifs, was used on the back, arms, and base.

Massive limestone mantelpiece from Alençon and chairs with X-shaped frames, France, 15th century. In the Metropolitan Museum of Art, New York, The Cloisters Collection.

Many of these chairs had exaggeratedly high backs terminating in elaborately carved canopies; some were free-standing, while others had their backs fixed to the wall in the manner of a church stall. Settees were also used for seating during the 15th century. An innovation on the Continent was the settle with a pivoted bar forming the backrest, which could be swung over to allow a person to sit on either side—evidence of the weight of the furniture of this period.

#### Tables

Tables were mainly of trestle construction (with a braced frame serving as a support for the tabletop) with long rectangular tops that could be dismantled. During the 15th century on the Continent, smaller tables were made which could be more conveniently moved and, especially, drawn up to the fire. Various forms of cupboards, ambries and dressoirs, were developed at this time, panelled and decorated with linenfold or Gothic carved ornament. All these types were basically a chest with doors, of simple rectangular form raised on legs; elaborations of construction and decoration soon followed, as did the specialization of their functions. Cupboards, dressoirs, and credence (sideboard or buffet) tables were used for the storing of plate and for serving at banquets, the plate being displayed on the top and on shelves above and below the main serving surface. Top shelves were sometimes cantilevered or projected on brackets to free the front corners of this surface for use. Other cupboards were made to hold food and day-to-day provisions; in the case of food, or dole cupboards as they were called, the front and sides were pierced for ventilation.

Medieval beds are known from documents and a few late examples. Recalling Egyptian beds, throughout most of this period a diagonal surface, lifting the head high,

was common. Some beds had daringly cantilevered ceilings supported from the headboards.

Little English furniture survives from medieval times, and, as on the Continent, information must be sought in contemporary references and from the picture of domestic interiors in illustrated manuscripts. Most of these manuscripts are of French or Flemish origin, but they furnish reliable evidence on English interiors because the governing classes, who were practically the sole possessors of proper furniture, copied the domestic habits of the Continent. English oak was the chief material, but softer woods also were used. A certain amount of furniture was imported from abroad, providing new ideas for the English carpenter and joiner. The furniture usually found in important houses consisted of beds, chests, cupboards, tables, benches, and stools.

**The Renaissance. Italy.** From the beginning of the Renaissance in the early 15th century, there were changes in furniture forms that were to spread over Europe. The growth of a wealthy and powerful bourgeoisie caused the building of more substantial houses and a demand for good furniture. Italian Renaissance furniture shows a strong architectural bias, and the purpose of the piece, as in Roman furniture, was subordinate to its form. The furniture of the early Italian Renaissance is often restrained, with beautiful, simple designs carved in walnut. For more elaborate work, sculpture in low relief and stucco modelled in intricate patterns were much used. The stucco was usually gilded all over and picked out in bright colours.

The cassone, or marriage coffer (hope chest), was a form on which the craftsman's skill was lavished. In addition to elaborate relief work and gilding, these coffers often were painted on the front and sides and occasionally inside the lid as well, with appropriate biblical or mythological scenes. Motifs popular with the Italian carver included cupids, grotesque masks, scrolled foliage, and strapwork. The fixed writing desk is the forerunner of the writing bureau, which became an indispensable article of furniture as writing became more general.

A type of chair called a sgabello was much favoured at this time in Italy. The seat was a small wooden slab, generally octagonal, supported at front and back by solid boards cut into an ornamental shape; an earlier variety was supported by two legs at the front and one in the rear; a solid piece of wood formed the back. Another chair of the period was the folding X-shaped chair, sometimes called a Dante chair. Tables were generally oblong, supported by columns, consoles (brackets), or terminal figures, with a long central stretcher running from end to end. Italian Renaissance furniture forms reshaped the furniture of the remainder of Europe.

**France.** The furniture of France was among the first to be influenced by the Italian Renaissance. Louis XII and many of his court visited Italy and soon took Italian artists and craftsmen and works of art into France. The French Renaissance of furniture can be divided into two stages. First was a period of transition and adaptation; during the reign of Louis XII and the first part of the reign of Francis I, the pieces were basically Gothic in form, and Gothic ornament was mixed with the cupids, medallion heads, and grotesque decorations of the incoming Renaissance style. During the second phase, from the end of the reign of Francis I, the new style displaced the Gothic. The more exuberant arabesque shapes of Renaissance decoration, however, gave way to increasingly architectural design, and oak was almost entirely superseded by walnut. Centres of furniture making were established at Fontainebleau, where Francis I employed several Italian artists and craftsmen; in Ile-de-France, headed by the work of Jacques du Cerceau; and in Burgundy, where, led by the craftsman and designer Hugues Sambin, design was influenced by the Renaissance style evolved in the Netherlands.

French furniture of the 16th century was remarkably graceful and delicate; it was enriched with inlay of small plaques of figured marble and semiprecious stones, sometimes with inlay or marquetry of ivory, mother-of-pearl, and different coloured woods.

Chairs began to be lighter in design; the back became narrower, the panelled sides and base were replaced by carved and turned arms and supports, and legs were joined by stretchers at their base. A specialized chair known as a *caquetoire*, or conversation chair, supposedly designed for ladies to sit and gossip in, had a high, narrow back and curved arms.

Elaborately carved oblong tables were supported by consoles or fluted columns connected by a stretcher surmounted by an arched colonnade. Chests decorated in the new style were still widely used, although frequently replaced by the *armoire* (a tall cupboard or wardrobe), which was sometimes made in two stages, the upper compartment containing numerous small drawers.

*Spain.* Because of the long occupation of Spain by the Moors, a style called *Mudéjar* evolved. While furniture in this style remained in form essentially European, decoration had an oriental flavour. A type of cabinet known as *vargueno* was typically Spanish. The upper part, in chest form, with drawers inside, had a fall front (a hinged writing surface that opened by falling forward), often elaborately mounted in wrought iron and backed by velvet, with a massive iron lock. The cabinets were richly carved, painted, gilded, and inlaid with ivory in a Moorish manner. There was a tendency for Italian models to be followed in the furniture of the 16th and 17th centuries.

*Low Countries.* In the 16th century, Italian Renaissance ornament was adopted and transformed by artists and designers of northern Europe, particularly in northern Germany and the Low Countries, who created an independent style of decoration. Strapwork, cartouches, and grotesque masks are characteristic features of this northern Renaissance style, and are found repeatedly in the pattern books of German and Flemish artists of the time—books of ornament which circulated among and influenced metalworkers, carvers, plasterers and furniture makers throughout the north.

Heavy oak tables, sometimes draw (extension) tables, had massive legs and solid stretchers. Beds were heavily draped to provide privacy, as the bed might be located in any room of the house. Folding wooden chairs and low stools, with more or less elaborate turnery, were still used, besides a new type with baluster-formed or twisted legs and arms, and straight backs heightening through the 17th century.

*England.* The Italian Renaissance did not affect the design or ornament of furniture in England until about 1520. Evolution from the Gothic style was a gradual process, influence coming first from Italy and, in the second half of the 16th century, from the Low Countries. In the early stages, furniture remained Gothic in form, though Italian motifs slowly replaced the older Gothic ornament. Many pieces of early Renaissance English furniture combined linenfold panelling with medallion heads and Italianate cupids, but by the middle of the century both new ornament and new forms had replaced the medieval style. About the middle of the century the direct influence of Italy weakened, and its place was taken by that of the Low Countries. The northern style of Renaissance ornament was propagated in England by pattern books, immigrant workmen, and imported Flemish and German furniture, and before long it was adapted by English craftsmen into an individual and peculiarly English style.

Characteristic of this style is the enrichment of every surface with flamboyant carved, turned, inlaid, and painted decoration, an exuberance which strongly reflects the spirit of the English Renaissance. During Elizabeth I's reign there was a considerable and fairly widespread increase in domestic comfort, to be seen in improved construction, multiplication of types, and the tentative beginnings of upholstered furniture. A series of inlaid chests with perspective architectural scenes, often called *nonessuch* chests, were either imported from Germany or made by German workmen in England. They were strongly influential in propagating the technique of inlaid decoration, which by the end of the century was being applied to every type of furniture.

Apart from the gradual change from Gothic to Renaissance ornament, the 16th century produced several changes in the design and construction of individual types. Chairs became slightly more common, though even in Elizabeth's own palaces, stools were the usual form of seating. From the box chair evolved a type in which the arms and legs were no longer filled in with panelling but which had plain or turned legs, with shaped arms resting on carved or turned supports. The backs of chairs were still panelled and decorated with carving and inlay or surmounted with a wide and richly carved cresting. Folding chairs, X-shaped and of varying construction, were also used. Chairs without arms, called

the reign  
of  
Elizabeth I

farthingale chairs, were introduced in the early 17th century to accommodate the wide skirts, called farthingales, that were popular at the time. Farthingale chairs had upholstered seats and a low, rectangular upholstered back raised on short supports a little above the seat. Armchairs of similar design were made. Turkey work (a type of needlework) and velvet were usually employed for upholstery.

Early in the 16th century a new style of bed design appeared; the greater part of the frame was left exposed and was enriched with carving and other decoration, making the frame itself an important part of the design. Favourite carvers' motifs for beds and other types of furniture included strapwork, grotesque masks, and caryatids (draped female figures), bulbous turned pillars and supports, arcading (decorating consisting of arches or arcades), and patterns of scrolled foliage. The heavily turned "cup and cover" motif is frequently found on bedposts in the later 16th century. The cumbersome Gothic trestle tables were replaced by "joyned tables," with tops fixed to the frames. Draw tables, which could be conveniently lengthened by pulling out the two leaves concealed under the top, were also introduced. Table legs and sides were decorated with carving and inlay, and the cup and cover motif is often found on the legs. Various types of cupboards were made, usually in two stages, or levels. In court cupboards both stages were left open. A simple form of chest of drawers was introduced about 1620.

**17th century: the Baroque style.** During the 17th century, the Baroque style had a marked effect upon furniture design throughout western Europe. Large wardrobes, cupboards, and cabinets had twisted columns, broken pediments, and heavy moldings. In Baroque fur-

niture the details are related to the whole; instead of a framework of unrelated surfaces, each detail contributes to the harmonious movement of the overall design. The Baroque style was adopted in the Low Countries in the 1620s and extended late into the 17th century, when Germany and England began to develop it. It owed much to the Oriental influence that swept over Europe in the 17th century, when several maritime countries, particularly Portugal, Holland, and England, established regular trading relations with India and the Far East. Lacquered furniture and domestic goods were imported from the East, where Oriental craftsmen also worked in a pseudo-European style from designs supplied by the traders. Before the end of the 17th century, Oriental decorative techniques were being widely imitated in Europe, and the roots of the "Chinese taste" were firmly entrenched. Heavy tropical woods were also brought to Europe, and from these, furniture was made that borrowed much from the prevailing taste for Oriental elaboration.

Influence of Oriental decorative techniques

**Flanders and Holland.** The early Flemish Baroque furniture, dating from the second quarter of the 17th century, was but a slight adaptation of the late Renaissance style. Typical are the oak cupboards with four doors and the chairs with seats and backs of velvet or leather held in place by nails.

In Holland the Baroque style did not encroach on late Renaissance furniture until nearly 1640. Dutch furniture of this period can be distinguished by its simpler design and a preference for molded panels over carved ornament. Later, marquetry decoration and walnut-veneer surfaces became the most common decorative treatments. At the end of the century lacquered furniture became popular.

**Italy.** Though it was in Italian architecture, painting, and sculpture that the Baroque style was evolved, Italy was not the first to apply this style to furniture. But by the mid-17th century Italy was producing flamboyantly carved, painted, and gilded furniture, decorated with such typical motifs as cupids, acanthus, shells, and boldly drawn scrolls, and was further enriching chairs and stools with fine-cut velvets and table tops with marble or *pietra dura* (a mosaic-like technique in which coloured stones are cut and shaped and inlaid in a design). Chairs and stools with exaggerated scrolled arms and legs, and

handsome walnut and ebony cabinets and cupboards with carved decoration on the pediments, friezes, and corners and sometimes inlaid with marble or *pietra dura* set in molded panels, typify the Italian furniture of the later Baroque phase.

**France.** In France the Italian influence of the 16th century was gradually assimilated, and a national style of furniture was evolved that soon spread its influence into neighbouring countries. The reign of Louis XIII, covering most of the first half of the 17th century, was a time of transition. The Gobelins factory was founded by Louis XIV for the production of deluxe furniture and furnishings for the royal palaces and the national buildings. The painter Charles Le Brun was appointed the director in 1663. Furniture was veneered with tortoiseshell or foreign woods, inlaid with brass, pewter and ivory, or heavily gilded all over. At times it was even completely overlaid with repoussé (formed in relief) silver. The name of André-Charles Boulle is particularly associated with this style of decoration. His cabinets and tables were completely covered by sheets of tortoiseshell and brass cut into intricate patterns so as to fit into one another, the tortoiseshell alternately forming the pattern and the ground; hence the two types, *boulle* (*buhl*) and *counterboulle*. The light, fanciful designs of the architect and designer Jean Berain were much used for this work. Heavy gilt bronze mounts protected the corners and other parts from friction and rough handling, and provided further ornament.

**England.** After the Restoration, from 1660 onward, there was almost revolutionary progress in English cabinetmaking, as it came to be called at about this time. On its return, the exiled court introduced French and Dutch fashions, and the English craftsmen were considerably helped in supplying the tastes of the nobility by a large influx of foreign workmen. Furniture became lighter, more highly finished, and better adapted to varying needs. The general increase in technical skill of the cabinetmaker between 1660 and about 1690 is astonishing. Walnut was the favourite wood, though the use of oak continued in the country districts for many generations. New processes appeared, notably veneering wide surfaces with thin sheets of wood into which floral patterns in marquetry often were inserted. In the earlier period of the Restoration these patterns were large, but toward the end of the century they grew smaller and more intricate, leading eventually to the type of marquetry made up of numerous small scrolls and called seaweed marquetry.

The passion for colour found an outlet in lacquer decoration in England as in other European countries. The importation of works of art from the East had begun in Tudor times but was of little account until after the Restoration, when the taste became widespread. The diarist John Evelyn and others reported their friends' houses to be furnished with Indian screens or panelled in the finest "japan" (the process that imitated Oriental lacquetry was called "japanning" in England).

New forms of furniture began to develop: the daybed, a form of couch with an adjustable end; the winged armchairs; the upholstered armchair called in the 17th century a sleeping chair; and, a little later, toward the end of the century, sofas with backs and arms carried comfort a step further. Velvet, silks, and needlework were the usual materials for upholstery. Various kinds of writing furniture were rapidly developed, including toward the end of the century, the bureau with enclosed desk and interior fittings of small drawers and pigeonholes.

Chests of drawers came into more general use. Mirrors were no longer rarities, though glass remained expensive. The frames were carved, lacquered, or decorated with marquetry. Fashions succeeded each other with great rapidity. Chairs show these changes most clearly, developing in a brief period from mere seats of Charles II, while, later, straight tapering baluster forms were used. In the grander beds of this period, the tester (canopy), back, and posts were covered with material. The beds were of enormous height with elaborately molded cornices and had ostrich plumes or vase-shaped finials at

the corners of the tester. These state beds were strongly influenced by the designs of the French architect Daniel Marot, who went from France to England to work for William and Mary.

Edwin Smith

During the late 17th century and on into the first half of the 18th century, a certain amount of elaborately carved and gilded furniture, much influenced by the style of Louis XIV, was produced in England. Foremost among the makers of this deluxe furniture were three cabinetmakers: John Pelletier, Gerrit Jensen, and James Moore. Toward the end of the 17th century, during the reign of William and Mary, Baroque furniture tended to become simpler and the use of ornament was somewhat restrained. At the beginning of the 18th century, during the reign of Queen Anne, a new and simpler style arose, much influenced by the contemporary furniture of Holland. Carving and applied ornament were reduced to a minimum and the beauty of a piece was made to rely on carefully designed curved lines and the colour of fine walnut veneers. The cabriole leg, originally devised in classical times and based on the curve of an animal's leg, was introduced into England from the Continent about 1700. Terminating in a claw-and-ball or paw foot and soon discarding the stretcher, it was widely used on chairs and tables and for every kind of support. The stretcher had become obsolete because of improved joining and gluing. Chairs had hooped up-rights, and fiddle-shaped splats curved to support the back. Tallboys, or double chests of drawers, cabinets fitted with shelves, and bureaus in two stages met the demand for greater convenience, as did a new range of dining, card, and other tables.

**The American colonies.** As in all colonial settlements, the furniture of the American colonies reflected the style preferences of the individual national groups. This influence, coupled with the existence of new ma-

terials and the time lag in transmitting styles and tastes from the home country, in some instances produced highly individual furniture.

Information in inventories and wills about 17th-century furniture of the English colonies indicates that it existed in its simplest forms—stools, benches, tables, cupboards, and a few chairs. This furniture, often made of oak, recalled the tradition of Elizabethan England and was turned and decorated with chip carving, often picked-out in earth colours. By the end of the century, pine, maple, and other woods were used.

The Dutch and Scandinavian settlers carried with them individual furniture forms whose influence remained local.

By 1700 the effect of French and Dutch fashions on late Stuart furniture in England had become evident in the American colonies. Fashion consciousness appeared, though for decades to come the furniture of the average colonial home kept to the earlier tradition evolved from medieval joining. The box chest was succeeded by the chest of drawers, often placed on a stand with turned legs. Chairs began to replace stools; and the early heavy, turned, and wainscot (panelled back) types gave way to simplified versions of the high-back scrolled forms of the English Restoration fashion. The daybed appeared with its upholstered pad. Small folding tables, cabinets, and the tiered dresser to store and display tableware testify to the rapidly increasing standard of comfort among the more prosperous. Carved surface decoration was largely replaced by colour, through the use of paint, veneers, or inlays of contrasting wood.

These innovations accompanied the use of the cabriole, or reverse curve, which, about 1725, became the favoured form for legs of chairs, tables, cabinets, and stands. At first it had little or no carving and a simple paw foot, but the design was elaborated, and this cabriole leg became the principal feature of the so-called Queen Anne style that dominated colonial furniture designs until the Revolution. Walnut became the principal wood of the early 18th century.

**18th century: the Rococo style.** The influence of French furniture was predominant in Europe during the 18th century. In the second half of the century England played a leading role in establishing the Neoclassical style, and for supreme craftsmanship provided an inspiration to workshops in several countries; but in the diffusion of the two styles, the Rococo and the Neoclassic, French designs were universally imitated, with varying degrees of success.

**France.** The transitional phase in French furniture from Baroque to Rococo is called Regence. The heavy, monumental style of the earlier part of Louis's reign was gradually replaced by a lighter and more fluent curvilinear style. The leading exponent of the Regence style was Charles Cressent, *ébéniste* ("cabinetmaker") to the regent Philippe II, duc d'Orléans. In his work the ormolu (a brass imitation of gold) mounts, so important a part of the design of French furniture in the 18th century, became equal to if not more important than, the marquetry decoration of the carcass. The curvilinear form was introduced not only to externals, such as legs and supports, but, in the bombé (rounded sides and front) commodes that first appeared during this period, to the case itself. High-quality marquetry in coloured woods replaced ebony.

The Rococo style, a development of the Regence, affected French furniture design from about 1735 to 1765. The word is derived from *rocailles*, used to designate the artificial grottoes and fantastic arrangements of rocks in the garden of Versailles; the shell was one of the basic forms of Rococo ornament. The style was based on asymmetrical design, light and full of movement. The furniture of this period was designed on sinuous and complicated lines. Designs of Juste Meissonier, goldsmith to Louis XV, sculptor and architect, were instrumental in creating the Rococo. The repertory of ornament was large and included the C-scroll, scrolled foliage, floral motifs, ribbon and, on occasion, trophies formed of musical instruments or gardening implements.

The Rococo Chinese taste had conventions of its own: pagodas, exotic birds, Chinese figures, icicles, and dripping water. The graceful bombé commode, often with marble top and two or three drawers, the surface enriched with finely modelled ormolu mounts, was popular. Under Cressent's influence the mounts predominated, though later in the century the marquetry decoration gained first importance. Commodes and other pieces were decorated with marquetry of floral or geometrical patterns, or sometimes with lacquer decoration, again combined with ormolu mounts. The most celebrated makers of mounts during Louis XV's reign were Jacques Caffieri and his son Philippe. Jean-François Oeben was made *ébéniste du roi* (cabinetmaker to the king) in 1754; a pupil of Boulle, he was the most celebrated cabinetmaker of the period.

Giraudon

Rococo writing desk, the *bureau du roi*, with intricate pictorial marquetry and elaborate ormolu mounts made for Louis XV, begun by Jean-François Oeben in 1760 and completed by Jean-Henri Riesner, 1769. In Versailles.

**England.** About 1720, mahogany was imported into England and slowly superseded walnut as the fashionable wood for furniture. The Palladian (after the Italian Renaissance architect Andrea Palladio) interiors demanded furniture more striking and larger in scale than the walnut-veneered pieces of the early 18th century. Inspired by the interiors of French and Italian palaces, architects such as William Kent began to design furniture. The design was classical, in keeping with the traditions of Palladio and the English architect Inigo Jones; the ornament was Baroque. At Holkham Hall in Norfolk, Rousham Hall in Oxfordshire, and elsewhere, Kent's furniture may be seen in its proper environment: gilt mirrors and side tables with sets of chairs and settees covered with patterned velvets matching the grandeur of elaborate architectural Palladian interior decoration.

Despite the resistance of the Palladian classicists who deplored its asymmetrical principles, in the 1740s the Rococo style crept into English decoration and furniture design. During this decade pattern books of ornament in the full Rococo style by Matthias Lock and Henry Copeland were published in London; and in 1754 Thomas Chippendale published his *Gentleman and Cabinet Maker's Director*, which provided patterns for a wide range of English furniture in the Rococo style and its Chinese and Gothic offshoots. During the following years several similar works were published by such craftsmen and designers as William Ince and Thomas Mayhew, Thomas Johnson, and Robert Manwaring. The Rococo style was firmly established in England through-

The work of Thomas Chippendale

Awakening of fashion consciousness

Influence of French furniture

Characteristics of the Rococo style

out the 1750s and into the 1760s. Chippendale and other cabinetmakers borrowed not only ornament from the French rocaille but designs for individual types. Chippendale's fame rests largely on his publication, though in fact it has now been more or less conclusively proved that he himself was not responsible for the designs, but employed two other designers, Lock and Copeland. There were several cabinetmakers—for example, William Vile and John Cobb—whose only memorial is a small quantity of furniture attributable to them. Though it has become the practice to speak of a Chippendale chair or a Vile commode, this does not imply that the pieces were actually made by these craftsmen but that they were made in their workshops.

By mid-18th century every act of the day that necessitated the use of furniture was catered to by some specialized piece, while the basic furniture such as chairs, cupboards, beds, and tables were designed and decorated in innumerable forms. The number of variants on the Rococo chair splat runs into several hundreds. The ingenuity of the cabinetmaker and carver knew few limitations.

The Gothic taste

An offshoot of the Rococo style, the Gothic taste was particularly well developed in England. Starting early in the century as a literary device, in the 1740s it began to take more solid shape in architecture, interior decoration, and furniture. As with furniture in the Chinese taste, Gothic furniture bore no relation to its medieval equivalents; the ornaments, such as tracery and cusped (a point formed by the intersection of two arcs or foils) arches, applied to furniture were borrowed from Gothic architecture. The Gothic taste was much publicized by the writer Horace Walpole's celebrated villa, Strawberry Hill, in Middlesex, England. Chippendale included designs for furniture in the Gothic taste in all three editions of his *Director*.

*The American colonies.* Shortly after 1750 the earlier cabriole style was transformed by two factors. One was the rapidly increasing popularity of mahogany. The other was the influence of the English version of free Rococo ornament, as reflected in the publication of Chippendale's book of patterns.

While the Southern planter still depended largely upon London for his fine furnishings, the merchants of Philadelphia, New York, Newport, and Boston were well rewarded by their patronage of local craftsmen. In Philadelphia a local version of the Chippendale style was brought to the highest mastery by such craftsmen as Thomas Affleck, Jonathan Gostelowe, Benjamin Randolph, and William Savery. In Newport, Rhode Island, the genius of the John Goddard and John Townsend cabinetmaking families evolved an equally distinctive style by developing a block front decorated by the patterns of the wood grains instead of carving, as used by their contemporaries in Philadelphia. In spite of the Philadelphians' evident desire to match the works of the best London shops, they actually created their own style as distinct from that of England as the innovations of their Newport colleagues. The cabinetmakers of Boston, New York, and the Connecticut valley also produced work of high quality and a definitely local flavour. Maintaining its hold on popular taste until well after the Revolution, this colonial Chippendale retained more of the sturdy elegance of the earlier cabriole style than did its English equivalent. The tendency of English design to massiveness and surface decoration contrasts with the vertical and linear tendency in much colonial design.

Colonial Chippendale

**18th century: the Neoclassical style.** *France.* The Neoclassical style, sometimes called Louis Seize, or Louis XVI, began in the 1750s. Tiring of the Rococo style, craftsmen of the 18th century turned for inspiration to classical art. The movement was stimulated by archaeological discoveries, by travel in Italy, Greece, and the Near East, and by the publication, all over Europe, of works on the classical monuments. The Neoclassical style, based on straight lines and rectilinear forms and using a selection of classical ornaments, was first applied to French furniture during the 1760s. Classical motifs at first were sparingly applied to furniture of unchanged

form, but slowly the curved line of rococo was replaced by a simpler and more severe rectilinear design: chair legs became straight, tapered, and fluted; commodes and other storage furniture were no longer of bombé form. Marquetry was still widely used for decoration, and some cabinets were made of ebony inset with panels of Japanese lacquer. Boulle, which had not been employed in Louis XV's reign, returned to fashion. A greater number of pieces were signed during this period (signing had been made compulsory in Paris), and Jean-Henri Riesener, Martin Carlin, and Jean Saunier were a few of the leading cabinetmakers. Several German craftsmen migrated to France because of the royal patronage, among them Abraham and David Roentgen, Adam Weisweiler, and Guillaume Beneman. Of workers in bronze mounts, Pierre Gouthière was supreme.

These craftsmen were often directly under the patronage of the king, having their workshops in the cellars of the Louvre. Within the shop there was a division of labour, with one craftsman specializing in furniture construction, another in lacquering, and so forth. The craftsmen and the shop were licensed by the government.

*England.* The classical reaction, which set in shortly after 1760, reimposed a classical discipline on design, though of a lighter and more delicate touch than that of the previous classicists, the Palladians. Robert Adam, whose name is inseparably associated with this movement, had, like earlier architects, studied in Italy. There he sought inspiration in the monuments of both classical times and the Renaissance. When given a free hand, he included interior decoration and furniture in his architectural schemes, one of the best examples being his alterations and redecorations at Osterley, Middlesex, where he provided harmonious designs for even the lock plates and chimney pieces. His furniture makes restrained use of classical ornament; but paterae (disks with a design in relief or intaglio), husks (a drop ornament made of whorls of conventionalized foliage usually in a diminishing series), rams' heads, and urns are less eloquent of the change than the symmetrical structural lines. Marquetry, ormolu mounts, and painting were employed as decoration. Adam's furniture was copied and modified by contemporary cabinetmakers such as George Hepplewhite in his *Cabinet-Maker and Upholsterer's Guide* (1788).

In the last 20 years of the 18th century there was a tendency toward greater refinement, lightness, and delicacy in furniture design. Symmetry of form and excellence of proportion were retained for the most part. Heart- and shield-shaped backs on chairs and settees and tapered and fluted supports for tables and other pieces are characteristic; feathers, wheat ears, and shells are prominent in the painted or inlaid decoration. This refinement, strongly feminine in character, is represented in Thomas Sheraton's *Cabinet-Maker and Upholsterers' Drawing Book* (1791).

The work of Thomas Sheraton

*The United States.* The new classicism introduced into England by Robert and James Adam in the 1760s came into vogue in the new republic during the last years of the century. The shipowners and merchants of Salem, Boston, and New York equipped their mansions with the work of Samuel McIntire, John Seymour, and Duncan Phyfe, each of whom produced individual interpretations of the Hepplewhite-Sheraton mode. This early Federal style is characterized by small-scale rectangular design and by a preference for light-toned wood finishes. Surfaces are generally unbroken but decorated with bandings and inlays of contrasting woods, or in Phyfe's case with low relief carvings in the Adam manner. The most typical pieces are the sideboard (a piece of dining room furniture with compartments and shelves for dishes) and the small secretary desk, both of which developed a peculiarly American form.

**19th century.** The Empire style began in Paris about the time of the Revolution and quickly spread throughout Europe, each country adapting it to its own national taste. In England it is commonly called the Regency style. Two French architects, Charles Percier and Pierre Fontaine, who designed the furnishings for the state-

rooms of Napoleon, contributed in great measure to the creation of the style. Their ideas were incorporated and propagated in *Recueil de décorations intérieures* (1801 and 1812; "Collection of Interior Decoration").

Basically the new style was a continuation of the Neoclassical style, with a much stronger archaeological bias, leading to direct copying of classical types of furniture; to this was added a new repertory of Egyptian ornament, stimulated by Napoleon's campaigns in Egypt. Mahogany-veneered furniture with ormolu mounts assumed the shapes of Roman, Greek, and Egyptian chairs and tables, with winged-lion supports and pilasters headed with sphinxes' busts or palm leaves; where no classical prototypes existed, contemporary designs were enlivened with classical ornament.

In England, Thomas Hope, an amateur designer with some knowledge of antiquities, was the chief exponent of the Regency style and entirely decorated his country house, Deepdene, Surrey, in it. When the fashion was taken up by cabinetmakers, the results were often woefully incongruous. Mahogany and rosewood were used with bronzed or gilt ornament, and metal inlay, a cheaper technique, replaced inlay and marquetry. Along with this style came a renewed enthusiasm for the Chinese taste, as best exemplified in the furniture and decoration of the Brighton Pavilion. Between the 1820s and 1830s, in the final stages of the Regency style, both the design and construction of furniture in England and on the Continent showed signs of heaviness and overelaboration that heralded the general decline throughout Europe in the 19th century.

In the United States the style was widely adopted. Its chief native practitioner was the New York cabinetmaker Duncan Phyfe, who in the first decade of the century produced furniture for the wealthy of his city. His designs gave a unique interpretation to Empire ideas. French cabinetmakers, such as Charles-Honoré Lanuier, emigrated to the United States at this time and produced furniture in a stricter French style.

By the 19th century, with increases in the efficiency of transportation and communication, styles became more universal in their adoption but still maintained national and regional differences.

The Empire style, which carried over into the 19th century, began a series of styles that revived form and deco-

ration from the past. This reinterpretation often resulted in a product removed from the principles of the original style. The introduction of the machine and of the factory method sometimes brought about a decline in quality in furniture production.

The Biedermeier style, which originated in Germany and Austria, flourished in the prosperous middle class homes of Europe from about 1815 to 1848. This style is characterized by classical simplicity. Chairs had curved legs, and sofas had rolled arms and generous upholstery. Mahogany veneers and light birch, grained ash, pear, and cherry were used. The design and much of the ornament were influenced by the Empire style, in particular the Grecian element. The style took its name from "Papa Biedermeier," a fictitious character whose column, offering opinions on taste in furniture, appeared in Austrian newspapers.

In the 1820s there was a revival of the Gothic style, which in England was partly stimulated by romantic literature such as the novels of Sir Walter Scott. Losing all the lightness and humour of the mid-18th-century Gothic revival, heavy medieval motifs were profusely and indiscriminately applied to every type of furniture.

A series of other revival styles followed the Gothic. The Rococo revival was one of the most popular; it borrowed the curvilinear elements of the French Louis XV style, especially the cabriole leg, and restated them in a heavier idiom. Entire suites of this furniture were fashioned in mahogany, rosewood, and walnut, the price being highly dependent upon the amount of carving on the frame.

During the first half of the 19th century (the exact date is unknown), metal springs were introduced into furniture construction. The spring construction made chairs and sofas much more comfortable than had the stuffing employed by cabinetmakers during the 18th century.

Another technical improvement introduced into furniture design was the use of plywood. Plywood had great strength and stability and could be more intricately curved than a natural piece of wood. One of the chief exponents of this technique in the United States was John Henry Belter, who was born in Germany in 1804 and served his cabinetmaker's apprenticeship in Württemberg. He reached a height of popularity in the 1850s. Belter's work is mainly in the Louis XV revival style.

The work  
of Duncan  
Phyfe

Parlor furniture made by Duncan Phyfe for Samuel A. Foot, New York, 1837. In the Metropolitan Museum of Art, New York, 19th Century Centennial Exhibition, 1970. By courtesy of the Metropolitan Museum of Art, New York, 1966 Purchase, L.E. Katzenbach Foundation Gift

Michael Thonet, an Austrian craftsman, experimented with bending layers of veneer in Boppard, Germany. Thonet was successful in perfecting a process for bending solid beechwood by heat into curvilinear shapes. His chairs, popular during the latter half of the 19th century, are still made.

Elizabethan and Louis XIV revival furniture was also very popular. The Baroque twisted upright was one of the chief elements employed. The straight, turned leg was also reintroduced. This elaborately upholstered furniture was produced in suites and was blocky and square in its overall form, in contrast to the Rococo revival form.

The Louis XVI style was reintroduced in suites of furniture with round tapering legs, oval backs on chairs and sofas, and elaborate upholstery. The Louis XVI leg was often used on comfortable upholstered furniture whose structure consisted primarily of a flexible metal, or "Turkish," frame. The only wood visible on this furniture was in the legs, the remainder of the frame being completely upholstered. In such furniture the art of the upholsterer reached its height through the use of elaborate tufting, tassels, and braids.

The English poet and artist William Morris has been called the father of the modern movement. Sickened by the shoddiness of the machine-produced goods of his own day, he turned for inspiration to the handicraftsmanship of the Middle Ages and, basing his own work on their designs and methods, attempted to revive a respect for fine craftsmanship and to stir the aesthetic sense of his contemporaries. His influence, though important, might have been greater if, instead of turning away from the machine, he had applied his high ideals to discovering a way in which machines might be used to the best advantage. Morris' followers in the field of cabinetmaking included such designer-craftsmen as Ernest Gimson and the Barnsley family who, working with a few assistants, produced small quantities of high-quality handmade furniture, the craftsmanship of which has never been rivalled. The example of Morris and his followers was so widely copied on the Continent that many people believe modern furniture design originated exclusively there.

During the third quarter of the century, there was a

movement in England toward greater simplicity and aesthetic beauty in furniture. The straight and simple lines of Japanese design served as a source of inspiration. The result was the aesthetic, or artistic, style; its chief exponents, producing both designs and furniture, were Edward Godwin and Christopher Dresser.

Henry van de Velde, a Belgian architect and designer, followed in the footsteps of William Morris and was the conscious propagandist of the Art Nouveau style, which flourished from about 1893 to 1910. Characterized by moving, sinuous curves, the style found its inspiration in organic and natural forms and in the Japanese prints that were so popular in Europe during the third quarter of the 19th century. Van de Velde's furniture was often designed *en suite* so that it would give an effect of totality to a room. The interiors of a house in Brussels, created by another Belgian architect, Victor Horta, well illustrate the sinuous curves and natural forms employed by the Art Nouveau designers. The movement was also adopted in France where Hector Guimard was one of its chief exponents. A variant of the style is seen in furniture produced by the Scottish architect Charles Rennie Mackintosh. The Art Nouveau style in furniture design was not as popular in England or in the United States as it was on the Continent. (J.T.B.)

**Modern.** After the late 19th century, furniture design in the West was divided into two main categories: revivals of past styles—only occasionally precise reproductions, more often free adaptations; and various expressions of changing modern life. The latter category absorbed the best as well as the most progressive talents of the era.

Modern furniture design after World War I was of three kinds: functionalist modern—progressive, adhering to an aesthetic of the machine and often designed by leading architects; transitional modern, which came to be called contemporary and was infused with elements from the past; and commercial modern, called "Borax" because hawkers of that cleanser used to offer premiums, and the word became associated with extra values which commercial furniture often offered by the manner in which it was advertised, or in overblown forms and gaudy veneers. All furniture design was influenced by the social and economic trends of the era: formal living de-

clined; mechanization of household labour expanded; living spaces shrank, particularly in height; and home entertainment became important. After World War II, especially, people married at a younger age, total population growth accelerated, and a generally rising standard of living was enjoyed by a vastly enlarged middle-income group. Furniture became smaller, lighter, easier to maintain, and more widely distributed.

**Functionalist modern.** About 1925, a new rationality began in furniture design, stimulated by the emergence of progressive experiments typified in the works and theories of the Bauhaus, a revolutionary German school of arts and crafts established in 1919 and staffed by leading architects, designers, and painters until Hitler closed it in 1933. Bauhaus instruction used crafts as experimental techniques and trained students to design for mass production. Low price levels, maximum utility, good quality, and simple, clear forms were considered essentials of well-designed consumer goods. The celebration of modern technology in progressive design was the most effective accomplishment of the Bauhaus. Forms, colours, and materials hitherto confined to shops and laboratories were introduced into homes and offices with programmatic earnestness and considerable stylishness. Tubular chrome-plated metal, black Bakelite, and large unframed planes of glass were typical. Much furniture used at midcentury in reception rooms, terraces, kitchens, or dining alcoves derived from Bauhaus originals. The availability of wood in Scandinavia led, in the 1930s, to similar rational, modern furniture, using a variety of laminating techniques. Related, more ambitious experiments in three-dimensional molding of wood laminates were undertaken in the United States around 1940. Then wartime austerity enforced a salutary simplicity.

Scandi-  
navian  
designers

After World War II, earlier design activity resumed. Scandinavian designers abandoned advanced technology for a time and launched a victorious campaign for sculptured, solid-wood furniture in matte finishes that notably enlarged the vocabulary of progressive design. Italian furniture was similar in trend, more open to structural and technological experiments but more accented and less acceptable generally. American modern furniture achieved its first international influence in molded plywood and plastic chairs and in semi-architectural storage units.

Functionalist modern furniture consciously related itself to progressive architecture, which aided its steady growth in the third, fourth, and fifth decades of the 20th century; at the same time it was also encouraged by

friendly periodicals, shops, and museums. Educational and cultural agencies earlier in the century had generally opposed modern design, but gradually there was a change in attitude and by mid-20th century, it was accepted.

**Transitional modern.** Conservative in style (but not imitative), well-constructed, and carefully finished, the best modern furniture earned its reputation of being in good, correct taste. Often relying on handcraft details and on wood, most factories used speeded-up variations of earlier cabinetmaking operations. This, along with the United States' emphasis on artificially stimulated obsolescence, affected all modern design between World Wars I and II. As in the case of stylistic revivals, favourite sources of inspiration for transitional modern were late 18th- and early 19th-century court and country house furniture, with variations in Chinese and Rococo. This furniture served a wide public that found the avant-garde forms and materials too cold and "clinical."

**Commercial modern.** Most modern furniture designed between 1930 and 1940 was bulky, bulbous, glowingly coloured, glossily finished, and rich with hardware or shiny fabric. It pleased the public but not critics and connoisseurs. Gradually, and more noticeably after 1945, stylistic details filtered down from more progressive design levels to appear as commercial fads, such as sectional seating and storage units, spidery metal frames, and plastic-shell seats; the Victorian whatnot (set of open shelves for the display of bric-a-brac) was revived, free-standing and rectilinear, as the room divider. Convertible sofa beds and radio and television cabinets were almost all designed in the commercial manner. The innovation of foam upholstery was bitterly fought by union workmen around 1940, but in 15 years had become commonplace in sleeping and seating furniture.

In time a continual flow of new production methods effected basic changes. Lighter masses, thinner silhouettes, and new forms made possible by new materials as well as new technologies seemed to put modern furniture design on the threshold of a new era. By 1970, however, faddism and commercial versions of bizarre and bloated shapes in seating furniture again ushered in a new brand of "Borax."

#### EASTERN

**China.** Remarkably little systematic study has been made of Chinese furniture. Its origins remain comparatively obscure, its workshops mostly unrecorded, its designers unknown; consequently, its dating is extremely difficult. Most of the forms of Chinese furniture, such as the low table and the covered bed, are found in the oldest Chinese paintings in existence; the designs have been remarkably conservative throughout the ages.

Chinese furniture can be divided into two main types: lacquered wood pieces either inlaid with mother-of-pearl or elaborately carved, and plain hardwood pieces.

Of the first, almost nothing is known, and dating of pieces is possible only from the designs of decorative motifs, such as dragons and peonies, and from their background motifs. The most important historically in this class are black lacquer pieces inlaid with mother-of-pearl that have been preserved in the Imperial repository (Shōsō-in) in Japan from the 8th century. Of the red lacquers, such as seats and tables, the earliest pieces date from the Ming dynasty (1368–1644); their workmanship is characterized by softer contours and freer, more spirited designs than the later pieces of the Ch'ing dynasty (1644–1912). These lacquered objects influenced European cabinetmakers.

The plain hardwood furniture is frequently encountered. Its deserved popularity both in China and the West has been won by its classical simplicity, reserved ornament, and lack of pretense. In these products of the finest workmanship, purity of line, plastic strength, and a flawless polish produce a harmonious, solid effect.

A Chinese house requires less furniture than a Western house. Correspondingly, the types of furniture are fewer, being limited mainly to wardrobes, chests, tables both high and low of all types and shapes (altar and couch tables, for example), stools, beds (sometimes tested

with curtains), screens and stools for use by the bed, and chairs.

Although the fundamentals of Chinese joinery must have been formed a millennium before the modern era, the great development in Chinese furniture took place with the introduction of Buddhism from India during the first centuries AD. Before that time the Chinese had sat cross-legged, or knelt on the floor or on stools. Buddhism introduced a more formal kind of sitting on stiff, higher chairs with back rests and with or without side arms. The chests and armoires are superb examples of careful joinery and often have finely worked metal mounts that greatly enhance the beauty of their solid design.

A number of hardwoods were used for the plain furniture: purple sandalwood (the most distinguished); rosewood of many varieties, mostly imported from Indochina and called "old," "new," and "yellow"; redwood; burl (especially for inlay); and so-called chicken-wing wood. Rosewood in its many varieties is perhaps the most frequently encountered and the most popular for its seeming translucence and satin, soft finish. It is above all the faultless workmanship, so typically Chinese, and the fine polish of Chinese furniture that attracts the Westerner. It was the Chinese respect for the spirit of wood and their command of line, curve, and cubic proportions that became the ideal of the 18th-century Western cabinet-maker.

**Japan.** Japan was one of the few civilizations that did not develop many specialized furniture forms. Instead, the interior architecture of the house, with the garden as its focal point, served the aesthetic and social requirements that furniture has served in many societies. The chief requirement for the few forms that were developed was that they be easily movable.

Thin mats made of rice straw called tatami covered the floors and were used for sitting. The tatami utilized only natural patterns for decoration, although they often were bound in cloth. Cloth cushions were also used, as were small tables of wood or lacquer, either folding or rigid. Dressing tables and writing tables were specialized forms that evolved from the simple table. The folding screen was an indispensable adjunct to the other furnishings as it could be moved to change the entire aspect of the room. The one stationary piece was the *shoin*, a type of bay window from which extended a fixed desk used for reading.

Japanese  
furniture  
forms

Japanese furniture forms have changed little for centuries. Because there are few extant pieces from the early periods, information about early furniture is gleaned from literary descriptions, engravings on mirrors, clay images, and graphic representations.

**India.** India's place in the history of furniture is that of an adapter or transformer of imported Western styles rather than a creator of independent styles of its own. Domestic furniture in the sense in which it is known in Europe was not traditional in India before the 16th century, and even such familiar objects as tables and chairs were rarely used until the spread of Portuguese, Dutch, and English furniture.

It was precisely the difficulty of obtaining suitable furniture locally for their settlements that encouraged the European traders to export Western prototypes for copying. It was soon found, however, that the Indian craftsman, although an inaccurate copyist, was a skilled and imaginative adapter of foreign decorative detail. This led to the emergence of an independent Indo-European style of furniture that was much admired for its own sake and subsequently exerted fresh influences in the West. Early Indo-European furniture can be divided into two distinct groups, according to whether the influence was primarily Portuguese or Dutch. (The English did not exert a national influence on styles until the late 18th century.)

The Indo-Portuguese group includes a northern Indian, or provincial Mughal, style and a southern, or so-called Goanese, style. The former is artistically the more interesting and includes a variety of furniture decorated with inlaid bone or ivory on ebony and other dark woods. Tables and writing cabinets in the Italian Renaissance form are found in this category because this was the dominant style in Portugal.

The second Indo-Portuguese style, sometimes called Goanese (though in fact more probably made on the Malabar coast, south of Goa), is more stereotyped in form and in decoration. It is distinguished by large and rather cumbersome cabinets of a type known in Portugal as *contador*, the inlay ornament being either geometrical or semiabstract. The Indian contribution to this style is more inhibited and lacks altogether the charm and fancifulness of northern Indo-Portuguese furniture.

Indo-Dutch furniture is easily distinguishable from Indo-Portuguese, since it reflects contemporary Dutch taste

Two  
groups of  
Indo-  
European  
furniture

Indo-Dutch furniture

as clearly as the latter reflects Portuguese. There are two types of Indo-Dutch furniture. The first, which was made on the Coromandel coast, was mainly in light-coloured woods, the decoration being inlaid bone, incised and lacquered. The second is a style of carved ebony furniture which, although commonly found in India and often thought to be Indian in origin, was in fact made at Batavia (modern Djakarta) in Java, the Dutch administrative headquarters in the East. The carved relief decoration of the ebony furniture is floral in character and closely related to the flowering-tree style of contemporary Indo-Dutch embroidered bedspreads and hangings in which the tulip is prominent.

With the growth of British power in India in the 18th century, all Indo-European furniture styles came increasingly under English influence. Whole suites were made in ivory in the manner of Chippendale and Sheraton, not only for European buyers but also for Indian rulers who increasingly favoured European styles of furniture.

In the 19th century, Indian artistic standards degenerated, as is clearly reflected in the furniture of the period. The emphasis was on decorative elaboration for its own sake and, although much 19th-century Indian wood carving shows great technical skill, this rarely compensates for formlessness and stereotyped ornament.

(Er.L./E.J.Wo./J.T.B.)

## Furniture Industry

The modern manufacture of furniture, as distinct from its design, is a major mass-production industry in Europe, the U.S., and other advanced regions. It is very largely a 20th-century industry, its development having awaited the growth of a mass consumer market as well as the development of the mass-production technique. Earlier furniture making was a handicraft, going back to the most ancient civilizations.

**History.** Examples of ancient furniture are extremely rare, but there is considerable knowledge of the pieces made by craftsmen in China, India, Egypt, Mesopotamia, Greece, and Rome from pictorial representations. Beds, tables, chairs, boxes, stools, chests, and other pieces were nearly always made of natural wood, though veneering was known in Egypt, where it was used to produce coffin cases of great durability. The Romans too used veneers, though chiefly for decorative purposes. Bronze was also used in Roman tables, stools, and couch frames. Pompeian wall paintings show that plain, undecorated wooden tables and benches were standard in kitchens and workshops and that panelled cupboards were common. Chests for valuables were covered with plates or bound with iron.

The early Middle Ages were much poorer in household furnishings of every kind than the Roman world, but in the 14th and 15th century a growing affluence brought a major revival of furniture making, with many new types of cupboards, boxes with compartments, and various sorts of desks appearing. The religious houses in particular were well supplied with furniture. Framed paneling, reintroduced in the Burgundian Netherlands, quickly spread. The mortise and tenon and mitre provided greatly improved joints.

The growing sophistication in technique brought a revolutionary change in the men who made furniture. Where previously carpenters and joiners had made furniture along with every kind of building construction in wood, several circumstances combined to create a new profession: that of cabinetmaker. The most important technical factor was the introduction, or reintroduction, of veneering, first in western Europe, then in Britain, North America, and elsewhere.

In the earlier system of framework and panel, the framing gave the required strength in both length and width, the panel being a mere filling held in grooves. Its attractive appearance was the result of highlights and shadows produced by the framing, moldings, and carving, which formed the chief means of decoration. The grain of the wood was incidental.

The introduction of veneering coincided with the use of walnut as a furniture wood. It was soon realized that the grain of such a wood could be of decorative value, especially as veneering made it possible to use such visually attractive parts of the wood as burrs, butts, and curls, unreliable if used as solid wood. It became the custom to have the grain of the veneer generally run crosswise because of its decorative appearance. Marquetry (a form of inlay in veneer) was another example of the decorative use of the grain and colour of wood in surfaces unbroken by panelling.

In addition to veneering and the new system of construction it involved, an impetus to the establishment of the trade of furniture making came from the increasing market demand provided by the growing affluence of the 17th and 18th centuries. In the new system of construction, plain, flat parts are dovetailed together and then veneered. It can be contrasted with the traditional framed method of rails and stiles put together with mortise and tenon joints, the panels fitting in grooves.

Coinciding with this change, or preceding it by a few years, was another breakaway: that of the chairmaker, who had become another specialized craftsman. At first chairmaking was closely associated with wood turning but by the 18th century turned legs were largely replaced by shaped legs of the cabriole type. Chairmaking has remained a separate branch of furniture making ever since.

This growth of cabinetmaking as a trade of its own eventually resulted in a considerable degree of standardization of methods of construction, particularly in the types of joints used and in the thicknesses of wood for the various parts. It also resulted in an increased division of labour. Turnery became a separate trade, while the cabinetmaker assembled the turned parts; veneer and marquetry cutting was not done by the cabinetmaker although he laid both; carving too called for the skill and experience and tools of a craftsman who did nothing

Introduc-  
tion of  
veneering

else. Another specialist, the upholsterer, did his work after the chairmaker had made the frame; and it seems likely that finishing was seldom done by the cabinetmaker. This was certainly the case later in the 19th century when French polishing became the standard method of finishing furniture.

Chippendale, Hepplewhite, Sheraton

An important 19th-century change was the separation within the industry of those who made furniture from those who sold it. Previously the customer commissioned a cabinetmaker, perhaps after consulting a design book by Chippendale, Hepplewhite, or Sheraton. Or he might work out his requirements in consultation with the cabinetmaker or, if he were sufficiently wealthy, employ an architect or designer. After the midyears of the 19th century the showroom gained popularity. A large store often retained its own workshops where special items were made to customers' requirements, but for the greater part it became the practice to buy wholesale from furniture making firms.

#### MODERN FURNITURE MANUFACTURE

**Materials.** Modern methods of furniture construction are largely based on the availability of man-made materials such as reliable plywood, laminated board, chipboard, and hardboard as distinct from natural solid wood. It is not merely that manufacturers prefer the one to the other but rather that these substances are free from the great drawback fundamental to wood—movement. Natural wood shrinks as it dries or swells as it absorbs moisture from an atmosphere more humid than itself, and this movement must be allowed for in the method of construction. Unless this is done troubles may arise: splits along the grain or open joints on the one hand or jammed drawers or doors on the other. Over the years cabinetmakers have worked out ingenious systems to avoid these troubles in the use of solid wood, but today made-up materials may be regarded as inert if of good quality. To an extent solid wood has still to be used, notably for items that have to be turned, cut to shape, or molded, and for lippings to conceal the edges of manufactured boards; but virtually everything in the form of flat panels is made up.

**Natural wood.** The increase in the demand for reasonably priced furniture has placed a premium on the economical use of wood. Natural wood is extremely wasteful as a material. Hardly more than 25 percent of the natural substance of a tree actually goes into the furniture made of solid wood. When account is taken of the loss in sawdust in conversion from the tree trunk (taking off the outer slab portions and sapwood) and the further loss in bringing the lumber to usable size in the workshop (the offcuts, waste in sawing shapes, in turning, in planing, cutting joints, and final cleaning up), it becomes evident that much more wood is wasted than used.

**Plywood.** In making plywood, the veneers are peeled rotary fashion from the log by a long knife fitted to a lathe-like machine. The resulting veneer can be of unlimited width to be cut up as required. There is no loss in sawdust, and the peeling is continued until only a polelike centre is left. Much the same applies to laminated board in which both the core material and the outer plies are peeled. In the case of chipboard the timber is merely regarded as raw material to be reduced to fine chips that are dried, compressed, and assembled into boards, with resin glue as an adhesive. Where a natural wood grain is desired, a veneer is flat sliced from a flitch (longitudinal section) selected for the beauty of its grain.

Certain materials, notably chipboard, must be machined, because trimming at the edges by hand almost always shows as a deterioration. It cannot be planed; the plane merely forms dust rather than taking shavings and, owing to the abrasive nature of the material, the edge of the cutter is quickly lost. Consequently, when a panel of a certain size is required, it needs to be machine sawed to size, no further trimming being needed. This is only practicable with a precision saw capable of fine adjustment. Furthermore it requires a saw blade having tungsten teeth to resist abrasion. The same applies to any plywood or laminated board assembled with resin glue.

Another influence on the construction of furniture is the introduction of new types of adhesives in place of the traditional animal glue. Many are highly water resistant, some waterproof. Some can be applied cold, avoiding the complication of heating joints before assembly. They can be cured by heat in a matter of minutes, leaving presses and other apparatus free for other work.

**Other materials.** Although wood has always been regarded as the traditional material for furniture making, several other materials are now used, either entirely replacing wood or combined with it. Plastic laminate, widely used for table and other tops, is obtainable in various colours and designs and in photographically reproduced natural wood grain. Its advantages are that it resists all liquid stains, is largely heat proof against burn marks, is mark free, and is easily wiped clean. It is laid as a form of veneer on any of the man-made materials—multiply, laminated board, or chipboard, usually with a contact adhesive. As a plastic edging is needed that must be applied before the main top is put down, an essential machine tool is the portable router with veneer-trimming unit. It trims the overlapping edges of the main plastic panel without cutting into the edging.

Plastic laminate

Metal is also used to some extent, particularly for the stands and legs of furniture. Iron is generally preferred, the parts joined by welding.

Finishes too have been revolutionized. French polish, the traditional finish of the Victorian period, and indeed up to the 1930s, has been largely replaced by gloss or eggshell lacquers, which are sprayed on and are heat and water resistant and are so hard as to be practically mark free.

**Storage and transport.** Two technologies important to furniture making are storage and transport. The space taken up by furniture in relation to the actual material used in its construction is disproportionately large; when furniture is mass-produced an enormous amount of storage space is required. This applies equally to its transport, especially when it has to be shipped abroad. Consequently a great deal of furniture is made of the "knock-down" type; that is, it can be taken to pieces and stacked flat. A wardrobe made in this way may occupy only a quarter of its assembled space when disassembled. Originally, parts were joined by screw fastenings, but a whole range of fittings has been devised to achieve the same result more easily and with more precision. Most such fittings require little more than recessing or the boring of holes, operations easily machined. Most work on cam, screw, or wedge action.

**Woodworking machinery.** The decline of the direct link between customer and maker, due to the rapid development of retail trade, was largely made possible by the invention of several woodworking machines, mostly steam powered. Much handwork remained, however, and only large manufacturers could afford major machinery installation. In the early 20th century it was still possible for a cabinetmaker in Britain or Europe to earn a living, though in most cases he installed a basic machine such as a circular saw or worked in a district in which machine shops were available. Thus in Shoreditch, London, whole streets of houses were occupied by cabinetmakers, often several in one house, who made pieces that varied from the finest individual items to the cheapest, turned out in pairs or perhaps six at a time. These men had their machining done in the trade machine shops that abounded in the district. The shops produced nothing themselves but performed any machining that was brought to them: sawing, spindle molding, fretting, turning, planing, and so on. These practices continued up to the beginning of World War I and for a time afterward, although most of the large stores also had their workshops where they made not only individual items for customers but also furniture in quantity to pattern.

The Shoreditch shop system

But in the U.S., the development of mass-production furniture manufacture was already well advanced, with the principal manufacturing centres at Grand Rapids, Michigan; Jamestown, New York; and High Point, North Carolina. "Grand Rapids" became a byword for inexpen-

Grand Rapids industry

sive furniture of reliable quality. Furniture factories have never become large in comparison with the huge production units in such industries as automobiles and steel—few today employ more than 100 persons—because of the continuing need for some hand operations. But their machines for many purposes and the volume in which they operated gave them insuperable advantages in cost over the old-fashioned craftsman. Mass-produced furniture began to have a serious impact in Britain and Europe between the wars.

The shortage of timber during and after World War II made conditions extremely difficult for the furniture maker; but in the 1950s there was a gradual return to more decorative furniture, marked by the introduction of new materials, new machines, adhesives, and finishes.

Modern commercial furniture production may be roughly divided into groups: general furniture—bookcases, wardrobes, tables, etc.; chairs and upholstered suites; and specialized items. Each of these may be further subdivided according to quality and type. In addition to this commercial furniture there are the specialized items made by a few hand craftsmen to special commission. Such goods are necessarily expensive, partly because they are individual pieces made singly to design and also because the best selected materials are used. Furthermore, hand methods are largely used that are costly because they are time-consuming. Even in this field, however, the machine has encroached to an extent. Thus a circular saw is invariably installed because its advantages are so obvious. There is no merit in laboriously ripping boards to size when a machine will do the work as well or better.

Though furniture produced by modern hand craftsmen is beautifully made from the best materials, it often requires considerable discernment to detect the difference between it and the best commercial furniture.

**Period furniture.** In a class by itself is the manufacture of reproduction period furniture. The best work in this field is of an extremely high standard; and, although it often has to make concession to modern materials in using veneered plywood or laminated board for parts, it usually follows traditional methods of construction, at least where visible machine work would be obvious. On the other hand, all veneers are put down in a press, moldings worked on the spindle molder, and shapes cut on the bandsaw or jigsaw.

It is in this work that wood carving is chiefly used. Because of its high cost, carving has largely disappeared from modern commercial furniture, but to the manufacturer of reproduction furniture it is an obvious necessity. From early times and certainly from the 17th century, wood carving has been a separate trade. A highly skilled calling, it demands artistic sense as well as manual dexterity. It has become divided into classes of which furniture and indoor decoration represent only one branch, with further subdivision within the branch.

In the commercial grade of furniture there is wide variation in quality, from the lowest priced goods to high-grade items in which individual hand workmanship is used for processes where the quality would suffer if the machine were used. Thus drawer dovetails are cut by hand, and sometimes even hand-cut joints are used.

**Modern factory layout.** Most modern factories are laid out on mass-production lines. The earlier factories often had a cabinet shop, which had its rows of benches for individual work; a cabinetmaker needing machining done carried his wood to the machinist. Today the timber is cut to usable sizes in a main conversion shop and brought to the required moisture content in a kilning section. In the kiln, air is forced through stripped stacks by fans that periodically change the direction of the air flow. In recent years radio-frequency heating has been widely used to dry both natural wood and plywood. The applied radio frequency produces molecular activity in wood and resins (such as those in plywood glue); part of the molecular energy is converted into heat that greatly reduces the time required to dry the wood thoroughly and evenly and to set the glue. The wood is placed in a press between

two metal plates to which the power is applied; great thicknesses of wood can be dried evenly by this method.

From the drying section the wood proceeds to the planing and jointing shop, in which it is reduced to the required section and any tenoning, dowelling, or dovetailing carried out. There is also a veneer department, and in many respects this has become one of the most important departments. In it veneers are jointed in width where necessary, and a remarkable recent invention is a machine that sews veneers together with fine fibreglass, the stitching passing through half the thickness of the veneer only. It does this with amazing speed and accuracy. Where required, veneers are matched, giving a balanced appearance; and any small defects are repaired by placing a waste veneer beneath, cutting through both simultaneously, and interchanging the cutout pieces. Veneer pressing follows, and, although multiplate presses are still used to an extent, the tendency in large-production work is toward the progressive presser. At one end of this the resin glue is applied with a spreader, the veneers placed in position on the groundwork, and the whole passed in batches beneath the presser where it is heat cured in about a minute and ejected at the other end ready for further operations.

It is in the assembly shop that the line or conveyor-belt system begins. This is not usually in continuous movement but takes the form of a series of loose rollers over which the work can easily be pushed by one man. Special cramping jigs are set up so that, for example, a wardrobe can be glued up in one operation by power-driven rams. The jig ensures squareness, and the resin glue is cured in a matter of seconds by radio-frequency heating. In fact, by the time the operator has applied glue to the joints of one set of parts, the previous assembly has hardened and can be removed to the conveyor, leaving the jig free for another cramping operation.

From this point onward the work remains on the conveyor belt, passing to a sanding shop where joints are levelled and finally to the finishing shop where it is stained, spray polished, and fine sanded and waxed. Lastly there is a fitters' shop, where doors are hinged, handles put on, mirrors fitted, and so on.

Before passing to stock or to the packers' department every piece has to be passed by an examiner who chalks any defect or attaches a small, coloured label indicating that there is a fault in either the woodwork or the finish.

Only a constant flow of orders in large quantities justifies such a setup. Smaller firms contract their veneering to outside specialists, have their turning done outside, and also any other work for which they are not equipped. The aim is to maintain a constant flow of production, which involves a balance in personnel in the various departments to avoid a holdup in any stage.

**The production process.** A basic preliminary in all furniture production is the provision of working drawings. In a firm of any size there is invariably a special department where full-size drawings are prepared from small-scale drawings provided by the designer. In some cases the designer may make his own full-size, detailed drawings; but in a large firm it is more usual for a draftsman to work out the practical details, though usually in consultation with the designer, who advises on proportions and decorative details. The hand craftsman, in contrast, usually does the whole thing himself. In the small-scale drawing the general form and essential requirements are worked out; the full-size drawing shows proportions and constructional details. A sample piece is made to check the design and cutting problems. Cutting lists are prepared; the cost of materials, fittings, finish, etc. figured; and an estimate of machining and assembly time worked out. When the work is to be produced in quantity, costs are lowered considerably because only one setting of the machine and only one set of cutters are needed for the whole run of any particular part.

Selection of timber, already passed through the seasoning kiln and converted to standard thicknesses, follows. The wood passes to the machine shop, where it is sawed to size, planed, molded, grooved, or rebated as required.

Modern  
hand  
craftsmen

Sanding,  
finishing,  
and fitting

When a number of parts must be cut exactly alike, they are clamped in forms having the proper contour and are then brought in contact with high-speed rotating knives that shape the part to proper size as the form rides against a guide on hand or automatic shapers and routers. Intricately carved pieces such as legs are roughly carved on multiple-spindle carving machines. These duplicate a master leg by means of a follower point that is guided along the surface of the model and imparts the same motions to as many as 32 high-speed rotating knives as they whittle the leg blanks. After the rough carving, the pieces are machine sanded and finished by a hand carver.

If veneering is required, this is now done. Jointing follows—tenoning, dowelling, dovetailing, etc. Automatic machines often combine several operations. Exposed parts are sanded on edge belt sanders, three-drum traveling-bed sanders, or belt sanders. Rounded parts are sanded on soft pneumatic drums, and carved parts are sanded on a buffer, a machine in which shredded sandpaper is supported by brushes on a revolving wheel.

Furniture  
assembly

Finally the work passes to the assembly shop where door frames are put together, drawers glued up, and carcasses assembled. After the glue has set, the parts may be returned to the machine department for machining that could not be performed before assembly, such as sanding the joints and shaping the edges. Then it returns to the assembly department for final assembly. Air-driven clamps are used when the design permits; otherwise the piece is pressed by hand clamps. Unless electronically cured glues are used, clamps must be applied long enough to ensure a good bond. The completed article is cleaned to remove excess glue, inspected, and hand sanded. Finally, staining and spray polishing is done and fittings added.

In individually crafted work there is always a great deal of fitting to be done—doors trimmed and drawers made to run easily without slackness. In mass-production work this problem would be serious. It is almost entirely avoided by making drawers an easy rather than snug fit and by sanding the edges of doors to templet size so that they automatically fit the carcasses, which in their turn are made to standard size.

**The art of chairmaking.** Chairmaking has been a separate branch of furniture making since the mid-17th century. One of the most intricate branches of woodworking, it involves odd angles, compound shapes, and awkward joints and at the same time calls for maximum strength, chairs being subjected to more strain than most other furniture. There are three main types of chairs: the Windsor chair, made largely from turned parts, with solid wood seat; the framed type of dining chair with either loose or stuff-over seat; and the upholstered chair.

In Britain the Windsor chair belongs traditionally to the High Wycombe District of Buckinghamshire where beechtrees abound. Until relatively recent times men worked in huts in the beech woods making turned parts for chairs. They felled the trees, cut the trunks and larger branches into suitable lengths, and split them into pieces of a section large enough to permit chair legs and uprights to be turned and also to provide lighter members for rails, etc. They turned the parts on a primitive pole lathe in which a cord was attached to a treadle, taken around the wood to be turned and up to a springy sapling anchored at the lower end to pegs outside the hut. The power was supplied by treadle, the cord revolving the wood; then as the foot was raised the spring of the sapling lifted the treadle and at the same time turned the work backward. The turning gouge or chisel could be used on the downward stroke of the foot only, but the economy of effort was amazing. A complete leg could be rounded, the curves and beads formed, and the ends brought to the required diameter in a matter of seconds. Of course, working in green timber enabled the turning to be done much more easily and quickly than if the wood were dry.

These bodgers, as they were called, made only the turned parts and delivered them to chairmaking firms for assembling. They had no overhead expenses, no power

costs, and the only lighting they needed in winter was an oil lamp or candles. They were long able to compete with powered workshops.

The manufacture of the Windsor chair of Victorian and Edwardian times was a specialized trade. The seat, invariably of elm, was hollowed out (bottomed) with a form of adze, and the holes for the legs were bored with a brace fitted with a spoon bit held at the required angle solely by judgment. The better chairs had a hooped back of yew. Today this hand work has been replaced by boring machines that are fitted with a jig to maintain the correct angle. The hollowing of the seat is machined to an extent, but the depth is only slight, compared with the early hand work. Furthermore, traditional timbers—elm, beech, and yew—are frequently replaced by imported timbers.

The quality of framed chairs of the dining type varies widely, but perhaps the outstanding general feature of modern dining chairs is the wide use of dowelled joints rather than mortise and tenon. In the late 19th century this had already occurred to a large extent, the chairmaker's kit of tools invariably including a dowel plate with a series of holes through which the craftsman hammered roughly squared pegs to form the dowels. Today machine-made dowels are universal, with a glue-escape slot cut in. Dowelling is a far quicker and consequently cheaper process than mortising and tenoning, especially in shaped work where the curved part frequently must be joined at odd angles.

When a chair has compound curvature it becomes difficult and expensive to make. A chair back may be shaped in both front and side elevation (and often in plan as well). Taste and experience are indispensable in providing a continuous curve that will be aesthetically satisfying from every angle. Over the years, experience has been built up, especially on traditional models following period lines; a chairmaker's workshop invariably carries bundles of templets in plywood for the various parts of chairs, with the fullness provided (where necessary) for a good line.

Dining chairs may be made in sets of half-dozens or dozens, or more cheaply in batches of 50 or 100, depending upon the capacity of the factory. In some cases parts are standardized and interchangeable in different designs of chairs.

The upholstering of dining chairs is a separate trade, though carried out in the same factory, and may be of the loose seat, stuff-over, or plywood-covered type. Traditional stuffing materials such as horsehair have largely been replaced by foam rubber and synthetics.

**Full upholstery furniture.** The manufacture of fully upholstered pieces is often a separate branch, though large manufacturers often make both upholstered and nonupholstered types. It remains to a great extent a handicraft, for the skill of trained and experienced craftsmen is needed in turning out quality pieces. The standard upholstery foundation consists of a system of coiled steel springs resting on a webbing of burlap and tied to the furniture frame, which may be of wood, fibre-glass, or plywood. The springs are embedded in a filling material, such as rubberized hair, foam rubber, palm fibre, or Spanish moss; and the spring system is topped by a thick padding of cotton or foam rubber in sheet form. Muslin is frequently employed as an inner covering for this assembly, while a durable upholstery fabric is used as an outer and finishing cover. Loose cushions are filled with special spring units in a bedding of foam rubber or down; the springs are covered with layers of cotton, and the entire assembly is encased in upholstery fabric.

Only a few mechanical aids have proved satisfactory in upholstering. Multiple layers of fabric can be cut efficiently and economically by machines in production-line operations, and staples are used instead of tacks on less expensive pieces. But the mass production of such components as the basic coiled-spring system and the mechanical handling of such materials as the bedding, or filler, have not proved efficient and economical. Some

The  
Windsor  
chair

useful substitutes have been found, however, for the coiled-spring supporting unit; they include the modern nonsagging springs that may be clipped to the frame and the steel bands that are held to the frame by helical springs. Sponge rubber may be molded to constitute a complete seat that is firm and comfortable. Webbed seat frames also are used, and the natural resiliency of wood is utilized in building springy plywood supporting structures.

**Future trends.** Despite the developments in modern upholstery, there is still a demand for traditional methods, particularly in the reproduction trade, but even here the scarcity of traditional materials is a problem and frequently synthetics are used.

The future will doubtless see a continued decline in the use of natural wood except in veneer form. Large trees yielding finely figured woods are becoming ever scarcer and more expensive. The days when huge, 30-inch table tops, panels, cabinet ends, and other large items could be made of solid Cuban or Honduras mahogany without a joint are past. The finest figured woods are sliced into veneers. Where solid wood is essential, as in turned or shaped parts, an inferior wood stained to match is frequently used. Plastic laminates are a strong rival even to natural wood veneers, especially for such parts as table tops that are subjected to considerable wear and are likely to be used on an increasing scale.

Yet it is doubtful if wood will ever be entirely replaced. Something about the nature of wood appeals to aesthetic taste. It is likely to be used increasingly in the form of manufactured boards. Apart from the increased demand for furniture and the growing shortage of finely figured woods, such boards carry certain advantages such as freedom from movement and availability in large unjointed dimensions, advantages that outweigh the minor drawback of the necessary lipping of edges.

The use of materials made to size as needed rather than natural wood (which might in some circumstances require the adaptation of design to suit the peculiarities of the timber), plus ever-increasing mechanization, has resulted in the trend of woodwork towards engineering, a trend likely to accelerate. Yet in the 1970s both in Europe and America the most striking characteristic of the furniture industry is its continued decentralization, with great numbers of small and medium-sized producers.

**BIBLIOGRAPHY.** Information on the furniture industry and trade may be found in W. SKINNER *et al.*, *Manufacturing Policy in the Furniture Industry*, 3rd ed. (1968); D.E. BOND and R.J. WONNACOTT, *Trade Liberalization and the Canadian Furniture Industry* (1968); S.H. SLOM, *Profitable Furniture Retailing* (1967); and J.L. OLIVER, *The Development and Structure of the Furniture Industry* (1966). Descriptions and illustrations of types of furniture, mostly antique, are given in J.E. GLOAG, *A Short Dictionary of Furniture*, rev. and enl. ed. (1969); and ERNEST JOYCE, *The Technique of Furniture Making* (1970). Works by C.H. HAYWARD include: *English Period Furniture Designs* (1969), a history of styles from the 16th through the mid-19th centuries; *Period Furniture Designs*, rev. ed. (1968), measured drawings of period pieces and their construction; and *Antique or Fake?* (1970), on how old furniture was made. A handbook on woodworking techniques and on the design and construction of modern furniture is J. and R. HOOPER, *Modern Furniture and Fittings*, 2nd ed. rev. (1955). For descriptions and illustrations of craftsman-made furniture, see A.E. BRADSHAW, *Handmade Woodwork of the Twentieth Century* (1962); and L.J. MAYES, *History of Chair Making in High Wycombe* (1960).

## Furs

Fur, the fine, soft, hairy covering—or coat—of a mammal, usually consists of a layer of relatively short, soft, barbed hairs next to the skin, helping to maintain body temperature, and a top layer formed by longer, stiff, smooth hairs growing up through the underlying layer, serving to shed rain.

Man, in using the fur of animals for both its warmth and its attractive appearance, applies various processes that make furs wearable and enhance their attractiveness. This article provides a brief history of man's use of

furs; gives characteristics of the furs of various animals; surveys the modern fur trade; and treats the processes involved in preparing fur pelts for use in the manufacture of fur garments.

## HISTORY

The use of fur as an item of apparel apparently began in a prehistoric period. In the Earth's colder regions, where man required both food and warmth, it is likely that animal fur was used as a body covering soon after man began to eat animal flesh. Although fur was a necessity in the cold northern forests, almost every civilization has valued furs as an adornment. The Chinese are said to have esteemed furs 3,500 years ago; the Greek legend of Jason and the Golden Fleece may have originated in some unusually perilous but successful fur-trading voyage to the Euxine (Black Sea); and furs were among the luxuries Rome adopted from Greece. The narrowing distinction between fur as a necessity and fur as a luxury influenced subsequent development of the fur trade.

In medieval Europe, furs, mainly of northern and central European origin, were an important element in commerce. The Hanseatic League, an association of trading towns in the Baltic area, was especially active in the fur trade, importing many types of skins from Novgorod, Russia, to western Europe.

Although sumptuary regulations forbade furs to monks and to all but the highest ecclesiastics and placed restrictions on their use by the laity, they were widely popular in all parts of Europe, especially for men's attire. Ermine, sable, and marten were among the most esteemed.

The fur trade played an important role in the exploration and settlement of North America. Patents of discovery and charters to early settlements frequently mentioned "trade in furs," and much interior exploration resulted from the search for furs, especially by French trappers and traders who penetrated to the Mississippi.

The English Hudson's Bay Company entered the fur trade in the latter half of the 17th century, eventually spreading its trading posts and interests from Vancouver, British Columbia, to Prince Edward Island and northward to the Arctic Ocean.

The fur trade of the 18th and early 19th centuries, involving extensive barter with Indian trappers, was a profitable business. The supply of furs appeared inexhaustible, and the demand grew steadily as the Industrial Revolution in Britain and western Europe created new wealth and a desire for more goods.

Russian fur trappers and hunters in the meantime pressed eastward; at the beginning of the 18th century they were active in the Kamchatka area in eastern Siberia. Fur trading was a Russian government monopoly under which the crown acquired all furs, including sable, ermine, and sea otter, at modest prices. Following the discovery of the breeding islands of the sea otter, these animals were almost exterminated by hunters. The northern fur seal population of the newer hunting grounds of Alaska was also greatly reduced by excessive hunting.

In the 20th century the Soviet Union, the United States, and Canada were among the world's major suppliers, and the United States was the leading consumer. The need for conservation measures, especially among endangered species, gained increasing recognition in the late 1960s and early 1970s.

## PELT CHARACTERISTICS

Fur pelts are animal skins with the hair forming the body covering remaining intact. The true furs consist of a soft, dense undercoat, called ground hair, underhair, or underwool, and a longer protective covering called guard hair or top hair. The pelts of certain animals, lacking either guard or ground hair, are not true furs, although used commercially as furs. Persian lamb, for example, sold as a fur, has only underwool and no guard hairs; monkey fur has guard hairs but no underhair. Mink, with its dense ground hair and long, glossy guard hair, is an example of a true fur. The Table gives pelt characteristics for the major furs used commercially and also indicates the chief countries of origin for each.

North  
American  
fur trade

Fur pelts

The skin is composed of a lower layer, or dermis, consisting mainly of connective tissue, toughened during processing to form the leather; and the upper layer, or epidermis, composed mainly of nonliving cells. The epidermis is removed during processing.

**Effects of seasons.** Furbearing animals in northern regions produce their fullest coats in response to shortening day length prior to the cold season, when they will require protection from the cold. The fur becomes denser and glossier, reaching its peak quality by the time the heavy frosts begin. The animal also stores up a layer of fat beneath the skin from earlier feeding and, as food becomes scarce, metabolizes the fat to obtain energy. In mild winters, with food supplies remaining available, the animal does not use up the fat layer. Furbearers in cold climates produce long, lustrous hair and thin, somewhat weak skin; warm climates produce shorter, coarser, less dense hair and thicker, stiffer skin.

In spring, with a full coat no longer required for warmth, the animal begins to shed its fur, and the skin toughens. By summer, with much of the ground and guard hair lost, the coat colour becomes dull, and the remaining hair coarsens. At the end of summer, with little reserve fatty tissue remaining, the skin takes on a bluish colour. Fur pelts taken at this period are described as "blue pelts." With the return of colder temperatures, the bluish colour gradually fades, and the skin becomes clear, creamy in colour, and more supple. Ground and guard hairs have the greatest amount of colour pigment in the summer and are lightest in colour during late winter and in the spring.

**Pelt nomenclature.** The various divisions of fur pelts, as used in the fur industry, are identified in Figure 1. The term grotzen refers to the centre back strip, usually darker than other areas, dividing the pelt into two large sec-

Figure 1: Pelt sections used in the fur industry.

tions. It is usually the coarsest portion, and when the hair is very long and coarse, it may protrude, as in the wolf.

#### THE FUR INDUSTRY

Furs traded commercially originate from both wild sources and fur farms (or ranches), with the greatest proportion obtained by farming. The 1970-71 world production of mink pelts, for example, accounting for about 60-70 percent of the world's fur trade, was approximately 25,492,000, with 25,062,000 from ranches and only 430,000 from wild sources. Countries producing over 1,000,000 ranch pelts included the Soviet Union (5,800,000), the United States (5,000,000), Denmark (3,900,000), Finland (2,900,000), Norway (2,400,000), Sweden (1,650,000), and Canada (1,300,000). The leading wild mink sources were the United States (250,000), Canada (100,000), and the Soviet Union (70,000).

**Wild sources.** Wild furs for commercial use are obtained from over 80 countries distributed on all six continents, but they come mainly from cold climates where the temperature ensures the growth of thick, luxuriant fur. North America has the greatest variety of furbearers, with 40 different indigenous types.

In the late 1960s and early 1970s, both individual governments and international organizations became concerned about the possible extinction of endangered species, and some countries enacted legislation restricting or

prohibiting commercial use of certain furbearing animals. Such animals included spider monkeys from Guatemala and Costa Rica and squirrel monkeys from Costa Rica; Canada's northern kit fox; the giant otter of the Amazon Basin; the southern fur seal of Peru, Argentina, and Ecuador; the Mediterranean monk seal, native to countries of the Mediterranean area; the Asiatic cheetah of the Soviet Union, Afghanistan, Iran, and Saudi Arabia; the Spanish lynx, native to Spain; India's Asiatic lion; the Sinai leopard of Sinai and Saudi Arabia; the Amur leopard of Korea and the Soviet Union; the Barbary leopard, found in Morocco, Algeria, and Tunisia; the Bali, Javan, and Sumatran tigers of Indonesia; and the Caspian tiger, native to Afghanistan and Iran.

Wild furbearing animals are usually caught with baited traps. Trapping in most of the world is licensed by, and subject to, control of state, provincial, or other governmental agencies, and, in order to preserve a reservoir of animals, the season in which animals may be trapped and the numbers that can be taken are generally restricted.

Trapping is usually practiced during the season in which the fur reaches its prime. The kind and size of trap employed depends on the animal to be taken, its habitat, and weather conditions. Traps are usually dyed and treated with orange shellac or a mixture of asphalt and varnish, making them less noticeable to the animals. The choice of lure depends upon the animal to be taken. Fox urine, for example, is a common fox lure.

The traps, concealed in areas frequented by the animal, are secured by chains attached to stakes, trees, or large stones. Muskrat and mink traps are often set underwater to drown the trapped animal quickly.

**Fur farming.** Fur farming, the keeping and breeding of animals for their pelts, is an ancient practice. Although livestock techniques were generally adapted, certain problems peculiar to the raising of wild species under confinement required special research.

An early research station was established by the Canadian government, in cooperation with the Canadian National Silver Fox Breeders Association, at Summerside, Prince Edward Island, in 1920, and a United States experimental station was started at Saratoga Springs, New York, in 1923, moving in 1953 to Ithaca, New York, where it functioned in cooperation with Cornell University. By 1940 the U.S. government was involved in cooperative research programs with several colleges and universities, with some stations concentrating on diseases of furbearing animals. The United States fur fibre laboratory at Beltsville, Maryland, became involved in studies on fur fibre origin, development, and growth. Several Canadian provinces have undertaken furbearing animal research. Sweden, Norway, and Denmark began similar research as the importance of fur farming in their economies increased.

Although the quality of early pelts was not as fine as that of the wild types, research eventually resulted in improved techniques of management, feeding, and breeding, producing many of the most desirable furs available. Thousands of mutations resulted from controlled matings of animals in captivity (see also ANIMAL BREEDING).

**Fox farming.** The silver fox, especially popular in the late 1930s and early 1940s, is a mutation of a red fox, with the reddish-orange colour replaced by black, and the white band on the guard hairs giving a silvery effect. Silver foxes obtained by trapping were nearly black, but controlled mating over a 20-year period produced the bright silver fox, with extremely wide white bands and the black portions free from the original rusty brown. Because the black colour is dependent upon a single genetic recessive factor, the mating of black or silver foxes always produces silver-black foxes. Such matings are rare in the wild state, and only a small percentage of wild foxes are of the silver type.

The breeding of silver foxes in captivity, first accomplished on Prince Edward Island in 1894, was at first carried on with much secrecy. After an especially beautiful silver fox skin brought £580 (nearly \$3,000) at auction in London, and other skins commanded high prices

Silver fox

in Europe and the United States, the cost of breeding stock rose rapidly. A pair of foxes worth \$3,000 in 1910 jumped to \$35,000 in 1913, and extensive speculation developed even for options on newborn pups.

At first, any odd-coloured fox pups in a litter were discarded for fear that the purity of the stock would be questioned. Later, enterprising fox farmers eventually mated these pups, developing such profitable mutant colours as white, platinum, pearl, and blue.

Pair, or monogamous, mating of foxes was at first deemed necessary to obtain the desired colour, but polygamous breeding eventually became common. Foxes produce one litter per year, whelped after a gestation period of 49–55 days. An average of four young per litter is considered satisfactory. At about seven months of age the pups weigh from 10 to 15 pounds (four to seven kilograms). They are pelted in November and December of the first year, and those pups selected for the herd are bred during late winter and early spring of the following year.

Peak production of silver and other mutation fox skins was reached in 1939, with the United States, Canada,

and the Scandinavian countries being the major producers. By the early 1950s production of silver fox pelts was drastically reduced as mink became more fashionable, and many fox farmers reduced their operations or changed to mink. In the early 1970s, however, there was a trend toward renewed importance of fox as a fashionable fur.

**Mink ranching.** Minks, raised in captivity for their fur as early as 1866, were not produced in quantity until about 1930 but have grown steadily in popularity, accounting for about 75 percent of the fur trade by the early 1960s.

Mature female minks weigh about one and one-half or two pounds, and the males weigh about four pounds. Minks can be bred when about 11 months old, and mating, commonly polygamous, is usually in March. Because there is a varying time of delayed implantation of the embryos, the gestation period varies from 40 to 76 days, with a litter average of four considered satisfactory. Pelt-ing takes place about the last of November.

Much of the increased popularity of mink fur has resulted from the development of such mutant colours as

### Major Furs in Commercial Use

	chief countries of origin	pelt characteristics		chief countries of origin	pelt characteristics
Badger	Asia, Europe, North America	long, white ground hair; coarse, white guard hair with blackish-brown or pale brown bands; good wearing qualities	Silver fox	North America, Europe, Asia	mutation of red fox; usually ranch-bred; blue-black ground hair; silvery guard hair with black base, white centre portion, and black tip
Baum Marten (see <i>Marten</i> )			Guanaco or its young, the guanacito	southern South America	dense, soft, fawn-coloured fur
Beaver	North America	glossy tan to dark brown colour; dense, silky, medium length ground hair; guard hair is coarse and frequently removed; good wearing qualities; medium weight	Hamster, black-bellied	Europe, Asia	flat yellow-brown fur with black markings; fairly thick ground hair and longer, somewhat scant guard hair; good wearing qualities
Broadtail (see <i>Lamb</i> )			Karakul (breed name; see <i>Lamb</i> )		
Calf, young of the ox	Northern Hemisphere	short, thick, dark hair; frequently sheared and dyed to resemble such flat furs as pony or leopard; poor wearing qualities	Kid, young of the goat	Asia, Africa	short, black, gray, or white hair, usually curly or wavy; no ground hair; frequently dyed; poor wearing qualities; thin leather
Chinchilla	South America (Andes mountains); also raised on ranches in the U.S.	fine, soft, lustrous, bluish-gray fur; short to medium length; fragile, lightweight; luxury fur	Kolinsky (yellow weasel)	U.S.S.R. (Siberia), China, Korean peninsula, Japan	yellow-brown with short, fine ground hair and long, silky guard hair; frequently dyed brown; fair to good wearing qualities; lightweight
Civet cat (or civet)	Africa	short, thick, dark ground hair; silky, black guard hair with white markings; fair to good wearing qualities	Lamb, young of the sheep		woolly ground hair; no guard hair; wavy or curly
Coney (see <i>Rabbit</i> )			Broadtail	Turkistan, Afghanistan, Southwest Africa	very young or unborn karakul lamb; flat, lustrous hair with curl not yet formed; waviness produces moiré effect; thin leather; poor to fair wearing qualities
Coypu (see <i>Nutria</i> )			Broadtail processed lamb	Argentina	sheared, pressed, and dyed to resemble broadtail; fair to good wearing qualities
Ermine	Europe, Asia, U.S.S.R. (Siberia)	white colour, some species turning tan in summer; white fur is sometimes dyed brown or bleached; poor to fair wearing qualities, lightweight, luxury fur; Soviet ermine has most dense fur and commands highest price	Indian lamb	India	curled and lustrous white, gray, or black hair; sometimes dyed beige or brown; pelts light in weight
Fisher	North America	dark brown ground hair; long, black, lustrous guard hair; good wearing qualities	Karakul, or caracul, lamb	U.S.S.R., China	short to long, glossy, curled or wavy hair; white, brown, or black colour; poor to fair wearing qualities
Fox		soft, dense, fine ground hair; long guard hair; lower grades have coarser hair; poor to fair wearing qualities	Mouton-dyed lamb (process)	North America, South Africa, South America	unkinked, dyed, and sheared to resemble beaver; also dyed novelty colours
Arctic fox (blue fox, white fox)	frigid zone of North America, Greenland, Iceland, Europe, Asia	blue fox combines gray, brown, and blue or may have gray ground hair with brown guard hair; white fox is more delicate and is often dyed various shades	Persian lamb	Turkistan, Afghanistan, Southwest Africa	fur of very young lambs; lustrous and tightly curled; gray, brown, or black colour; may be dyed for uniformity; poor to good wearing qualities
Black fox	North America, Europe	mutation of red fox; bluish-black or brownish-black in colour; usually ranch-bred	Lapin (see <i>Rabbit</i> )		
Cross fox	North America, Europe, Asia	mutation of red fox; yellowish to orange in colour with darker marking forming cross on spine and shoulders; frequently dyed	Leopard	Africa, Ceylon	short, flat, silky guard hair; tawny or buff colour with black or dark brown rosettes; good wearing qualities
Kit fox	North America	soft, creamy yellow ground hair and white top hair; sometimes dyed grayish-blue	Lynx	North America, northern Europe, Asia	soft, long, silky ground and guard hair; grayish-buff to tawny colour with darker markings; sometimes dyed pale blue, pale brown, or black
Red fox	throughout Northern Hemisphere, North Africa, Australia	colour pale to deep red, with darker shades preferred; frequently dyed			

Mink  
mutations

pale brown, medium brown, white, and a very dark brown sometimes described as black. The pelts of new mutations are usually the most costly, since the number of skins available is quite low until sufficient offspring can be bred to meet the demand.

*Chinchilla raising.* During the early 1900s many wild chinchillas were trapped for their fur, eventually leading to a scarcity. Chinchilla farming began at that time, and 50 years later more than 500,000 chinchillas were being raised in captivity in the United States, one-fourth as many in Canada, and a small number in other countries.

Until 1954, operations were largely in selling breeding stock. In June of that year, however, the first auction of a large quantity of chinchilla pelts from ranch-raised animals was held. The fur is marketed through associations of breeders such as the Empress Chinchilla Breeders of America, Inc., or through United Chinchilla Associates. Chinchilla is a luxury fur, extremely soft, fine, and silky, and blue-gray in colour, and may have varying widths of white bands on the guard hair.

*Marten farming.* Martens, forest fur animals closely related to the sable, weigh from one and one-half to three

pounds at maturity. Many attempts to raise martens in captivity have failed because only about 15–20 percent of the females produce young.

Martens breed in July and August and, after several months of delayed implantation, whelp in April. The delay in implantation can be shortened by artificial lighting, simulating early spring conditions and causing the martens to whelp in December instead of April.

*Other fur animals.* Karakul sheep and somewhat similar breeds of sheep, raised in the Soviet Union and the Middle Eastern countries for hundreds of years, produce the desirable black Persian lambskins and similar types. The best pelts are obtained from newborn lambs, for at that age the curl is in its prime. Southwest Africa produces several million Persian lambskins annually. These sheep were developed after many years of selective mating of Karakul rams to progeny originating from white sheep. Selected skins from white lambs are sheared and usually dyed to be sold as mouton.

The farming of several other fur animals has been initiated but has not materialized commercially because of availability of furs from the wild supply. Among these

## Major Furs in Commercial Use (continued)

	chief countries of origin	pelt characteristics		chief countries of origin	pelt characteristics
Marmot	U.S.S.R., Mongolia	brownish to black fur; frequently dyed brown with darker tips to resemble mink; poor to fair wearing qualities	Pony, young of the horse	Europe, South America	lustrous, flat guard hair; no ground hairs; may have moiré-like pattern; frequently dyed black or bleached and dyed tan; poor to fair wearing qualities
Marten		dense underfur with long, stiff, glossy guard hair	Rabbit	regions throughout the world	white, gray, brown, fawn, black, or mottled fur; frequently plucked and dyed to resemble other furs, or in novelty colours; poor to fair wearing qualities
American marten	North America	colour ranges from blue-black through various brown shades to a pale yellow that is usually dyed; medium length fur; fair wearing qualities	Raccoon	North America, South America	long fur, gray to black colour, sometimes with reddish tint; good wearing qualities; heavy weight
Baum marten	Europe, Asia Minor, Asia	yellowish-brown colour; frequently dyed deep brown; fair wearing qualities	Sable	U.S.S.R. (Siberia)	bluish-black or brown colour; dense ground hair and long, silky, lustrous guard hair; fair wearing qualities; medium weight; luxury fur; finest type is called crown sable
Stone marten	Europe, Asia Minor, Asia	grayish-white ground hair and dark brown guard hair; good wearing qualities	Seal, fur	U.S. (Alaska), South Africa, South America, Japan, U.S.S.R. (Siberia)	frequently dyed black or brown with black tips; guard hairs are coarse and usually removed
Mink	North America, Europe	colour ranges from very dark brown through reddish-brown and also includes various mutant colours; dense, short, fine ground hair; lustrous guard hair; good wearing qualities; fairly lightweight; luxury fur	Seal, hair	North America, Scandinavia	bluish-black colour; some types have white blotches giving a mottled effect; sometimes dyed brown; no ground hair; flat, wiry guard hair
Mole	Europe	gray to black colour with fine, soft, lustrous ground and guard hairs that are of similar length; poor wearing quality; lightweight	Seal, harp	North Atlantic and Arctic oceans	very young animals have fluffy white fur; adults have light grayish or yellowish, flat, coarse guard hair and no ground hair
Mouton (see Lamb)			Skunk	North America, South America	dense, bluish-black ground hair; long, glossy guard hair; two white stripes extend down the pelt back; frequently plucked and dyed; good wearing qualities; heavy weight
Muskrat	North America, U.S.S.R.	soft, dense, gray ground hair; long, lustrous, stiff, dark brown guard hair; fair to good wearing qualities; medium weight	Squirrel	U.S.S.R. (Siberia)	lustrous, fluffy steel-blue fur, sometimes with red streaks; frequently dyed; long, dense ground hair and slightly longer, silky guard hair; poor to fair wearing qualities; lightweight
Nutria (coyupu)	U.S., South America	short, dense, dark bluish-brown ground hair; stiff guard hairs are usually plucked; fair wearing qualities	Weasel	throughout Northern Hemisphere	pure white fur in winter, turning yellowish in spring and brown in summer; frequently dyed beige or brown; short, thick fur; fair to good wearing qualities
Ocelot	Mexico, Central America, South America	flat fur with short ground hair and little guard hair; black markings on tawny-yellow or gray ground; poor to fair wearing qualities	Wolf	throughout Northern Hemisphere	long-haired fur with dense ground hair; off-white, yellowish, brownish-gray, or black colour; frequently dyed gray, brown, or black; fair to good wearing qualities; heavy weight
Opossum	North America, South America, Australasia	yellowish-brown or gray colour; medium length, coarse fur; fair to good wearing qualities; medium weight	Wolverine	North America, U.S.S.R. (Siberia)	blackish or bluish-brown colour with tan stripe on sides; coarse texture; good wearing qualities
Otter	regions throughout the world	dense, fine, short, ground hair is gray, medium brown, or dark brown in colour; the stiff, long, silvery guard hairs have lighter tips; frequently plucked and dyed; good wearing qualities; medium weight			
Otter, sea	U.S. (Alaska), U.S.S.R. (Siberia)	light brown to black colour with sprinkling of white hairs; silky-textured ground and guard hairs			
Persian lamb (see Lamb)					

are beaver, nutria, fisher, muskrat, fitch, raccoon, and skunk. The potential of such farming depends upon the demand created by fashion trends and the development of new and desirable colours.

Rabbit skins from animals raised in hutches primarily for their meat have been used in the fur trade from time to time. Selected skins from the older animals of Europe have proved satisfactory in the natural state or sheared and dyed, but only a small percentage of the skins from the eight-week-old "fryer" rabbits in the United States are suitable for fur garments. Very few rabbits are raised primarily for their fur.

**Collection and distribution.** Many fur skins are delivered or sold to collecting agents, who sell them to merchants in various fur centres. Skin merchants maintain stocks of furs, selling to manufacturers or retail furriers. Most raw fur skins, however, are shipped to auction houses, which act as marketing agents, offering the skins at public auction to skin merchants, manufacturers, and commission brokers who buy for merchants and manufacturers. The auction houses receive fees based on the prices paid at auction.

Auction  
centres

Major fur auction centres are in New York City, London, Leningrad, and Montreal. Regular auctions of secondary importance are held in Greenville, S.C., where dressed fur sealskins are sold semi-annually; Seattle, Wash.; Minneapolis, Minn.; Winnipeg, Man.; Edmonton, Alta.; Vancouver, B.C.; Regina, Sask.; Copenhagen, Den.; Oslo, Nor.; and Stockholm, Swed. Melbourne and Sydney are the main centres for rabbit skin auctions, which are also held in London. The Hudson's Bay Company is the dominant fur-collecting organization and marketing agent in the world, with auction houses in London, Montreal, and New York City. The London Public Sales holds major auctions in the spring, summer, autumn, and winter.

The major auctions in London, New York, and Montreal draw an international audience and often last a week or longer. The Leningrad sales, held in January, July, and October, are conducted by Soyushpushnina, an official Soviet agency, which buys the skins from state and collective farms and controls domestic and foreign marketing.

**Fur processing.** *Fur dressing.* Fur skins are dressed to make them suitable for use. The fur dresser aims at the creation of a soft, pliable leather; the removal of superfluous matter from the pelt; and the preservation and enhancement of the natural lustre of the fur. The details of

the process vary with the nature and condition of the skin treated, but there are usually at least four distinct stages in the operation. First, there is the preliminary cleaning and softening of the pelt; then fleshing (removal of fleshy matter from the skin) and stretching; then leathering, a tanning process that results in the formation of a leather on the skin (see also LEATHER AND HIDES); and then a final cleaning. Separate processes in the fur dresser's art are unhairing, or plucking (the removal of guard hairs where necessary); shaving of the leather side to decrease weight, impart suppleness, and improve draping qualities; and sometimes shearing of the ground hair of such furs as fur seal, muskrat, raccoon, and beaver to achieve a desired depth.

Though it originated in a primitive and haphazard manner, modern fur dressing is a highly developed process that requires considerable mechanical equipment. The largest fur processing centre is in New York.

*Fur dyeing.* Fur dyeing is an ancient art, but its modern development began in the latter part of the 19th century with the development of chemical compounds known as fur bases. Before that period fur was mainly dyed with vegetable or mineral colouring matters, but the fur bases have largely superseded the older materials because of their simplified application. The use of synthetic compounds has enabled fur dyers to produce a wider variety of colours, leading to the use of many skins that are unattractive in their natural colours but that can be dressed and dyed to make attractive furs. Furs may be bleached to eliminate yellowish colour in white pelts, to lighten colour so that pelts may be dyed light shades, or to eliminate natural colour that would interfere with a desired shade in dyeing. They may also be tipped, or top blended, a process in which the guard hairs, and sometimes the ground hairs, are lightly brushed with a dye-stuff. New colours are an important selling point among fur retailers, making possible such shades as blonde, beige, charcoal and platinum gray, blue, white, and even pink and red, in addition to the traditional browns and blacks of natural furs and the various mutation colours developed in such furs as minks. Innovations made possible by the fur processor's art have produced changes in the handling of furs. For example, the long-haired, brown raccoon coat of the 1920s became a sheared, lighter weight fur available in blonde, beige, or white, as well as the natural colour. Dyers often keep their techniques secret, guarding them from competitors.

Bleaching

Europe's chief dyeing centres are in France, Belgium,

and London. Leipzig was the major centre until after World War II, when its experts relocated in Frankfurt, London, and New York.

**Fur manufacturing.** Furriery, the production of fur garments, has progressed from primitive methods of sewing skins together to a highly skilled and intricate process. Fashion influences both the popularity of specific furs and the design of fur garments. Designs are created by custom furriers, by stylists working for individual manufacturers, and by commercial designers who sell patterns to manufacturers and retailers. Fur manufacturing remains, essentially, a handicraft industry. The cutter, for example, matches pelts according to colour and quality in order to achieve uniformity of colour and texture in the finished garment and also cuts the skins to conform to the designer's pattern with a minimum of wastage. Sewing, performed on power-driven machines, requires much skill.

There are two main types of fur manufacture, the letting-out method and the skin-on-skin method.

**Letting-out process.** This technique, usually applied to mink, is employed to accentuate length, minimize width, and improve draping qualities. It involves slicing every skin into diagonal strips one-eighth to one-quarter inch in width and sewing the strips together to make a longer and narrower skin that will run the full length of the garment without seams showing on the fur side (see Figure 2, left). In recent years the letting-out process has been used with furs other than mink, such as nutria, sheared raccoon, and beaver, but with modifications to enhance the beauty of the particular fur.

**Skin-on-skin process.** The less costly skin-on-skin method consists of sewing one full skin adjacent to another in a uniform alignment. This method is sometimes employed to sew the leftovers of full skins, such as paws and flanks, into blanket-like "plates" that are then fashioned into garments.

**Finishing operations.** After the skins are prepared by the cutter, they are made up into sections that are dampened, then stretched and nailed to fit a pattern on a wooden nailing board and dried on the form (see Figure 2, right). The dried sections are then sewn together.

In the glazing operation that follows, the fur is again dampened, and the hair is arranged in the desired direction by mechanical means. Gums and similar materials are applied to hold the hairs in position, and the fur is slowly dried. The setting materials frequently increase the lustre of the fur.

After this treatment, the lining is sewn in, and any additional sewing is completed.

**Retail distribution.** Fur manufacturers distribute their products by selling to retailers or to wholesalers who sell to retailers. Custom furriers design and manufacture garments for sale to the consumer and may also carry stocks of ready-to-wear furs. Apparel specialty stores and department stores often carry ready-to-wear furs as part of a general stock. Retailers usually maintain fur-servicing departments that clean, repair, and remodel garments for customers and also store furs in refrigerated vaults.

In the United States, the Fur Products Labeling Act of 1951, amended in 1961, requires that the animal name and country of origin be specified on the labels of all furs. Garments made of pelts that have been altered to resemble another fur must be labelled with the name of the actual pelt used. A garment made of Canadian muskrat that has been sheared and dyed black to resemble fur seal can no longer be called Hudson seal but must be labelled "dyed muskrat; origin: Canada." Government regulations in other countries vary but are generally less stringent than those of the United States.

Man-made synthetic furs, usually made from synthetic fibre blends, increasingly simulate natural furs, even duplicating the ground and guard hairs. Usually woven or knitted to a backing, they are either dyed in the yarn stage or printed with colour in the fabric stage. Less expensive than natural furs, and sometimes combined in garments with furs, they are not considered luxury products.

**BIBLIOGRAPHY.** F.G. ASHBROOK, *Furs Glamorous and Practical* (1954), discusses the history, sources, uses, design, and care of furs. MAX BACHRACH, *Fur*, 3rd ed. (1953), is an extensively illustrated work describing furbearing animals, the classification of their furs, the determination of fur pelt quality, fur dressing and dyeing methods, and the use of microscopy in the study of fur fibres. ARTHUR SAMET, *Pictorial Encyclopedia of Furs*, rev. ed. (1950), with 600 illustrations, provides a comprehensive treatment of the fur industry, including geographical origin of furs, seasonal changes in furbearers, fur manufacturing, and fur care and handling. WILLIAM E. AUSTIN, *Fur Dressing and Fur Dyeing* (1922), treats the various phases of fur dressing and the techniques of fur dyeing, including related equipment and the various fur dyes. *Fur Age Weekly* is a trade publication for the fur industry.

(O.Gi.)

## Futures

From very early times, and in many lines of trade, buyers and sellers have found it advantageous to enter into contracts—termed futures contracts—calling for delivery of a commodity at a later date. Dutch whalers in the 16th century entered into forward sales contracts before sailing, partly to finance their voyage and partly to get a better price for their product. Potato growers in Maine in the U.S. from early times made forward sales of potatoes at planting time. The European futures markets arose out of import trade. Cotton importers in Liverpool, for example, entered forward contracts with U.S. exporters from around 1840. With the introduction of the fast transatlantic Cunard mail services, it became possible for cotton exporters in the United States to send samples to Liverpool in advance of the slow cargo ships, which carried the bulk of the cotton. Futures trading within the United States in the form of "to arrive" contracts appears to have commenced before the railroad days (1850s) in Chicago. Merchants in Chicago who bought wheat from outlying territories were not sure when they would obtain delivery or what their quality would be. Under these conditions, the introduction of "to arrive" contracts enabled the sellers to get a better price for their product and buyers to avoid serious price risk.

Futures trading of this sort in grains, coffee, cotton and oilseeds also arose in other centres such as Antwerp, Amsterdam, Bremen, Le Havre, Alexandria and Osaka between the 17th and the middle of the 19th centuries. In the process of evolution, "to arrive" contracts became standardized with respect to grade and delivery period, with allowances for grade adjustment when the delivered grade happened to be different. These developments helped to enlarge the volume of trade, encouraging more trading by merchants who dealt in the physical commodity and also the entry of speculators, who were interested not in the commodity itself but in the favourable movement of its price in order to make profits. The larger volume of trading lowered the transaction costs, and by stages the trading became impersonal. The rise of the clearing house depersonalized the buyer-seller relations completely, giving rise to the present form of futures trading.

### ECONOMIC FUNCTIONS OF THE FUTURES CONTRACT

Commodity futures markets provide insurance opportunities to merchants and processors against the risk of price fluctuation. In the case of a trader, an adverse price change brought either by supply or demand change affects the total value of his commitments; and the larger the value of his inventory, the larger the risk to which he is exposed. The futures market provides a mechanism for the trader to lower the per unit inventory risk on his commitments in the cash market (where actual physical delivery of the commodity must eventually be made) through what is known as hedging. A trader is termed a hedger if his commitments in the cash market are offset by opposite commitments in the futures market. An example would be that of a grain elevator operator who buys wheat in the country and at the same time sells a futures contract for the same quantity of wheat. When his wheat is delivered later to the terminal market or to

Origins  
and de-  
velopment

Glazing

the processor in a normal market, he buys back his futures contract. Any change of price that occurred during the interval should have been cancelled out by mutually compensatory movements in his cash and futures holdings. The hedger thus hopes to protect himself against loss resulting from price changes by transferring the risk to a speculator who relies upon his skill in forecasting price movements.

For a better understanding of the process involved, the distinctive features of the cash market and the futures market should be made clear. The cash market may be either a spot market concerned with immediate physical delivery of the specified commodity or a forward market, where the delivery of the specified commodity is made at some later date. Futures markets, on the other hand, generally permit trading in a number of grades of the commodity to protect hedger sellers from being "cornered" by speculator buyers who might otherwise insist on delivery of a particular grade whose stocks are small. Since a number of alternative grades can be tendered, the futures market is not suitable for the acquisition of the physical commodity. For this reason, physical delivery of the commodities in fulfillment of the futures contract generally does not take place, and the contract is usually settled between buyers and sellers by paying the difference between the buying and selling price. Several futures contracts in a commodity are traded during a year. Thus, five wheat contracts, July, September, December, March, and May, and six soybean contracts, September, November, January, March, May and July are traded on the Board of Trade of the City of Chicago. The length of these contracts is for a period of about ten months, and a contract for "September wheat" or "September soybean" indicates the month the contract matures.

Hedging as insurance

Though hedging is a form of insurance, it seldom provides perfect protection. The insurance is based on the fact that the cash and futures prices move together and are well correlated. The price spread between the cash and futures, however, is not invariant. The hedgers, therefore, run the risk that the price spread, known as the "basis," could move against them. The possibility of such an unfavourable movement in the basis is known as basis risk. Thus hedgers, through their commitment in the futures market, substitute basis risk for the price risk they would have taken in carrying unhedged stocks. It must be emphasized, however, that risk reduction is not the final objective with merchants and processors; what they seek to do is to maximize profits.

The availability of capital for financing the holding of inventories depends on whether they are hedged or not. The bankers' willingness to finance them increases with the proportion of the inventory that is hedged. For example, the banks may advance loans to the extent of only 50 percent of the value of unhedged inventories and 90 percent if they are all hedged, a difference explained by the fact that hedging reduces the risk on which the amount of the loan and the interest rate depend. Merchants and processors can therefore derive a twofold advantage from futures trading; they can insure against price decline and they can secure larger and cheaper loans from the banks.

#### THE THEORY AND PRACTICE OF HEDGING

There are two rival hypotheses concerning the motives for and costs of hedging. The first of these, advanced by John Maynard Keynes and J.R. Hicks, suggests that risk reduction is the prime motive for hedging and that hedgers pay a risk premium to speculators for assuming risk. The Keynes-Hicks hypothesis states that under normal conditions in commodity markets, when demand, supply, and spot prices are expected to remain unchanged for some months to come and there is uncertainty in traders' minds regarding these expectations, the futures price, say, for one month's delivery is bound to be below the spot price that traders expect to prevail one month later. This condition exists because inventory holders would be ready to hedge themselves from the risk of price fluctuations by selling futures to speculators below the ex-

pected spot price. By selling futures below the expected spot price, according to the theory, inventory holders who hedge pay a risk premium to speculators.

The rival hypothesis of Holbrook Working maintains that hedging is done with the expectation of a profit from a favourable change in the spot-futures price relation, to simplify business decisions, and to cut costs, and not for the sake of reducing risk alone. Hedgers, according to Working, are arbitrageurs; *i.e.*, they take advantage of a temporary price difference between two markets to buy in one and sell in the other. They thus speculate on the basis and assume risk.

A compromise between these rival theories and a more balanced view regarding the need for hedging and the scope of hedging activities is that hedging is motivated by the desire to reduce risks, as suggested by the Keynes-Hicks theory, but that the levels of inventory held by merchants and processors are determined by expected hedging profits, as Working has emphasized.

There are two categories of hedgers in the futures market: they are called short and long hedgers. Short hedgers are merchants and processors who acquire inventories of the commodity in the spot market and who simultaneously sell an equivalent amount or less in the futures market. The hedgers in this case are said to be long on their spot transaction and short in the futures transaction. Wheat merchants or wheat flour mills who either have 100,000 bushels of wheat as inventory or have bought it for later delivery are said to short hedge if they sell 100,000 bushels of wheat in futures contracts. By holding inventories, both merchants and processors can make their purchases when it is most opportune and lower their transaction costs through fewer transactions. Another advantage to the processing firm in holding inventory is that it makes it possible to avoid interruption in production. It must be borne in mind that short hedgers do not normally deliver the physical commodity in fulfillment of the futures contract. They "lift the hedge" by repurchasing the futures contract at the prevailing futures price when they sell the raw material or the processed good in the spot market.

The long and short hedger

The merchants and processors do not generally hedge all their inventories for the sake of reduced risk. The decision on what part of inventories to hedge is based on their expectations relating to return from holding hedged and unhedged inventories in storage, given the cost incurred in both forms of inventory holding. The return per unit inventory to merchants and processors on their hedged inventories, when liquidated, is the change in the spot price less the change in the futures price and the storage costs. Their return on per unit unhedged inventory is the change in spot price less storage costs.

Long hedgers, in contrast, are merchants and processors who have made formal commitments to deliver a specified quantity of raw material or processed goods at a later date at a price currently agreed upon and who do not now have the stocks of the raw material necessary to fulfill their forward commitment. The parties who have made the commitment generally seek to hedge against the risk of price rise in the raw material between the time of making the forward contract and the time of acquiring the raw material stocks for fulfilling the contract. The hedging is done by buying futures contracts of the raw material equal in quantity to what is needed to fulfill the forward commitment.

The question arises under what circumstances the long hedger might prefer the purchase of futures to the alternative of immediately buying the raw material through spot or forward purchase to meet the obligations of his forward sale. He may prefer buying futures to buying in the cash market (spot or forward) if current cash prices are high because of scarcity. Generally there is an increase in the amount of long hedging when, as the season advances, spot prices rise, inventory holdings fall, and the new crop is not yet available. Long hedging is not as risk-reducing as it may appear at first sight. The long hedger processor, for example, who buys raw material futures to satisfy his forward commitment of the processed good may find that the raw material delivered to

him in futures is not of suitable grade and quality to meet the obligations of the forward sale. Quite often, therefore, he may sell his futures contract and purchase raw material of the grade needed. If the spot price of the raw material moves unfavourably relative to the price of the processed good sold forward by him, the long hedger actually increases the risk by buying futures instead of buying the raw material in the cash market. Long hedging, unlike short hedging, may serve to increase risk, and the total risk on long hedging increases with the size of the commitment.

The volume of short hedging tends to be large when stocks in commercial hands are large and when the cash price is below the futures price; a reversal in this situation brings a decline. Conversely, the volume of long hedging is large when stocks are small and the cash price is above the futures price. Short hedging has a marked seasonal pattern, reaching a peak when commercial stocks are largest and the basis is favourable and then declining as the season advances. The seasonal pattern is less marked in long hedging. Generally there is an excess of short over long hedging during the bulk of the crop year.

The  
speculator's  
role

Apart from hedgers, the futures market includes speculators, and these can also be classified in two categories, namely, long and short speculators. The long speculators are those who expect the price to rise above the current level and assume risks by purchasing futures contracts. Short speculators are those who expect the price to fall. They sell futures contracts. In a futures market the total short selling position, made up of short hedgers and short speculators, and the total long buying position, made up of long hedgers and long speculators, must always be equal. Any excess of short over long hedging must be balanced by an equal excess of long over short speculation. Since short hedging exceeds long hedging for most of the crop year, hedgers are generally short and speculators, therefore, are generally long.

Futures markets have flourished and become important in commodities where sizeable inventories have to be stored and carried forward for meeting the consumption needs of the entire season. Successful futures trading requires a large volume with low transaction costs and that spot and futures prices be well correlated in order to make hedging effective.

#### IMPORTANT FUTURES MARKETS

Based on the number and volume of commodities in which active futures trading exists, the United States occupies first place. The Chicago Board of Trade, the largest of the world's futures markets in terms of volume and value of business, is the centre for trading in wheat, corn, oats, rye, soybeans, soybean oil, and soybean meal. About 30 commodities in all are traded on organized exchanges in the United States. The wheat market in Minneapolis, the cotton and wool markets in New York, and the markets in frozen pork bellies and live hogs in the midwestern United States are among them. The number of commodities in which futures trading takes place are far fewer outside the United States.

There are futures markets for wool in London, Paris, and Sydney; for cotton in Liverpool and Bombay; for sugar in London and Paris; for jute goods in Calcutta; for black pepper in Cochin; and for turmeric in Sängli. As a result of government controls on futures markets and also of international commodity agreements, the volume of futures trading in several countries has been adversely affected. The commodity markets in England and Europe, with few exceptions, have been dormant since the end of World War II. Many of the Indian commodity markets, such as those in gur, jute, and oilseeds, which were once active, have met the same fate. The recurrent arguments in the United States, India, and elsewhere against the futures markets is that they encourage speculation and that the participation of speculators causes price instability. These arguments have led to the demand that markets be controlled or prohibited from functioning. To refute such allegations requires a comparison between price variations in the presence and absence of

speculation, which is impossible for commodities that have futures markets, since it is not meaningful to say for these markets what the price would have been in the absence of speculation.

(L.S.V.)

## Gabon

The Gabon Republic (République Gabonaise), on the west coast of Africa, sits astride the Equator, with a total area estimated at 103,347 square miles (267,667 square kilometres) and a population early in the 1970s of about 950,000. The republic is bordered by the Atlantic Ocean to the west, Equatorial Guinea (Río Muni) and Cameroon to the north, and the People's Republic of the Congo (Congo [Brazzaville]) to the south and east. The capital is the port city of Libreville.

Although it has been independent since 1960, Gabon—formerly one of the four territories comprising French Equatorial Africa (AEF)—has retained close economic and political ties with France, her former colonizer. One indication of this is that the French expatriate population of Libreville rose, after ten years of independence, from 5,000 in 1960 to 14,000 in the early 1970s. France also purchases a major part of Gabon's increasing output of iron ore and is the sole purchaser of uranium from the country's rich mines. France is also funding a new 45-kilowatt radio transmitter, as well as a major part of the railroad from Belinga in the northeast to the port of Owendo on the coast. It was expected that the railroad would be completed by 1979-80.

While in need of such outside aid and investment, the Republic was at the same time pursuing a policy of "Gabonization," and, as a first step, in 1970 ordered all boards of directors of foreign companies (not all of them French-owned) to make arrangements to hold their meetings in Gabon. Nationalization is seen as a future possibility. Thus there is an inherent tension between

Links  
with  
France

the government's thrust to attract foreign investment and its increasing emphasis on the "Africanization" of the economy. Relations with neighbouring African countries (including the Marxist-oriented Republic of the Congo) are generally good. Gabon is a full member of the Central African Economic and Customs Union (UDEAC), Common Afro-Malagasy Organization (OCAM), and other international organizations. Diplomatic relations are maintained with some 20 countries outside Africa, although none with Communist countries. (For historical aspects, see CENTRAL AFRICA, HISTORY OF.)

**The landscape.** *Relief and drainage.* The very narrow coastal plain—often no more than 20 miles wide in the south—is formed of sandstone and alluvium; northward it broadens to a width of 100 miles, with outcrops of chalk, limestone, and cretaceous sandstone. North of the most westerly point, Cap Lopez, the contour of the coast is also more jagged than that in the south, since the northward-flowing Atlantic Benguela Current, which softens the coastline by creating sandbars that cause lagoons to form at river mouths, is no longer effective here. Inland, the relief is characterized by a series of granite plateaus, ranging generally northeast to southeast and rising to heights of from 1,000 to 2,000 feet. Further to the west and north, the Monts de Cristal (Crystal Mountains) surround the rolling hills associated with the Ivindo Basin and the Woleu and Ntem rivers. To the south, the Ogooué River drains through a sandstone saddleback before emptying into the lowlands through the granite formations of the Lambaréné region. Granite also forms the Massif du Chaillu (mountainous mass), Gabon's central watershed, south of the Ogooué, which rises to an elevation of approximately 3,000 feet, except where topped by the 5,167-foot (1,575-metre) height of Mont Iboundji.

*Climate, vegetation, and animal life.* Gabon is characterized by the heat and humidity typical of an equatorial region. Rainfall varies from an annual average of 120 inches at Libreville to 150 inches on the northwest coast, with almost the total amount falling between October and May. In the period from June to September there is virtually no rain, but humidity remains high. Temperature shows little seasonal variation, the daily average being about 81° F (about 27° C).

About 75 percent of the country is covered by a dense equatorial rain forest containing more than 3,000 species of vegetation, including the okoume, a hardwood tree that forms the backbone of Gabon's wood industry. The lush jungle vegetation makes the country an animal paradise; and antelopes, monkeys, gorillas, leopards, and tropical birds, as well as several varieties of elephants, flourish in abundance.

*The landscape under human settlement.* Gabon's seven major towns—Libreville (105,000 inhabitants), Port-Gentil (48,000), Lambaréné (18,000), Mouila (15,000), Mouanda (11,000), Oyem (12,000), and Bitam (6,000)—contain about 23 percent of the total population. The remainder is scattered among about 4,500 rural villages, concentrated along the rivers and roads, with an average population of some 120 inhabitants each. While Port-Gentil has developed mainly as an industrial town, Libreville attempts to achieve more sophistication; broad boulevards, European-style cafés, two discotheques, and modern office buildings (some occupied by government ministries) occasionally alternate with thatched huts. Libreville also has the second highest cost of living in the world because of the scarcity of land for accommodations and the necessity of importing a high percentage of the food consumed because of the underdevelopment of local agriculture.

Although the majority of the population lives in rural villages, where traditional family life and customs tend to be preserved, the government is making a concerted effort to break down the customary concept that a woman's role is akin to that of a beast of burden and, instead, to prepare her to embark upon a useful public life. In part this new emphasis is being introduced for reasons of economic expediency, because one of the reasons for Gabon's underdevelopment has been underpopulation

Gabon, Area and Population

and consequent shortage of personnel. Young men and women are now educated together and are trained to serve as magistrates, teachers, and nurses, as members of the armed forces and in other posts. The effect of this on traditional village life, however, remains to be seen.

**People and population.** *Linguistic, ethnic, and religious groups.* Any ethnographic map of Gabon would necessarily be extremely complicated, showing more than 40 tribal groups with different languages and customs. The one indigenous element among the tribes is represented by the few thousand Pygmies (Babinga) who support themselves in the forests by hunting. The Fangs (Pahouins) are a relatively homogeneous group of about 225,000 persons, living to the north of the Ogooué-Ivindo line, whereas the Bantus in the south are divided into numerous groups. Among these are the Adouma (Bandjabi; about 107,000), Eshiras (Bapouno; about 121,000), Okandés (about 52,000), Bakotas, Bandzabis, Mienes, Bakélés, and others number about 265,000. The adoption of French as the official language and its use in the schools has proved a unifying force among these disparate groups.

It was estimated in the mid-1960s that about 51 percent of the population was Christian (about 234,000 Roman Catholics and about 100,000 Protestants), with the remainder of the population adhering either to Islām (about 2,000 people) or to animism. In 1970 the Salvation Army and Jehovah's Witnesses were officially banned from the country.

*Demography.* With a population estimated in the early 1970s at about 950,000 (not including about 14,000 Frenchmen), Gabon has a population density of nine persons per square mile—one of the lowest densities in Africa. The growth rate is put at 1 percent per annum. This situation is partially explained by a high instance of infertility, caused by disease and malnutrition. Unhealthy climatic and living conditions also contribute to a low average life expectancy—about 25 years for males, 45 years for females.

**The national economy.** *Agriculture.* Although about 85 percent of the population is engaged in agriculture (primarily subsistence farming), it plays but a small part in the economy of the country as a whole. Thus President Bongo's second Five-Year Plan (1971-75) lays its emphasis on agriculture in an attempt to reduce both the proportion (14 percent) of total imports which consists of food, and to revitalize the commercial production of cacao, palm oil, coffee, and peanuts (groundnuts). In 1971 a total of about 6,000 tons of cacao was produced (showing little change over ten years), whereas coffee actually decreased from 1,200 tons in 1960 to less than 500 tons in 1971. Under the development plan, cattle raising will also be encouraged.

*Forestry.* For many years Gabon's forests, covering 75 percent of its territory, were its principal natural resource. Newly discovered and exploited mineral wealth had by the early 1970s forced raw wood and forest products into second place, although these still represented about 40 percent of the country's total exports. The principal forest districts are at Kango, Booué, Fougamou, Ndjolé, Mitzié, and Mouila. The forest resources near the

The  
towns

coast and rivers are practically exhausted, but little exploitation has been undertaken in the interior because of the lack of transportation facilities. With the completion of the Belinga to Owendo railroad it is estimated that the tonnage of cut wood could be doubled, and the value of other forest products increased by 50 percent.

**Mining.** Manganese mined at Moanda, Bakoumba, and Makabana (west of Franceville) has made Gabon the fourth ranking world producer of this metal—after the Soviet Union, South Africa, and Brazil. Although the country supplies only 7 percent of the world total, it is the chief exporter, with more than 20 percent of the total (725,000 tons exported in 1970). Principal purchasers are the United States, France, West Germany, Norway, and Japan. Reserves estimated variously from 100,000,000 to 200,000,000 tons will probably last another 100 years.

In 1956, a reserve of about 1,000,000 tons of uranium ore, with a concentration of at least 4 percent, was discovered at Mounana. Exploitation was in progress by 1961, with a processing factory constructed on the site. Another vein was subsequently discovered at Okolo and a third at Mingara. Total production was more than 1,000 tons in 1971, with France the sole purchaser.

#### Petroleum production

Petroleum now represents 40 percent of Gabon's total exports, with an estimated reserve of 100,000,000 tons. In the early 1970s, eight companies were drilling on the continental shelf in the offshore fields at Anguille and Torpille, in addition to exploiting the two already established fields at Gamba and Ivinga in the south and at Port-Gentil. Production in 1971 was about 5,785,000 tons, with output projected at 8,000,000 tons by 1980.

Iron ore of good quality (65 percent iron) has been discovered at Belinga in the northeast. Reserves are estimated at 566,000,000 tons at Belinga, and 1,200,000,000 tons in all of Gabon. Because of the inaccessibility of the deposits, however, full-scale mining was not expected to begin until about 1980, upon the completion of a railroad linking this remote interior region to the coast. The combine that will carry out the exploitation represents 50 percent U.S. and 34 percent French interests, and 16 percent interests from other European countries.

**Industry, trade, and foreign aid.** Light industry has been expanding and diversifying since the opening in 1967 of a petroleum refinery at Port-Gentil (partially

financed under UDEAC auspices). In 1969, a textile printing factory (the first textile industry in Gabon) was launched by a combine representing an international group of investors. A flour mill soon followed (importing flour is now banned), as well as a new electrical center at Makokou. In the early 1970s, projects planned included an explosives factory at Libreville and factory installations connected with industrial fishing. A large dam at Kinkélé, partially financed by the European Economic Community (EEC), was also planned to provide hydroelectric power to the Libreville area. Assuming that foreign investment could continue to be attracted, Gabon's greatest problem in further developing industry was the lack of trained workers and managerial skills.

In 1970, about 90 percent of total exports were composed of oil, manganese, and forest products—shipped primarily to France, Netherlands Antilles, West Germany, The Netherlands, and the U.S. Since then, however, the tendency has been to diversify in terms of markets. With exports of U.S. \$121,000,000 exceeding imports of U.S. \$80,000,000 by U.S. \$41,000,000 in 1970, Gabon preserved the healthy trade balance established in its first year of independence. Exports, however, decreased by 8 percent from 1969, while 1970 imports increased by 10 percent over the previous year, probably due to increasing industrial needs. Imports of machinery and vehicles alone increased by 8 percent. Other imports include metals and metal products, food products, chemicals, pharmaceuticals, textiles, and clothes; these came from France, other EEC members, the United States, the United Kingdom, Spain, Senegal, Morocco, Japan, and Canada.

The close ties between Paris and Libreville are seen most clearly in the fact that more than 60 percent of all monies obtained either through direct foreign aid or investment come from France. In 1971 this sum was expected to exceed U.S. \$4,000,000. West Germany is also contributing an estimated U.S. \$7,500,000 to help with the completion of the Belinga-Owendo railroad. In 1969 the World Bank granted a loan of U.S. \$6,000,000 for roads to open up the forest regions of the interior, whereas the European Development Fund made credit available for the port of Owendo. Gabon also receives some funding from the UDEAC. United States investments in the country (primarily in oil and in the projected Belinga

mines) probably represent considerably more than U.S. \$100,000,000.

**Management of the economy.** President Bongo has described his economic policy as one of "directed economic liberalism"—which is to say there is little direct state intervention; but private enterprise must move within the larger outline developed by the government (in this case within the priorities of the 1971–75 development plan). The 1970 budget balanced at more than 20,000,000,000 CFA francs, with the largest expenditure going towards building the kind of transportation system needed to further economic development. When such a system has been completed, it is probable that the 1969 per capita income (based on the gross national product) of U.S. \$320, which placed Gabon third in rank among African countries, would rise proportionately.

**Transport.** In the early 1970s there were about 3,750 miles of roads intended for vehicular traffic, of which about 1,200 were national highways. An extensive road-building program has been undertaken—partly to transport products from the interior to one of the port cities and partly to link important economic and industrial centres throughout Gabon. The completion of a route from Basse Obiga to Lastoursville (running through the Abeilles forest) is expected to solve the former problem. Also under construction are roads due for completion between Libreville and Owendo, a north-south

connection between Makokou and Franceville, and routes from Lara to Mitzi and Koumameyong; a connection from Port-Gentil to the petroleum installations at Cap Lopez is also projected.

The Ogooué River is navigable upstream from the point where it drains into the Atlantic only as far as Ndjolé (about 150 miles inland). The Ogooué and other rivers, such as the Abanga and the Nyanga, can, however, be used to transport logs floated downstream from the forest areas.

At the moment, there are two principal ocean ports—Port-Gentil (primarily handling the exportation of wood), and Libreville. Uranium and manganese usually leave from the neighbouring Congolese port of Pointe-Noire. A deepwater port at Owendo is due to be completed in 1973. Situated approximately nine miles south-east from the centre of Libreville, it will serve both as a commercial port and as a mining port—the terminus of the Belinga-Owendo railway containing installations for treating raw materials before exporting them by sea.

Without the discovery of iron deposits at Belinga in the northeast, Gabon might not have been able to convince investors of the necessity for a railroad. As it is, the construction of the "Transgabonais"—as the railroad is generally known—forms part of the larger scheme to open up Belinga for exploitation by connecting it with the port of Owendo. While private interests are providing

The ports

the bulk of the funds, the French and Gabon governments have each contributed about U.S. \$15,000,000 towards the projected cost of U.S. \$362,000,000. West Germany has contributed U.S. \$7,500,000, and it is expected that the World Bank will also make some funds available. In the early 1970s, the first section from Owendo to Booué had been completed, enabling timber companies to consider opening up new land; the new rail link may also lead to development of some of the rich farm land of the north.

Air travel connections are poor, although two lines link Libreville and Port-Gentil with Paris and cities elsewhere in Africa. Domestic air service is provided by three companies, whose planes land at one or another of about 30 public and more than 50 private airports (many of the latter connected with the petroleum or forestry industries). Of the public airports (aside from the two international ones), 13 are for light planes only.

**Administration and social conditions.** According to the revised constitution of February 15, 1967, Gabon is a republic under the executive direction of a president elected by direct universal suffrage for a period of seven years. Provision is also made for a National Assembly of 47 members to assume legislative responsibilities and for an independent Supreme Court. A two-party system does not, however, exist. In 1968, the Democratic Party of Gabon (PDG) was declared the only legal party permitted to exist by the state, and the president and head of state himself assumed the portfolios of the ministries of national defense, planning, development, and (most recently) mines. The trend seems to be toward centralization of power in one man, ostensibly in the service of national unity and economic progress. The president was, nevertheless, democratically elected; he helped to promote harmony by pardoning a number of prisoners involved in an earlier coup.

Administratively, Gabon is divided into nine regions, each consisting of many districts. A prefect heads each region, and there is a subprefect in charge of each district.

The judicial system consists of a series of customary law courts at the lowest level, above which jurisdiction moves upwards to a criminal court, a court of appeals, and the Supreme Court (all three of which are located in Libreville).

In the early 1970s, the armed forces comprised an army of 900 men (one infantry battalion, two commando companies, one reconnaissance squadron); a navy of 50 men with one patrol vessel; and an air force of approximately 160 men with no equipment to speak of. There was also a gendarmerie of 850 men and a civil police of 900.

#### Education

Education has been made mandatory from ages six to 16 in a massive effort to counter what was once an alarming illiteracy rate. By 1971 the program had achieved some results—literacy was variously estimated at between 20 and 35 percent of the total population over 13 years of age. In early 1972 there were about 106,000 pupils in primary schools; over 9,000 (not counting foreign students) in secondary schools; and over 1,800 in technical schools; about 700 students were also studying at universities abroad. In Libreville, various technical and administrative courses at different "pre-university" levels are available, and a University of Gabon is in the planning stages.

In the early 1970s, health facilities were still inadequate. In 1969 there were a total of some 5,000 hospital beds available, including those in leprosy institutions. The ratio of doctors to patients averages one for every 5,100; the doctors are assisted by a handful of sanitary engineers, nurses, and midwives.

**Cultural life and institutions.** Radio-Gabon at Libreville possesses three transmitters, which broadcast nationally, and one regional band. Radio-Moanda-Franceville has one transmitter serving that region alone. There are two television stations—one at Libreville and one at Port-Gentil. The *Gabon Matin* newspaper (published by the Gabonese Press Agency, Libreville) appears daily. *Gabon d'Aujourd'hui* (published by the Ministry of Information, Libreville) appears weekly; and a monthly re-

view entitled *Actualités gabonaises* is produced by the Embassy of Gabon in Paris. Another monthly, *Patrie Gabonaise*, is published in Libreville.

**Prospects for the future.** Always one of the wealthier African nations, Gabon entered the 1970s with a rapidly expanding economy and the probability of wider horizons opening up once her great store of iron, uranium, petroleum, and manganese was made fully available for exploitation. This type of development effort, however, demands a disproportionate amount of foreign investment, with the chance that—particularly in relation to France—the country could find itself in the de facto situation of a "client-state." The country hopes that a policy of "Gabonization" of the economy may forestall any such situation, but without a trained cadre of workers, whether bureaucratic or technical, Gabon will remain dependent on the French. The desperate quest for foreign capital could also lead to friction with African neighbours, particularly the majority of members of the Organization of African Unity, who do not look with favour on Gabon's proposal of a "dialogue" with South Africa—a dialogue designed primarily to attract investment. While the country obviously needs such investment, some degree of political restraint would at the same time seem desirable as Gabon moves more into the centre of the African political and economic arena. The solidity of the economy would, however, seem to guarantee a high degree of internal political stability.

**BIBLIOGRAPHY.** Historical background useful for an in-depth understanding of Gabon's current political, cultural, and economic status is provided in VIRGINIA THOMPSON and RICHARD ADLOFF, *The Emerging States of French Equatorial Africa* (1960); and with a more contemporary focus in EUROPA PUBLICATIONS, *Africa South of the Sahara* (1971). The best English-language review of political and economic developments in the country is contained in COLIN LEGUM and JOHN DRYSDALE (eds.), *Africa Contemporary Record: Annual Survey and Documents* (1968–). The editors combine incisive analysis with solid statistical material. French sources such as "L'Afrique d'expression française et Madagascar," *Europe France Outremer*, 11th ed. (1971), tend to inflate figures slightly; but this volume and its 1970 supplement, *L'Economie Gabonaise: dix ans de progrès*, no. 486 (1970), give detailed analyses and much factual information on all aspects of contemporary Gabonese life. Monthly statistical surveys are also published in the *Bulletin Mensuel de la Statistique de la République Gabonaise*. Specific social and developmental problems and outlines of proposed solutions are discussed in the WORLD COUNCIL OF CHURCHES, *Ecumenical Programme for Emergency Action in Africa* (1967); and in the *World Food Program Interim Evaluation Report on Gabon* (1971). Documentation on the work of voluntary agencies in the country may be found in the U.N. *Economic and Social Council Directory of Activities of Non-Governmental Organizations in Rural Development in Africa* (1971). Information on the religious situation is contained in both H. WAKELIN COXILL et al. (eds.), *World Christian Handbook* (1967); and in the *North American Protestant Ministries Overseas Directory*, 9th ed. (1970).

(J.v.H.)

#### Gabrieli Family

The two composers Andrea and Giovanni Gabrieli, uncle and nephew, made a contribution to the development of music in Venice in the late 16th and early 17th centuries that proved to be of great significance in the history of music in general. This was because of Venice's pre-eminent position as a cultural, artistic, and musical centre during the late Renaissance. Independent of Rome and the papacy, Venice was the focus for liberal ideas in the arts, but, like any other large Italian city at the time, it also had a court life of splendour. The basilica of St. Mark's, where the Gabrieli were organists, was the doge (duke) of Venice's chapel, not an ecclesiastical entity on its own, so that the music with which its musicians were involved was concerned as much with the pomp and ceremony of court and civic events as with the liturgy of the church. The civic pride and culture of Venice's mercantile middle class also helped to foster music, and Venice was the centre of music printing throughout this period, resulting in the dissemination of an enormous amount of Venetian music. Such considerations of en-

vironment are as important as the genius of the two Gabrieli themselves in accounting for the fame they achieved in their lifetime, a fame fully appreciated in the 20th century.

**Andrea Gabrieli.** He was born c. 1520 in the Cannareggio (now Cannareggio) quarter of Venice, but nothing is known about Andrea Gabrieli until 1536, when he became a singer at St. Mark's and a pupil of its music director, the great Franco-Flemish composer Adriaan Willaert. From Willaert he learned the art of writing polyphonic motets (choral settings in four or more vocal parts) and in particular that of composing for separated choirs placed in different parts of the church with consequent stereophonic effect, a new and exciting way of exploiting the acoustical properties of a large building like St. Mark's. It is possible that Andrea was a singer at Verona Cathedral around 1550. In 1558 he became organist at the church of S. Geremia in Venice but soon left for an extended period of foreign travel. He served in the Bavarian court chapel at Munich under another great Franco-Flemish, Orlando di Lasso, then visited the court of Graz in Austria, and finally was patronized by the noble Fugger family in Augsburg. This transalpine sojourn afforded a chance for Andrea to cement Venetian ties, musically, with Catholic areas to the north.

Organist at  
St. Mark's

In 1564 he returned to Venice to become second organist at St. Mark's, which he remained until 1584, when he succeeded the virtuoso performer Claudio Merulo as first organist—a position he held until his death in 1586. Despite his profession, not much of his output in these years was organ music; there were several volumes of madrigals, socially enjoyable settings of Italian poetry to be sung at private houses or cultural academies, where musical life flourished. And there was the large-scale choral and instrumental music for ceremonies of church and state, for which Andrea is best known today. Some of these works were published posthumously in 1587: one of the finest is the *Magnificat* for three choirs and orchestra, doubtless intended to be performed in St. Mark's.

**Giovanni Gabrieli.** Born probably in 1556, Giovanni Gabrieli studied with his uncle, whom he regarded with almost filial affection. To the latter's foreign travels and connections, Giovanni owed his chance to become known abroad. Giovanni also served (1575–79) under di Lasso in Munich, during which time his early talent and fame were apparent (one of his madrigals was published in 1575 in a collection of Munich composers). In 1584 he returned to Venice and a year later succeeded his uncle as second organist of St. Mark's—the post he held for life. After Andrea's death in 1586, Giovanni quickly assumed the limelight in the field of ceremonial music, though he was never so active as a madrigalist. The publication of his uncle's music in 1587 was a mark of respect but also included some of his own church music, which demonstrated his musical debt to Andrea. Giovanni's foreign connections included Hans Leo Hassler, the German composer and former pupil of Andrea, who avidly adopted the Venetian style; and patrons, such as the Fugger family and archduke Ferdinand of Austria. In later years Giovanni became a famous teacher who attracted many pupils from northern Europe. His most notable student was the German Heinrich Schütz, who studied with Gabrieli from 1609 to 1612. After 1587 Giovanni's principal publications were the two immense *Sacrae symphoniae* of 1597 and 1615 (printed posthumously), both of which contained purely instrumental music for church use or massive choral and instrumental motets for the liturgy. Like his uncle, he usually conceived the music for separated choirs but showed an increasing tendency to specify which instruments were to be used and which choirs were to consist of soloists and full choir, as well as to distinguish the musical style of each, thus initiating a completely new approach to the creation of musical colour and orchestration. In the well-known *Sonata pian'e forte*, for eight instruments, directions to play loud and soft are given. Among the motets, his masterpiece is perhaps *In ecclesiis*, for four soloists, four-part choir, violin, three cornets, two trombones, and

organ, these forces pitted against one another in an endless variety of combinations.

There is no record of Giovanni's marriage, but because he often pleaded for a salary advance from the St. Mark's authorities "on account of his numerous family," he obviously had a wife and children. He died in Venice, probably on August 12, 1612.

#### MAJOR WORKS

##### *Andrea Gabrieli*

Madrigals for three to six voices in various collections; masses in six parts, *Primus liber missarum* (1572); *Magnificat* for three choirs; motets; various *ricercari* and *canzoni*.

##### *Giovanni Gabrieli*

Various motets, among them *In ecclesiis*; madrigals in various collections; *Canzoni e sonate* (1615); *Sacrae symphoniae*, book 1 (1597), including the *Sonata pian'e forte*; *Sacrae symphoniae* (1615); *Concerti di Andrea et di Giovanni Gabrieli a 6–16 voci* (1587, containing pieces by Andrea).

**BIBLIOGRAPHY.** E.F. KENTON, *The Life and Works of Giovanni Gabrieli* (1967), is not very reliable and tends to contradict itself. The best feature is the thematic index, though this is difficult to use. The opening chapters are a translation of those from C. VON WINTERFELD, *Johannes Gabrieli und sein Zeitalter*, 3 vol. (1834), still the definitive work on Giovanni. More recent summary information and stylistic criticism may be found in G. REESE, *Music in the Renaissance* (1954).

(J.L.A.R.)

## Gainsborough, Thomas

Of all the 18th-century English painters, Thomas Gainsborough was the most versatile and original, always prepared to experiment with new ideas and techniques. He alone among the great portrait painters of the era also devoted serious attention to landscapes. Unlike his contemporary Sir Joshua Reynolds, he was no great believer in an academic tradition and laughed at the fashion for history painting; an instinctive painter, he delighted in the poetry of paint. In his racy letters Gainsborough shows a warm-hearted and generous character and an independent mind. His comments on his own work and methods, as well as on some of the old masters, are very revealing and throw considerable light on contemporary views of art.

Career as  
a teacher

**Early life and Suffolk period.** Gainsborough was baptized at Sudbury in Suffolk on May 14, 1727, the youngest son of John Gainsborough, a maker of woollen goods. When he was 13, he persuaded his father to send him to London to study on the strength of his promise at landscape. He worked as an assistant to Hubert Gravelot, a French painter and engraver and an important figure in London art circles at the time. From him Gainsborough learned something of the French Rococo idiom, which had a considerable influence on the development of his style. In 1746 in London he married Margaret Burr, the illegitimate daughter of the Duke of Beaufort. Soon afterward he returned to Suffolk and settled in Ipswich in 1752; his daughters Mary and Margaret were born in 1748 and 1752. In Ipswich Gainsborough met his first biographer, Philip Thicknesse. He early acquired some reputation as a portrait and landscape painter and made an adequate living.

Gainsborough declared that his first love was landscape and began to learn the language of this art from the Dutch 17th-century landscapists, who by 1740 were becoming popular with English collectors; his first landscapes were influenced by Jan Wynants. The earliest dated picture with a landscape background is a study of a bull terrier—"Bumper—A Bull Terrier" (1745; Sir Edward Bacon Collection, Raveningham, Norfolk), in which many of the details are taken straight from Wynants. But by 1748, when he painted "Cornard Wood," Jacob van Ruysdael had become the predominant influence; although it is full of naturalistic detail, Gainsborough probably never painted directly from nature. "The Charterhouse," one of his few topographical views, dates from the same year as "Cornard Wood" and in the subtle effect of light on various surfaces proclaims Dutch influence. In the background to "Mr. and Mrs. Andrews," he anticipates the realism of the great English landscapist of the next century, John Constable, but for the most part fancy held sway. In many of the early landscapes the influence of Rococo design learned from Gravelot is evident, together with a feeling for the French pastoral tradition. "The Woodcutter Courting a Milkmaid" is an Anglicized version of a French theme, which recalls compositions by Jean-Honoré Fragonard. Although Gainsborough preferred landscape, he knew he must paint portraits for economic reasons. The small heads painted in Suffolk, although sometimes rather stiff, are penetrating character studies delicately and freely pencilled, particularly the jaunty self-portrait in a cocked hat at Houghton. Gainsborough painted few full-length portraits in Suffolk. "Mr. William Woollaston," although an ambitious composition, is intimate and informal. The "Painter's Daughters Chasing a Butterfly," composed in the last years at Ipswich, is, in its easy naturalism and sympathetic understanding, one of the best English portraits of children.

As well as straight portraits, he painted in Suffolk a number of delightful spontaneous groups of small figures in landscapes closely related to conversation pieces. "Mr. and Mrs. Andrews," which has been described as the most English of English pictures, is set in a typical Suffolk landscape. "Lady and Gentleman in Landscape" is more Frenchified, with its vivacious Rococo rhythms, but "Heneage Lloyd and His Sister" is more stylized, the charming little figures being posed against a conventional background of steps and decorative urns.

**Bath period.** To obtain a wider public, Gainsborough moved in 1759 to Bath, where his studio was soon thronged with fashionable sitters. He moved in musical and theatrical circles, and among his friends were members of the Linley family, whose portraits he painted. At Bath he also met the actor David Garrick, for whom he had a profound admiration and whom he painted on many occasions. His passion for music and the stage continued throughout his life. In the west country he visited many of the great houses and at Wilton fell under the spell of Anthony Van Dyck, the predominating influence in his later work. In spite of the demand for portraits, he continued to paint landscapes.

In 1761 he sent a portrait of Earl Nugent to the Society

of Artists, and in the following year the first notice of his work appeared in the London press. Throughout the 1760s he exhibited regularly in London and in 1768 was elected a foundation member of the Royal Academy. Characteristically he never took much part in the deliberations.

After he moved to Bath, Gainsborough had less time for landscape and worked a good deal from memory, often drawing by candlelight from little model landscapes set up in his studio. About 1760 Peter Paul Rubens supplanted the Dutch painters as Gainsborough's chief love. This is particularly noticeable in "Peasants Returning from Market," with its rich colour and beautiful creamy pastel shades. The influence of Rubens is also apparent in "The Harvest Wagon" in the fluency of the drawing and the scale of the great beech trees so different from the stubby oaks of Suffolk. The idyllic scene is a perfect blend of the real and the ideal. The group in the cart is based on Rubens' "Descent from the Cross" (1611–14) in Antwerp Cathedral, which Gainsborough copied.

In Bath, Gainsborough had to satisfy a more sophisticated clientele and adopted a more formal and elegant portrait style based largely on a study of Van Dyck at Wilton, where he made a free copy of Van Dyck's painting of the Pembroke family. By 1769, when he painted "Isabella Countess of Sefton," it is easy to see the refining influence of Van Dyck in the dignified simplicity of the design and the subtle muted colouring. One of Gainsborough's most famous pictures, "The Blue Boy," was probably painted in 1770. In painting this subject in Van Dyck dress, he was following an 18th-century fashion in painting, as well as doing homage to his hero. The influence of Van Dyck is most clearly seen in the more official portraits. "John, 4th Duke of Argyll" in his splendid robes is composed in the grand manner, and "Augustus John, Third Earl of Bristol" rivals Reynolds' portraits of the kind. Gainsborough preferred to paint his friends rather than public figures, and a group of portraits of the 1760s—Uvedale Price, Sir William St. Quinton, and Thomas Coward, all oldish men of strong character—illustrate Gainsborough's sense of humor and his individual approach to sympathetic sitters.

**London period.** In 1774 he moved to London and settled in part of Schomberg House in Pall Mall. Fairly soon he began to be noticed by the royal family and partly because of his informality and Tory politics was preferred by George III above the official court painter, Sir Joshua Reynolds. In 1781 he was commissioned to paint the King and Queen.

Gainsborough continued his landscape work. "The Watling Place" was described by Horace Walpole, the English man of letters, as in the style of Rubens, but it also has much of the classic calm of Claude Lorrain, whose etchings Gainsborough owned. In 1783 he made an expedition to the Lake District to see for himself the "wild" scenery extolled by the devotees of the picturesque. On his return he painted a number of mountain scenes that have analogies with the work of Gaspar Dughet, whose works were widely distributed in English country houses. Some sea pieces dating from the 1780s show a new kind of realism, harking back to the Dutch seascape tradition. During his last years Gainsborough was haunted by his nostalgia for Arcadia in the English countryside and painted a series of pictures of peasant life more ideal than real, for example, "The Cottage Door." But one of the latest landscapes, "The Market Cart," is less idealized and more true to nature and looks forward to Constable in its treatment of the light breaking through the massive foliage.

Gainsborough was the only important English portrait painter to devote much time to landscape drawing. He composed a great many drawings in a variety of mediums including chalk, pen and wash, and watercolour, some of them varnished. He was always eager to find new papers and new techniques. He produced a magic lantern to give striking lighting effects; the box is still in the Victoria and Albert Museum, together with some of the slides. In addition Gainsborough made a series of soft-ground etchings and aquatints. He never sold his drawings and, al-

Early  
landscapes

Influence  
of  
Van Dyck

Idealized  
country  
scenes

though many of them are closely related to pictures, they are not studies in the ordinary sense but works of art in their own right.

Gainsborough was not methodical in keeping sitter books, and comparatively few of the portraits in the early years in London are dated. In 1777 he exhibited at the Royal Academy the well-known "Mrs. Graham," "C.F. Abel," "William Henry, Duke of Gloucester," and "Maria, Duchess of Gloucester," all deliberately glamorous and painted in richly heightened colour. "Queen Charlotte" is more restrained; the painting of the flounced white dress decorated with ribbons and laces makes her look every inch a queen. It is significant that Gainsborough, unlike most of his contemporaries, did not generally use drapery painters. In 1784 he quarrelled with the Academy because they insisted on hanging the "Three Eldest Princesses" at the normal height from the floor, which Gainsborough maintained was too high to appreciate his lightness of touch and delicate pencilling. In protest he withdrew the pictures he had intended for the exhibition and never showed again at the Academy.

In some of Gainsborough's later portraits of women, he dispensed with precise finish, and, without sacrificing the likeness, he concentrated on the general effect. "Mrs. Sheridan" melts into the landscape, while "Lady Bate Dudley," a symphony in blue and green, is an insubstantial form, almost an abstract. "Mrs. Siddons," on the other hand, shows that Gainsborough could still paint a splendid objective study. Few of the later male portraits are of a pronounced character, but exceptions are two particularly good pictures of musicians, "Johann Christian Fischer" and the unfinished "Lord Abingdon" (private collection).

A new venture in 1783 was "The Mall in St. James' Park," a park scene described by Horace Walpole as "all a flutter like a lady's fan." "The Morning Walk," with romanticized figures strolling in a landscape, is painted in the same spirit.

The "fancy pictures" painted in the 1780s gave Gainsborough particular pleasure. They are full-sized, idealized portraits of country children and peasants painted from models—for example, "The Cottage Girl with a Bowl of Milk." The idea appeared in immature form in the little rustic Suffolk figures, and he may have been fired to exploit it further by seeing the 17th-century Spanish painter Bartolomé Murillo's "St. John," which he copied.

He died August 2, 1788, and was buried in Kew churchyard. Gainsborough was the most inventive and original of 18th-century portraitists, and yet he complained of Reynolds, "Damn him, how various he is."

#### MAJOR WORKS

##### Paintings

PORTRAITS: "Lady and Gentleman in Landscape" (1746; Louvre, Paris); "Mr. and Mrs. Andrews" (c. 1750; National Gallery, London); "Heneage Lloyd and His Sister" (c. 1750; Fitzwilliam Museum, Cambridge); "Mr. William Woollaston" (late 1750s; Christchurch Mansion Museum, Ipswich); "Painter's Daughters Chasing a Butterfly" (c. 1758; National Gallery, London); "Ann Ford, Mrs. Philip Thicknesse" (1760; Cincinnati Art Museum); "Maria, Duchess of Gloucester" (early 1760s; Los Angeles County Museum); "Gertrude, Lady Alston" (mid-1760s; Louvre); "John, 4th Duke of Argyll" (1767; Scottish National Portrait Gallery, Edinburgh); "Hon. Thomas Needham" (1768; Ascott House, Berkshire); "John, 10th Viscount Kilmorey" (c. 1768; Tate Gallery, London); "Augustus John, Third Earl of Bristol" (1768; National Trust, Ickworth); "Isabella, Countess of Sefton" (1769; Croxeth Hall, Lancashire); "The Blue Boy" (c. 1770; Henry E. Huntington Library and Art Gallery, San Marino, California); "Penelope, Viscountess Ligonier" (1771; Henry E. Huntington Library and Art Gallery); "Dr. Ralph Schomberg" (1771-72; National Gallery, London); "The Linley Sisters—Mrs. Sheridan and Mrs. Tickell" (c. 1772; Dulwich College Picture Gallery, Dulwich); "William Henry, Duke of Gloucester" (c. 1775; Chewton Manor, North Somerset, Somerset); "Mrs. Graham" (c. 1777; National Gallery of Scotland, Edinburgh); "C. F. Abel" (1777; Henry E. Huntington Library and Art Gallery); "Johann Christian Fischer" (1780; Buckingham Palace, London); "Mrs. Robinson," popularly nicknamed "Perdita," (1781; Wallace Collection, London); "Queen Charlotte" (1781; Windsor Castle); "Lord Rodney" (1783; Earl of Roseberry Collection, Dalmeny, West

Lothian); "Mrs. Siddons" (c. 1783; National Gallery, London); "Three Eldest Princesses," also called "Princess Charlotte and Her Two Sisters," (1784, painted for the Royal Academy but not exhibited; Buckingham Palace); "Mrs. Sheridan" (c. 1785; National Gallery of Art, Washington, D.C.); "Lady Bate Dudley" (1787; Lord Burton Collection, Needwood House, Derbyshire).

LANDSCAPES AND "FANCY PICTURES": "The Charterhouse" (1748; Foundling Hospital, London); "Cornard Wood," popularly nicknamed "Gainsborough's Forest" (1748; National Gallery, London); "The Woodcutter Courting a Milkmaid" (1753; Duke of Bedford Collection, Woburn Abbey, Bedfordshire); "Peasants Returning from Market" (c. 1767; Toledo Museum of Art, Ohio); "The Harvest Wagon" (c. 1770; Barber Institute, Birmingham, England); "The Watering Place" (1777; National Gallery, London); "The Cottage Door" (c. 1780; Henry E. Huntington Library and Art Gallery, San Marino, California); "The Mall in St. James' Park" (1783; Frick Collection, New York); "The Morning Walk" (1785; National Gallery, London); "The Cottage with Dog and Pitcher" (1785; Sir Alfred Beit Collection, Russborough, Co. Wicklow, Ireland); "The Cottage Girl with a Bowl of Milk" (1786; South African National Gallery, Capetown); "The Market Cart" (1786; Tate Gallery, London); "The Wood Gatherers," also known as "Cottage Children" (1787; Metropolitan Museum of Art, New York); "Boy with a Cat-Morning" (1787; Metropolitan Museum of Art, New York).

**BIBLIOGRAPHY.** WILLIAM T. WHITLEY, *Thomas Gainsborough* (1915), the definitive biography; ELLIS WATERHOUSE, *Gainsborough* (1958), the most complete catalog of the paintings, very fully illustrated with an important critical introductory essay; MARY WOODALL (ed.), *The Letters of Thomas Gainsborough*, rev. ed. (1963); JOHN HAYES, *The Drawings of Thomas Gainsborough*, 2 vol. (1970), the definitive work on the drawings with a catalog of 900 items, 462 illustrations, and a full up-to-date bibliography of Gainsborough literature.

(M.Wo.)

## Gajah Mada

The prime minister of the Majapahit empire, which ruled Java in the 13th-16th century, Gajah Mada is believed to have united the whole of Indonesia in the 14th century. No information is available on his early life, except that he was born a commoner. He rose to power on his intelligence, courage, and loyalty to King Jayanagara (1309-28) during a rebellion led by Kuti in 1319. He served as the head of the royal bodyguard that escorted King Jayanagara to Badander, when Kuti captured the capital of Majapahit. After finding a safe place for the King, he returned to the capital and spread the rumour that the King had been killed. He discovered that many officers were upset by the King's supposed death and that Kuti was apparently unpopular among the people. Knowing, therefore, that the King still had loyal followers, Gajah Mada secretly organized a counterinsurrection, in which Kuti was killed and the King was restored. As a reward, Gajah Mada was appointed as the *patih* (minister) of Daha and, later, the *patih* of Daha and Janggala, a position that made him a member of the ruling elite. Prapanca, a court poet and historian, described Gajah Mada as "eloquent, sharp of speech, upright, and sober-minded."

Gajah Mada's loyalty to Jayanagara waned, however, when the King took possession of his wife. In 1328, when Jayanagara was ill, Gajah Mada instructed Tancha, the court physician, to kill the King during an operation. Upon the death of the King, Tancha was blamed and executed by Gajah Mada. Since the King had no son, his daughter Tribhuvana became ruler.

During the reign of Tribhuvana (1328-50), Gajah Mada gradually became the most powerful figure in Majapahit. In 1331 a rebellion took place in Sadeng (eastern Java). Gajah Mada immediately sent a military expedition to the area, but a minister of Majapahit named Kembar attempted to stop him from entering Sadeng. Gajah Mada broke the blockade and won the battle.

Upon his return, Gajah Mada was appointed as *mapatih*, or prime minister, of Majapahit. At the same time, he took a solemn oath before the council of ministers that he would not enjoy *palapa* (privileges of vacation or the revenue from his fief) before he conquered the whole archipelago for Majapahit. When Kembar and other ministers ridiculed this fantastic boast, Gajah Mada, with

Later  
portraits

Rise to  
power

the help of the Queen, removed Kembar and his followers from office. In 1343, in accordance with his plans, Gajah Mada led a military expedition that conquered Bali.

Tribhuvana abdicated in 1350 and was succeeded by her son Hayam Wuruk, perhaps the best-known king of Majapahit. During his reign, Majapahit reached the zenith of its power and controlled the whole of the Indonesian archipelago. The young king seemed content to leave the direction of affairs entirely in the hands of his prime minister.

The year after Hayam Wuruk's accession, Gajah Mada attempted to spread Majapahit influence to the western Java kingdom of Sunda. He sent a mission to Sunda expressing the wish of Hayam Wuruk to marry the daughter of the King of Sunda. The King consented and brought the Princess, together with some of his noblemen, to Majapahit. They camped in Bubad, north of the capital, in a large field where the wedding was supposed to take place. A disagreement ensued between Gajah Mada and the Sundanese king. The former wanted the King to surrender the Princess to Hayam Wuruk, but the King and his noblemen insisted that the Princess, as the queen of Majapahit, should have a status equal to that of Hayam Wuruk.

Gajah Mada brought in troops and intended to decide the issue by force. The Sundanese noblemen preferred death to dishonour; instead of a happy wedding, a bloody massacre took place. The King of Sunda was killed, as were the Princess and the Sundanese noblemen. After the massacre, Sunda seems to have acknowledged the overlordship of Majapahit for a time but, ultimately, recovered its independence.

Terra-cotta head identified as Gajah Mada. In the Trawulan Site Museum, Indonesia.

To glorify his power, Gajah Mada built a temple on the boundary line of Singhasari kingdom in eastern Java to equate himself with the last king of Singhasari. It was under his patronage that Prapanca began the composition of *Nāgarakertāgama*, the epic of Majapahit. A law book that had a great significance in Javanese history was also compiled under his instructions.

Gajah Mada also played a major role in the direction of internal policy. He occupied numerous positions, including that of chief officer of the palace. The range of his activities was so great that when he died, Hayam Wuruk found it necessary to appoint four ministers to take over the positions that had previously been the responsibility of Gajah Mada alone. Gajah Mada's death (1364) occurred under mysterious circumstances. Some writers claim that he was poisoned by Hayam Wuruk, who had come to fear his minister's power. The evidence, however, is inconclusive.

Gajah Mada's role in unifying the Indonesian archipelago caused early Indonesian nationalists to consider him a great national hero, and the first Indonesian university in Jogjakarta, established in 1946, was named after him.

## Galápagos Islands

The Galápagos archipelago (Archipiélago de Colón) in the Pacific Ocean lies athwart the Equator about 600 miles west of the coast of Ecuador. It consists of 16 islands, as well as numerous islets and rocks, with a total area amounting to 3,000 square miles (8,000 square kilometres), scattered over approximately 23,000 square miles (60,000 square kilometres) of ocean. The islands are formed of lava piles, dotted with volcanoes that are not all extinct.

The archipelago, the geologic origin of which remains in dispute, is renowned for its unusual animal life. It takes its name from its giant land tortoises (the old Spanish word for which is *galápagos*), which are considered among the oldest living creatures on earth. Discovered in 1535, the islands remained unsettled until 1832, when Ecuador annexed them. The islands became internationally famous after Charles Darwin (*q.v.*), the English naturalist generally credited with being the originator of the theory of evolution, visited the islands in 1835 and, from his observations of animal life there, received inspiration for many of his views on natural selection. The population of the islands numbered about 3,800 in 1971; it consisted mainly of Ecuadorians, who subsist on agriculture and fisheries.

The nomenclature of the islands tends to be confusing. In 1832 the group was renamed Archipiélago de Colón, but this name has not been generally used; even Ecuadorians call the islands the Galápagos. Most of the islands have at least two and sometimes more names. The English names of individual islands date from the 18th-century buccaneering era. The official Spanish names from 1832 are replacing the old ones in common use, but in scientific literature the old names are still preferred.

The largest of the islands, Isabela (Albemarle), is approximately 82 miles long and comprises more than half of the total land area of the archipelago. In places it reaches heights of 5,600 feet above sea level. The second largest island is Santa Cruz (Indefatigable Island), upon which the Charles Darwin biological station is located. It is sponsored by the Ecuadorian government in cooperation with the Charles Darwin Foundation in Brussels, Belgium, and has been established to promote scientific studies and to protect the indigenous vegetation and animal life.

**Geomorphology.** The archipelago is of volcanic origin. The islands are located along fracture zones in the earth's crust that run north-northwest and are crossed by other fracture lines running east-northeast.

The islands themselves are mainly shield volcanoes (volcanoes formed from lava flows, which make gently sloping, broadly rounded cones) and volcanic rocks that rise from 7,000 to 10,000 feet above the sea floor and up to 6,000 feet above sea level. Most of the volcanoes measure 10 to 20 miles across at the base. The calderas (a caldera is a crater, the diameter of which is many times that of the volcanic vent, that is formed either by the collapse of the central part of the volcano or by explosions of unusual violence) at the summits are large and deep; that on Fernandina Island (Narborough) is 2 by 4½ miles across, and 2,700 feet deep. The largest caldera is Volcan Sierra Negra in southeast Isabela, measuring about six to four miles across. The age of the islands is unknown, but beds of rock containing fossils on Santa Cruz and Baltra (South Seymour) islands date to the Pliocene Epoch, which lasted from 7,000,000 to 4,500,000

Volcanoes

years ago. Potassium-argon dating, a radioactive method of determining age (see DATING, RELATIVE AND ABSOLUTE), indicates that the oldest lavas on Española (Hood Island) are 2,000,000 years old. Recent volcanic eruptions have occurred on Fernandina (1968) and on Isabela (1957 and 1963) as well as on Pinta (Abingdon), Marchena (Bindloe), and San Salvador (James).

The rocks forming the islands are predominately basalts—blackish fine-grained rocks, formed under heat and pressure—most of which contain large crystals of plagioclase, one of the commonest rock-forming minerals. A few rocks are rich in olivine, a silicate formed of magnesium and iron, after which andesites, dark-grayish volcanic rocks, are the most frequently encountered.

Older theories assuming a former land connection with South America have now been abandoned, since there is neither geological nor other evidence to support them. The submarine platform from which the islands arise is separated by a trench from the continental shelf.

The rugged appearance of the landscape is striking. The high volcanoes of the western islands are scarred by recent lava flows and marked by numerous volcanic craters. Bizarre cliffs guard the coastline. The older islands are worn down and appear less spectacular.

**Climate.** The climate is characterized by low rainfall, low humidity, and relatively low air and water temperatures. These peculiarities are caused by the Humboldt Current, a cold ocean current coming from the south. The cool layer of air above the current moves landward, then warms up, and desiccates the islands. Only the higher regions experience precipitation—amounting to about 50 inches a year—during most seasons, and permanent freshwater lakes and ponds are found only at these levels. Mean daily maximum temperatures along the coast range from 80° to 88° F (26° to 31° C), while minimum temperatures range from 66° to 74° F (18° to 27° C).

Effects of  
the trade  
winds

The islands lie in the path of the southeast trade winds, which, when crossing the Equator, curve to the west, so that their usual direction is nearly south. In July and August a subsidiary wind system is dominant and curves east. The prevailing currents run toward the west and northwest at an average speed of one knot (1.15 mph). The surface water is warmest (80° F or 26° C) during January to April; from July to September the temperature drops to 62° F (16° C). Low stratus clouds predominate from April to December. They break up during the day and form again at night. On the windward side they are thicker, causing fog rains, called *garúa*, in the upper regions. The heaviest drizzle occurs from June to December, called the *garúa* season. The coastal regions experience a relatively dry season at this time. From January to May the highlands have a dry season with much sunshine and only occasional showers; at the same time, however, a rainy season occurs in the arid lowlands. Average annual rainfall on the coast amounts to ten inches. February to April are the warmest months and August to October the coolest.

**Vegetation.** There are about 700 species of higher plants. Of these, 250 species, or 40 percent, are endemic. The plant life shows close affinities to that of South and Central America.

Due to the climatic changes at different altitudes four main vegetational zones can be distinguished. These are: (1) The arid lowlands, which are covered by an open cactus forest. (2) The transition zone, covered with a forest in which pisonia, fish fuddle, and guava trees dominate. The underbrush is dense. Cacti occur only in the lower half of this zone. (3) The moist forest region, which is dominated by a *Scalesia* forest (a relict form of vegetation) with dense underbrush. (4) The treeless upland zone, which is covered with ferns and grasses.

**Animal life.** The close affinities to the fauna of South and Central America demonstrate that the bulk of the island animals originated there. The difficulty of crossing the ocean accounts for the paucity of animal life. The British Isles, for example, possess over 20,000 species of insects, whereas only about 700 species have been named in the Galápagos Islands so far. The same pattern pre-

vails for other forms of animal life. Amphibians are lacking, reptiles are poorly represented, and land mammals are represented by only seven rodents and two bats. There are only about 80 species and subspecies of birds breeding on the islands; the bulk of land birds consist of the Darwin finches, named for the English naturalist.

Galápagos animal life is nevertheless of extreme interest for several reasons, which include the following. Firstly, there is a high percentage of endemic forms; all of the reptiles, with the exception of one night lizard, and most of the resident birds are endemic. Secondly, species have developed subspecies on the different islands. Thirdly, the Darwin finches have developed a multitude of adaptive types from one common ancestor. They differ mainly in beak shape and size. Fourthly, there are many other types that have evolved by adaptation. The marine iguanas, for example, which feed on seaweed and in some places cover the coastal rocks in hundreds, are unique. Another species of interest is the flightless cormorant. Fifthly, the giant tortoises survive as a relic on the larger islands. Giant tortoises were once widespread on the continents but became extinct. (The only other giant tortoises to survive are a different species, found in the Seychelles Islands in the Indian Ocean.) Sixthly, many terrestrial vertebrates show a striking lack of fear of land predators and of man. In addition, species of Antarctic origin, such as penguins and fur seals, live on the islands side by side with tropical animals.

The endemic Galápagos animals are today endangered by numerous animals that have been introduced and run wild. Goats, for example, compete with endemic types for food, while hogs, dogs, cats, and introduced rats attack mainly the eggs and young of the reptiles and birds. Both animals and plants are protected by laws, which are enforced by the Darwin Foundation. Many of the islands have the formal status of nature reserves.

**The inhabitants.** The island settlers, who are mostly Ecuadorians but also include some Europeans, live in small settlements on San Cristóbal (Chatham), Santa María (Charles), Isabela, and Santa Cruz islands. Fishing and agriculture are the two main sources of income. The islands were discovered in 1535 by Bishop Tomás de Berlanga. They were first marked on a map in 1570 by the Flemish cartographer Abraham Ortelius. They were later frequented by English buccaneers, and later still by whaling ships.

**Economic resources.** In the past, shipping, and especially Pacific whalers, visited the islands to obtain supplies of water and giant tortoises. Today wild goats live on many of the islands; wild cattle, a source of food for the settlers, are common on Isabela, Santa Cruz, Santa María, and San Salvador.

Less than 4 percent of the land area of the islands is fit for agriculture. Parts of the moist highlands on Santa Cruz, San Cristóbal, Santa María, and southern Isabela are cultivated, producing common vegetables, tropical fruits, and field crops. Coffee is exported to the mainland. Cattle are also raised for export. The people living close to the coast subsist mainly by fishing; groupers (large fish related to the sea bass) form the most profitable export. Spiny lobsters are abundant; there is a freezing plant at Academy Bay on Santa Cruz Island. Tuna fishing in the waters around the island is practiced by United States firms. Forest resources are mainly for local use. There are few mineral resources. Salt of high quality is mined near Villamil. Efforts to mine salt on San Salvador and sulfur on Isabela proved unprofitable.

**Prospects for the future.** Breeds of cattle and crops could be improved, but since Ecuador produces the same types of crops, export prospects are not promising. Prospects for the development of tourism, however, seem favourable, providing that the characteristic fauna remains intact. In the early 1970s the vegetation and animal life were endangered by man. Of the main islands only Fernandina, Genovesa (Tower), Darwin (Culpepper), and Wenman (Wolf) remained virtually untouched by man.

## Galaxies, External

Galaxies are vast systems of stars that also contain gas and dust in various concentrations and are distributed in groups and clusters throughout space to the limits of astronomical observation. The thousands of stars distinguishable to the unaided eye and the millions more making up the Milky Way system belong to the same Galaxy of which Earth's solar system is a vanishingly small part. This Galaxy is often given a capital *G* in print to distinguish it from others, but it is only one of innumerable systems and no more than a typical member of its class.

Observers looking out beyond the Galaxy find the external galaxies ever fainter and more numerous as more powerful telescopes reach ever farther into space. In apparent diameter and apparent brightness they range from the Large Magellanic Cloud, readily visible to the unaided eyes of observers in the Southern Hemisphere, to specks of the 23rd magnitude, scarcely distinguishable by the largest telescopes. Each of these galaxies, sometimes called island universes, is composed of myriads of stars—probably between  $10^9$  and  $10^{11}$  stars per galaxy. In many, as in the Galaxy, nebulae, star clusters, and interstellar matter can be detected.

Most, perhaps all, galaxies are arranged in groups or clusters of from a few to a few thousand members each. The nearest external galaxies, the Magellanic Clouds, lie perhaps 150,000 light-years from the Earth (a light-year is the distance traversed by light in a year of travel at a constant 300,000 kilometres [186,000 miles] per second, roughly 9.5 times  $10^{12}$  kilometres [5.9 times  $10^{12}$  miles]). The most distant galaxies observable are at several times  $10^6$  light-years' distance. Diameters of galaxies are measured generally in tens of thousands of light-years, while the distance between galaxies within a cluster averages perhaps 1,000,000 or 2,000,000 light-years, and the spaces between clusters of galaxies may be a hundred times again as great. The observable universe may contain about as many galaxies (on the order of  $10^{11}$ ) as the Galaxy in which Earth lies contains individual stars.

### EARLY HISTORY OF THE STUDY OF GALAXIES

Until the 20th century the existence of external galaxies was uncertain. Lumped together in the broad class of "nebulae" were all nebulous-appearing celestial objects except comets, whose transient nature set them apart. Included were galaxies, star clusters whose individual members were rendered indistinguishable by distance, and the galactic (*i.e.*, within the Galaxy) clouds of glowing interstellar gas now called bright nebulae. The external galaxies continued to be called extragalactic nebulae well after the middle of the century, although their true nature had been effectively demonstrated in the 1920s.

Historical records of observations of luminous patches in the sky go back as far as Hipparchus (2nd century BC), who included some nebulous star clusters in the earliest known star catalog. The Andromeda Nebula (with the Magellanic Clouds, one of three external galaxies visible without optical aid) was recorded by the Arabian astronomer as-Şūfī, in *Book of the Fixed Stars*, epoch AD 964.

Following the invention of the telescope in the first years of the 17th century, "nebulae" of all kinds began to be extensively studied and cataloged. Speculation arose, in the writings of the 18th-century philosophers Immanuel Kant from Germany, Emanuel Swedenborg from Sweden, and Thomas Wright from England, that some of these nebulous objects might be systems like the Milky Way, so distant that their individual stars could not be distinguished. Not until the early years of the 20th century, however, had enough observational data been collected to permit a scientific attack on the problem. In 1917 a U.S. astronomer, George Willis Ritchey, discovered, on a photograph of the "nebula" known by its catalog number as NGC 6946, taken at Mount Wilson Observatory (now part of the Hale Observatories), in California, what appeared to be a nova. Novae, or exploding stars, are fairly common in the Galaxy, but this one seemed unusually faint, as if it were extraordinarily distant. Looking through other Mount Wilson photographs, Ritchey found that two more novae had appeared in the Andromeda Nebula in 1909. Heber D. Curtis, at Lick Observatory, also in California, searched his photographs and found other novae had occurred in other nebulous objects. Because of the faintness of the novae, he concluded that these objects must be well outside the stellar system of the Galaxy. A U.S. astronomer, Harlow Shapley, who had made an early attempt to measure the size of the Galaxy, did not believe the starlike objects found by Ritchey and Curtis were novae and supposed all nebulae to be associated with the Galaxy. A controversy arose, culminating in 1921 in a debate between Curtis and Shapley before the United States' National Academy of Sciences. The matter was not settled until 1924, when Edwin Powell Hubble, working with the 100-inch telescope at Mount Wilson, discovered stars of a type called Cepheid variables in the Andromeda and Triangulum nebulae and in NGC 6822, and he demonstrated that these stars were the exact counterparts of similar Cepheid variables known in the Milky Way system; from their faintness he calculated the distances of the nebulae in which they occurred and proved conclusively that these nebulae were star systems far outside the Milky Way and similar to it.

Discovery of extragalactic novae

Discovery of Cepheid variables

### STATISTICAL PROPERTIES OF GALAXIES

**Classification.** The most generally accepted scheme of classification for the galaxies is one proposed by Hubble in 1926. It is represented schematically in Figure 1. This system arranges in a single homogeneous pattern nearly 98-percent of the numerous galaxies that are sufficiently large and bright to show appreciable structure on photographs taken with telescopes of moderate power (regular galaxies); the remaining 2 or 3 percent that do not readily fall into the system are called irregular galaxies. The basic feature of the classification is, to use Hubble's words, "conspicuous evidence of rotational symmetry about dominating, central nuclei." It was formerly thought that individual galaxies evolved through the various stages of the classification sequence, but this view is no longer generally held.

Figure 1: Hubble's system of classification for galaxies (see text).

Elliptical galaxies, denoted by E in Figure 1, have forms ranging from globular to lenticular, with the degree of ellipticity indicated by numerals from 0 to 7. Statistical analysis of the frequency of occurrence of the different

Components of galaxies

forms shows that there are actually globular, or spherical, galaxies and that not all of the apparently round ones can be accounted for as flattened galaxies with polar axes in the line of sight. The analysis shows, however, that the lenticular objects are much more common and that there is a definite limiting ellipticity at a 3:1 ratio of the axes. When the flattening becomes greater, the galaxies no longer appear as smooth, unresolved objects, and, at a certain stage of the sequence, indicated by S0, they begin to show structure that in general is of spiral character. Two different spiral forms are found: normal spirals, designated by S, and barred spirals, symbolized by SB. Within these two classes spirals are designated a, b, or c, in order of the degree of resolution possible—i.e., of the increasing clarity of the structure of the spiral arms; thus, a well-resolved normal spiral would be referred to as Sc, a barred one as SBc. The prefix “d” indicates a dwarf galaxy. Several dwarf elliptical (dE) galaxies are known in relatively nearby space; many others may exist, undetected, at greater distances.

Morgan's  
classification  
system

In 1958 William W. Morgan of the Yerkes Observatory, Wisconsin, devised a supplementary classification scheme aimed at describing the stellar population of galaxies having different Hubble types. By analogy with the classification of stars according to their temperatures, in which stars are designated O, B, A, F, G, K, and M in decreasing order of temperature, Morgan classified galaxies as a, af, f, fg, g, gk, and k according to the type of stars providing most of their light. There is a strong correlation between Hubble type and Morgan type, with the irregular galaxies predominantly a and af, the Sc galaxies af-fg, and the E galaxies being gk and k.

**The extragalactic distance scale.** Distances of galaxies are most accurately determined from studies of objects within them that may be recognized and compared with their counterparts in the Milky Way. These objects may be brightest stars, variable stars, star clusters, gaseous nebulae, or novae. When these can be identified, their apparent magnitudes,  $m$ , are measured and compared with their absolute magnitudes,  $M$ , which are assumed to be the same as those for corresponding galactic objects. By definition,  $M$  equals  $m$  at a distance of 32.6 light-years.

Distance  
formula

Once an extragalactic object's apparent magnitude is measured and its absolute magnitude assumed to be known, the distance,  $d$ , is computed from the simple formula

$$5 \log d = (m - M + 5),$$

which assumes that the apparent brightness of an object varies inversely as the square of the distance. If there is reason to believe that somewhere along the line of sight to the extragalactic object there is matter that absorbs some of the light, a correction is determined or estimated for the apparent magnitude, which, of course, is made too faint by any obscuring material. Such matter may be present in the Galaxy, in the external galaxy whose distance is sought, or possibly in intergalactic space. Correction for its effect often is difficult to make, and there may be considerable uncertainty even with the best procedure.

In practice, the use of individual objects within galaxies for distance determination is limited to a few hundred of the nearest and brightest galaxies. Vast numbers of galaxies are so far and faint that even the largest telescopes cannot single out objects within them for individual study. Thus it is necessary to use other distance criteria, which may be apparent diameter, total magnitude (entire light of a galaxy), and red shift (a shift of spectrum lines toward the red end of the spectrum, which increases with increasing distance of the source). These quantities all have to be calibrated, or evaluated, in terms of the distance criteria used for the nearer galaxies, before they can be used to obtain distances on an absolute scale of light-years.

**Apparent distribution of galaxies.** As a result of extensive counts of galaxies on photographs, it is now known that their distribution is nonrandom over the sky and approximately uniform in depth. This last result is of great theoretical and practical value for cosmological studies.

**Counts per unit area of sky.** Long before the advent of photography, it was generally known from visual observations that the “white” nebulae, now called galaxies, tended to avoid the Milky Way and that there was appreciable clustering in high galactic latitudes, especially in the constellations Coma Berenices and Virgo close to the north pole of the Galaxy. With the development of photography, more and ever more galaxies were counted. The zone of avoidance around the central plane of the Milky Way (a zone characterized by an apparent absence of galaxies) and the regions of clustering became more precisely defined. A number of counts in the early 20th century suggested the general outlines of the distribution and gave hints as to the total number of galaxies within reach of certain telescopes, but the problem of counts of galaxies was not put on a firm quantitative basis until 1934. In that year Hubble published the results of surveys in which more than 44,000 galaxies were counted in 1,300 sample regions rather evenly distributed over three-quarters of the sky. For the first time, the counts were calibrated and referred to specified limiting magnitudes. With all the data reduced to standard conditions, it became clear that the numbers of galaxies decreased in a very regular way as the Milky Way was approached. The rate of decrease, in fact, was just that to be expected from a thin obscuring layer in which the absorption is proportional to the light path in the stratum—a familiar analogy is the dimming of stars as they approach the horizon. What is called the zone of avoidance along the Milky Way is thus but the effect of looking in the plane of the stratum, where the absorption is at a maximum that approaches complete opacity; toward the poles of the Galaxy the absorption is at a minimum, with the light reduced by only 20 percent. In the more populous areas, on the other hand, there is a conspicuous tendency for the galaxies to cluster. They occur in pairs, in small to large groups of several to 100 galaxies, and in great clusters that include more than 500 members, as in the aggregations in the constellations Coma Berenices and Virgo.

**Numbers and distribution in depth.** Galaxies populate space with an approximately constant density as far as telescopes can reach. This determination has been made from counts of galaxies to successively fainter limiting magnitudes. For the brightest objects, it is only necessary to total to each limiting magnitude the number of galaxies whose magnitudes have been individually determined. For the faintest objects, on the other hand, it is much simpler to count galaxies to limiting magnitudes determined by exposures of different lengths, or by telescopes of different light-gathering power. This indirect procedure is expedient because the faintest galaxies are overwhelmingly too numerous to estimate their individual brightnesses. With the numbers of galaxies established to increasingly fainter magnitudes, it is relatively easy to test the hypothesis of constant space density. This is done by noting whether the numbers of galaxies counted are proportional to the volumes of space in which they are found. More precisely, a simple calculation shows that the rate of increase is by a factor of 4 when the limiting brightness decreases by one magnitude. For galaxies fainter than about the 18th magnitude photographic magnitudes become abnormally faint, with the result that the observed number falls below that expected on the basis of a uniform distribution.

Extensive surveys have shown that clustering of galaxies is by far the rule rather than the exception. A Swiss astronomer, Fritz Zwicky, reported in 1952 that, on one plate covering about 40 square degrees in Corona Borealis, nearly 100 clusters could be identified. The existence of so many clusters suggests that they, instead of individual galaxies, may be the fundamental building blocks of the universe. If this is the case, then clusters of galaxies promise to provide significant information on the structure of the universe, in addition to having served as stepping-stones for determination of the extragalactic distance scale.

If only the brighter galaxies to the 12th or 13th magnitude are considered, they show a tendency, first noted in 1923, to occur in a great circle band around the sky. It is

Zone of  
avoidance

Clusters  
and super-  
clusters

a belt with an average width of  $12^\circ$  that runs nearly perpendicular to the Milky Way, which it crosses in the northern constellation of Cassiopeia and again in the southern one of Circinus. The northern arc includes the Virgo cluster with its extensions to the south in Centaurus and to the north in Coma Berenices, Canes Venatici, and Ursa Major. The southern part is less populous, but there are series of groups of bright galaxies in Andromeda, Pisces, Cetus, Sculptor, and beyond into far southern skies.

The possibility that these brightest galaxies may form in space an extended "metagalactic" system or cloud, which may also include the Galaxy, has been suggested by a number of investigators. In shape it would be a flattened system of some tens of millions of light-years in diameter and one-tenth as thick. But this interpretation is uncertain. Evidence found in the early 1950s gave strong support to the concept of a "local supergalaxy" that includes the Milky Way and has the great Virgo cluster of galaxies as a dominant feature near its centre. If this is a valid assumption, then the Galaxy, in addition to being close to the principal plane of the supersystem, would be about three-fourths of the way from the centre to the edge, since the bright galaxies in the Coma Berenices-Virgo region around the north galactic pole are thought to be three times more distant than some groups of large spirals in the opposite direction toward the south galactic pole. The supersystem would be, of course, many millions of light-years in diameter.

A local supercluster of bright galaxies may not be unique. The existence of similar systems has been suggested by other observers. Firm observational evidence is difficult to obtain, and some astronomers prefer the interpretation that a patchy distribution of clusters is caused by dark obscuring intergalactic material, distributed in patches. Either interpretation has profound significance for attempts to infer the structure and nature of the universe; there is no theoretical understanding of how such superclustering or such extensive dark intergalactic clouds could have come into existence. To resolve the problem on an observational basis, much time with large telescopes will be required.

*The nearby galaxies.* What is known as the Local Group comprises Earth's Galaxy and 18 or 20 others, occupying a volume of space perhaps 2,000,000 light-years in diameter. The Local Group is in no way remarkable among clusters of galaxies. Like other clusters, it is probably held together by the mutual gravitational attraction of its members, of which the Galaxy seems to be one of the largest. About half of the Local Group are elliptical galaxies, with the remainder spiral or irregular in shape. There may be undiscovered members of the group; one probable member, the giant elliptical Maffei I, was discovered by its infrared radiation in the late 1960s. Intervening dust clouds had prevented its visible light from reaching Earth.

#### PHYSICAL PROPERTIES OF GALAXIES

The stellar content of galaxies, their masses, rotations, and the ratio of mass to total luminosity are physical properties that bear on the structural forms, evolution, age, and ultimately, one may hope, on the problem of the origin of galaxies.

**Stellar populations and evolution.** In 1944 the U.S. astronomer Walter Baade, using the Mount Wilson 100-inch reflector to maximum advantage in a sky darkened by a wartime blackout of city lights, reported the resolution for the first time of the amorphous nuclear region of the Andromeda Nebulae into myriads of faint stars. At the same time he also resolved the several fainter elliptical companions of the large spiral. These were results of great importance, for they showed that the generally smooth and featureless light in elliptical galaxies and in nuclei of spirals comes from stars of a different kind than those forming spiral arms. In the latter the brightest stars are blue-white supergiants often enmeshed in dark and bright nebulous material, while in the nuclear regions and in elliptical galaxies the brightest stars are yellow-red giants, and in these regions there is no

dust and bright gaseous matter. Since blue-white supergiant stars may be hundreds of times intrinsically more luminous than giants, it is easy to understand why elliptical galaxies were, and still are, so difficult to resolve into stars, even with the largest telescopes.

Baade's observations represented a telescopic triumph, and his interpretation of them proved to be of surpassing significance. First, he stressed the close association of blue supergiants, interstellar material, and diffuse bright and dark gaseous nebulae in spiral structure, which he termed stellar Population I. Second, he emphasized the similarities of the spherical distributions, colours, and luminosities of the galactic globular cluster stars with the elliptical galaxies and the nuclear-region red giants, which he called stellar Population II. These two populations can be distinguished in the Galaxy, because they have different dynamics (properties related to motion): type I participates primarily in the general rotation in the principal plane and has a small internal velocity dispersion; type II, on the other hand, shows little tendency toward general rotation and has a high internal velocity range. Thus type I is essentially a disk, or fundamental-plane, population, while type II is a halo-like population surrounding and permeating the entire system. The distinction between the two populations, however, goes even deeper than their differences in spatial distribution and dynamics. As the result of much modern work stimulated by Baade's discoveries, it is known that the two populations represent separate stages in stellar evolution: Population II is older, perhaps by several times  $10^9$  years.

The blue supergiants of Population I pour out radiation at so high a rate that they consume their hydrogen fuel in the astronomically short time of a few millions or tens of millions of years. Since these stars are present in the spiral arms of galaxies generally and can be identified in galaxies over a wide range of distances, their relatively brief lifetimes mean that they must be continually forming in the spiral structure; otherwise, they should not be seen over such a long range in time as inferred from their distances. Since their formation and fleeting cosmic existence require enormous quantities of hydrogen, the basic fuel, the conclusion is almost inescapable that they originate from the hydrogen-rich interstellar gas and dust. The red giants of Population II, on the other hand, have spent most of their lives as relatively faint stars, not much brighter intrinsically than the Sun, and so they have been rewarded for their economical rate of spending energy by lifetimes hundreds of times longer. The red stars in the centre of the Andromeda Nebula and in its elliptical companions are embedded in an innumerable swarm of dwarf stars, which will in turn become red giants when they have reached a certain stage in their evolution and will replace the red giants seen now when those burn out. But because there is no dust or gas in that region, new bright blue stars can no longer form there. The dwarf stars must originally have formed out of an interstellar medium, but their present properties suggest that they did so at a time far in the past and have long since diffused out of the regions where they were born. The oldest of them may have formed at a time when the entire parent system consisted largely of a primeval turbulent mass, rather than a well-defined, rotating, thin disk.

Following Baade's fundamental work, it was realized that two distinct stellar populations are not sufficient to describe the variety of stars observed (see also STAR). Five types are often distinguished: extreme Population II, intermediate Population II, disk population, intermediate Population I, and extreme Population I. Although it appears that there is a continual gradation from one type to another, consideration of the evolutionary differences among the several types, or populations, of stars sheds light on the question of how a whole galaxy may evolve. Detailed spectroscopic analysis shows that the oldest observable stars have very small abundances of the heavier elements in their makeup, compared with the young, hot, blue stars and the gaseous nebulae. By relating the ages, population types, and locations of the different kinds of stars in the Galaxy with their chemical composition,

Stellar  
populations

Extension  
of Baade's  
classification

The "local  
super-  
galaxy"

it has been possible to build up a qualitative picture of a progression from an initial turbulent, roughly spherical cloud of gas, out of which the oldest stars formed, to the building of increasing amounts of the heavier chemical elements in successive generations of stars, and the gradual shrinking of the uncondensed material to a central plane, leading to the Galaxy's present form. New stars can form only where there are gas and dust, and so they are confined to this central plane. But the details of the picture remain obscure, and it seems that the process of heavy-element synthesis in the Galaxy has been an uneven and patchy one.

For other galaxies the sort of precise photometric and spectroscopic information obtainable for stars and gas clouds in the Milky Way is much more difficult to acquire, and the necessary observations take a long time, even with the largest telescopes. Astronomers hope to be able to relate this information to the structural forms of galaxies and see whether the various kinds—irregulars, barred spirals, normal spirals, and ellipticals—can be arranged chronologically. But basic properties of galaxies, such as their masses, the amount of their rotation (their angular momenta), and quantitative values of their primeval magnetic fields and turbulent motions, may all play an important part in determining their evolution. It remains to be seen whether or not the variety of forms of galaxies indicates a great range in age.

**Rotation of spiral galaxies.** The most casual glance at photographs of spiral galaxies suggests rotation, which is readily revealed spectroscopically for systems tilted toward the line of sight. It was proven in 1914 that the central parts of several of the brightest spirals, including the Andromeda Nebula (M31), have a component of rotation in the line of sight. Earth's Galaxy, a spiral similar to M31, was shown in 1927 to be rotating. Because of the extreme faintness of the light from galaxies, further progress was slow, and even by 1950 only the two nearest and apparently largest spirals, M31 and M33, had been studied in any detail. In these, astronomers were able to follow the character of the rotation out to the extreme limits shown on photographs.

In succeeding decades, new spectrographic methods were used. By the mid-1960s it was clear that rotation is a very general property of galaxies of all structural forms; it is easiest to measure in spirals with plenty of interstellar gas, but it is also present in S0 galaxies and ellipticals with little or no interstellar matter. These rotations can be used to determine the masses of galaxies (see below *Masses of galaxies*).

**Direction of rotation in spirals.** Closely allied with the character of the rotational motion of spirals is the question of how the movement takes place with respect to the curvature of the spiral arms; in other words, whether the arms appear to be winding or unwinding. A U.S. astronomer, Vesto Melvin Slipher, pioneered in this field, and, on the basis of his rotation measures and his inferences of the true spatial orientation of the galaxies from their apparent or projected forms, he concluded that all spirals probably rotate in the same manner: the central part turns into the spiral arms like a coil spring being wound up.

The interpretation of photographs of spirals, to determine which edge is nearer the observer, is not easy, and not until the 1940s was it generally accepted that all spirals rotate in the same way: as the central part turns, the arms lag behind.

**Persistence of spiral structure.** Spiral galaxies have in general two arms, starting at diametrically opposite sides of the nucleus and having the form of equiangular spirals making one to one and a half complete windings. If galaxies were rotating like solid wheels, any structure, spiral or otherwise, would remain undisturbed. The spectroscopic measurements, however, clearly show that galaxies do not rotate as solid bodies but differentially, like a cup of coffee being stirred. The time for one rotation in a well-studied spiral galaxy, NGC 5055, varies from about 20,000,000 years near its centre to 200,000,000 years at its outer edges. In its total lifetime of about 10,000,000,000 years, one would expect any spiral structure initially

possessed by the galaxy to have been wound up so many times as to be now unrecognizable. The only way to resolve this difficulty is to show that spiral structure is a transient but continually renewed property, and this was plausibly done in 1963–64 by the U.S. astronomer Chia-Chiao Lin and colleagues, at the Massachusetts Institute of Technology. They showed mathematically that a uniform, thin, infinitely large rotating disk is unstable and will form a density wave in the gaseous material, and the most likely form of this density wave is a two-armed trailing spiral. The wave will always be present but will travel slowly through the galaxy; since new, hot, massive, highly luminous stars can form only where the gas and dust tend to collect, this spiral structure will always be outlined by the successive generations of short-lived blue-white supergiant stars. In the late 1960s an alternate explanation of spiral arms was suggested, namely, that they are formed by material thrown out from the spinning galactic nuclei.

**Masses of galaxies.** According to Newton's law of gravitation, the centrifugal acceleration at any point in a rotating galaxy must balance the gravitational attraction of all the mass lying interior to that point. Since the centrifugal acceleration is determined by the rotational velocity and by the distance from the centre, measurement of the rotation curve can be used to calculate the distribution of mass and the total mass of any galaxy. By this means the masses of the Galaxy, of the Andromeda and Triangulum nebulae, and of about 50 other spiral galaxies have been determined. These masses range from approximately 300,000,000,000 times the mass of the Sun, for giant galaxies like the Andromeda Nebula, to values about one-hundredth of that for small galaxies. In even smaller galaxies it becomes more difficult to detect and measure rotation; therefore, most of the determinations lie in the range given above. The rotational velocities, plotted against distance from the centre, give graphs that are usually concave to the axis on which distance from the centre is plotted; mathematical analysis of such curves shows that the mass concentration is greatest in the centre and the density of matter decreases smoothly outward from the centre.

As well as being commonly distributed in groups and clusters, galaxies often occur in pairs in the same way as do stars. As with double stars, measurements of the separations and orbital velocities of double galaxies yield their masses. For elliptical galaxies the average masses, determined in this way, come out to be about ten times greater than for spirals. Since the diameters of ellipticals and spirals are about the same, this difference points to a striking difference in average density and raises the question as to whether this might be the cause of the different forms and different stellar populations in the two kinds of galaxies. A reasonable hypothesis is that star formation might be much more rapid in ellipticals, as a consequence of their greater density; virtually all the gas and dust might have been used up early in their lifetimes so that only the old, long-lived stars remain to be seen now. The difference in masses and densities between ellipticals and spirals militates against the earlier theory that galaxies might evolve through the sequence irregulars–spirals–ellipticals. Such evolution would have to be accompanied by an increase in mass and density.

If knowledge of the masses of elliptical galaxies rested solely upon average determinations from double galaxies, the difference between spirals and ellipticals could be explained as the result of some spurious statistical effect. Although it is very difficult to determine rotations of ellipticals, since, unlike spirals, they have no interstellar gas to produce the emission that is spectroscopically easy to measure for motion in the observer's line of sight, there is another way of determining masses in stellar systems. In the centres of galaxies, the average random speeds of the stars are governed by the gravitational force acting upon them and hence by the total mass. It is possible to measure the average speeds of stars in the centres of galaxies by measuring the broadening of spectrum lines produced by the aggregate of stars. From the average speeds of these stars in the centre, the mass of the whole galaxy can

Density waves

Pairs of galaxies

be calculated. In 1968 about six individual determinations had been made in this way. These individual determinations span a very wide range, from  $3 \times 10^8$  solar masses for M32, the small elliptical companion of the Andromeda Nebula, to about  $10^{12}$  solar masses in the giant ellipticals in the nearby Virgo cluster; throughout this range the densities of the ellipticals seemed to be about ten times greater than those of the spirals.

**Peculiar galaxies.** There are some galaxies so irregular in form that they are well described by the term peculiar. These are interesting because they may represent transient structural forms and hence might throw light on the evolution of galaxies. In Moscow, the Soviet astronomer B.A. Vorontsov-Velyaminov in 1959 made a photographic catalog of about 350 of such strange objects; seven years later, in 1966, at Mount Wilson and Palomar observatories (now Hale Observatories), the U.S. astronomer Halton Arp made a more detailed photographic atlas and catalog.

Compact  
galactic  
systems

Another class of peculiar galaxies is the compact systems. Some of these are so compact as to be barely distinguishable from stars on the photographs, yet, when examined with spectrographs, they are clearly seen to be galaxies of a very dense structure. In the late 1960s their relationship to normal galaxies was not understood.

Among the galaxies, some are emitting intense radio radiation (see below *Radio observations of galaxies*). These, the radio galaxies, often have peculiar structures, such as prominent clouds and lanes of dust, as in NGC 5128, or a fountain of hot gas spurting out of the central region, as in M82. These structural peculiarities, together with the spectroscopic information, suggest that those galaxies have been subjected to violent explosions in their centres (see below).

#### RADIO OBSERVATIONS OF GALAXIES

Radio radiation from the Milky Way was first detected in 1932, but this work was largely neglected until after World War II, when the men who had developed radar built the first radio telescopes and began systematically to do astronomy at radio wavelengths. It is convenient to divide radio observations into those dealing with spectral lines and those dealing with the continuous radiation at all radio wavelengths.

**Line radiation.** The radiation of 21-centimetre wavelength emitted by clouds of hydrogen in space was first detected in an extragalactic system in 1953 by Australian radio astronomers, who observed both Magellanic Clouds and in 1954 determined the distribution of neutral hydrogen in both clouds and in the common envelope in which they appeared to be embedded. Later work has confirmed and refined these results. The neutral (not ionized) hydrogen in the Large Magellanic Cloud amounts to approximately 10 percent of its total mass; about the same total amount of hydrogen is in the Small Magellanic Cloud, whose mass, not accurately known, is probably less than that of the Large Magellanic Cloud.

As previously noted (see above *Masses of galaxies*), 21-centimetre radiation has been detected in many other spiral and irregular galaxies, where it has been used to derive the mass of neutral hydrogen and the rotation and hence the total mass of the galaxy. In cases in which both optical spectroscopic and 21-centimetre measurements have been made for the same galaxy, the red shifts have been found to be in good agreement over the long range of wavelength. The 21-centimetre radiation has not yet been detected, however, in any very distant galaxies.

Other radio line radiations that have been detected in gaseous nebulae in the Milky Way are those caused by the molecule OH, at rest frequencies of 1,612, 1,665, 1,667, and 1,721 million cycles per second (megahertz), or wavelengths of 17–19 centimetres, which have been seen in absorption and in emission, and high-order lines produced by the recombination of ionized hydrogen, which have been seen in emission at a number of wavelengths. None of these has been detected in other galaxies.

**Continuum radiation.** A few years after the end of World War II, radio astronomers found that the sky con-

tains a number of discrete sources of continuum radio radiation—i.e., radiation spread continuously over a wide range of radio wavelengths (see *RADIO SOURCES, ASTRONOMICAL*). Australian radio astronomers in 1949 pinpointed three of the discrete sources with sufficient accuracy to make reasonably certain their correspondence with three optically known celestial objects, including the peculiar elliptical external galaxies NGC 5128 and NGC 4486 (M87).

The two strongest radio sources in the sky (not counting the Sun) were Cygnus A, and Cassiopeia A, and their identification was achieved in 1954. Cygnus A was found to be a peculiar, rather distant galaxy with a double nucleus, while Cassiopeia A was discovered to be a faint galactic nebula—i.e., one within the Galaxy. Optical spectrograms of these two sources showed that both contained much highly excited hot gas and that the filaments of Cassiopeia A were moving at enormous speeds, several thousand miles per second. The suggestion of I.S. Shklovsky in the U.S.S.R. that Cassiopeia A is the remnant of a supernova (violently exploding star) was generally accepted by 1958, when a detailed study of the speeds in the gas had shown that the nebula was expanding.

In the decade following 1954, astronomers in England and Australia produced catalogs of radio sources whose positions were gradually refined in accuracy, and the identification of sources continued. Until 1960 the identified extra-solar-system sources were always found to be either galactic nebulae or external galaxies. The galactic nebulae proved to be of two kinds, either arcs or expanding clouds of gas that were shown to be most probably remnants of supernovae or clouds of hot gas such as the Orion Nebula. The physical processes producing the radio radiation proved to be different in the two cases.

In nebulae like that in Orion the random motions of the negatively charged particles, electrons, in the vicinity of the positively charged protons, or hydrogen nuclei, produce optical radiation and radio radiation. This radiation depends upon the temperature of the gas and is called thermal radiation. Galactic nebulae that consist of hot clouds of gas, mainly hydrogen, and that are not the remains of supernova explosions emit radio radiation by this process.

The radio and optical radiation of much of the Crab Nebula and the radio radiation of the external galaxies cannot be explained in this way. A suggestion by Swedish astronomers, that radiation of the kind known in the giant laboratory synchrotrons (machines used by physicists to accelerate subatomic particles) might be astrophysically important, was developed by a group of Soviet theoreticians. This synchrotron radiation is produced by charged particles being accelerated in magnetic fields; it is highly polarized, and the way in which the intensity varies with wavelength, dependent upon the energies of the charged particles, has a characteristic form that fits well the observations of the discrete radio sources. It was discovered in 1956 that the light in the raylike blue jet extending from the centre of the strongly radio-emitting galaxy NGC 4486 (M87) is strongly polarized, which meant that it must be synchrotron radiation. By 1958 the theory of synchrotron radiation was generally accepted for the nonthermal sources.

**Violent events in nuclei of galaxies.** Very large total energies are necessary to produce the synchrotron radiation. Such energies were known to be released in the supernovae (violent stellar explosions), but some even larger energy supply was required for the much more powerful radio sources in galaxies. In 1943 the U.S. astronomer C.K. Seyfert, working at the Mount Wilson Observatory, studied a small class of about a dozen spiral galaxies that have very small, intensely bright centres, or nuclei. He showed that these nuclei contain hot gas moving very violently, at speeds of several thousand miles per second. The proportion of spiral galaxies that are like this and have come to be called Seyfert galaxies is about 2 percent.

The galaxy M87, a powerful X-ray and radio source, was found in 1960 to have hot gas in its nucleus, with large outward motions of nearly 600 miles (1,000 kilo-

Physical  
processes  
that  
produce  
radio  
radiation

The  
Seyfert  
galaxies

metres) per second. Such observations suggest some violent explosive event in the centre of the galaxy.

In 1962 evidence was presented that a violent explosion occurred about 1,000,000 years ago in the nucleus of a bright irregular radio-emitting galaxy in Ursa Major, NGC 3034 (M82). This galaxy had been shown in 1960 to be rotating. Its orientation to the line of sight is close to edge-on (see Figure 2). Speeds of nearly 100 miles

By courtesy of Hale Observatories

Figure 2: Exploding galaxy M82 in Ursa Major. The inner-region filaments, mainly hydrogen, seem to have been ejected from the nucleus about 1,500,000 years ago in galactic time, or 11,500,000 years ago in Earth time; M82 is 10,000,000 light-years distant. The farthest filaments are more than 20,000 light-years from the nucleus, and the mass thrown out is equivalent to 5,000,000 Suns.

(160 kilometres) per second were measured in gaseous filaments along the minor axis, where there should be no effect of rotation visible, so that the only way the filaments could be moving was outward from the centre of NGC 3034. Other astronomers measured a high degree of polarization in some of these filaments, thus showing that they were shining by means of synchrotron radiation.

In 1965 it was found that a similar explosion had occurred in the centre of the peculiar spiral NGC 1275, also a strong emitter of radio radiation and the brightest member of the Perseus cluster of galaxies. This galaxy has a complicated pattern of filaments on one side of it, with a velocity of nearly 2,000 miles (3,000 kilometres) per second relative to its centre. In 1954, after the very strong radio source Cygnus A had been identified with a faint double-centred galaxy, it was suggested that all radio galaxies were the results of collisions between galaxies. Such collisions would involve enormous amounts of energy. But several of the brighter radio galaxies were obviously single. Even NGC 1275, which had been considered a prime example of a pair of colliding galaxies, proved under more detailed examination to be better explained as the result of a gigantic explosion some one or two million years ago. The detailed physics of all these violent processes in galaxies remained in doubt.

**BIBLIOGRAPHY.** There are sections on galaxies in many general textbooks in astronomy that are not highly technical—for example, in GEORGE O. ABELL, *Exploration of the Universe*, 2nd ed., ch. 31–32 (1969); JOHN C. BRANDT, *New Horizons in Astronomy*, ch. 13 (1972); and ALBRECHT UNSOLD, *Der neue Kosmos* (1967; Eng. trans., *The New Cosmos*, pt. 3, 1969). A classic that is highly readable, written by the founder of modern studies of galaxies, is EDWIN P. HUBBLE, *The Realm of the Nebulae* (1937). A more technical book that can still be read easily by high-school students and undergraduates in science is PAUL W. HODGE, *The Physics and Astronomy of Galaxies and Cosmology* (1966). Hodge's book does not contain much mathematics but gives more information than the chapters listed in the works above; some familiarity with astronomical nomenclature is assumed. Forms of galaxies are treated in ALLAN SANDAGE, *The Hubble Atlas of Galaxies* (1961), which gives a beautiful collection

of photographs of galaxies, together with a detailed introduction describing the classification scheme and a historical account of early work. At a much more technical level, suitable for advanced undergraduates or graduate students, there are several long chapters in the numerous volumes of the series *Annual Review of Astronomy and Astrophysics*, on various topics concerning galaxies. Attention is drawn especially to the following chapters: MORTON S. ROBERTS, "The Content of Galaxies: Stars and Gas," and IVAN R. KING, "The Dynamics of Galaxies," both in vol. 1 (1963); GEORGE O. ABELL, "Clustering of Galaxies," vol. 3 (1965); B.J. BOK, "Magellanic Clouds," and ALAN T. MOFFET, "The Structure of Radio Galaxies," both in vol. 4 (1966); G.R. BURBIDGE, "The Nuclei of Galaxies," vol. 8 (1970); and PAUL W. HODGE, "Dwarf Galaxies," vol. 9 (1971).

(E.M.B.)

## Galaxy, The

The term galaxy derives from the Greek word *galaxias*, meaning "milky way," given to the luminous band of stars that crosses the celestial sphere. The term was later extended to cover the whole Milky Way system. Other such star systems, formerly called extragalactic nebulae, are now called galaxies with a lowercase initial.

The Galaxy is a lens-shaped system containing about 100,000,000,000 ( $10^{11}$ ) stars and a great amount of interstellar matter made up of gas and dust. It has a central nucleus in which the star density is greater than that of the outer parts of the lens, and it is surrounded by a very tenuous halo with few stars and almost no gas and dust. The solar system is very near the galactic plane—i.e., the plane of symmetry of the lens—out far from the nucleus. From the Earth, the stars and interstellar matter near the galactic plane are seen from a point almost in the plane, and the concentration of stars gives rise to the luminous band of the Milky Way. In the northern sky it stretches from the constellation Aquila through Cygnus, Cepheus, Cassiopeia, Perseus, Auriga, Taurus, and Gemini to Orion, and in the southern sky from Monoceros through Puppis, Vela, Carina, Crux, Centaurus, Circinus, Norma, and Scorpius to Sagittarius. The centre of the Galaxy lies in the direction of Sagittarius.

The Milky Way band is very irregular, and parts of it differ appreciably in brilliance. Among the most conspicuous bright areas are the star clouds in Scutum, Norma, Carina, Cygnus, and Sagittarius. Dark spots and lanes are caused by interstellar dust that is obscuring the stars behind it. Best known in the northern sky is a dark band called the Great Rift, which divides the Milky Way into two branches between Cygnus and Sagittarius. In the southern constellation of Crux, the Coalsack appears to the naked eye as a black cloud, blacker than any other part of the sky.

If the Milky Way is studied with the aid of a good pair of binoculars or with a small telescope, most of its bright clouds are resolved into thousands of faint stars; some, called nebulae, remain unresolved and are gaseous objects. Many open or galactic clusters may be seen in or near the Milky Way band; for instance, the Pleiades in the north and the Jewel Box (Kappa Crucis) in the southern constellation Crux. A rich galactic cluster may contain 3,000 stars. Some distance away from the bright band, much denser and apparently nearly spherical groups called globular clusters are found; these may contain up to 1,000,000 stars. Clusters, nebulae, stars, and gas can all give important information about galactic structure.

Photographic techniques are frequently used for Milky Way research. The complexity encountered in the Milky Way is obvious from Figure 1, which shows a two square degree field in the southern Milky Way.

The idea that the Galaxy might be a spiral galaxy, now well established, arose about 1930. The spiral arms have been traced by optical and radio observations. The rotation of the system around the galactic centre is known; Earth's Sun moves with the system at a speed of about 250 kilometres per second.

The formation of the Galaxy, its evolution, and the development of the spiral structure are still not fully understood (see, however, below).

## I. Investigations of the Galaxy

### THE 18TH AND 19TH CENTURIES

At the middle of the 18th century it was generally accepted that there was a “stellar system” in which the stars were arranged in space more or less symmetrically about the Milky Way. Philosophical speculations populated the whole universe with similar stellar systems.

The first systematic observational approach to the problem of the structure of the Galaxy was made by Sir William Herschel. His method of star counts, which he called “star gauges,” gave the first overall picture of the Galaxy

in 1785. The number of stars in a given area of the sky were counted for several thousand fields, chosen to represent the distribution of stars relative to the Milky Way.

Herschel assumed that the stars were uniformly distributed over the sky, that the system was finite, and that the penetrating power of his telescopes was sufficient to reach the borders of the system in all directions. He concluded that the Galaxy extended about five times as far in the galactic plane as it did perpendicular to the plane. According to him, the Sun was near the centre of the system.

Herschel became impressed by the patchy structure of the Milky Way, the star clouds, the bright nebulae, and the areas apparently devoid of stars. As a result, he abandoned the picture of a system with uniformly distributed stars and decided to determine the relative distances of the stars from their apparent brightnesses (apparent magnitudes, the smallest magnitude representing the brightest star). He took the same absolute luminosity (absolute magnitude), that of the Sun, for all stars. He was aware that this would not be strictly true for individual stars, but he assumed it to be statistically correct so that the mean distance of stars of the sixth magnitude would be greater than that of stars of the fifth magnitude.

With larger and larger telescopes, Herschel found fainter and fainter stars in the directions in the galactic plane, while in directions perpendicular to the plane the number of faint stars diminished rapidly. He concluded that the Galaxy was a thin disk of nearly infinite extension in the direction of the galactic plane.

Sir John Herschel extended his father's star gauging to the southern hemisphere, and he was probably the first person to notice, in 1847, the remarkable distribution of the bright stars spread out across the sky in a great circle inclined at an angle of about  $20^\circ$  to the galactic plane. About 30 years later an astronomer named Benjamin Gould suggested that this arrangement, now called Gould's Belt, indicated that the Sun was in a small star cluster. Its significance is still under discussion.

Sir John Herschel's extensive studies of “extragalactic nebulae,” other galaxies, were also important for comparison with and understanding of the Galaxy. In 1833 he described the Whirlpool Nebula, designated M51 in the Messier catalog, as consisting of a bright round nebula surrounded at some distance by a ring that was double in one part. He pointed out that, for an observer near the central mass, the ring, if it consisted of stars, would appear much as the Milky Way does from Earth.

The coordinates of the apex (the point in the sky toward which the Sun in its peculiar motion appears to be moving in relation to the stars), found about the middle of the 19th century, confirmed the direction of the solar motion toward the constellation of Hercules, as found by Sir William Herschel nearly a century earlier. The *Bonner Durchmusterung*, a major star catalog with accompanying charts, gives positions and estimated brightnesses for nearly 400,000 stars in the sky north of  $23^\circ$  southern declination. It appeared between 1859 and 1886 and was followed by two southern surveys: the *Córdoba Durchmusterung*, published between 1892 and 1932, for nearly 610,000 stars south of  $22^\circ$  S, and the *Cape Photographic Durchmusterung*, published between 1896 and 1900, with over 450,000 stars south of  $19^\circ$  S. Photographs were needed to reveal the nature of the many regions devoid of stars in the Milky Way, almost always due to obscuration by dark nebulae. In 1927 a list of 349 such objects with a brief description of each was published. Dark markings that might be only vacancies among the stars were left out, implying that the remainder were considered to be nonluminous, obscuring clouds. At about the same time a method of star counts to be used to obtain the distances to the obscuring clouds was proposed. Also nearly simultaneously with the nebula catalog there appeared a list of 1,550 dark nebulae found from studies of the stellar density variations on photographic survey charts of the entire sky (see ASTRONOMICAL MAPS).

### THE 20TH CENTURY

In the last decades of the 19th century, two quite different contributions to the progress of stellar astronomy,

analyses of star positions and of motions, gave much the same picture of the Milky Way system; this picture was generally adopted by early 20th-century astronomers.

In both, the fluctuations of density along the galactic equator were first considered to be of minor importance but were later taken into account. The system based on positions was found to be finite whereas the one based on motions faded out to zero, but the models otherwise show much similarity; in both, the Galaxy is a strongly flattened spheroid with, in the finite system, a diameter of 7,000 parsecs and a thickness of 1,850 parsecs. (One parsec = 3.26 light-years. The mean distance from the Earth to the Sun—the astronomical unit—subtends an angle of one second of arc at a distance of one parsec.) The available observational material—distances, motions, and spectra of the stars—was too scanty to allow reliable solutions. In 1906 an extensive program for observations of visual and photographic magnitudes, spectra, parallaxes, distances, proper motions, and radial velocities (speeds in the line of sight) of the stars in 206 areas was proposed as a way of revealing the characteristics of the stellar system. International cooperation in this program (Jacobus Cornelis Kapteyn's plan of Selected Areas) is still going on.

Many stars form close groupings and apparently belong together. These groupings are called open, or galactic, clusters; the Pleiades is a typical example. Sir William Herschel used them in his study of the form and extent of the Galaxy. He and his son, Sir John, also knew most of the globular clusters known today, and both had noticed the difference in distribution of stars in the two types of cluster. The globular clusters have a high central concentration of stars (in contrast to the open clusters) and, as indicated by the name, a spherical symmetry.

At the end of the 19th century, photographic research on star clusters made rapid progress. The spectra of more than 1,000 stars in galactic clusters were studied, and hundreds of variable stars, including a type called RR Lyrae variables, were detected in some globular clusters. The importance of the two types of clusters for understanding the structure of the Galaxy became clear through the work of two United States astronomers, Harlow Shapley and Robert J. Trumpler. Shapley determined the distances of 69 globular clusters from their total brightness, apparent diameters, and the magnitudes of their RR Lyrae variables and of the 25 brightest stars. He was able to show that the galactic centre was in Sagittarius at a great distance from the Sun. His work on the galactic clusters also helped to establish a picture of galactic structure. His catalog gives a total of 93 globular and 249 galactic clusters; from them he derived a value of 70,000 parsecs for the diameter of the Galaxy and a thickness of about 7,000 parsecs. These results were revolutionary, as the Galaxy's size was increased about tenfold over the model obtained from star counts; and the Sun was now assigned a highly eccentric position.

Most astronomers continued for awhile to support the star-count model. The proponents for the two models agreed on three points: (1) there is no interstellar absorption; (2) the relative distances of the globular clusters as determined by Shapley are correct; and (3) the stars in the clusters and in remote parts of the Milky Way are not peculiar but resemble those in the Sun's neighbourhood. Except for accepting point (1), Shapley was more correct in the determination of the dimensions of the Galaxy.

Trumpler in 1930 determined the distances of 100 galactic clusters from a study of the magnitudes and spectral types of their stars; his catalogs give a total of 334 clusters. From his study of the relation between the diameter and distances of the clusters he showed that there is absorption of light in the Galaxy. This absorption occurs mainly in a thin layer in the galactic plane, but it may be observed at all galactic latitudes. The existence of a general absorption (which produces a dimming of the light of distant stars) of 0.5 magnitude per kiloparsec had been found in 1929, but definite acceptance of it came only in 1930, when Trumpler published the results of his investigations. With proper corrections for the effects of interstellar absorption, the dimensions of the Galaxy be-

came: diameter between 25 and 30 kiloparsecs; the Sun 8.2 kiloparsecs from the centre.

## II. Basic information

### DISTANCE DETERMINATIONS IN THE GALAXY

Further investigations were aimed at determining the internal structure of the Galaxy. Accurate distances for individual objects, and, to this end, ways of discovering intrinsic brightness and details of the spectra of stars, were needed. The quantity that can then be deduced is the absolute magnitude of a star; that is, its brightness on a logarithmic scale.

All distance determinations depend on certain fundamental methods, which are described in PARALLAX, ASTRONOMICAL.

**Trigonometric parallax.** The basic quantity called trigonometric parallax is determined geometrically by direct measurement. The annual parallax,  $p$ , of a star is defined as the angle in seconds of arc (") that the mean distance,  $r$ , from the Earth to the Sun subtends at the star. The relationship between the distance,  $d$ , of a star and the parallax is  $p = 206,265'' \times r/d$ . Corresponding units of parallax and distance are seconds of arc and parsecs. A star at a distance of one parsec (pc) will have a parallax of one second of arc; the distance,  $r$ , would subtend an angle of one second of arc at the star at this distance. The parsec is equal to 206,265 astronomical units. Thus,  $d$  (pc) is  $1/p''$ . Since  $r = 1.49675 \times 10^{13}$  cm, 1 pc =  $3.086 \times 10^{18}$  cm.

The nearest star has a parallax of 0.76 second of arc. The direct method is useful to a distance of 20 parsecs. Other methods must be used for greater distances.

**Photometric methods.** The fundamental relation between the apparent brightness,  $m$ , and the intrinsic (absolute) brightness,  $M$ , both in magnitudes (logarithm of light energy), is

$$5 \times \log d = (m - M) + 5. \quad (1)$$

The quantity  $m - M$  is called the distance modulus of the star. For the determination of distances with the aid of the relation above,  $m$  is obtained from photometric observations.  $M$  must be obtained from established and calibrated luminosity criteria. The most important are derived from analysis of the stellar spectra (see STAR).

The stars are divided into spectral types and luminosity classes on the basis of the appearances of their spectra, the intensity ratio of certain absorption lines, and the intensities of selected lines. The currently most used classification system is the Yerkes system, with spectral types O, B, A, F, G, K, M, R, N, and S and luminosity classes I to V. The classification by spectral type is essentially a temperature classification; the O stars are the hottest, with surface temperatures up to 40,000° K. Their spectra are dominated by lines of ionized atoms. The Sun is a typical G star of about 6,000° K. The spectra of this class are dominated by lines caused by the presence of metals, as in the Sun. The cool red stars of class M have temperatures below 4,000° K; and R, N, and S stars are equally cool with spectra rich in molecular bands.

The luminosity classes group the stars according to size: class I (a and b) contains supergiants; class II, bright giants; class III, normal giants; class IV, subgiants; and class V, main sequence and dwarfs. A giant star has a much more extensive atmosphere, a much lower density, and a much brighter absolute magnitude than a dwarf has. Assignment of a spectral class and luminosity class places a star uniquely in the two-dimensional Yerkes classification system. Once the luminosity classes have been calibrated in absolute magnitudes by observations of nearby stars with well-known distances, they serve for determinations of distances for those stars for which spectra may be obtained but for which geometrical distances cannot be determined.

The absolute magnitudes of very distant stars may also be determined by multicolour photometry. The colour index of a star is defined as the difference between its apparent magnitude in two well-defined spectral regions; e.g., blue and visual (yellow). A combination of two or more colour indices (blue — visual, ultraviolet — blue,

Absolute magnitudes and the distance modulus

Discovery of interstellar absorption

etc.) gives quantities that may be calibrated to yield the value of  $M$ . Photometric observations of selected spectral lines have been used successfully in the direct determination of  $M$ .

For certain types of variable stars (Cepheids, RR Lyrae stars), relations that exist between the period, the luminosity, and the colour permit the determination of  $M$ .

For the "exploding" stars, the novae and supernovae, the absolute magnitudes at maximum light are well defined and may be considered known. The apparent magnitude,  $m$ , at maximum light is also needed to find the distance from equation (1). It may be observed if the nova is seen at maximum, or it may be derived from the light curve.

The main difficulties in determining the distances for the very distant stars are:

1. The effect of the interstellar absorption, mentioned above, and usually written  $A_\lambda$ . With this correction, which enters as a subtraction from  $m - M$ , equation (1) above becomes

$$5 \times \log d = (m - M) - A_\lambda + 5. \tag{2}$$

The absorption is usually determined from the interstellar reddening, denoted by  $R$ , and the colour excess, denoted by  $E$ , of the star. The following relation holds:

$$A_\lambda = R \times E. \tag{3}$$

The coefficient  $R$  may vary with the direction in space, but to what extent is not yet known. The colour excess,  $E$ , is determined as the difference between the observed colour, which is affected by distance of a star, and the intrinsic colour of its class in the Yerkes classification system.

2. The accurate calibration of spectroscopic and photometric criteria.

3. Lack of knowledge of the extent and influence of a variation in chemical composition of stars from one part of the Galaxy to another.

STELLAR VELOCITIES

**Components of stellar motion.** The speeds of the stars in the line of sight and across the sky are called radial velocities and proper motions. The radial velocities cause shifts of the wavelengths,  $\Delta\lambda$ , of the spectral lines due to the Doppler effect. If  $c$  stands for the velocity of light, and  $\lambda_0$  for the laboratory position of the line in question, the wavelength,  $\Delta\lambda$ , is then related to the radial velocity,  $V$  km/sec, by the formula  $V/c = \Delta\lambda/\lambda_0$ . A red shift means that the star is moving away from the Earth. The proper motions,  $\mu$ , of the stars are measured first as a change in position, a very small angle expressed in seconds of arc per year. The star positions are measured at intervals of 10 to 50 years relative to very distant stars or external galaxies with no significant motion (see STAR). To find the actual speed across the sky, called the tangential velocity,  $T$ , a scale provided by the star's distance (or parallax) is needed. Then, if  $p$  is the parallax of the star in seconds of arc,

$$T = 4.74 \frac{\mu}{p} \text{ (km/sec).}$$

The space velocity  $v$  of the star is the square root of the sum of the squares of the radial and tangential components,  $V$  and  $T$ :  $v = (V^2 + T^2)^{1/2}$ , and the angle between the space velocity and the line of sight is also readily determined.

For many studies of motions in the Galaxy the space motion  $v$  is divided into a set of components related to directions in the Galaxy:  $U$ , directed away from the galactic centre;  $V$ , in the direction of galactic rotation; and  $W$ , toward the north galactic pole.

**The solar motion.** Radial velocities are always referred to the Sun and are normally reduced to the local standard of rest (LSR). This is a point moving at the mean speed of all stars near the Sun. The motion of the Sun relative to the LSR is referred to as the solar motion. The point on the celestial sphere toward which the Sun is moving is called the apex of the solar motion; the stars located in that direction appear on the average to be approaching,

while stars in the antapex direction appear to be receding. Star streaming is observed as a reflex of the solar motion. It is, of course, seen in the radial velocities as well as in the proper motions of the stars, and both types may be used for the determination of the direction of the solar motion. The radial velocity data will also give the velocity of the Sun relative to the LSR. If, in addition, the distances of the stars are known, their space motions may be used.

Different spectral classes of stars yield different solutions for the solar motion, largely reflecting the fact that the stars of the various classes differ appreciably in age. Table 1 gives the adopted components of the solar motion.

Table 1: Adopted Components of the Solar Motion and Velocity Dispersions

type	solar motion (km/sec)			spread in velocities (km/sec)

Frequently the standard solar motion is used. It is defined as the solar motion relative to the stars forming the majority in the general catalogs of radial velocities and proper motions. It has the values  $U_s = -10.4$  km/sec,  $V_s = +14.8$  km/sec,  $W_s = +7.3$  km/sec, corresponding to  $v_s = 19.5$  km/sec in the direction with galactic coordinates  $l = 56^\circ$ ,  $b = +23^\circ$ .

III. Interpretations of observational data

THE STARS AND STAR CLUSTERS NEAREST THE SUN

**The nearest stars.** Within five parsecs from the Sun, 41 stars are known. Of these, 11 are visual binaries or multiple systems, so that the total number of known components is 55. Only four of these stars are more luminous than the Sun, viz., Sirius, Altair, Procyon, and Alpha Centauri, which are also among the 20 brightest stars seen in the sky. Five of the stars in the immediate neighbourhood of the Earth are white dwarfs; the others are main-sequence stars, preponderately dwarf stars of class  $M$  (see Figure 2). Within 20 parsecs from the Sun, about 1,100 stars (including all components in multiple systems) are known. Knowledge of these stars is incomplete; if the space density of stars for the interval from zero to four parsecs is one, it is only 0.28 for the interval 15-20 parsecs. Ninety percent of these stars are main-sequence stars of type G to M.

**The nearby clusters.** The stars of a galactic cluster are close together in space. If a cluster is real and stable, all its stars should share a common motion. They should move through space in parallel paths and with identical speeds. If they are sufficiently close to the Earth to show measurable proper motions, they are referred to as moving clusters. The importance of the Hyades cluster, which is the prototype of this class, is notable. The most complete study of the Hyades cluster shows it to be a flattened system with its shortest axis perpendicular to

Problems in establishing distances for very distant stars

From van de Kamp in B.J. Bok and P.F. Bok, *The Milky Way*, 3rd ed. (1957); Harvard University Press.

the galactic plane and about two-thirds as long as the axis in the plane. The cluster is only 40 parsecs from the Sun. The stars are concentrated somewhat irregularly toward the centre of the cluster. The bluest star is of spectral type A2, and there are a few G- and K-type giant stars. The majority of the cluster members are G- and K-type main-sequence stars. The average density of cluster stars is at least three times the average density for the region around the Sun.

The total number of moving clusters is small, since almost all galactic clusters are so far away that they do not show measurable proper motions. The Ursa Major cluster, the Alpha Persei association, and the Scorpius–Centaurus association are well-proved moving clusters. A number of moving groups have recently been identified. Among the stars studied are the bright A-type stars. Their distribution in the velocity plane ( $U$ ,  $V$ ) is roughly elliptical, but it shows also a high degree of clumpiness; the clumps have been identified with five groups of kinematically related stars.

#### THE HERTZSPRUNG–RUSSELL DIAGRAM

A graphic representation in which spectral type is plotted against absolute magnitude is called a Hertzsprung–Russell (H–R) diagram, after the two astronomers who discovered the relations between the spectral types and the absolute magnitudes of the stars (Figure 2; see also STAR CLUSTERS AND STELLAR ASSOCIATIONS).

Stars are never distributed at random in an H–R diagram but form sequences according to which the stars are classified. The reasons for the existence of sequences is that for stars of the same chemical composition there is a certain value of the intrinsic brightness, luminosity ( $L$ ), and temperature ( $T$ ) for each value of the mass. When groups of stars of the same mass form different sequences in the H–R diagram it is concluded that they have different chemical composition.

Two stellar populations with differences in metal content, space distribution, and kinematic properties exist. A German astronomer, Walter Baade, was the first to realize this from his observations of the Andromeda galaxy, M31 (31 in the Messier catalog). Population I stars are young, metal-rich objects found in the spiral arms and associated with interstellar dust and gas. Population II stars

are old and metal-poor and much less concentrated to the galactic plane than the young stars. A sequence of intermediate populations is likely.

The spectral type is nowadays frequently replaced by the colour index,  $B - V$  (blue magnitude minus visual), in the H–R diagram; it is then also called a colour–magnitude diagram. A diagram for a number of young galactic clusters belonging to Population I and similar diagrams for an old galactic cluster and for globular clusters, representing Population II, are given in the article STAR CLUSTERS AND STELLAR ASSOCIATIONS.

The galactic clusters serve the important purpose of calibrating the H–R diagram. Several of them are nearby clusters: the Hyades, the Pleiades, Praesepe, the Coma Berenices cluster, and NGC 752 (NGC stands for Johann Dreyer's *New General Catalogue of Nebulae and Clusters of Stars*). Some more remote clusters have been added for the completion of the zero-age main sequence (ZAMS); notable are NGC 2362,  $h$  and  $\chi$  Persei, M67. The ZAMS is the path or locus in the colour–absolute magnitude diagram of stars that have completed their gravitational contraction but have not yet evolved further as a result of the hydrogen burning in their cores. The calibration of the diagram started with the Hyades, for which the distance is known from direct measurements. Some of its stars on the lower part of the sequence have not yet had time to evolve. To this part of the sequence the unevolved parts of the Pleiades, a well-known cluster in the constellation Coma Berenices, and others are fitted; and the ZAMS is thus extended to the younger and more luminous stars.

The composite colour–absolute magnitude diagram of the nearby young clusters gives a tool for the determination of accurate distances to remote galactic clusters; after correcting for interstellar absorption, their apparent magnitude–colour diagrams are fitted to the ZAMS and the distance modulus,  $m - M$ , is read directly. The diagrams also give a reliable method for estimating ages of galactic clusters; the spectral type or colour of the hottest star still on the ZAMS, at the turnoff point, gives the age of the cluster. Thus, NGC 2362 is about  $10^6$ , the Pleiades  $2 \times 10^7$ , the Hyades  $4 \times 10^8$ , and M67  $5 \times 10^9$  years old.

#### THE STARS AND INTERSTELLAR MATERIAL

To discover the size and shape of the Galaxy, the Sun's position in the system, and the distribution and total content of stars and interstellar material, regions at great distances must be surveyed. At the time that the program for the Selected Areas was proposed, it appeared reasonable to count the stars in successive magnitude intervals to faint limits in many parts of the sky and to determine from these counts the stellar density at various distances from the Sun. It is necessary to assume that the general luminosity function (*i.e.*, the number of stars per unit volume and interval of absolute magnitude), is the same everywhere in the galactic system and equal to the one known for the solar neighbourhood.

This approach has given valuable information out to distances of about one kiloparsec, particularly when the material has been divided according to spectral classes. At greater distances, however, it is not certain that the general luminosity function applies, and a different approach has to be used. Certain types of objects have turned out to be particularly suitable for galactic studies. A summary of typical objects representing the most well-defined population is given in Table 2. Some of the groups are considered below in more detail.

**Extreme Population I.** All objects in this class are important in outlining the spiral structure of the Galaxy.

**The gas.** The optically identifiable gas is mainly hydrogen, emitting radiation, notably at the wavelength called H-alpha in the red. The locations in which the gas is found are called H II regions. For observable emission to be produced, the combination of a hot exciting star and an interstellar density of one to 10 hydrogen atoms per cubic centimetre is necessary.

When the Andromeda galaxy, M31, was searched for H II regions in 1951, about 300 discrete emission regions were found, almost all of them clearly associated with the

The general luminosity function

Stellar populations

Figure 3: The distribution of emission nebulae in galactic coordinates. The sizes of the circles and dots indicate the apparent sizes of the nebulae (see text).

shows the observed distribution of about 400 H II regions (bright emission nebulae) in galactic coordinates. Most of them are probably within two kiloparsecs of the Sun, indicating that at least 10,000 H II regions may exist in the Galaxy. Figure 3 shows that the concentration of H II regions is high in the direction of the galactic centre ( $l = 0^\circ$ ,  $b = 0^\circ$ ) and that there is a pronounced gap in the interval between  $l = 298^\circ$  and  $l = 333^\circ$ . Other concentrations and gaps may be seen. Their positions are related to the spiral structure of the Galaxy in a way similar to that observed in M31.

**The galactic clusters.** The distances to remote galactic clusters can be obtained with high accuracy by fitting their observed main sequences to the zero-age main sequences as described above. The space distributions thus obtained will give useful information about the structure of the Galaxy. In addition, because the ages of the various clusters can be relatively well determined, valuable information is obtained about the evolution of various features in the Galaxy with which the clusters are connected.

Over 500 galactic clusters are known, most of them within two kiloparsecs of the Sun. The local space density of clusters is about 700 per cubic kiloparsec, indicating a total number of between 10,000 and 100,000 in the Galaxy. The young clusters (*i.e.*, those containing O and B stars) show a strong tendency to concentrate in the

same regions as the ionized hydrogen clouds, whereas the older clusters do not.

**The high-luminosity stars.** The high-luminosity stars of early type, the O-B stars (O to B2), frequently form associations. An association, unlike a cluster, has a star density considerably less than that of the surrounding field and is thus likely to dissipate rather rapidly, probably in about  $10^7$  years. Many associations are also expanding. It appears likely that all O- and B-type stars in the Galaxy originated in O-associations, and the existence of these very young groupings indicates that star formation is still going on in the Galaxy.

Several thousand O-B stars have been found in spectral surveys using telescopes equipped with objective prisms. Most of them are within two or three kiloparsecs of the Sun. Their distribution is similar to that of H II regions and young clusters.

The distribution of 27 O-B stars within 400 parsecs from the Sun is similar to that of the nearby H II regions. They define a plane inclined about  $20^\circ$  to the galactic plane, coinciding well with Gould's Belt, which may be a tilted system relatively close to the Sun.

The supergiant stars of spectral types A5 and later are probably distributed rather similarly to the O-B stars. For most types the absolute magnitudes are not sufficiently well known for accurate distance determination. The M-type supergiants have been found in O-associations in the Galaxy as well as in the Large Magellanic Cloud. Best known in the Galaxy are the 13 M-type supergiants in the region of *h* and *chi* Persei, belonging to the O-association I Persei. This type of association may represent a brief period in the evolution when the most massive stars have evolved away from the main sequence but the association has not yet diffused into the field.

M supergiants are relatively easy to detect in low-dispersion spectral surveys in infrared light, in which the effect of interstellar absorption is less pronounced. They should therefore give information about the galactic structure at distances not attainable by means of the blue luminous stars.

Very important for studies of galactic structure are the so-called Wolf-Rayet stars, recognized by their strong emission features caused by helium, carbon, oxygen, nitrogen, and other atoms. They have been identified in the Galaxy up to 10 kiloparsecs from the Sun. Their connection with O-associations and H II regions has been clearly established by their distribution in the Large Magellanic Cloud, the galaxy nearest to the Earth. Unfortunately, there are only about 120 objects of this class known in the Galaxy so far.

Supergiant and Wolf-Rayet star

**The T-associations.** T Tauri variables are young stars formed out of the interstellar dust and gas clouds in which they are found. They are faint dwarf stars, usually identified from their variability or their emission-line spectra. They are usually found in groups, named T-associations. One of the best known is in the Orion Nebula.

**The classical Cepheids.** These stars belong to a class of pulsating variables with regular luminosity variation, named after the prototype, Delta Cephei. The periods of the galactic Cepheids lie mainly between two and 40 days. Together with the luminosity variation occurs a colour change; the star becomes redder as it becomes fainter. An extremely important relation between the period and the average brightness of a Cepheid was found in 1912 through studies of the Cepheids in the Small Magellanic Cloud, one of the two nearest galaxies: the longer the period, the more luminous the Cepheid. As all the stars in the Small Magellanic Cloud are at about the same distance from the Earth, it may be concluded that this relation is due to the intrinsic qualities of the stars.

When a zero-point has been established, this relation provides a method for the determination of accurate distances of individual Cepheids. The zero-point depends strongly on observations of Cepheids in clusters with known distances.

Nowadays, the distances of the classical Cepheids are determined from the period-luminosity-colour relation. It is also possible to estimate rather accurately the age of a Cepheid from its period. The youngest Cepheids,  $3 \times 10^7$  years old or younger (with periods longer than 11.25 days), have a galactic distribution similar to that of the H II regions and the youngest clusters.

**Older Population I.** The majority of stars identified in spectral surveys are main-sequence stars from B5 to F5 and normal giant stars from F8 to M. Knowledge of this group of common stars is limited to a rather small volume near the Sun. Occasionally, in unobscured regions, their distribution has been obtained out to two kiloparsecs; the normal limit is more like 1,000 parsecs.

Concentrations of B5 stars have been found between 500 and 1,000 parsecs from the Sun, concentrations of B8 to A0 stars within 500 parsecs from the Sun as well as at distances of one kiloparsec, and between 1.5 and two kiloparsecs in certain directions.

A conspicuous grouping of F0 to F5 stars occurs around the Sun. An average decrease in space density of 65 percent has been observed over the first 600 parsecs from it. It has been proposed that the grouping is a transient phenomenon with a maximum age of  $2 \times 10^7$  years.

The G8 to K3 giant stars are uniformly distributed in the region from the Sun, and the whole group of common giants shows a remarkably constant space density from two kiloparsecs in the anticentre direction to two kiloparsecs toward the galactic centre.

Further studies of the B8 to A3 stars within 500 parsecs of the Sun indicate that they are associated with the local spiral structure, and, if the Sun is situated toward the inner edge of the local spiral arm, the A-type stars also predominate toward the inner edge of this arm.

**The disk population.** *Planetary nebulae.* The planetary nebulae are gaseous objects that often appear as faint, greenish disks, not unlike the images of Uranus and Neptune. Their spectra are rich in emission lines of hydrogen, helium, and forbidden lines (so called because they violate certain rules governing transition probabilities) of oxygen, neon, nitrogen, and other elements. There is also a continuous bright background that is often faint. The emission lines make these objects easy to identify at great distances, and their radial velocities can likewise be determined. With few exceptions, however, the distances of these objects are still poorly known.

The distribution of the presently known 1,000 or so planetary nebulae shows a high concentration toward the galactic centre and a pronounced concentration toward the galactic plane. The majority of the planetary nebulae seen in the galactic centre direction are actually at the centre of the Galaxy.

**Novae.** Information about this group of "exploding" stars is incomplete. At distances beyond 800 parsecs from

the Sun most novae discovered are of high intrinsic brightness. Various expressions for the determination of their absolute magnitudes at maximum brightness have been given; the most reliable appear to be connected with the time it takes the nova to decrease three magnitudes in blue lights. The values vary between  $M = -6$  and  $-8$  magnitudes. In the H-R diagram the novae at minimum are intermediate between stars called white dwarfs and the subluminescent B stars. The novae are highly concentrated toward the galactic plane but also toward the galactic centre.

**The supernovae.** Supernovae, exploding stars that are immensely more powerful than ordinary novae, belong to two fundamentally different types. Type I objects form a group with closely similar light curves and spectra. At maximum their mean absolute magnitudes are  $-19$ , nearly 10,000,000,000 times more brilliant than the Sun. They belong to Population II. The type II objects form a group with some similarities in light curves and spectra but also with marked individual differences. At maximum they are bluer than type I but less luminous; the mean absolute magnitude is about  $-17.7$ . They are members of Population I.

Remnants of several supernovae have been identified in the Galaxy; best known are the Crab Nebula (supernova of 1054), Tycho's star (1572), and Kepler's star (1604).

The frequency of supernovae in the Galaxy is one supernova per  $26 \pm 10$  years. The type II supernovae have a frequency of one event per 38–60 years; this is compatible with the assumption that all stars in the mass range from four to nine solar masses eventually become first supernovae and finally pulsars (see below). Type I supernovae are tentatively identified with exploding white dwarf stars whose parent stars had masses greater than nine solar masses. During the lifetime of the Galaxy there may have been  $2.6 \times 10^9$  supernovae of type II involving nearly 10 percent of the mass of the Galaxy. The corresponding estimates for type I supernovae are  $5 \times 10^8$  and 4 percent of the mass (see also STAR).

**Intermediate Population II.** Most stars near the Sun have velocities relative to it not above 30 kilometres per second, but some, the high-velocity stars, greatly exceed this value. Stars with velocities in excess of 60 kilometres per second are generally counted in this class. Over 600 such objects have been cataloged.

The velocity vectors for the high-velocity stars within 20 parsecs of the Sun are concentrated almost entirely in one hemisphere; no high-velocity star is seen moving toward the Cygnus section of the Milky Way. Their velocity vectors are also concentrated toward the galactic plane.

The percentage of high-velocity stars for the various spectral types is given in Table 3. The H-R diagram for the high-velocity stars resembles mostly that of the cluster known as M67, which contains the old Population I.

The high-velocity stars

Table 3: High-Velocity Stars in Various Spectral Types

stellar type	percentage with high velocities	stellar type	percentage with high velocities
O	0	G0–G9 (main sequence)	16
B0–A3 (supergiants)	0	K0–K9 (giants)	5.7
B0–B9 (main sequence)	0.4	K0–K9 (main sequence)	18
Cepheids	0	M (giants)	1.7
A0–A9 (main sequence)	0.1	M (dwarfs)	47
F0–F9 (main sequence)	3.4	RR Lyrae stars	72
G0–G9 (giants)	3.9	Globular clusters	100

Peculiarities in the spectra of the high-velocity stars are: in the range F5 to G5 they show a general weakening of the atomic lines; and in the range G6 to K4 the giants and subgiants show a deficiency in cyanogen. Thus, the high-velocity stars are metal-poor and may be found by the use of spectroscopic criteria.

**Halo Population II.** *The globular clusters.* About 200 globular clusters are known within the Galaxy. Their distribution in galactic longitude is remarkable; one-third of them are found in the general direction of the galactic

centre and practically all are in the “galactic-centre-half” of the sky as seen from the Sun. Their distribution projected on a plane perpendicular to the galactic plane is shown in Figure 4 together with some lines of equal mass density. The globular clusters form a spherical system. Their stellar content is different from that in the solar neighbourhood and is frequently used as prototype for Population II. There are, however, important differences in chemical composition between the globular clusters in different parts of the Galaxy. It is found that the more metal-rich globular clusters are concentrated toward the galactic centre, whereas the clusters of very low metal content are found from 12 to 16 kiloparsecs from the centre.

Figure 4: The distribution of globular clusters projected on a plane perpendicular to the galactic plane and passing through the galactic centre and the Sun. Lines of equal mass density are also drawn, but the high stellar density in the galactic centre is not indicated. North is at the top. Distances from the centre of the Galaxy in kiloparsecs are given below and to left of figure.

Absolute magnitudes for the stars in the globular clusters have been obtained by fitting the main sequences to a Hyades-like main sequence with low metal content; so far this has been done for four clusters. The mean absolute blue magnitude of the 25 brightest stars was thus found to be  $-0.8$  magnitudes and that for the RR Lyrae stars to be  $+0.5$  magnitudes.

**The RR Lyrae stars.** In the horizontal branch of the colour-magnitude sequence of a globular cluster is a region occupied by RR Lyrae stars in many clusters. These pulsating cluster variables identify two different types of globular clusters; those with RR Lyrae stars with periods around 0.54 day have a higher metal content than those with periods around 0.64 day.

The distribution of the RR Lyrae field stars (those not associated with any cluster) over the sky is uniform with no indication of any concentration. The average period for these stars is 0.54 day. The absolute magnitudes needed for the determination of their space distribution have been obtained from the RR Lyrae stars in the globular clusters.

**Interstellar lines in stellar spectra.** The first interstellar absorption line was discovered in 1904. The wavelengths of lines called H and K lines (of ionized calcium) in the spectrum of the spectroscopic binary Delta Orionis were found not to vary at all during the binary period. This showed that they were formed not in the star, but in front of it. In 1909 an interstellar origin for those features was suggested, and the existence of similar lines due to sodium was predicted. The “stationary” D-lines of sodium in

Discovery of the interstellar absorption lines

Delta Orionis and other stars were discovered 10 years later.

Systematic observations of such lines in 1933 firmly established that interstellar matter takes part in galactic rotation. The galactic-rotation wavelength shift of the interstellar Ca II lines in the spectra of 314 early-type stars was found to be about one-half that of the stars in which they were observed. Initially this was taken to indicate a nearly uniform density distribution of the absorbing matter between the Earth and the stars. It was, however, soon obvious that the interstellar matter was distributed differently.

Two American astronomers, O.C. Wilson and Paul Merrill, have concluded that “the observations can be accounted for by making the hypothesis that interstellar sodium occurs in discrete aggregations or clouds, which, while participating in the general galactic rotation, have in addition considerable random motions.” The known interstellar atomic and molecular lines are listed in Table 4 together with a number of diffuse lines that have not yet been identified.

Table 4: Interstellar Absorption Features				
atomic lines		molecular lines		diffuse lines
atom or ion	$\lambda$ (Å)	molecule	$\lambda$ (Å)	$\lambda$ (Å)
Na I	3302.34	CH	4300.31	4430.6
	2.94		3890.23	4760
	5889.95		86.39	5780.5
	95.92		78.77	5797.1
K I	7664.91		3146.01	6203.0
	98.98		43.15	6270.0
			37.53	6283.9

	83.76			
Fe I	3719.94			
	3859.91			

Interstellar lines of ionized calcium and of some molecules found in the spectra of 300 bright O and B stars were studied at high dispersions in the 1940s. Multiple components occurred frequently. Generally, the multiplicity indicated a series of clouds at different distances in the line of sight. Their different velocities caused different wavelength shifts and arose from galactic rotation.

Attempts have been made to describe the system of interstellar clouds by the mean number of clouds per kiloparsec in the galactic plane. For this to be possible, the clouds must have a random distribution, but while this may possibly be true in the solar neighbourhood, it is not in the Galaxy as a whole. A typical large cloud may have a radius of about 15 parsecs and a total mass of 7,000 solar masses, and its dust would absorb one magnitude in the blue spectral region. There would be 0.7 such clouds per kiloparsec. Smaller clouds must be present here and there to explain the observations.

**Interstellar dust.** Interstellar dust may be observed as reflection nebulae that scatter the light from bright stars near them, as dark nebulae that absorb starlight, and by polarization effects.

**Reflection nebulae.** Reflection nebulae have recently been found to form groups called R-associations. Some of them coincide with O-associations, others with T-associations. Their space density in the solar neighbourhood appears higher than that of O-associations. This is due to the higher density of late B and A stars, which dominate the R-associations. Their distribution is similar to that of O-associations. Most nebulae are found within  $20^\circ$  of the galactic plane. Their distribution along the galactic equator is somewhat uneven. Some parts appear almost unobscured, but photometric observations establish that no absorption due to scattered dust occurs.

Distances to dark nebulae can be determined from star counts in the observed area and in a clear comparison area (see NEBULA).

The discrete-cloud picture of the interstellar gas, based on the interstellar absorption lines, originates from the studies of the interstellar dust. It has been shown that the clouds of dust and gas may be regarded as identical. Certain small dust clouds have attracted great interest.

**Globules.** Globules are dust clouds of high density with diameters up to about one parsec and masses up to about 30 solar masses. Similar small units of the hydroxyl radical, OH, have been found by radio astronomers. It appears likely that these units will collapse gradually into stars or clusters of stars.

**Interstellar absorption and polarization of starlight.** The proportion of starlight absorbed increases with decreasing wavelength, producing selective absorption or reddening. Observations now extend out to wavelengths of two to five microns, and there is some doubt about the validity of a general law of reddening.

Polarization produces a preferred plane of vibration for the light waves; it is observed only in stars that also show interstellar absorption effects. The polarization,  $p$ , is connected with the colour excess,  $E_{B-V}$ , in such a way that  $p$  is less than or equal to  $0.195 \times E_{B-V}$ .

The directions of the electric vectors of polarized light tend to lie parallel to the galactic plane over a long range of galactic longitude, though there are more complex regions.

Effects of  
interstellar  
dust

Both the absorption and polarization effects are caused by the interstellar dust grains. To produce polarization effects the grains have to be elongated and aligned. The observations are best explained by assuming the alignment to be caused by a magnetic field.

A suggested explanation is that the elongated dust grains are paramagnetic—that is, that they behave like tiny permanent magnets—and rotate rapidly as a result of collisions with interstellar gas atoms. The short axes of the grains will be aligned with the direction of the magnetic field. As the field is frequently parallel to the galactic plane, the particles will be aligned with their short axes parallel to the plane. Hence, the strongest radiation will be received in the plane containing the short axis and the line of sight. This is the direction of the electric vector and gives the projection of the magnetic field on the plane of the sky.

The amount of polarization in any direction depends on the number of dust particles and the degree of alignment. The longitudinal dependence of polarization makes it possible to determine the mean direction of a spiral arm, provided that the axis of the arm and the direction of the magnetic field are parallel.

Observations show that the polarization decreases toward ultraviolet as well as toward infrared light from a maximum in between. This is quite different from the wavelength dependence of the interstellar absorption, which is approximately inversely proportional to the wavelength in the visual region. Theoretical computations indicate that the dust particles may consist mainly of ice and graphite, though complete agreement with observations has not yet been obtained. Various proposed grain types are: dielectric ("dirty" ice), metallic (iron), graphite, ferrite, coated grains (core of graphite, coated with dirty ice), and large free radicals (for further details, see INTERSTELLAR MEDIUM).

**Radio observations.** The radio continuum. Following the discovery of radio radiation from the Milky Way in 1931, many large-scale surveys have been completed in the radio continuum, the first in 1944. The common result of all surveys appears to be confirmation that the regions of equal intensity of radio radiation are arranged more or less symmetrically about the galactic equator. All surveys show that the radiation with maximum intensity reaches the Earth from the direction of the Milky Way centre in Sagittarius.

The observed radio spectrum extends over a wide wavelength range, from a few millimetres to about 30 metres, with the cutoff at each end produced by the Earth's atmosphere. At long wavelengths, the radio background

from the Galaxy extends over the whole sky with many superposed local sources of various sizes. There is a clear concentration toward the galactic plane. "Steps" in the longitude distribution can be seen near the plane; they correspond to spiral arms seen "end-on." A number of spurs are also noted; they extend frequently almost perpendicularly from the plane. At wavelengths less than 50 centimetres the background is detectable only in a narrow strip along the Milky Way, about four degrees wide. In this band are many stronger sources. Sources found outside the band are frequently extragalactic.

The difference in continuum distribution at different wavelengths (the spectral index) over the sky shows that more than one emission mechanism must be operating. Emission produced by exchange of energy between free electrons (called free-free emission) occurs in ionized hydrogen and is found in H II regions (some of the distant ones may be optically obscured) and in a general background concentrated to a thin layer. The synchrotron process (emission through acceleration in a magnetic field) is seen in the disk, the spurs, the radio halo, and in supernova remnants of which about 40 are known.

Polarization of radio wavelengths may be observed as:

1. Linear polarization of the galactic background radiation. Most of the areas with observable polarization lie in a band about  $60^\circ$  wide, containing a great circle through the galactic poles, intersecting the plane at longitudes  $340^\circ$  and  $160^\circ$ , a direction perpendicular to that of the main local field.

2. Faraday rotation (a rotation of the polarization direction during passage through a magnetic field) and depolarization of the polarized emission from the background are observed as a disappearance of the polarization for wavelengths over one metre.

3. Faraday rotation of the radiation from extragalactic sources gives information about the longitudinal component of the magnetic field through the nearby galactic disk.

Polarization studies can be used only to study the local region.

**The 21-centimetre line.** Produced by neutral hydrogen atoms, the 21-centimetre line is observed from galactic hydrogen all over the sky, with a major concentration along the Milky Way. No increase of intensity toward the galactic centre direction has been found. Some of the line detail is related to optically observable features.

The 21-centimetre line has a very small natural width at 1,420.406 megahertz. The broadening of the galactic profiles is essentially due to the Doppler effect, caused partly by thermal motions in the gas clouds but mainly by galactic rotation and mass motions. The main peaks of the profiles are closely related to the spiral structure of the Galaxy.

Several extensive surveys have been carried out along the Milky Way band, and an enormous amount of data is now available.

Twenty-one-centimetre absorption lines have been observed in the direction of discrete continuum sources; they can be used to estimate the distances to the sources and to investigate the excitation temperature of the hydrogen. So-called Zeeman splitting has been observed in the absorption lines.

**The hydroxyl (OH) lines.** The group of four lines, with wavelengths near 18 centimetres, is produced by an interaction between the spin of an unpaired electron and the molecular rotation with additional effects produced by hyperfine splitting (a separation of a spectral line into several components in a magnetic or electric field). The frequencies of the lines are 1,612, 1,665, 1,667, and 1,720 megahertz, with intensity ratios of 1:5:9:1 under local thermodynamic equilibrium. The transition probability of the main lines is 10,000 times that for the 21-centimetre line of neutral hydrogen.

The OH lines can be seen in absorption in front of many continuum sources. As the velocities are generally close to those found for H I, the OH is most likely widely distributed throughout the H I regions.

Nonthermal, very complex, OH emission has been detected from over 20 H II regions. Most of the line compo-

Studies of  
polariza-  
tion  
of radio  
wave-  
lengths

nents are very narrow, and the line-intensity ratios are anomalous. The sources are very small in angular size (e.g., in one source, less than  $0''.02$  or less than 35 astronomical units). Nothing optically significant has been seen at these positions.

Some of the sources show marked time variations, and many components show strong circular or linear polarization. There is general agreement that a maser phenomenon is responsible for the nonthermal emission, but the detailed mechanism is not yet understood. Nonthermal OH emission has also been observed in a number of infrared stars. Low-level thermal OH emission has been detected from nearby dust clouds.

**Recombination lines.** Many of the high-level transitions in excited hydrogen atoms have been detected at radio wavelengths from H II regions. These transitions occur when an electron cascades down through a series of levels during the recombination of a hydrogen atom. A frequently observed line occurs at 5,008.9 megahertz, near six centimetres, when the principal quantum number changes from 110 to 109; this is called the H-109 $\alpha$  transition. The recombination-line observations enable H II regions to be seen all over the Galaxy and their kinematics to be investigated.

Helium recombination lines and a possible carbon line have also been observed from many H II regions.

**Interstellar molecules.** A large number of molecules have now been discovered in interstellar space (see INTERSTELLAR MEDIUM). These discoveries provide new knowledge about the composition of the Galaxy. Although the molecules are trace constituents, typically less than one part per million of neutral hydrogen, the study of their excitations and abundances gives important measures of the present physical conditions in the Galaxy and of the history of the interstellar gas and dust clouds.

The processes that form these molecules are not well understood but are probably dependent on dust grains associated with the gaseous clouds. Some molecular species have been found only in specific directions in certain very dense clouds.

The interstellar clouds are frequently quite inhomogeneous and show rather large velocity spreads and temperature variations; the denser ones are probably subject to considerable instability and activity, which may include the formation of stars.

**Pulsars.** Pulsars can be considered as continuum emitters, since their radiation covers a very broad spectral range, and as line emitters, because the very precise pulse repetition rate corresponds to a sharp low-frequency spectral line (see PULSAR).

Studies of pulsars are often concerned with the intrinsic properties of the objects, but pulsars can also be used to study the mean electron density in the interstellar medium through measurements of the pulse dispersion effects. As more pulsars are detected, they should contribute information on galactic structure. The more than 60 known pulsars (December 1971) appear to be concentrated in the local and Sagittarius arms, and their mean height above the plane is consistent with that of known supernova remnants.

**Infrared observations.** The infrared spectral region includes wavelengths between one micron and one millimetre. Intensive studies using available atmospheric windows between one and 20 microns and airborne telescopes for wavelengths between 50 and 500 microns have been undertaken.

In a sky survey at 2.2 microns, between declinations  $-33^\circ$  and  $+80^\circ$ , about 5,600 sources brighter than  $4 \times 10^{-25}$  watts per square metre per hertz have been detected. Most of these sources are identified with late-type giants of type K5 and later. The 50 reddest sources, with colour-temperatures of the order of 1,000° K, have not been identified with cataloged optical sources.

Many of the galactic infrared sources are stars with an infrared excess over the blackbody radiation of a temperature corresponding to the spectral type.

Almost all stellar infrared excesses are assumed to arise from thermal radiation in a circumstellar dust shell. The amount of energy contributed by the circumstellar com-

ponent, however, varies widely from one type of star to another.

A strong correlation has been found between the visual polarization and the infrared excess at 11 microns; this is related to the scattering and absorption of the solid particles in the circumstellar clouds.

The origin of the dust shells may be either the remnants of the dust cloud from which the star was born, or material ejected from the central star.

In some objects infrared excess is of special interest:

The infrared excess in carbon stars is a smooth function of the wavelength. This may be explained by a dust shell forming an extension of the stellar atmosphere and composed of graphite particles.

The T Tauri stars in general have large infrared excesses. The circumstellar shell may be a remnant of the protostar but may also be partly ejected material.

All observed Be (emission) and Of stars have infrared excesses at 3.5 microns. The nonstellar component is consistent with free-free emission of ionized hydrogen.

At 20 microns the brightest known celestial source outside the solar system is a famous southern object called Eta Carinae. Its cool infrared component cannot be adequately represented by blackbody radiation at a single temperature. A more detailed dust model is needed to explain the data. The Orion Nebula (M42), the Lagoon Nebula (M8), and the Omega Nebula (M17) have been studied in detail in the infrared; strong sources are associated with all three.

Their infrared radiation is due either to dust heated by the radiation from the stars and gas in the nebula, or to dust and gas associated with the process of star formation and heated by gravitational contraction.

The main components of infrared radiation from the galactic nucleus are:

1. A one-degree source, observed between 1 and 5 microns. Its maximum brightness is within  $15''$  of the centre of the radio source Sagittarius A and within  $4'$  of the dynamical centre of the Galaxy. If the source of this radiation is stellar, the density of the stars in the core of the galactic nucleus has to be at least  $10^7$  times larger than that in the solar neighbourhood. The radiation from these stars is also affected by about 30 magnitudes of visual absorption. At 2.2 microns a point source is found with a luminosity  $3 \times 10^5$  times the solar luminosity, as if it were at the distance of the galactic centre. It is probably a bright star like Alpha Orionis (Betelgeuse).

2. A  $15''$  source coincident with Sagittarius A and isolated mainly at 10 and 20 microns. Its energy distribution suggests that there may also be a concentration of dust in the central one-parsec core and that the source is thermal re-emission of absorbed starlight.

3. A  $2^\circ \times 4^\circ$  source found at 100 microns and rich in fine structure. It has three major constituents that are similar to the distribution at 11-centimetre wavelength. The brightest region nearly coincides with the dynamical centre of the Galaxy, a weaker one with the H II region Sagittarius B. The origin of the 100-micron source is unknown, but the similarity to the 2.2-micron distribution suggests that a significant portion of the 100-micron flux is thermal re-radiation of starlight.

**X-ray and gamma radiation.** X-ray sources. X-rays occupy the spectral region below 100 Å, the soft X-rays from 100 to 1 Å and the hard X-rays below 0.1 Å. Rockets or satellites must be used for observations of the soft X-rays from cosmic sources; the hard X-rays and gamma rays can be detected from balloons.

About 50 cosmic X-ray sources are known, at least seven of which are extragalactic. It is believed that the emission takes place in optically thin clouds of plasma by thermal or nonthermal processes.

The galactic sources show a high concentration to the galactic plane. The optical counterparts appear to be either peculiar stellar objects or supernova remnants. Best studied is the stellar object Scorpius X-1. Its optical spectrum shows lines of hydrogen, helium, and oxygen in emission on a high-temperature continuum. The continuum shows variable intensity; the "star" shows rapid oscillations as well as slower fluctuations and also short flares.

Infrared emission from the galactic nucleus

**Observations of gamma radiation.** Galactic high-energy gamma radiation is observed from balloons or satellites, since the Earth's atmosphere is impenetrable to it. Several point sources have been found as well as a diffuse source at the galactic centre. The flux of gamma rays appears to be about four times greater along the galactic plane near the centre than in the rest of the sky. One source appears to be variable. There are many theories for the formation of gamma rays; many of them are based on the formation of subatomic particles known as  $\pi^0$  mesons (e.g., by cosmic ray protons colliding with interstellar hydrogen) and their subsequent decay into gamma rays. The only model allowing for variability pictures the gamma rays as produced in stars by events similar to solar flares.

#### IV. Galactic structure and dynamics

##### THE GEOMETRY OF THE GALAXY

**Galactic systems of coordinates.** The position of a celestial object in the sky is usually given by its equatorial coordinates, right ascension and declination. These are analogous to longitude and latitude.

For studies of the Milky Way the galactic system is better adapted. The plane of the galactic equator is defined by the great circle that best approximates the band of the Milky Way. The points  $90^\circ$  away from the galactic equator are called the north and south galactic poles. The galactic latitude,  $b$ , is the angular distance from the galactic equator to the object, positive to the north, negative to the south; the galactic latitude of the south galactic pole is  $b = -90^\circ$ . The galactic longitude,  $l$ , is measured in degrees along the galactic equator.

In the old system the zero point for the galactic longitude was the point at which the galactic equator intersected the celestial equator. The new system uses the direction to the galactic centre as zero point and has also a slightly different galactic plane. It corresponds to the position of the plane of neutral hydrogen in the Galaxy, whereas the plane in the old system was derived from the apparent distribution of the stars. The new system has been in general use since 1960; its north pole has the equatorial coordinates  $12^h 49^m, +27^\circ 24'$  (epoch 1950) and the direction to the galactic centre is at  $17^h 42^m.4, -28^\circ 55'$ .

**The dimensions of the Galaxy.** The main part of the Galaxy is shaped like a flat, round disk with a diameter of about 30 kiloparsecs and a thickness of about one kiloparsec near the Sun. The objects of the halo Population II are distributed in a flattened spheroid (axes in the ratio 1:2), concentric to the centre of the disk and with a diameter of about 50 kiloparsecs.

The distance of the Sun from the galactic centre is still uncertain. Since 1963 the value 10 kiloparsecs has been used, based on the space distribution of RR Lyrae stars and globular clusters in the galactic centre. The RR Lyrae stars may not be as luminous as previously assumed; this would tend to "shrink" the distance somewhat. Prior to 1963 a value 8.2 kiloparsecs was used.

##### REGIONS OF THE GALAXY

**The distribution of objects perpendicular to the galactic plane.** The distribution of disk population stars and halo stars at various distances from the galactic plane has been studied spectroscopically and photometrically in the directions of the poles and of other high-latitude areas. Figure 5 shows the distribution of some selected types of objects.

Halo stars have been successfully separated from the disk population by means of three-colour photometry. They have been identified in the north galactic pole area at distances of 14 kiloparsecs. A comparison of their density distribution in this direction and in a field at galactic latitude  $+21^\circ$  indicates that the halo may be flattened. In other fields there are signs of strong local variations, so that a symmetrical model may not be correct.

Almost no disk population objects are found beyond two kiloparsecs from the plane. From studies of the kinematics and the colours of bright F and G stars and of subdwarfs, now within 200 parsecs of the Sun, it has been

Figure 5: The space distribution of representative objects for various star populations projected on a plane perpendicular to the galactic plane and passing through the centre and the Sun. The horizontal lines indicate the distance from the galactic plane at which the density has fallen to one-tenth of that in the plane.  $R$  is the distance from the galactic centre. The RR Lyrae stars with high " $\Delta S$ " values have lowest metal content. The dashed lines indicate schematic (tentative) distributions (see text).

From A. Blaauw and M. Schmidt (eds.), *Galactic Structure*, © by the University of Chicago; all rights reserved

concluded that the stars with normal metal content will all remain within 800 parsecs of the plane, whereas the metal-poor halo objects will move much farther, maybe up to nine kiloparsecs, from the plane. The metal-richest stars will remain within about 400 parsecs of the plane. Even in this disk, however, about 10 percent of the dwarf F5 to K stars are halo objects.

The extreme Population II objects (globular clusters, RR Lyrae stars, subdwarfs) form a spheroidal subsystem with a radius of about 25 kiloparsecs from the centre of the Galaxy. Its concentration toward the centre is strong. The total mass is estimated to about  $16 \times 10^9$  solar masses.

There has been much discussion about the existence and the definition of a radio halo (corona). A division into a physical halo and a radio halo has been proposed. The physical halo is needed to explain the gradual transition from the galactic disk, with a gas density of  $10^{-24}$  gram per cubic centimetre and a magnetic field of  $10^{-5}$  gauss, to the intergalactic space, with a density of  $10^{-28}$  gram per cubic centimetre and a field of  $10^{-7}$  to  $10^{-8}$  gauss. It would extend to about one kiloparsec above the galactic plane and have a density higher than  $10^{-28}$  gram per cubic centimetre and a magnetic field of about  $10^{-6}$  to  $10^{-7}$  gauss.

The radio halo can be observed at metre wavelengths. It is assumed to have a radius of 15 to 20 kiloparsecs. The observed emission may be explained if the magnetic field is about  $3 \times 10^{-6}$  gauss and the density of relativistic electrons (moving at near the speed of light) equal to that observed near the Earth. The interpretation of the observations of this nonthermal radiation is still open to discussion.

**The galactic centre.** Most of the red giant stars in the central bulge of the Galaxy show a metal content between the metal-poor globular clusters, like M3, and the old metal-rich open clusters, like NGC 188. Optical observations of the centre itself are virtually impossible because of the heavy absorption. In the general region of the centre, globular clusters, RR Lyrae stars, novae, and planetary nebulae have been observed. Most other information about the centre is received from infrared and radio observations (see below).

**The spiral arms.** From observations of certain kinds of objects in the spiral structure in M31, it was evident that some of them were suitable for tracing out spiral structure in the Galaxy. Such objects all belong to the extreme Population I (Table 2); they are very young and thus cannot have moved very far from the positions in which they were formed. In 1952 a search for H II regions in the Galaxy similar to that undertaken earlier for M31 was made. Many were found, and a study of their distances was carried out using the stars exciting the radiation. The search led to the detection of portions of three spiral arms

Galactic longitude and latitude

Separation of halo stars

in the Galaxy: first, the arm extending from Cygnus to Orion and passing the Sun; next, the Perseus arm, about 2,500 parsecs from the Earth in the anticentre direction; and, third, the Sagittarius arm, about 1,500 parsecs closer to the centre than the Orion arm.

Since 1952 a number of photographic hydrogen-alpha surveys of the Galaxy have been carried out. Extensive surveys for other optical spiral tracers have likewise been undertaken. Long-period Cepheids define spiral arms very well and the dark nebulae of interstellar dust are also important spiral tracers.

Comparisons with spiral structure in other galaxies

The external galaxy NGC 1232 has much the same dimensions as the Galaxy. There are even portions of three spiral arms in width as well as mutual distances. Figure 6 shows the galactic H II regions and young clusters superposed on NGC 1232. The figure also illustrates the difficulties in determining the structure of the Galaxy; these spiral tracers are still limited to the Earth's immediate neighbourhood.

By courtesy of W. Becker

Figure 6: Space distribution of young galactic clusters and H II regions (open circles) superposed on a photograph of the spiral galaxy NGC 1232, which has the same dimensions as our Galaxy. Parts of three spiral arms outlined by the circles may be seen.

Some of the red giant stars have a distribution that is correlated with the spiral structure.

The carbon stars of class N tend to concentrate in spiral arm regions. They also tend to cluster and to form pairs.

The distribution of the R-type stars as well as their kinematics indicate that they belong to an older population with no obvious correlation to the spiral structure. The early M giant stars (M0–M2) show a concentration to the spiral arms; their space density is at least five to seven times as high in the spiral arms as in the interarm regions.

The intermediate M giant stars (M5–M6) are uniformly distributed in arm and interarm regions but show an appreciable increase in density toward the galactic centre.

The late M stars show a uniform density over the galactic disk with no increase toward the galactic centre.

The S-type stars are rather rare and apparently a mixture of two groups with different space distribution, one of which is closely related to the spiral structure. The stars in this group are frequently found embedded in nebulae and in dust clouds.

The 21-centimetre line of neutral hydrogen has turned out to be a powerful tool for studying the spiral structure at great distances. Interpretation of the observations faces two basic difficulties:

1. The distances are kinematic; the observed Doppler velocities are converted to distances under the assumption that differential rotation is the most important motion. Usually the rotation is assumed to be circular and axisymmetric.

2. An enormous amount of fine structure is observed and may confuse the large-scale pattern. Figure 7 shows

two interpretations of the neutral hydrogen distribution in the Galaxy.

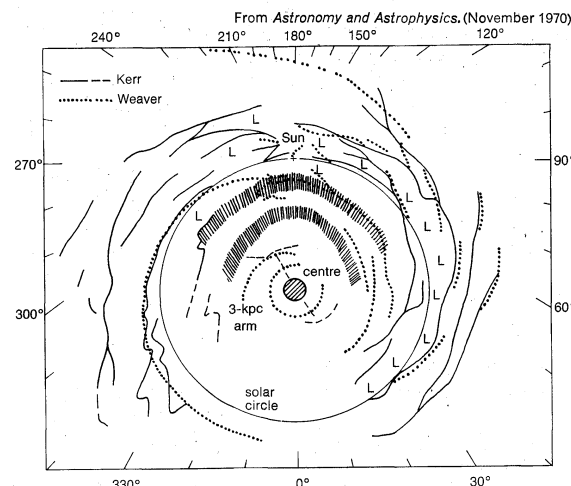

Figure 7: Two interpretations (by astronomers Frank Kerr and Harold Weaver) of the distribution of neutral hydrogen in the Galaxy. "L" marks regions deficient in H I, according to Kerr. Dashed lines and hatched areas indicate uncertain positions. The directions around the diagram are galactic longitudes (see text).

#### MAGNETIC FIELDS IN THE GALAXY

The existence of a magnetic field in the interstellar gas would account for: (1) the lack of a preferred direction for the arrival of the cosmic rays; (2) the Zeeman effect observed in the 21-centimetre line of atomic hydrogen; (3) the linear polarization of the light from many stars; (4) the synchrotron radiation observed as galactic background radio emission; (5) the rotation of the plane of polarization for extragalactic radio sources, called Faraday rotation. The amount of Faraday rotation is closely correlated with galactic latitude—that is, with the length of the line of sight in the disk of the Galaxy. It is the most convincing evidence that a magnetic field exists.

The intensity of the galactic interstellar magnetic field can be estimated from (2), (3), (4), and (5). The value found is about  $5 \times 10^{-6}$  gauss. This is very low but is of importance on a cosmic scale. The origin of the galactic magnetic field is not known.

*A theoretical model of the magnetic field.* Polarization measurements of 1,400 southern stars (mostly within 500 parsecs of the Sun) with northern hemisphere results (for a total of 7,000 stars) provide data for a description of the magnetic field in the solar neighbourhood. The observations are best understood if the magnetic field lines form tightly wound right-hand spiral curves (helices with pitch angle  $7^\circ$ ), which lie on the surface of imaginary tubes having elliptical cross sections with dimensions in the ratio one to three with major axes parallel to the galactic plane. The helical pattern is inclined at  $40^\circ$  to the plane of the Galaxy, anticlockwise viewed from the north galactic pole. The Sun is 100 parsecs toward the galactic centre from the magnetic axis and 10 parsecs below the galactic plane. Studies of the available data indicate that the optical polarization is produced within 500 parsecs from the Sun.

The model provides a simple explanation for the spurs and ridges of continuum radio emission, which may be tracers of the field lines. Nonthermal electrons are injected into the helix from sources near the plane and spiral away along the field lines; in this way, they can appear as spurs of emission.

To provide an explanation of the Faraday rotation (see above), it may be necessary to have a large-scale field in the direction of galactic longitude  $l = 90^\circ$  and  $b = 0^\circ$ ; the helix is then seen as an added local phenomenon.

*The Zeeman effect.* In a magnetic field, many spectral lines are split into a number of components, close together and separated in wavelength according to the field strength. This is the Zeeman effect. The possibility of measuring interstellar magnetic fields by Zeeman splitting

Explanations for difficulties with the field strengths

of the 21-centimetre line was proposed about 1957. Zeeman splitting has now been observed in many neutral hydrogen clouds. In all Zeeman observations made so far the directions of the fields fit the helical-plus-longitudinal field model. There are, however, large problems with the field strengths.

The strongest fields are found in the densest clouds, and the field strength is the result of amplification by contraction of the clouds. By extrapolation from the H I clouds to the average interstellar space, the mean interstellar magnetic field is found to be between one and three microgauss for mean interstellar densities of H I between 0.7 and two atoms per cubic centimetre.

**Pulsar data.** The rotation measures and the dispersion measures of the radiation from pulsars have been used to determine the magnetic field strength. The average value found is about 1.6 microgauss, in good agreement with the results from the Zeeman data.

**Elongation of gas and dust clouds by the magnetic field.** Data for eight intermediate-velocity H I clouds and for six of the high-velocity clouds show that they are elongated in the direction of the helical magnetic field. A similar study for 16 dust clouds showed that they are more closely aligned to the magnetic field than to the galactic plane.

#### THE STRUCTURE OF THE GALAXY AS A WHOLE

The most complete information comes from the 21-centimetre line observations.

In and near the galactic plane the profiles of the 21-centimetre line show various bumps that indicate large concentrations of neutral hydrogen moving at various speeds. These bumps appear to vary with the longitude and may represent sections of spiral arms.

If the gas moves in circular orbits around the galactic centre, a rotation curve can be derived from these observations. The velocities may then be converted into distances and a picture of the distribution of the gas throughout the galactic disk obtained (see Figure 7).

It is generally possible to follow the spiral arms of distant systems through an entire galaxy even though the arms are frequently broken up into spurs and branches. In the Galaxy this is more difficult and the effort has not yet been entirely successful.

Two rotation curves have been obtained between four and 10 kiloparsecs from the galactic centre (Figure 8). In

Figure 8: Galactic rotation curves from the 21-cm hydrogen emission line observations. Top curve refers to the gas north of (above) the galactic plane, bottom curve to points south of (below) the plane. The scale is set by the Sun's distance from the centre of the Galaxy, here taken as 10 kiloparsecs. The quantities  $l$  indicated above the curves are galactic longitudes.

them, two bumps may be seen at about the same distance on both sides of the centre. One bump seems to be caused by a systematic streaming of gas just outside the Sagittarius arm; this gas has a higher angular velocity in the direction of the general rotation than does the gas in the arm.

In the inner part of the Galaxy the derived density max-

ima for the hydrogen distribution fall rather well into a spiral pattern.

At a distance of four kiloparsecs from the galactic centre, radical changes in the distribution and motion of the interstellar gas occur.

The gas density is apparently about three times lower within four kiloparsecs of the centre than it is in the regions farther out. The gas in the central region could possibly be in a form unobservable in the 21-centimetre line, but it is more likely that it has been pushed away from the region. A similar emptiness has been observed in the central part of the Andromeda Nebula.

The most regular feature in the inner region is the so-called three-kiloparsec arm; its gas absorbs the radiation at 21 centimetres from the strong radio source Sagittarius A in the galactic centre. In this direction, the arm has an outward velocity of 53 kilometres per second. Some of the gas is moving toward the centre, but most of it moves outward. The total mass of the quadrant of this arm that can be adequately distinguished is about  $4 \times 10^7$  solar masses.

Gas is observed on the far side of the centre with still higher velocities away from the nucleus, up to 200 kilometres per second; the total amount of gas is about the same as in the three-kiloparsec arm.

If these arms were expanding continuously they would empty the inner region in 30,000,000 to 50,000,000 years. Just outside this region is an annular region in which the radiation from ionized hydrogen is exceptionally strong. This may be connected with a final stopping of the expanding gas.

Within 800 parsecs of the centre a new phenomenon occurs; very high negative velocities are observed between longitude  $-5^\circ$  and  $0^\circ$ . The whole structure appears to be a rotating disk. This region in the Galaxy can be matched in the Andromeda Nebula, and the same is true for the central concentrations as seen in the infrared observations.

The total mass of the nuclear disk is estimated to be  $5 \times 10^6$  solar masses. The disk must have an exceedingly sharp outer edge in the plane of the Galaxy, but there is some high-velocity gas outside the plane.

At somewhat higher latitudes near the centre, gas is seen streaming away from the centre at angles of  $45^\circ$  to the galactic plane. This may be gas expelled from the nucleus.

Even more complicated phenomena are found still closer to the nucleus. There is a concentration of fairly strong radio sources, mainly H II regions (see above). The radial velocities of these radio sources do not agree well with those found for the nuclear disk; velocities of  $+40$  to  $+60$  kilometres per second have been found, while the rotation velocity of the disk is  $+200$  kilometres per second.

The most striking radio source near the centre is non-thermal. It is situated very close to the dynamical centre of the Galaxy and may well be the centre. It is intrinsically very bright; its size is about seven by three parsecs. An infrared source of 15-parsec diameter coincides precisely with the nonthermal source; as noted above, this may be a large concentration of stars. The source contains a sharp nucleus with a diameter less than five seconds of arc (0.2 parsec).

Much information on the nuclear part has come from observations of the OH-absorption lines. These lines are very much stronger 200 parsecs from the centre relative to those of neutral hydrogen (H I) than elsewhere in the Galaxy. This indicates a great abundance of molecules, probably also of  $H_2$ . The OH lines also show a flow into the Sagittarius A source. Complicated streaming occurs near the centre of the nuclear disk. At higher latitudes, high-velocity neutral hydrogen is found in some places, though always with small surface density.

All neutral hydrogen velocities higher than 100 kilometres per second and at galactic latitudes greater than  $\pm 20^\circ$  are negative relative to the local standard of rest (see above). They are also limited to a relatively small region of the sky and are not as frequent in the southern hemisphere. They occur up to very high latitudes. At

The three-kiloparsec arm

these velocities the gas appears to be concentrated in fairly isolated, generally elongated clouds. Generally there is systematic streaming toward the galactic plane.

The most important problem is to find the distance to these clouds.

Intermediate-velocity neutral hydrogen has been found in the direction of stars with interstellar lines of ionized calcium. In three stars, at more than one kiloparsec from the galactic plane, the velocities of ionized calcium and neutral hydrogen agree well. For three other stars closer to the plane than 300 parsecs, no ionized calcium has been found, and it is then possible that the intermediate-velocity clouds are between 600 and 1,000 parsecs from the plane.

No data are available for the higher-velocity clouds. The properties of the intermediate-velocity and the high-velocity clouds are so similar that it is reasonable to assume that the latter are also within the Galaxy, at relatively large distances from the plane.

#### THE ROTATION OF THE GALAXY

In 1926 a Swedish astronomer, Bertil Lindblad, studied the motion of the high-velocity stars, which is asymmetrical with respect to the stars of the solar neighbourhood, the low-velocity stars. He reasoned that while the high-velocity stars cannot belong to the same system as the low-velocity stars because of the asymmetry in their motions, they must be related to the rest of the Galaxy because their motions are symmetrical about the galactic plane. He showed that the effect could be explained if (1) the Sun and other low-velocity stars have high rotation velocities around a distant centre, and (2) the high-velocity stars have much smaller velocities of rotations. Thus, the stellar system may be divided into a series of subsystems with rotational symmetry around one axis but with different speeds of rotation at the same distance from this axis. These systems would then also have different degrees of flattening. The most flattened systems have a high star density but one that decreases with decreasing speed of rotation. The centre of the stellar system should lie in the galactic plane in a direction at right angles to the direction of the asymmetrical drift.

anticentre and perpendicular to them, the radial velocities are zero. In between, smooth curves are obtained, giving a double wave for the whole system. Similar results are obtained for the proper motions.

The effect of differential galactic rotation shows up as a change in average speed of about 15 kilometres per second per kiloparsec. This is known as Oort's constant,  $A$ . If  $\mu_1$  is the proper motion in the direction of galactic longitude and another rotation constant  $B = -10$  kilometres per second per kiloparsec, Oort's rotation formulas are

$$RV = Ar \sin 2l$$

$$\mu_1 = Ar \cos 2l + Br.$$

The theory of galactic rotation also explains another problem that had puzzled astronomers. In 1904 more stars were found to move toward the constellations of Orion and Scutum (diametrically opposed directions) than toward any other point. The line connecting these directions lies in the plane of the Milky Way, and a connection was suspected between the motions and galactic structure. Lindblad suggested that small perturbations of the stars would result in departures from circular orbits, and these departures would be more pronounced in the directions of the centre and anticentre, nearly as observed.

Different values of the solar motion relative to stars of different spectral classes are obtained. This occurs because all stars are not of the same age, and their velocity distributions are affected by the local conditions at the time of their formation, and by encounters with other stars and interstellar matter.

Another possibly disturbing effect is the admixtures of different kinematic groups.

Table 1 shows that main-sequence stars and giants earlier than F and all supergiants show a markedly smaller velocity dispersion than main-sequence stars and giants of later types. These young stars appear to move in almost circular orbits around the galactic centre. The O and B stars with equal velocity dispersions in U and V are kinematically distinct from all other types. They still reflect the velocity distribution of the interstellar gas.

**The radial velocities of interstellar lines.** Studies at high spectral dispersion have shown that the calcium and sodium clouds that produce interstellar absorption lines are arranged in space essentially in the same way as the H II regions. Figure 10 shows the radial velocities of the two interstellar components for stars observed between 90° and 190° in the northern Milky Way, referred to the local standard of rest and plotted against galactic longitude.

The velocities of the interstellar lines in nearby stars together with the "near" component in the distant ones fol-

(Right) The arrows represent the velocities as observed. The radial velocity components are also shown (see text).

The work  
of  
Jan Oort

Observational evidence confirming this idea was provided about a year later by the Dutch astronomer Jan Oort, who also showed that the Galaxy does not rotate as a solid body; the innermost parts rotate fastest. If most of the mass is concentrated at the centre, the velocity of rotation should be nearly proportional to  $1/r^2$  ( $r$  = distance from the centre of the Galaxy), and differential effects proportional to the distance from the Sun would be observed in both the proper motions and the radial velocities (Figure 9).

The radial velocities ( $RV$ ) and proper motions of the stars in the solar neighbourhood vary systematically with the galactic longitude. In the directions to the centre and

Figure 10: The dependence on galactic longitude of the radial velocities measured from interstellar lines in stellar spectra. Small black circles indicate stars in the local (Orion) arm; small open circles, stars in the Perseus arm. Larger symbols indicate mean values (stars in associations whose names are given; the actual velocities are marked as asterisks). Vertical lines show the range of velocity of the various components. Theoretical curves for the radial components of galactic rotation for points in the galactic plane at distances from the sun of  $r = 1$  (top curve), 2, 3, and 4 kiloparsecs are drawn.

low the galactic rotation curve well for a distance of about 0.5 kiloparsec from the Sun. The distant components define a galactic rotation curve at a distance of between two and three kiloparsecs. The radial velocities of the distant stars are never far from those derived for the "remote" interstellar components. This indicates that these components arise very near the stars in whose spectra they are seen. It also implies that the mean density of sodium or ionized calcium is much lower between the clouds forming the two components than it is close to the Sun and other stars.

**The motions of the planetary nebulae.** The radial velocities of the planetary nebulae are shown in Figure 11, plotted against the galactic longitude. The distribution, except at  $0^\circ$  longitude, is easily understood if the planetary nebulae move in circular orbits at different speeds. The high dispersion of velocities near  $0^\circ$  longitude requires the presence of many objects with highly elliptical orbits. It is at present not possible to say whether all planetary nebulae form one kinematic subsystem or whether they are divided between a flattened rotating system with circular orbits and a spherical system with elliptical orbits and low rotation.

Figure 11: Radial velocities of planetary nebulae reduced to the local standard of rest. Heavy curves represent extremes between which the velocities should lie for circular orbits. Thin lines represent velocities at distances indicated (left) in parsecs from the Sun. Angles below the figure are galactic longitudes (see text).

**The motions of the local standard of rest (LSR) around the centre of the Galaxy.** Such motions can be determined only if there is an inertial frame in the Galaxy. Such a frame would be provided by reference objects that are not rotating or otherwise accelerating in the Galaxy. It can be assumed because of their spherical distribution that the system of globular clusters does not rotate relative to a frame of this type in the Galaxy. The tangential velocity of the LSR caused by galactic rotation may be determined from the radial velocities of individual clusters. The most recent result, from a study of 70 clusters, is a tangential velocity of  $167 \pm 30$  kilometres per second in the direction  $l = 90^\circ$ ,  $b = 0^\circ$ .

The galaxies in the Local Group may move at random relative to the Galaxy. If so, they can also be used to define an inertial frame. One study shows a velocity of  $292 \pm 32$  kilometres per second in the direction  $l = 106^\circ$ ,  $b = -6^\circ$ . From this it is concluded that the LSR has a rotational velocity of about 250 kilometres per second in the direction  $l = 90^\circ$ ,  $b = 0^\circ$ . The globular cluster system may then rotate around the galactic centre with a group velocity of about 80 kilometres per second.

## V. The origin and evolution of the Galaxy

### FORMATION OF THE GALAXY

The problem of how the Galaxy was formed is intimately connected with cosmology, the study of the formation and structure of the whole universe. The classical ap-

proach to cosmology is based on the red shift—apparent magnitude relation for the fainter galaxies; the more distant a galaxy, the higher is its apparent velocity as calculated from the red shift of the spectral lines. This general recession is the basis for the so-called "big-bang" cosmology, in which the universe is taken to have originated in a superdense state nearly 10,000,000,000 years ago, and for the "steady-state" cosmology in which the universe looks exactly the same all the time (see UNIVERSE, ORIGIN AND EVOLUTION OF).

Another basic cosmological phenomenon, which may be directly tested, is the following. If the universe began with a big bang, or primeval fireball, there must be an isotropic, thermal (blackbody) radiation field, which at the present time would have a temperature of a few degrees Kelvin.

Low-energy cosmic radiation was discovered in 1965 over a wavelength range from about 20 to three centimetres. It gave a typical blackbody curve with a temperature of  $3^\circ \text{K}$ ; this curve was extended to 2.6 millimetres from studies of the effect of radiation at this wavelength on the interstellar CN molecules. The isotropy of the radiation was also established to better than  $\pm 0.5$  percent.

A definite proof of the primeval fireball phenomenon would rule out a number of cosmologies. The steady-state theory would be ruled out because its universe was never in a dense state. Any cosmology including a visible edge to the matter-filled part of space would be ruled out, because the radiation produced in the early days would long since have left the universe.

There are, however, still conflicting data. Balloon observations have shown that a large flux of radiation much greater than expected at the peak of the  $3^\circ \text{K}$  blackbody curve is present. If these observations are correct and this excess radiation is cosmic, it could be line or continuum radiation superposed on the blackbody radiation from the primeval fireball. The only possibility consistent with the steady-state theory would be to interpret all background radiation as coming from a large number of discrete sources.

In the big-bang theory, all galaxies would have been formed at the beginning from original density fluctuations that led to gravitational instabilities and the formation of protogalaxies. In the steady-state theory, matter is created continuously in regions of highest densities, the nuclei of galaxies; and galaxies are formed continuously.

### GALACTIC EVOLUTION

In one classification scheme for galaxies—i.e., involving designations elliptical (E), lens-shaped (SO), spiral (Sa, Sb, Sc), and irregular (Irr)—the Galaxy is classified Sb or Sbc. This scheme is based on form alone (the apparent ratio of central bulge to the disk, openness of spiral pattern, resolution of the arms into luminous stars), but a systematic change in stellar content follows the order of the sequence of form. Along the sequence Irr—Sc—Sb—Sa—SO—E, gas and dust amounts and young stars decrease and the mean colours are increasingly red. These effects could be explained as an evolutionary sequence. In an Sc galaxy, luminous stars are still forming, and since it is still rich in gas and dust, new generations will form by further condensation. The galaxy will eventually be depleted of prestellar material, the young stars will have evolved, and there will be no new stars or spiral arms; a galaxy similar to the present SO system will be produced. It is not likely, however, that the present SO systems have evolved from Sc galaxies; the latter appear to have sufficient gas to sustain their present rate of star formation for  $10^{10}$  years and more. Also, all galaxies appear to have nearly the same age.

It also appears clear from studies of the intrinsic flattening of galaxies that true spirals and SO galaxies can never have evolved from or into elliptical galaxies. A Swedish astronomer named Erik Holmberg studied the mean total mass density of galaxies and found that the early-type (E) systems have the greatest values. He argued that evolution along the sequence from Sc to SO was therefore impossible (the density would have to increase

The "big-bang" and "steady-state" theories

Collapse  
of the  
Galaxy  
from its  
protocloud

too much) and that the only effect of aging is that a galaxy becomes redder. It is not yet clear that the difference in densities is as large as Holmberg found.

From a study of the motions of the very old stars in the solar neighbourhood, it has been inferred that the Galaxy collapsed from its protocloud on a time scale of about  $2 \times 10^8$  years. During the collapse, some stars were formed and an enrichment in metals occurred. Much of the protocloud remained in gaseous form and settled, after energy losses, into a stable centrifugal disk. This disk in the Galaxy contains stars at least  $8 \times 10^9$  years old. Similar disks may be seen in external spiral and SO systems.

The old stellar disk and spheroidal components, which contain most of the mass of spiral systems, may not have changed since their formation. The amount of gas left over after the formation of the old stellar components would have determined the present morphological type of the spiral systems.

It is not yet known how galaxies form and how they evolve. The result from a collapsing protocloud could equally well have been obtained if matter were ejected from a centre to form halo stars and spiral arms.

If the spiral arms represent the tracks of material ejected from centres of a galaxy, the mechanism for forming the arms may be found. Many galaxies have expelled pairs of plasma clouds in opposite directions. Also, luminous material has been seen, apparently ejected from nuclei of galaxies. (The "jets" in M87 show opposing ejections of luminous material.) As soon as differential rotation affects any jet or similar phenomenon in the disk of a galaxy, it will be drawn out into a spiral form much as in an ignited pinwheel. The tendency for opposite ejections will then lead to the predominant symmetrical two-arm spiral galaxies.

According to this theory, the spiral arms of the Galaxy were established at one time and will be wound up by differential rotation. The bright supergiant stars and the gas excited by them would fade in about  $10^7$  to  $10^8$  years. During this period, the shearing effect of the differential rotation would make the arms longer and thinner. Thus, galaxies with well wound-up, circular, thin arms would have gone through this evolution; those observed are of type Sa with a large nuclear bulge.

The ejection theory also explains the class of galaxies with companions on the ends of spiral arms. Such companions are most likely rather short-lived, and they and the arms will decay after a few revolutions of the Galaxy. More ejections from the nucleus are required for new arms to form. Split and bifurcated spiral arms are explained by secondary ejections in the arms. They are hard to account for by gravitation-interaction theories.

**Hydromagnetic and gravitational theories of the formation of spiral structure.** Undoubtedly, the magnetic field must play an important role in the equilibrium and motion of the interstellar medium. A weak, large-scale intergalactic magnetic field has been proposed; also a slightly ionized intergalactic gas may be present that would affect the protogalaxies in different ways depending upon the angle between the field and the axes of rotation. This would also explain the formation of spiral galaxies with the typical two-arm pattern and an internal helical field of about  $5 \times 10^{-6}$  gauss. Proponents for the gravitational models claim, however, that the magnetic field plays only a secondary role in the formation of the spiral pattern and that the necessary systematic field would have to be stronger than that observed in order to affect its development; it would then be too strong for star formation to occur.

The concept of density waves as a basis for spiral structure goes back to Bertil Lindblad, who proposed leading spiral arms, whereas observational evidence suggested trailing arms. Both types of arm systems are possible. Lindblad emphasized individual stellar orbits, and this made it difficult to derive the collective behaviour of the stars that form the spiral structure. Work on the gaseous interstellar medium has shown how a rather inconspicuous density wave in the stellar distribution may produce a spiral gravitational field as a fluctuation in the

smooth field. The gas, which will react strongly to even small fluctuations, will gather in these regions and act as an efficient spiral tracer. With a pattern speed of 13.5 kilometres per second per kiloparsec and the Schmidt mass model for the Galaxy, a system of two trailing arms is derived. The Schmidt model consists of a central mass point,  $0.07 \times 10^{11}$  solar masses; a spheroid,  $0.82 \times 10^{11}$  solar masses; and a shell,  $0.93 \times 10^{11}$  solar masses. Of the total mass of  $1.8 \times 10^{11}$  solar masses, one half is inside a spheroidal surface with axial ratio 0.05 drawn through the Sun.

The density wave theory accounts for the grand design of the spiral pattern over the whole disk and also for the absence of regular arms of ionized hydrogen in the inner four kiloparsecs of the Galaxy. It also stresses the coexistence of material arms and density waves and possibly of several wave patterns. Thus, of the local arms, the Sagittarius and Perseus arms belong to the primary spiral pattern, and the Orion arm is a material arm. The Carina-Cygnus feature would be an arm in a secondary spiral pattern.

**Chemical evolution.** Most cosmologies based on an expanding universe require that the Galaxy was originally formed almost entirely out of hydrogen and helium. The remainder of the elements must have been formed later, but at a comparatively early time in the history of the Galaxy. Observations show that the metal abundance has not increased smoothly with time; there are old galactic cluster stars with normal solar abundances.

There are two possibilities for early nucleosynthesis. Supermassive stars, of the order of 100,000 solar masses, may have formed and by small "big-bang" explosions caused the heavy elements to form. It is also possible that a very large number of stars of about 20 solar masses were formed and that the heavy elements resulted from explosive oxygen-burning and other reactions in them. This early burst of formation of massive stars would have led to enough ultraviolet radiation to keep the galactic gas fully ionized and at a kinetic temperature high enough to make it fill the spherical halo. The rapid evolution of the massive stars would then also have injected heavy elements into the halo. Stars may have formed in it before the general collapse to the galactic plane.

**Star formation.** The physical conditions of the interstellar material from which stars are formed are not yet exactly known. Apart from the general layer of neutral hydrogen, however, which in the spiral arms has a density of about one atom per cubic centimetre, there are clouds of appreciably higher densities, up to  $10^3$  atoms per cubic centimetre. There is some ionization in these clouds; probably the electron density is about  $10^{-4}$  times the hydrogen density. The clouds are also in motion, with average velocities of about 15 kilometres per second, in some cases up to 100 kilometres per second.

The major uncertainty is the galactic magnetic field. Though reasons given above suggest a rather weak field of  $5 \times 10^{-6}$  gauss, there is some evidence for a field of up to  $2 \times 10^{-5}$  gauss.

The first stage in the formation of stars is the formation of an interstellar cloud. This cloud has to reach gravitational stability and then start contracting.

The second stage, the collapse of the cloud, will occur when the external pressure has reached a certain value. The critical point is represented by a certain value of the mass, above which instability sets in. If strong magnetic fields are not involved, it is relatively easy to find many clouds that are now on the verge of gravitational instability. With a strong magnetic field ( $2 \times 10^{-6}$  gauss) present, star formation would become impossible except in extremely massive clouds, whereas the lower value of the field strength of  $5 \times 10^{-6}$  gauss would not be incompatible with observations.

The fragmentation of the collapsing cloud into stars would also tend to be difficult with a magnetic field present. The magnetic field would need to be separated from the gas at an early stage, or its strength sharply reduced during the later stages, to permit the fragmentation to proceed. How this could be achieved is not yet clear.

Theories  
of early  
nucleo-  
synthesis

The  
density  
wave  
theory

The fragmentation ceases (third stage) when the temperature of the fragment, the protostar, is so high that isothermal collapse no longer occurs. An adiabatic contraction follows with the rate of change of total energy equal to the rate of radiation from the surface. During this stage the protostar approaches the zero-age main sequence; *i.e.*, the internal temperature is reaching the values at which nuclear reaction starts.

The density wave theory for the spiral structure indicates a possible way for the formation of stars over a large region of the Galaxy more or less simultaneously.

When the gravitational potential field of spiral shape rotates within the Galaxy in the galactic plane, it produces rather dense concentrations of gas and dust that are observed as spiral arms. The density waves lead to sudden compression of the gas along a front of several kiloparsecs; this shock collects the cosmic grains into prominent dust lanes and brings the individual gas clouds into a state of gravitational collapse. Once started, the collapse will continue even after the decompression has set in. Stars will thus form simultaneously over several kiloparsecs of the central line of a spiral arm. The dust lanes are mainly seen on the inside of the arms and slightly separated from the bright young stars; the distance is due to the motion during the time necessary for star formation, and may be a few hundred parsecs.

## Galen

In the history of ancient science, Galen stands as the most important physician after Hippocrates, who laid the foundations of rational medicine in the 5th century BC. Galen flourished under the Roman Empire in the 2nd century AD and achieved great renown in both East and West not only as a physician but also as a philosopher and philologist. His thinking exercised a profound influence on Byzantine and Islāmic civilizations and contributed substantially to the rise of Western science during the Renaissance.

Born in 129 in Pergamum, a city in Mysia, now Bergama, Turkey, Galen was the son of a gifted architect. The city of his birth, site of a shrine of the healing god Asclepius, significantly affected Galen's education. Many of the most distinguished personalities of the Roman Empire visited the shrine for cures, which Asclepius was thought to prescribe through revelations in the patients' dreams. A medical school was attached to the shrine, and there Galen met important men and observed the treatment of a variety of diseases. The high priest maintained a troupe of gladiators, which provided Galen with the opportunities to examine wounds and to judge the effects of medical treatment.

Since theoretical philosophy and practical medicine were closely related, Galen's father decided that he

should study both subjects in his native city. His teachers represented the four principal philosophical sects: Platonism, Aristotelianism, Epicureanism, and Stoicism. This doctrinal variety helped to mold the philosophical eclecticism that characterized his entire life. He continued his studies in the educational centres of Smyrna on the west coast of Asia Minor, Corinth in Greece, and Alexandria in Egypt, where he practiced the dissection of animals and broadened his contacts with contemporary physicians. In 157 he returned to Pergamum, where, as chief physician for the gladiators, he increased his practical knowledge of anatomy and tested the best remedies for treating wounds.

In 161 the ambitious Galen, like many other successful Easterners, travelled to Rome, where he cured the ailing Aristotelian philosopher Eudemus, through whom he met many important persons in the capital city. His willingness to take on patients whom other doctors had pronounced incurable, his signal success as physician, and his immodesty concerning his conspicuous achievements aroused his colleagues' envy, which Galen arrogantly described in his books. He was soon admitted to the court of Marcus Aurelius, then co-emperor with Lucius Verus, and wrote with pride of the luminaries who attended his public lectures and dissections. These public performances greatly enhanced his prestige.

Galen abruptly ended his sojourn in the capital in 166. Although he claimed that the intolerable envy of his colleagues prompted his return to Pergamum, the plague that entered Rome with Verus' troops after a foreign war was probably a more compelling reason. In 168-169, however, he was recalled by the emperors. When Verus died of the plague, Marcus appointed Galen as physician to Commodus, his son, and the heir to the throne. The security of the appointment gave Galen the opportunity to write even more prolifically than before.

Galen based his descriptive anatomy on the dissection of lower animals, particularly the African monkey, often called the Barbary ape. Because this animal is a primate and shares certain characteristics with man, Galen made inferences concerning human anatomy. There is no doubt that he was an accurate observer, particularly of the muscles and bones. He distinguished seven pairs of cranial nerves, described the valves of the heart, and observed the structural differences between veins and arteries. Notable also were his vivisection experiments, such as tying off the recurrent laryngeal nerve to show that the brain controls the voice, performing a series of transections of the spinal cord to study muscle control, and tying off the ureters to demonstrate kidney and bladder functions. One of his most important demonstrations was that the arteries carry blood, not air, as had been taught for 400 years.

Although Galen did not discover that the blood circulates, he did achieve a valid and rational interpretation of the observed facts. According to his view, the most important organ in the vascular system was the liver, where blood was formed and the veins originated; blood vessels carried the blood out to the periphery of the body, where, according to him, it was transformed into flesh. He accounted for the large amount of blood in the aorta—the largest blood vessel leaving the heart—by suggesting a passage from the right ventricle to the left ventricle of the heart through minute pores in the wall that separates the two and by suggesting that a small amount of blood seeps through the lungs between the pulmonary artery and pulmonary veins, and so from the right to the left ventricle.

Galen believed that human health required an equilibrium between the four humours—phlegm, black bile, yellow bile, and the blood—and that, furthermore, the pneuma (thought to be a material but very subtle component carried by the blood) was responsible for guiding many body processes. As a continuation of the earlier Hippocratic conception of the unity of the organism, Galenic physiology became a powerful influence in medicine for the next 1,400 years.

Although Galen's work was primarily in medicine, he believed that a good physician must also be a philosopher

Medical  
training

The  
Galenic  
system

and wrote an extant essay on that subject. He was fully aware of, and critical of, the impact of Judaism and Christianity on Roman life. In particular, he accused the Jews of what he called unreasoned assertions. And he cited Christians to illustrate his view that even nonphilosophers could by good behaviour approximate the philosophic ideal. Even though he believed that nature expressed a divine purpose, he was not a monotheist in the sense of believing in one transcendent deity. Rather, in line with his eclecticism, he drew on diverse sources for his philosophical interpretations. He fully accepted Aristotle's view that "Nature does nothing in vain" and sought to show that all organic structures, such as the muscles and bones of the hand, serve the functions for which they were designed, which he attributed sometimes to a creator and sometimes to a beneficent nature.

Greek manuscripts were collected and translated by enlightened Arabs during the 9th century. Hunayn ibn Ishāq, an Arab physician and philologist, prepared an annotated list of 129 works of Galen that he translated from Greek or Syriac versions. During the late 11th century, copies of Hunayn's translations and commentaries on them by Arab physicians were translated into Latin. These Latin versions helped to enlighten European scholars as to the achievements of Greek antiquity. When medical humanists of the 15th and 16th centuries saw the need to prepare new Latin versions of Galen directly from the Greek, it was inevitable that physicians should wish to repeat the experiments and observations that Galen had recorded. This renewal of the Galenic tradition during the Renaissance was an important element in the rise of modern science. Many of Galen's writings have been lost, especially those on philosophical and literary subjects; others survive only in Arabic copies, and only a few have been translated into English. Little is known of Galen's final years. He probably never returned to Pergamum and died in about 199.

**BIBLIOGRAPHY.** The only full account of Galen in English is G. SARTON, *Galen of Pergamon* (1954), written in a popular style and not always reliable. The classic and invaluable study of Galen's career and medical practice is J. ILBERG, "Aus Galens Praxis," *Neue Jahrbücher für das Klassische Altertum, Geschichte und deutsche Literatur und für Pädagogik*, 15:276-312 (1905). See also R. WALZER, *Galen on Jews and Christians* (1949), a scholarly study of the relevant Galenic texts. For an examination of Galen in the social context of his time, see G.W. BOWERSOCK, "The Prestige of Galen," in *Greek Sophists in the Roman Empire*, ch. 5 (1969). Still the best introduction to the Arabic transmission of Galen's works is G. BERGSTRASSER, "Hunain ibn Ishāq: Über die syrischen und arabischen Galen-Übersetzungen," *Abhandlungen für die Kunde des Morgenlandes*, vol. 17, no. 2 (1925). Hunain's list of the books of Galen he translated is a source of valuable information on Galen's total work; how it was transmitted to the West is discussed by M. MEYERHOF in "New Light on Hunain Ibn Ishāq and His Period," *Isis*, 8:685-724 (1926). R.E. SIEGEL, *Galen's System of Physiology and Medicine* (1968), is a comprehensive survey of Galenic medical thought. See also R. WALZER, "New Light on Galen's Moral Philosophy," in his *Greek into Arabic*, pp. 142-163 (1962). English translations with commentaries of Galen's major work in anatomy and physiology are: A.J. BROCK, *On the Natural Faculties* (1942 and 1963); C. SINGER, *On Anatomical Procedures* (1956); W.L.H. DUCKWORTH, *On Anatomical Procedures, the Later Books* (1962); and M.T. MAY, *Galen on the Usefulness of the Parts of the Body*, 2 vol. (1968). There is a partial list of the new discoveries of Galen's works in Arabic translation in Sarton (op. cit.), pp. 99-100.

English translations of Galen's works down to 1954 are also listed in Sarton, pp. 101-107. English translations after 1954 are listed in J. SCARBOROUGH, *Roman Medicine*, pp. 165-166 (1969).

(G.W.Bo.)

## Galilee, Sea of

The Sea of Galilee (Lake Tiberias), a lake through which the Jordan River flows, is located in Israeli territory, although from 1948 to 1967 it was bordered immediately to the northeast by the cease-fire line with Syria. It is famous for its biblical associations. Located 686 feet below the level of the Mediterranean, it has a surface area of 64 square miles (166 square kilometres). The sea's

maximum depth, which occurs in the northeast, is 157 feet. Measuring 13 miles from north to south and 7 miles from east to west, it is pear-shaped. Its Old Testament name was Sea of Kinneret (Kinerot), but after the exile of the Jews to Babylon in the 6th century BC it was called the Lake of Gennesaret. In the New Testament it is called the Sea of Galilee and sometimes the Sea of Tiberias. In Arabic it is called the Buḥayrat Ṭabariyā, and in Hebrew, Yam Kinneret. (For an associated physical feature, see JORDAN RIVER.)

**Historical and religious associations.** Because of a pleasant climate, level topography, fertile soil, and relatively abundant water, the rivers flowing into the lake and the adjacent plains have throughout history been the source of livelihood for various peoples. At El-'Ubeidiya, two miles south of the lake, lacustrine formations dating from about 400,000 to 500,000 years ago have revealed prehistoric tools and two human fragments, which are among the oldest in the Middle East. Canaanite (ancient Palestinian) structures have been uncovered that date back to between 1000 and 2000 BC. In the 1st century AD the region was rich and populated; the Jewish historian Flavius Josephus wrote of nine cities on the shores of the lake in ancient times, but of these only Tiberias has survived. Tiberias, on the western shore, was one of the four Jewish holy cities, and Kefar Naḥum (Capernaum), near the northwestern shore, has preserved one of the most beautiful synagogues of the Galilee region, dating from the 2nd and 3rd centuries AD. A sanctuary for the Druzes (an independent sect founded in the 11th century that followed a creed containing elements of Islām, Judaism, and Christianity) is located near Kefar Hittim near the western shore. The Sea of Galilee is especially well known to Christians because it was the scene of many episodes in the life of Christ. The region was also the site of the first Jewish kibbutz, Deganya, established in 1909.

**Relief and environment.** The Sea of Galilee is located in the great depression of the Jordan. The Plain of Gennesaret extends in a circular arc from the north to the northwest, and the Plain of Bet Zayda (Buteiha) in Syria extends to the northeast. To the west and the southwest the hills of Lower Galilee fall abruptly to the lake's edge. In the mid-eastern sections, the cliffs of the Plateau of Golan overlook the lake; the plateau reappears again in the southeast, becoming larger as it approaches the valley of the Yarmuk River, a tributary that has its confluence with the Jordan a few miles to the south of the lake. Also to the south, the Plain of al-Ghawr begins, but the Sea of Galilee is separated from it by a narrow ridge through which the Jordan River flows. The greatest part of the region is covered by basalts that have been formed since the Miocene Epoch began about 26,000,000 years ago and that are part of the vast area of Jebel Druze and Hauran, both located in Syria. Since the Miocene Epoch began, lacustrine limestones and marls (calcareous clays) have been deposited. The Great Eastern Rift, which forms the Jordan Trench, passes to the east of the lake; smaller and less important faults occur to the west. The depression was hollowed out at the end of the Pliocene Epoch (from 7,000,000 to 2,500,000 years ago) and was partially filled in again by lacustrine and fluvial sediments. During the humid periods of the Quaternary Period (within the last 2,500,000 years) the Dead Sea (q.v.) extended up to this point. During the mid-Pleistocene Epoch (about 1,250,000 years ago) structural movements of the earth's crust occurred, while flows of molten basalt reached the lower end of the depression through the Valley of Yarmuk. In the course of the last pluvial period, which occurred about 20,000 years ago, a great lake, called the Lake of Lisan, covered the region, with the result that formations of marls were deposited. Since then, the waters have receded; the present lake was conserved following the damming of the Jordan waters by basalt deposits.

**Climate.** Because of its sheltered location, low altitude, and the influence of the lake itself, the winters are mild, with temperatures averaging 57° F (14° C) in January. The absence of freezing temperatures has facilitated the cultivation of bananas, dates, citrus fruit, and vege-

Galen's  
influence

Archaeo-  
logical  
remains

tables. The summers are hot, with temperatures averaging 88° F (31° C), and the precipitation—almost 15 inches at Deganya—falls, in the course of a winter of less than 50 days, in the form of brief but violent showers. The winds generally alternate daily, especially in the summer, blowing onshore in the morning and offshore at night. During the winter violent winds occasionally rush into the Jordan depression, creating storms on the lake.

**Hydrology.** The Sea of Galilee is fed primarily by the Jordan River; the lake governs the river's flow, and strains its waters. Among streams and wadis flowing into the lake from the hills of Galilee are two small permanent streams, the Nahal 'Ammud and the Zalmon, and one wadi (seasonal watercourse), the Nahal Arbel, all of which flow from the northwest; and four moderate-sized streams that flow down from the Golan Heights. In the rivers associated with the lake and at the bottom of the lake itself are many mineral deposits. Because of these deposits and because of the strong evaporation, the waters of the lake are relatively salty; seasonal variations, however, result in maximum salinity occurring in summer and fall. Annual variations also occur.

**Animal life.** The lake's fish life has an affinity with that of the East African lakes. Fish species to be found include damselfish, scaleless blennies, catfish, mouth-breeders, and barbels. Apart from its permanent fish population, the lake is also visited by migratory fish.

The agricultural development of the region has resulted in a modification of its animal life. Wild boars, for example, abundant during earlier periods, have greatly decreased in numbers.

**Resource development.** For the past few centuries the Plains of Gennesaret, to the northwest, and the area around Deganya, to the south, have been systematically developed through irrigation and intensive agricultural techniques. Fishing has also been developed, notably from Tiberias and Gennesaret and at En Gev, on the eastern shore. About 1,000 tons of fish are netted annually from motorboats and trawlers; sardines are mainly caught in winter, although, together with larger fish, they are also caught at other seasons. Thermal springs have enabled modern health resorts to be created, and the baths at Tiberias are among Israel's most important winter resort attractions. Similar baths are to be found at Tabigha, or 'En Sheva' (the seven springs of Bathsheba) on the northwest shore.

In the 1960s, the Sea of Galilee became the starting point of the "National Water Carrier," a large canal that conveys water from the Jordan River to the coastal region, as well as south to the Negev Desert. The level of the lake has been raised slightly by a dam constructed downstream; the water, flowing into the lower reaches of the Jordan River, is used as a source of hydroelectric power. Some of the water, however, is pumped by pipe to the northwest to a height almost 800 feet above the lake's level, from where it is siphoned across the gorges of Nahal 'Ammud and Zalmon to irrigate the country's western sector.

**Transport.** The small market towns on the shores of the lake rely for transport of goods and passengers to a great extent on a regular motorboat service that is maintained between them.

**Prospects for the future.** Before 1967, when the cease-fire line with Syria bordered the lake to the northeast, political tensions hindered the development of normal navigation and fishing activities on the lake. The future development of such activities depends upon the maintenance of political stability in the area.

The excessive salinity of the water has created problems which it is hoped will be solved by the diverting of thermal springs that now flow into the lake and by sealing apertures on the lake floor, which are now sources of salinity.

(P.Sa.)

## Galileo

Galileo Galilei, Italian mathematician, astronomer, and physicist, made several significant contributions to modern scientific thought. As the first man to use the tele-

scope to study the skies, he amassed evidence that proved the Earth revolves around the Sun and is not the centre of the universe, as had been believed. His position represented such a radical departure from accepted thought that he was tried by the Inquisition in Rome, ordered to recant, and forced to spend the last eight years of his life under house arrest. He informally stated the principles later embodied in Newton's first two laws of motion. Because of his pioneer work in gravitation and motion and in combining mathematical analysis with experimentation, Galileo often is referred to as the founder of modern mechanics and experimental physics. Perhaps the most far-reaching of his achievements was his re-establishment of mathematical rationalism against Aristotle's logico-verbal approach and his insistence that the "Book of Nature is written in mathematical characters." From this base, he was able to found the modern experimental method (see RATIONALISM: *Religious Rationalism*).

Alinari

Galileo, oil painting by J. Sustermans, 1686. In the Uffizi, Florence.

**Early years.** Galileo was born at Pisa on February 15, 1564, the son of Vincenzo Galilei, a musician. He received his early education at the monastery of Vallombrosa near Florence, where his family had moved in 1574. In 1581 he entered the University of Pisa to study medicine. While in the Pisa cathedral during his first year at the university, Galileo supposedly observed a lamp swinging and found that the lamp always required the same amount of time to complete an oscillation, no matter how large the range of the swing. Later in life Galileo verified this observation experimentally and suggested that the principle of the pendulum might be applied to the regulation of clocks.

Until he supposedly observed the swinging lamp in the cathedral, Galileo had received no instruction in mathematics. Then a geometry lesson he overheard by chance awakened his interest, and he began to study mathematics and science with Ostilio Ricci, a teacher in the Tuscan court. But in 1585, before he had received a degree, he was withdrawn from the university because of lack of funds. Returning to Florence, he lectured at the Florentine academy and in 1586 published an essay describing the hydrostatic balance, the invention of which made his name known throughout Italy. In 1589 a treatise on the centre of gravity in solids won for Galileo the honourable, but not lucrative, post of mathematics lecturer at the University of Pisa.

Galileo then began his research into the theory of motion, first disproving the Aristotelian contention that bodies of different weights fall at different speeds. Because of financial difficulties, Galileo, in 1592, applied for and was awarded the chair of mathematics at Padua, where he was to remain for 18 years and perform the bulk of his most outstanding work. At Padua he contin-

The legend of the lamp

Salinity

The "National Water Carrier" canal

ued his research on motion and proved theoretically (about 1604) that falling bodies obey what came to be known as the law of uniformly accelerated motion (in such motion a body speeds up or slows down uniformly with time). He also gave the law of parabolic fall (e.g., a ball thrown into the air follows a parabolic path). A legend that he dropped weights from the leaning tower of Pisa apparently has no basis in fact.

**Research with the telescope.** Galileo became convinced early in life of the truth of the Copernican theory (i.e., that the planets revolve about the Sun) but was deterred from avowing his opinions—as shown in his letter of April 4, 1597, to Kepler—because of fear of ridicule. While in Venice in the spring of 1609, Galileo learned of the recent invention of the telescope. After returning to Padua he built a telescope of threefold magnifying power and quickly improved it to a power of 32. Because of the method Galileo devised for checking the curvature of the lenses, his telescopes were the first that could be used for astronomical observation and soon were in demand in all parts of Europe.

Early astronomical discoveries

As the first person to apply the telescope to a study of the skies, Galileo in late 1609 and early 1610 announced a series of astronomical discoveries. He found that the surface of the Moon was irregular and not smooth, as had been supposed; he observed that the Milky Way system was composed of a collection of stars; he discovered the satellites of Jupiter and named them *Sidera Medicea* (Medicean Stars) in honour of his former pupil and future employer, Cosimo II, grand duke of Tuscany. He also observed spots on the Sun, the phases of Venus, and the rings of Saturn. His first decisive astronomical observations were published in 1610 in *Sidereus Nuncius* ("The Starry Messenger"; see TELESCOPE: *Early History*).

Although the Venetian senate had granted Galileo a lifetime appointment as professor at Padua because of his findings with the telescope, he left in the summer of 1610 to become "first philosopher and mathematician" to the grand duke of Tuscany, an appointment that enabled him to devote more time to research.

**Conflict with Rome.** In 1611 Galileo visited Rome and demonstrated his telescope to the most eminent personages at the pontifical court. Encouraged by the flattering reception accorded to him, he ventured, in three letters on the sunspots printed at Rome in 1613 under the title *Istoria e dimostrazioni intorno alle macchie solari e loro accidenti* . . . , to take up a more definite position on the Copernican theory. Movement of the spots across the face of the Sun, Galileo maintained, proved Copernicus was right and Ptolemy wrong.

His great expository gifts and his choice of Italian, in which he was an acknowledged master of style, made his thoughts popular beyond the confines of the universities and created a powerful movement of opinion. The Aristotelian professors, seeing their vested interests threatened, united against him. They strove to cast suspicion upon him in the eyes of ecclesiastical authorities because of contradictions between the Copernican theory and the Scriptures. They obtained the cooperation of the Dominican preachers, who fulminated from the pulpit against the new impiety of "mathematicians" and secretly denounced Galileo to the Inquisition for blasphemous utterances, which, they said, he had freely invented. Gravely alarmed, Galileo agreed with one of his pupils, B. Castelli, a Benedictine monk, that something should be done to forestall a crisis. He accordingly wrote letters meant for the Grand Duke and for the Roman authorities (letters to Castelli, to the Grand Duchess Dowager, to Monsignor Dini) in which he pointed out the danger, reminding the church of its standing practice of interpreting Scripture allegorically whenever it came into conflict with scientific truth, quoting patristic authorities and warning that it would be "a terrible detriment for the souls if people found themselves convinced by proof of something that it was made then a sin to believe." He even went to Rome in person to beg the authorities to leave the way open for a change. A number of ecclesiastical experts were on his side. Unfortunately, Cardinal Robert Bellarmine, the chief theologian of the church, was un-

able to appreciate the importance of the new theories and clung to the time-honoured belief that mathematical hypotheses have nothing to do with physical reality. He only saw the danger of a scandal, which might undermine Catholicity in its fight with Protestantism. He accordingly decided that the best thing would be to check the whole issue by having Copernicanism declared "false and erroneous" and the book of Copernicus suspended by the congregation of the Index. The decree came out on March 5, 1616. On the previous February 26, however, as an act of personal consideration, Cardinal Bellarmine had granted an audience to Galileo and informed him of the forthcoming decree, warning him that he must henceforth neither "hold nor defend" the doctrine, although it could still be discussed as a mere "mathematical supposition."

The suppression of Copernicanism

For the next seven years Galileo led a life of studious retirement in his house in Bellosguardo near Florence. At the end of that time (1623), he replied to a pamphlet by Orazio Grassi about the nature of comets; the pamphlet clearly had been aimed at Galileo. His reply, titled *Saggiatore* . . . ("Assayer . . ."), was a brilliant polemic on physical reality and an exposition of the new scientific method. In it he distinguished between the primary (i.e., measurable) properties of matter and the others (e.g., odour) and wrote his famous pronouncement that the "Book of Nature is . . . written in mathematical characters." The book was dedicated to the new pope, Urban VIII, who as Maffeo Barberini had been a longtime friend and protector of Galileo. Pope Urban received the dedication enthusiastically.

In 1624 Galileo again went to Rome, hoping to obtain a revocation of the decree of 1616. This he did not get, but he obtained permission from the pope to write about "the systems of the world," both Ptolemaic and Copernican, as long as he discussed them noncommittally and came to the conclusion dictated to him in advance by the pontiff—that is, that man cannot presume to know how the world is really made because God could have brought about the same effects in ways unimagined by him, and he must not restrict God's omnipotence. These instructions were confirmed in writing by the head censor, Monsignor Niccolò Riccardi.

Galileo returned to Florence and spent the next several years working on his great book *Dialogo sopra i due massimi sistemi del mondo, tolemaico e copernicano* (*Dialogue Concerning the Two Chief World Systems—Ptolemaic and Copernican*, 1953).

As soon as it came out, in the year 1632, with the full and complete imprimatur of the censors, it was greeted with a tumult of applause and cries of praise from every part of the European continent as a literary and philosophical masterpiece.

On the crisis that followed there remain now only inferences. It was pointed out to the Pope that despite its noncommittal title, the work was a compelling and unabashed plea for the Copernican system. The strength of the argument made the prescribed conclusion at the end look anticlimactic and pointless. The Jesuits insisted that it could have worse consequences on the established system of teaching "than Luther and Calvin put together." The Pope, in anger, ordered a prosecution. The author being covered by license, the only legal measures would be to disavow the licensers and prohibit the book. But at that point a document was "discovered" in the file, to the effect that during his audience with Bellarmine on February 26, 1616, Galileo had been specifically enjoined from "teaching or discussing Copernicanism in any way," under the penalties of the Holy Office. His license, it was concluded, had therefore been "extorted" under false pretenses. (The consensus of historians, based on evidence made available when the file was published in 1877, has been that the document had been planted and that Galileo was never so enjoined.) The church authorities, on the strength of the "new" document, were able to prosecute him for "vehement suspicion of heresy." Notwithstanding his pleas of illness and old age, Galileo was compelled to journey to Rome in February 1633 and stand trial. He was treated with special in-

Galileo's trial

dulgence and not jailed. In a rigorous interrogation on April 12, he steadfastly denied any memory of the 1616 injunction. The commissary general of the Inquisition, obviously sympathizing with him, discreetly outlined for the authorities a way in which he might be let off with a reprimand, but on June 16 the congregation decreed that he must be sentenced. The sentence was read to him on June 21: he was guilty of having "held and taught" the Copernican doctrine and was ordered to recant. Galileo recited a formula in which he "abjured, cursed and detested" his past errors. The sentence carried imprisonment, but this portion of the penalty was immediately commuted by the Pope into house arrest and seclusion on his little estate at Arcetri near Florence, where he returned in December 1633. The sentence of house arrest remained in effect throughout the last eight years of his life.

Although confined to his estate, Galileo's prodigious mental activity continued undiminished to the last. In 1634 he completed *Discorsi e dimostrazioni matematiche intorno a due nuove scienze attenenti alla meccanica* (*Dialogue Concerning Two New Sciences* . . ., 1914), in which he recapitulated the results of his early experiments and his mature meditations on the principles of mechanics. This, in many respects his most valuable work, was printed by Louis Elzevirs at Leiden in 1638. His last telescopic discovery—that of the Moon's diurnal and monthly librations (wobbling from side to side)—was made in 1637, only a few months before he became blind. But the fire of his genius was not even yet extinct. He continued his scientific correspondence with unbroken interest and undiminished acumen; he thought out the application of the pendulum to the regulation of clockwork, which the Dutch scientist Christiaan Huygens put into practice in 1656; he was engaged in dictating to his disciples, Vincenzo Viviani and Evangelista Torricelli, his latest ideas on the theory of impact when he was seized with the slow fever that resulted in his death at Arcetri on January 8, 1642.

**Value of his work.** The direct services of permanent value that Galileo rendered to astronomy are virtually summed up in his telescopic discoveries. His name is justly associated with a vast extension of the bounds of the visible universe, and his telescopic observations are a standing monument of his ability. Within two years after their discovery, he had constructed approximately accurate tables of the revolutions of Jupiter's satellites and proposed their frequent eclipses as a means of determining longitudes on land and at sea. The idea, though ingenious, has been found of little use at sea. His observations on sunspots are noteworthy for their accuracy and for the deductions he drew from them with regard to the rotation of the Sun and the revolution of the Earth.

A puzzling circumstance is Galileo's neglect of Kepler's laws, which were discovered during his lifetime. But then he believed strongly that orbits should be circular (not elliptical, as Kepler discovered) in order to keep the fabric of the cosmos in its perfect order. This preconception prevented him from giving a full formulation of the inertial law, which he himself discovered, although it usually is attributed to the French mathematician René Descartes. Galileo believed that the inertial path of a body around the Earth must be circular. Lacking the idea of Newtonian gravitation, he hoped this would allow him to explain the path of the planets as circular inertial orbits around the Sun.

The idea of a universal force of gravitation seems to have hovered on the borders of this great man's mind, but he refused to entertain it because, like Descartes, he considered it an "occult" quality. More valid instances of the anticipation of modern discoveries may be found in his prevision that a small annual parallax would eventually be found for some of the fixed stars and that extra-Saturnian planets would at some future time be ascertained to exist and in his conviction that light travels with a measurable although extremely great velocity. Although Galileo discovered, in 1610, a means of adapting his telescope to the examination of minute objects, he did not become acquainted with the compound micro-

scope until 1624, when he saw one in Rome and, with characteristic ingenuity, immediately introduced several improvements into its construction.

A most substantial part of his work consisted undoubtedly of his contributions toward the establishment of mechanics as a science. Some valuable but isolated facts and theorems had previously been discovered and proved, but it was Galileo who first clearly grasped the idea of force as a mechanical agent. Although he did not formulate the interdependence of motion and force into laws, his writings on dynamics are everywhere suggestive of those laws, and his solutions of dynamical problems involve their recognition. In this branch of science he paved the way for the English physicist and mathematician Isaac Newton later in the century. The extraordinary advances made by him were due to his application of mathematical analysis to physical problems.

Galileo was the first man who perceived that mathematics and physics, previously kept in separate compartments, were going to join forces. He was thus able to unify celestial and terrestrial phenomena into one theory, destroying the traditional division between the world above and the world below the Moon. The method that was peculiarly his consisted in the combination of experiment with calculation—in the transformation of the concrete into the abstract and the assiduous comparison of results. He created the modern idea of experiment, which he called *cimento* ("ordeal"). This method was applied to check theoretical deductions in the investigation of the laws of falling bodies, of equilibrium and motion on an inclined plane, and of the motion of a projectile. The latter, together with his definition of momentum and other parts of his work, implied a knowledge of the laws of motion as later stated by Newton. In his *Discorso intorno alle cose che stanno in su l'acqua* ("Discourse on Things That Float"), published in 1612, he used the principle of virtual velocities to demonstrate the more elementary theorems of hydrostatics, deducing the equilibrium of fluid in a siphon, and worked out the conditions for the flotation of solid bodies in a liquid. He also constructed, in 1607, an elementary form of air thermometer.

**BIBLIOGRAPHY.** The first complete edition of Galileo's works was that of EUGENIO ALBERI, 16 vol. (1842–56). It is now superseded by the final *Edizione nazionale delle opere di Galileo Galilei*, 20 vol., by the Galileo scholar ANTONIO FAVARO (1890–1909, reprinted 1929–39). It contains every obtainable document and scrap of correspondence. The documents of the trial are in vol. 19.

The original documents from the archives of the Inquisition, relating to the events of 1616 and 1633, were first published in their entirety by HENRI DE L'ÉPINOIS, *Les Pièces du procès de Galilée* (1877). The earliest authoritative discussions are by KARL VON GEHLER, *Galileo Galilei und die römische Curie*, 2 vol. (1876–77, reprinted 1968); and EMIL WOHLWILL, *Galilei*, 2 vol. (1875–1907). More recent is GIORGIO DE SANTILLANA, *The Crime of Galileo* (1955). On the Roman Catholic side are F.R. WEGG-PROSSER, *Galileo and His Judges* (1889); ADOLF MÜLLER, *Galilei und die Katholische Kirche* (1910); and FILIPPO SOCCORSI, *Il Processo di Galileo* (1947).

The most important collection of monographs and scholarly sources are ANTONIO FAVARO, *Galileo Galilei e lo studio di Padova*, 2 vol. (1883, reprinted 1966), and *Scampoli Galileiani* (1886); STILLMAN DRAKE, "Galileo Gleanings," *Isis*, 6 pt., 48: 393–397, 49:26–33, 155–165, 409–413, 50:245–254 (1957–59); and *Osiris*, 13:262–290 (1958). The *Bibliografia Galileiana*, 1568–1895, by ALARICO CARLI and ANTONIO FAVARO (1896), lists more than 2,000 publications; its continuation by GIUSEPPE BOFFITO (1943) lists another 2,000.

The first English translation of Galileo's writings was THOMAS SALUSBURY, *Mathematical Collections and Translations*, 5 vol. (1661–62). Other English translations include *Dialogues Concerning Two New Sciences*, trans. by HENRY CREWE and ANTONIO DE SALVIO (1914, reprinted 1954); *Dialogue Concerning the Two Chief World Systems—Ptolemaic and Copernican*, trans. by STILLMAN DRAKE, 2nd ed. (1967); *Dialogue on the Great World Systems, in the Salusbury Translation*, ed. by GIORGIO DE SANTILLANA (1953); *Letters on Sunspots, . . .*, abridged in STILLMAN DRAKE, *Discoveries and Opinions of Galileo* (1957); and *On Motion, and On Mechanics*, trans. by I.E. DRABKIN and STILLMAN DRAKE (1960).

Work in  
mechanics

## Galliformes

The bird order Galliformes, or gallinaceous (*i.e.*, fowl-like or chicken-like) birds, includes about 240 species, of which the best known are the turkeys (family Meleagrididae); chickens, quail, partridge, pheasant and peacock (Phasianidae); guinea fowl (Numididae); and grouse (Tetraonidae). Lesser known members of the order are the megapodes (Megapodiidae); chachalacas, guans, and curassows (Cracidae); and the hoatzin (Opisthocomidae). The last is so aberrant that many authorities place it in a separate order, Opisthocomiformes.

### GENERAL FEATURES

**Size range and diversity of structure.** Most galliforms are medium-sized birds, from the size of a pigeon to that of a domestic chicken, 40 to 60 centimetres (16 to 24 inches) long and 500 to 2,500 grams (one to five pounds) in weight. The smallest members of the order are the sparrow-sized painted quail (*Excalfactoria*), about 13 centimetres (five inches) long and about 45 grams (1½ ounces) in weight. The heaviest galliform is the common, or wild, turkey (*Meleagris gallopavo*), wild specimens of which may weigh up to 11 kilograms (about 24 pounds); the longest is the argus pheasant (*Argusianus argus*), the male of which reaches two metres (79 inches) in breeding plumage, including wing and tail feathers, whose length exceeds one metre.

The majority of gallinaceous birds are heavy bodied, with short, rounded wings and strong, four-toed feet, adapted for life on the ground; a few, such as cracids and the hoatzin, live mainly in trees. The bill is short and slightly downcurved. The flight is fast but rarely sustained for long distances, most being sedentary, nonmigratory birds.

**Distribution.** Some members of the order are found in virtually every habitat in sub-Arctic, temperate, and tropical regions of the larger landmasses, and a few species (ptarmigan, *Lagopus*) live within the Arctic Circle. The phasianids, the 178 species of which comprise by far the largest family, have nearly the distribution of the order. The cracids, with about 34 species, are restricted to tropical woodlands of Central and South America. The 18 species of grouse are found in northern temperate and

Arctic regions of both hemispheres. The remaining groups are more restricted in distribution. The ten species of megapodes inhabit forests from the East Indies east to the Fiji Islands and south to central Australia. Guinea fowl are restricted to Africa south of the Sahara but have been widely introduced on other continents. The two turkeys are native to North and Central America; the common, or wild, turkey in temperate woodlands of eastern United States and Mexico; and the ocellated turkey (*Agriocharis ocellata*) in Guatemala, British Honduras, and the Yucatán Peninsula of Mexico. The hoatzin (*Opisthocomus hoazin*) inhabits wooded river edges in northern and eastern South America.

### IMPORTANCE TO MAN

Gallinaceous birds are unquestionably the most important avian group from the human standpoint. The chicken (*Gallus domesticus*) was domesticated in southern Asia at least 4,000 years ago from a parental stock of one or more species of jungle fowl (principally *G. gallus*). Selective breeding has produced well over 100 varieties, most of which are specialized for the production of either eggs or meat. In North America and to a lesser extent in northern Europe, the turkey is raised in numbers second only to those of the chicken. Domestic breeding of the turkey has been primarily for rapid growth and high market weight, the birds being raised solely for meat. Mature toms (males) may reach 23 kilograms (about 51 pounds). In many parts of the world, guinea fowl are an important barnyard species and are valued for the readiness with which they give alarm at the approach of a predator. (For a complete account of domestic gallinaceous birds, see LIVESTOCK AND POULTRY FARMING.)

Galliform birds constitute the large majority of land game birds, in number both of species and of individuals. Populations in North America and in western Europe are often carefully managed through habitat manipulation, supplemental feeding, and artificial rearing to ensure maximum hunting yields. The common pheasant (*Phasianus colchicus*, called the ring-necked pheasant in the United States) was introduced in North America late in the 19th century and has become widely established. Several species of quail (especially those of the genera *Coturnix* and *Colinus*) and partridge (*Perdix* and *Alectoris*)

Origin of the domestic chicken

Body plans of galliform birds.

provide much sport hunting. A widespread tendency in game-bird management has been the introduction of species to areas where they have not been found previously.

The North American wild turkey, once nearly exterminated by overhunting, has responded to careful management and is now taken in fair numbers in the hardwood forests of the eastern United States. Grouse (including ptarmigan) are hunted throughout their range. (For further information on game birds, see HUNTING, SPORT.)

#### NATURAL HISTORY

**Habitat selection and food habits.** As an order, the galliforms inhabit a wide variety of vegetational types, including dense and open forest, open grasslands, scrub and second-growth forest, and flooded riparian (river) forests. Megapodes live in dense jungle, some appearing in the open only to lay eggs on sandy beaches. The mallee fowl (*Leipoa ocellata*) is an exception, inhabiting the eucalyptus thickets that characterize the arid interior of Australia. The majority of galliforms roost on elevated perches at night, even those species that spend the daylight hours foraging on the ground. Virtually the only ones that live in treeless regions are certain of the grouse, such as the tundra-inhabiting ptarmigan, the prairie chickens (*Tympanuchus cupido* and *T. pallidicinctus*), the sage grouse (*Centrocercus urophasianus*), and the sharp-tailed grouse (*Pedioecetes phasianellus*). The Eurasian black grouse (*Tetrao tetrix*) occurs in open country and in forested regions. Most of the true pheasant, including the peafowl, are residents of open forest with clearings. Guinea fowl of the genera *Guttera* and *Agelastes* and quail of the New World genus *Odontophorus* inhabit dense tropical forest. The hoatzin is closely associated with water and is almost never found far from it.

The food of galliforms is varied, most species being basically vegetarian, but they also take large numbers of insects, worms, and other invertebrates. Many use their feet to uncover food in leaf litter. The hoatzin feeds on leaves and fruit, especially those of arums (Araceae), rarely descending to the ground but occasionally entering the water to take small crabs or fish.

**Courtship and mating.** Gallinaceous birds vary considerably in reproductive behaviour, some exhibiting monogamous pair formation with a pair bond lasting through the breeding season, others showing varying types of polygamy, usually with members of both sexes being more or less promiscuous. Many, if not most, quail and partridge are monogamous, as are ptarmigan, guinea fowl, the hoatzin, some pheasant, and those megapodes and cracids that have been studied. Polygamy is known to occur in many grouse, including the North American grassland species, and in peafowl (*Pavo*) and some other phasianids. In the social displays of grouse, a number of males assemble in a special assembly area, called a court, dancing ground, arena, or lek. The dancing ground lies outside of all nesting territories, and the same ground is used year after year. Each of the males, which may number up to several dozen, has his own area within the dancing ground. There he struts and postures, producing strange calls (some of which are produced in special esophageal air sacs) to attract the females, who visit the dancing ground to select a male and copulate. Dominant males occupy central positions in the arena group and may copulate with several females. Some species, such as the black grouse and the capercaillie (*Tetrao urogallus*), are variable in the degree to which males gather for display purposes, populations in more open areas tending more toward social displays. Males of the North American ruffed grouse (*Bonasa umbellus*) and those of some phasianids, the peacock pheasant (*Polyplectron*) and argus pheasant being examples, live in isolation, displaying to and copulating with any receptive female.

**Nesting.** The large majority of gallinaceous birds nest on the ground, the nest being only a shallow scrape, lined with soft grass or leaves. Cracids, the hoatzin, and the horned pheasant (*Tragopan*) build nests in trees, those of the cracids being relatively small for the size of the birds.

The nesting of megapodes is unique among birds. The eggs of all species are placed in sand or soil, the heat for

Male sage grouse (*Centrocercus urophasianus*) in courtship display, revealing the bare air sacs in the sides of its neck.  
Harry Engels—National Audubon Society

incubation coming from solar radiation, fermentation of plant matter, or even volcanic steam. Young megapodes, extremely precocious at hatching, dig their way to the surface and forage for themselves. They are fully feathered when hatched and can fly when 24 hours old. The simplest form of nesting, found in the maleo (*Macrocephalon maleo*), Wallace's megapode (*Eulipoa wallacei*), and some individuals of Freycinet's megapode (*Megapodius freycinet*, called jungle fowl in Australia), consists of placing each egg in a hole dug in sand to a depth of up to one metre (about one yard) in a site chosen for receiving the appropriate amount of solar radiation. Once laid and buried, the egg receives no further attention from the parents.

Some members of the genus *Megapodius* (including jungle-dwelling members of *M. freycinet*) build mounds of decaying vegetation, up to ten metres (35 feet) long and five metres high. Mounds built by the brush turkeys (*Alectura*, *Aepyodius*, and *Talegalla*) are smaller, up to about four metres in diameter and a metre high. The mallee fowl, the most studied of the megapodes, uses a combination of solar radiation and fermentation to maintain the incubation temperature.

In the mound-building species of megapodes, the male maintains the mound for much of the year. Prior to and during the incubation period, he opens the mound once or twice a day to control the generation, absorption, and radiation of heat. It is generally believed that the bird measures the temperature of the egg chamber when opening the mound. The temperature sensing organ is not known, but the most likely organ is the tongue. By instrumentation of mallee-fowl mounds, an Australian biologist, H.J. Frith, has found that the mound is maintained within a degree or two of 33° C (91° F) throughout the period of several months that there are eggs in it. Observations of one species of brush turkey, *Alectura lathami*, indicate that the frequent opening of the mound may be as important for ventilation as for temperature control.

The eggs of most gallinaceous birds are solidly coloured in white, buff, or olive, but those of species nesting in open areas are usually protectively coloured with blotches of brown or black. There is great variation in the number of eggs laid. Most members of the order are indeterminate layers, the female producing eggs until a certain number has accumulated in the nest. This characteristic has allowed man to exploit galliforms (especially the domestic hen, of course) for egg production. If the domestic hen were a determinate layer, as are members of many other bird orders, each individual would produce her clutch of about a dozen eggs and, regardless of whether

Construction of "incubators" by megapodes

Determinate versus indeterminate layers

Polygamous and monogamous types

or not the eggs were removed, would discontinue laying for at least two months.

The clutch size varies from two to about two dozen, the largest number occurring in megapodes. Partridge, quail, and the smaller pheasant lay from 12 to more than 20 eggs, but the larger pheasant, such as the crested argus (*Rheinardia ocellata*) and the great argus, normally lay only two eggs. The hoatzin and the cracids lay two or three eggs, three being the rule in the smaller cracids, such as chachalacas. Guinea fowl lay seven to 20 eggs, and turkeys eight to 18.

Incubation is usually performed by the female alone. Males of some New World quail, including the Montezuma quail (*Cyrtonyx montezumae*), the bobwhite (*Colinus virginianus*), and other members of the genus *Colinus*, incubate for short periods. The female of the southern European red partridge (*Alectoris rufa*) has been reported to lay two clutches, one incubated by the male, the other concurrently by herself. This behaviour, unique among birds, is in need of further investigation.

It is uncertain whether or not the male hoatzin incubates the eggs. Both sexes have been observed in nest building and taking care of the young, so it is possible that the male also assists in incubation.

**Care of the young.** Young gallinaceous birds (except those of the hoatzin) are extremely precocious, walking and feeding within a few hours of hatching. Parental behaviour parallels mating behaviour: males of species in which a pair bond is formed usually assist in shepherding the young. Although clad in a protective coat of down and usually camouflaged with spots and streaks, the chicks suffer high mortality from predators and adverse weather. Mortality rates of 50 percent or more are reported to occur in the period of a few months between hatching and independence of the young. Partridge, quail, and grouse maintain family groups (coveys) of a dozen or more birds that remain together until the next breeding season.

The hoatzin, unusual in many ways, also differs from other galliforms in that its nestlings are hatched practically naked and are fed by the parents in the nest. The young are fed regurgitated food from the crops of their parents. Although they have a long fledging period, young hoatzins scramble about in the branches around the nest, holding on with the clawed first and second digits of the wings and, in the manner of parrots, with their bills. The fact that the second digit of the wing (now considered to be digit III, in the evolutionary sense) is free and bears a functional claw was once thought (erroneously) to indicate affinities with the reptilian forebears of birds. Most authorities now believe that the free digits are a secondary adaptation that allows the young hoatzin great mobility during its flightless period and allows it to climb out of the water, into which it may deliberately drop when danger threatens.

Most gallinaceous birds reach sexual maturity at the age of at least one year. Some species, however, may be physiologically capable of reproduction at a much earlier age. The common quail (*Coturnix coturnix*), wild individuals of which normally breed at one year of age, matures to breeding condition in seven weeks in captivity. It is uncertain whether wild birds, hatched in the spring, actually do breed during the summer; environmental control factors, especially decreasing daylength, probably prevent the attainment of breeding condition by two-month-old birds in natural situations. Even the Congo peacock (*Afropavo congensis*), a relatively large species, is able to reproduce at one year of age when reared in captivity.

**Vocalizations.** Like many other birds that inhabit dense cover, forest galliformes are endowed with strong voices, ranging from musical whistles to harsh screams. The repertoire of most species includes alarm notes, food calls, "crowing" by males to advertise territories, and notes used to maintain social groups. Many species are especially vocal at daybreak; a few are reported to call at night. Megapodes give clucking and cackling calls during the day and mewing calls at night. Cracids produce loud calls that have immense carrying power. Males of some species have elongated, looped tracheae (wind-

pipes), which are believed to add to the carrying power of the calls. Members of the social groups often cackle noisily together. Male peafowl utter a long mournful scream that sounds quite like a child in distress.

#### FORM AND FUNCTION

With the exception of the hoatzin, all galliforms have the same general body plan, being adapted for a primarily terrestrial existence. The feet and claws are large in all families, particularly so in the megapodes, reflecting their use for scratching and digging. The hind toe is larger and more functional in groups, such as the cracids, that spend much time in trees; it is smaller in the more terrestrial groups, but in none has it been lost, as it has in terrestrial birds of some other orders.

The short, rounded wings, powered by strong breast muscles (the white meat of the chicken), are indicative of the need for short, rapid bursts of flight, such as the escape from predators. Although no galliform is flightless, none is capable of long flights. The tail varies from extremely short (e.g., in painted quail) to strikingly long; in many male pheasant the tail may be more than two-thirds of the bird's total length. The tails of some pheasant and of most megapodes are vaulted, having an inverted V-shape in cross section.

Male ornamental plumage is often remarkable in shape and coloration, combining spots or bars of silver, green, or purple iridescence with areas of brilliant orange, yellow, or white. Sculptured, fleshy wattles on the faces of male pheasant and grouse are often coloured a bright blue or red. In some male pheasant, such as the firebacks (*Lophura*), impeyans (*Lophophorus*), and peafowl, the head is ornamented with a small tuft of modified plumes, forming a tiny fan. Many cracids have patches of bare skin on the face or throat, usually red, yellow, or blue. Males of many curassows and guans possess head ornaments in the form of a brightly coloured fleshy knob or a bony casque (helmet) on the top of the head.

Ornamental plumage of the male

#### CLASSIFICATION

**Distinguishing taxonomic features.** The limits and interrelationships of galliform families have been determined on the basis of general body proportions, muscle and bone configurations, plumage, clutch size and egg characteristics, the appearance of the young, and some aspects of behaviour. Recent studies have utilized the biochemistry of egg white and blood proteins to indicate relationships.

**Annotated classification.** The classification presented below was established by the American ornithologist Alexander Wetmore, based on studies by many earlier workers.

#### ORDER GALLIFORMES

##### Suborder Galli

##### Family Megapodiidae (megapodes or mound builders)

All use heat other than body heat to incubate their eggs. Large feet, small heads. Tail often vaulted. Medium to large birds, 25–65 cm (10–25 in.); sexes alike. One fossil, *Chosornis praeteritus*, from the upper Pleistocene; 7 Recent genera, 12 species; Australia and East Indies to central Polynesia.

##### Family Cracidae (chachalacas, guans, and curassows)

Tail moderately long and broad. Plumage black or brown, duller in female. Most species with bare skin between eyes and beak (lores), some with fleshy wattles or other ornaments on face or crown. Medium to large; length 52–99 cm (20–39 in.); lower Eocene to present; 11 fossil and 11 Recent genera, 34 Recent species; New World tropics and subtropics, from southern Texas to Paraguay.

##### Family Tetraonidae (grouse)

Distinguished by having lower leg (tarsus) and sometimes feet at least partially feathered; nostrils also feathered. Tail strong; ornamental in some species. Many with brightly coloured bare skin over eye. Medium to large; 30–90 cm (12–36 in.). Lower Miocene to present; 3 fossil and 9 Recent genera, 17 Recent species; North America and northern Eurasia.

##### Family Phasianidae (pheasant, quail, partridge, and relatives)

Nostrils, feet, and (usually) tarsus unfeathered; esophageal air sacs lacking. Many species with spurs on the back of the tarsus. Plumage, especially of males, bright in many species, often with ornamental feathers; sexes usually different. Small

Chick mortality

to large; length 13–200 cm (5–80 in.); lower Miocene to present; 11 fossil and about 40 Recent genera, about 178 Recent species; virtually worldwide, except southern third of South America, northern Eurasia, and some oceanic islands.

**Family Numididae** (guinea fowl)

Distinguished by presence of small whitish spots on dark bluish or slate body feathers; head and neck bare or slightly feathered, often brightly coloured. Legs and feet large; spurs present only in *Phasidus* and *Agelastes*. Medium to large; length 43–75 cm (17–30 in.). No fossil species; 5 genera, 7 species; Africa south of the Sahara and Madagascar.

**Family Meleagrididae** (turkeys)

Distinguished by metallic sheen on feathers, bare head with red and blue skin and wattles or caruncles. Tarsal spurs of male long, of female short. Size large, length 84–110 cm (33–43 in.). Upper Pliocene to present; 1 fossil genus (Pleistocene) and 2 Recent genera, each with 1 Recent species; eastern and southern United States, Mexico, northern Guatemala, British Honduras.

**Suborder Opisthocomi**

**Family Opisthocomidae** (hoatzin)

Rather long neck and small head, with prominent crest of long feathers; beak short, stout, laterally flattened. Wings large and rounded; tail long and broad. Brown above, marked with white and russet; buff below. Nestling with 2 free, clawed digits on each wing. Adult size large, length about 61 cm (24 in.). One fossil genus (*Hoazinoides*, middle Miocene); 1 Recent genus with 1 species; river systems of northern South America.

**Critical appraisal.** Although the classification presented here has broad acceptance, modern authorities disagree on the numbers of species and, especially, genera in many groups. Forms once regarded as distinct are now often considered to be geographical races of larger species. The problem is particularly acute where island populations are involved, for the usual biological criterion of free interbreeding cannot be applied, and the taxonomist must infer from external appearance whether or not two forms belong to the same species. The genus *Megapodius*, for example, was considered by the American ornithologist James L. Peters, in his 1934 volume of the classic *Check-list of Birds of the World*, to comprise nine species with 25 subspecies. Another authority, Dean Amadon, in a study published in 1952, recognized only three species, with 15 subspecies.

At the generic level, taxonomy is more subjective than at the species level, the boundaries of the genus being subject only to the general views of the taxonomist as to what constitutes a genus. Recent years have seen a drift toward "lumping," with the result that what were once regarded as discrete genera are now frequently merged (lumped), a family often having fewer genera but about the same number of species. Details of the anatomy, behaviour, and distribution of many galliform species remain unknown. As more information accumulates, further changes in the lower levels of classification may be expected.

**BIBLIOGRAPHY.** The following works are arranged by families.

*Megapodiidae:* H.J. FRITH, *The Mallee-Fowl: The Bird That Builds An Incubator* (1962), is an extensive study of the breeding habits of *Leipoa ocellata*.

*Cracidae:* A.F. SKUTCH, "Habits of the Chestnut-winged Chachalaca," *Wilson Bull.*, 75:262–269 (1963), presents information on the breeding habits of *Ortalis garrula*. C. VAURIE, "Taxonomy of the Cracidae (Aves)," *Bull. Am. Mus. Nat. Hist.*, 138:133–259 (1968); and F. VUILLEUMIER, "Relationships and Evolution Within the Cracidae (Aves, Galliformes)," *Bull. Mus. Comp. Zool. Harv.*, 134:1–27 (1965), are two analyses of the taxonomic relationships within this family.

*Tetraonidae:* A.W. BOBACK, *Das Auerhuhn* (1952), is a short monograph on the capercaillie; and A.W. BOBACK and D.W. MULLER-SCHWARZE, *Das Birkhuhn* (1968), is a study of the black grouse. G.L. GIRARD, "Life History, Habits, and Food of the Sage Grouse, *Centrocercus urophasianus* Bonaparte," *Univ. Wyo. Pubs.*, 3:1–56 (1937), provides insight into the natural history of this grassland species. G. BUMP *et al.*, *The Ruffed Grouse: Life History, Propagation, Management* (1947), is a classic study of this woodland grouse.

*Phasianidae:* C.W. BEEBE, *A Monograph of the Pheasants*, 4 vol. (1918–22), is a classic work on the pheasants, mag-

nificently illustrated with colour plates. A revised, less technical edition was published in two volumes under the title *Pheasants: Their Lives and Homes* (1926) and later in one volume (1936). J.T. DELACOUR, *The Pheasants of the World* (1951), is a fully illustrated treatment of the group, leaning heavily toward aviculture. H.L. STODDARD, *The Bobwhite Quail: Its Habits, Preservation and Increase* (1931), is an important book on this game species. P. WAYRE, *A Guide to the Pheasants of the World* (1969), is an extensively illustrated work with emphasis on conservation and on breeding in captivity.

*Numididae:* A.R. LEE, "The Guinea fowl," *Fmrs' Bull. U.S. Dep. Agric.* 1391 (1924), presents information on the guinea fowl, from an avicultural standpoint.

*Meleagrididae:* H.S. MOSBY and C.O. HANDLEY, *The Wild Turkey in Virginia* (1943), is a broad study of the natural history of *Meleagris gallopavo*. A.W. SCHORGER, *The Wild Turkey: Its History and Domestication* (1966), is primarily a historical treatise.

*Opisthocomidae:* C.W. BEEBE, "A Contribution to the Ecology of the Adult Hoatzin," *Zoologica*, 1:45–66 (1909); and *Tropical Wildlife in British Guiana*, pp. 155–182 (1917), present information from the author's field observations of the hoatzin.

(F.H.)

## Galois, Évariste

Before his tragic death in a duel at age 20, the French mathematician Évariste Galois had proposed structural and unifying concepts that were to perpetuate his memory in "Galois field," "Galois group," and "Galois theory," all among the most important topics studied in modern algebra. Although he was embittered by political oppression and frustrated by lack of educational opportunity, his work constitutes one of the finest achievements of 19th-century mathematics.

By courtesy of the Bibliothèque Nationale, Paris

Galois, detail of an engraving by an unknown artist, 1848, after a drawing by Alfred Galois.

Galois was born October 25, 1811, in the Paris suburb of Bourg-la-Reine, where his father, Nicolas-Gabriel Galois, was an important citizen. In 1815, during the Hundred Days regime that followed Napoleon's escape from Elba Island, his father was elected mayor. Galois's mother, Adelaïde-Marie Demante, was of a distinguished family of jurists. She gave Galois an excellent education at home until 1823, when he entered the Collège Royal de Louis-le-Grand. There his education languished at the hands of mediocre and uninspiring teachers. But his mathematical ability suddenly appeared when he was able to master quickly the works of Adrien-Marie Legendre on geometry and Joseph-Louis Lagrange on algebra.

Under the guidance of Louis Richard, one of his teachers at Louis-le-Grand, Galois's further study of algebra soon led him to take up a major challenge. Mathematicians for a long time had used explicit formulas, involving only rational operations and extractions of roots, for the solution of equations up to degree four. (For example,  $3x^2 + 5 = 17$  is an equation of the second degree,

Birth and early life

## The Galois theory

since it contains the exponent 2; solving an equation of this type is called a solution by radicals, because it involves extracting the square root of an expression composed of one or more terms whose coefficients appear in the equation.) The solution of quadratic, or second degree, equations goes back to ancient times. Formulas for the cubic and quartic were published in 1545 by Gerolamo Cardano, Italian mathematician and physician, after their discovery a few years earlier by the mathematicians Niccolo Tartaglia and Ludovico Ferrari. The equation of the fifth degree then defeated mathematicians until Paolo Ruffini in 1796 attempted to prove the impossibility of solving the general quintic equation by radicals. Ruffini's effort was not wholly successful, but the Norwegian mathematician Niels Abel (*q.v.*) in 1824 gave an essentially correct proof (see MATHEMATICS, HISTORY OF).

Galois was unaware of Abel's work in the first stages of his investigation although he did learn of it later. This was perhaps fortunate because Galois actually had launched himself on a much more ambitious study; while yet a student, at about age 16, he sought, by what is now called the "Galois theory," a deeper understanding of the essential conditions that an equation must satisfy in order for it to be solvable by radicals (see ALGEBRAIC STRUCTURES). His method was to analyze the "admissible" permutations (a change in an ordered arrangement) of the roots of the equation. That is, in today's terminology, he formed the "group" of automorphisms (a particular kind of transformation) of the "field," obtained by adjoining the roots of the equation. His key discovery, brilliant and highly imaginative, was that solvability by radicals is possible if and only if the group of automorphisms is solvable, which means essentially that the group can be broken down into prime-order constituents (prime numbers are positive numbers greater than 1 divisible only by themselves and 1) that always have an easily understood structure. The term solvable is used because of this connection with solvability by radicals. Thus Galois perceived that solving equations of the quintic and beyond required a wholly different kind of treatment than that required for the quadratic, cubic, and quartic.

While still at Louis-le-Grand he published several minor papers. Soon disappointments and tragedy filled his life with bitterness. Three memoirs that he submitted to the Academy of Sciences were lost or rejected by the academicians, who as mathematicians were authorized to act as editors. The first was lost in 1829 by Augustin-Louis Cauchy. In each of two attempts (1827 and 1829) to enter the École Polytechnique, the leading school of French mathematics, he had a disastrous encounter with an oral examiner and failed. Then his father, after bitter clashes with conservative elements in his home town, committed suicide in 1829. The same year, realizing that his career possibilities as a professional mathematician had ended, Galois enrolled as a teacher candidate in the less prestigious École Normale Supérieure and turned to political activism. But he continued his research.

A second memoir, on algebraic functions, which he submitted in 1830 to the Academy of Sciences, was lost by Jean-Baptiste Fourier (*q.v.*). The revolution of 1830 sent the last Bourbon monarch Charles X into exile. But republicans were deeply disappointed when yet another king, Louis Philippe, ascended the throne—even though he was a citizen king who wore the tricolour of the revolution. When Galois wrote a vigorous article expressing these views, he was promptly expelled from the École Normale Supérieure. Subsequently he was arrested twice for republican activities; he was acquitted the first time but spent six months in prison on the second charge. His third memoir in 1831 was returned by Siméon-Denis Poisson with a note that it was virtually incomprehensible and should be expanded and clarified.

The circumstances that led to his death on May 31, 1832, in a duel in Paris have never been fully explained. It has been variously suggested that it resulted from a quarrel over a girl, that he was challenged by royalists who detested his republican views, or that an *agent provocateur* of the police was involved. Alexandre Dumas,

in his autobiography *Mes Mémoires* (1863–65), implicated Pécheux d'Herbenville as the man who shot Galois. In any case, anticipating his death in the coming duel, Galois in feverish haste wrote a scientific last testament to his friend and former schoolmate Auguste Chevalier. In his distracted notes, there are hints that Galois had begun to develop the theory of algebraic functions, the full development of which was achieved 40 years later by the German mathematician Bernhard Riemann.

Galois's manuscripts, with annotations by Joseph Liouville, were published in 1846 in the *Journal de Mathématiques Pures et Appliquées*. In 1870 the French mathematician Camille Jordan published the full-length treatment of Galois's theory, *Traité des Substitutions*. These works rendered his discoveries fully accessible and his place secure in the history of mathematics. On June 13, 1909, a plaque was placed on Galois's modest birthplace at Bourg-la-Reine, and the mathematician Jules Tannery made an eloquent speech of dedication, which was published the same year in the *Bulletin des Sciences Mathématiques*.

**BIBLIOGRAPHY.** LEOPOLD INFELD, *Whom the Gods Love* (1948), is a full-length biography, in part fictional, based on a thorough examination of all available materials, with an extensive bibliography of earlier works. PAUL DUPUY, *La Vie d'Évariste Galois*, published in the *Annales Scientifiques de l'École Normale Supérieure*, 3rd Series, vol. 13, pp. 197–266 (1896), is the basic biographical work. See also ERIC TEMPLE BELL, *Men of Mathematics*, ch. 20 (1937, reprinted 1961), for a highly readable biographical sketch, featuring strong opinions of the Establishment's disastrous mistreatment of Galois. The *Écrits et mémoires mathématiques*, ed. by ROBERT BOURGNE and J.-P. AZRA with a preface by J. DIEUDONNE (1962), contains all the available writings of Galois, with a running commentary, and reproduces photographically many pages of his original manuscripts. In "Évariste Galois," *Osiris*, 3:241–259 (1937), GEORGE SARTON presents a brief critical biography. GARRETT BIRKOFF, "Galois and Group Theory," *ibid.*, pp. 260–268, is a nontechnical account of the development of Galois's ideas and their subsequent impact on group theory. Another historic survey is B. MELVIN KIERNAN, "The Development of Galois Theory from Lagrange to Artin," *Arch. Hist. Exact Sci.*, 8:40–154 (1971). Accounts of Galois theory are found in nearly every treatise on modern algebra. Brief, elegant, and self-contained is EMIL ARTIN, *Galois Theory*, 2nd ed. (1944).

(I.K.)

## Galton, Sir Francis

English scientist, explorer, and anthropologist, Francis Galton, a cousin of Charles Darwin, was among the first to recognize the implications for mankind of Darwin's theory of evolution. He saw that it invalidated much of contemporary theology and that it also opened possibilities for planned human betterment. Galton coined the word eugenics to denote scientific endeavours to increase the proportion of persons with better than average genetic endowment through selective mating of marriage partners.

Francis Galton was born of Quaker ancestry on February 16, 1822, near Sparkbrook, Birmingham. His family life was happy, and he gratefully acknowledged that he owed much to his father and mother. But he had little use for the conventional classical and religious teaching he received in school and church. Indeed, he later confessed in a letter to Charles Darwin that the traditional biblical arguments had made him "wretched."

His parents had planned that he should study medicine, and a tour of medical institutions on the Continent in his teens—an unusual experience for a student of his age—was followed by training in hospitals in Birmingham and London. But at this time, in Galton's words, "a passion for travel seized me as if I had been a migratory bird." A visit to the University of Giessen, Germany, to attend lectures on chemistry was broken off in favour of travel in southeastern Europe. From Vienna he made his way through Constanza, Constantinople, Smyrna, and Athens, and he brought back from the caves of Adelsberg, in present-day Yugoslavia, specimens of a blind amphibian named *Proteus*—the first to reach England. On his return Galton went to Trinity College, Cambridge, where, as a result of overwork, he broke down in his third

#### Travels and ex- ploration

year. But he recovered quickly on changing his mode of life, as he did from similar attacks later.

After leaving Cambridge without taking a degree, Galton continued his medical studies in London. But before they were completed, his father died, leaving him "a sufficient fortune to make me independent of the medical profession." Galton was then free to indulge his craving for travel. Leisurely expeditions in 1845–46 up the Nile with friends and into the Holy Land alone were preliminaries to a carefully organized penetration into unexplored parts of southwest Africa. After consulting the Royal Geographical Society, Galton decided to investigate a possible opening from the south and west to Lake Ngami, which lies north of the Kalahari desert some 550 miles east of Walvis Bay. The expedition, which included two journeys, one northward, the other eastward, from the same base, proved to be difficult and not without danger. Though the explorers did not reach Lake Ngami, they gained valuable information. As a result, at the age of only 31, Galton was in 1853 elected a fellow of the Royal Geographical Society and, three years later, of the Royal Society. In 1853, too, Galton married. There were no children of the marriage. Galton wrote nine books and some 200 papers. They deal with many diverse subjects, including the use of fingerprints for personal identification, the correlational calculus (a branch of applied statistics)—in both of which Galton was a pioneer—twins, blood transfusions, criminality, the art of travel in undeveloped countries, and meteorology. Most of Galton's publications disclose his predilection for quantifying; an early paper, for example, dealt with a statistical test of the efficacy of prayer. Moreover, over a period of 34 years, he concerned himself with improving standards of measurement.

Although he made contributions to many fields of knowledge, eugenics remained Galton's fundamental interest, and he devoted the latter part of his life chiefly to propagating the idea of improving the physical and mental makeup of the human species by selective parenthood. In his *Hereditary Genius* (1869), in which he used the word genius to denote "an ability that was exceptionally high and at the same time inborn," his main argument was that mental and physical features are equally inherited—a proposition that was not accepted at the time. It is surprising that when Charles Darwin first read this book, he wrote to the author: "You have made a convert of an opponent in one sense for I have always maintained that, excepting fools, men did not differ much in intellect, only in zeal and hard work." This book doubtless helped Darwin to extend his evolution theory to man. Galton, unmentioned in *Origin of Species* (1859), is several times quoted in Darwin's *Descent of Man* (1871). Galton's conviction that mental traits are no less inherited than are physical characteristics was strong enough to shape his

personal religious philosophy. "We cannot doubt," he wrote, "the existence of a great power ready to hand and capable of being directed with vast benefit as soon as we have learned to understand and apply it."

Galton's *Inquiries into Human Faculty* (1883) consists of some 40 articles varying in length from 2 to 30 pages, which are mostly based on scientific papers written between 1869 and 1883. The book can in a sense be regarded as a summary of the author's views on the faculties of man. On all his topics, Galton has something original and interesting to say, and he says it with clarity, brevity, distinction, and modesty. Under the terms of his will, a eugenics chair was established at the University of London. He was knighted in 1909 and died near London on January 17, 1911.

In the 20th century Galton's name has been mainly associated with eugenics. Insofar as eugenics takes primary account of *inborn* differences between human beings, it has come under the suspicion of those who hold that cultural (social and educational) factors heavily outweigh inborn, or biological, factors in their contribution to human differences. Eugenics is accordingly often treated as an expression of class prejudice, and Galton as a reactionary. Yet to some extent this view misrepresents his thought, for his aim was not the creation of an aristocratic elite but of a population consisting entirely of superior men and women. Galton's ideas, like those of Charles Darwin, were sharply limited by his lack of an adequate theory of inheritance; the rediscovery of the work of Mendel (*q.v.*) came too late to affect Galton's contribution in any significant way.

**BIBLIOGRAPHY.** The most important work on Galton is KARL PEARSON, *The Life, Letters and Labours of Francis Galton*, 4 vol. (1914–30). The last volume contains letters and a comprehensive index of Galton's publications.

#### Galvani, Luigi

The use of electricity as a powerful form of energy developed from studies in the 18th century in northern Italy by Luigi Galvani. His discoveries led to the invention of the voltaic pile, a kind of battery that makes possible a constant source of current electricity. Galvani also performed the experiments that made possible a recognition of electrical phenomena in living things.

Galvani was born on September 9, 1737, in Bologna, Italy. He followed his father's preference for medicine by attending the University of Bologna, graduating in 1759. On obtaining the doctor of medicine degree, with a thesis (1762) *De ossibus* on the formation and development of bones, he was appointed lecturer in anatomy at the University of Bologna and professor of obstetrics at the separate Institute of Arts and Sciences. In 1762, also, he married Lucia, the only daughter of Professor Galeazzi of the Bologna Academy of Science, of which Galvani became president in 1772.

Beginning with his doctoral thesis, his early research was in comparative anatomy—such as the structure of renal tubules, nasal mucosa, and the middle ear—with a tendency toward physiology, a direction appropriate to the later work for which he is noted. Galvani's developing interest was indicated by his lectures on the anatomy of the frog in 1773 and in electrophysiology in the late 1770s, when, following the acquisition of an electrostatic machine (a large device for making sparks) and a Leyden jar (a device used to store static electricity), he began to experiment with muscular stimulation by electrical means. His notebooks indicate that, from the early 1780s, animal electricity remained his major field of investigation. Numerous ingenious observations and experiments have been credited to him; in 1786, for example, he obtained muscular contraction in a frog by touching its nerves with a pair of scissors during an electrical storm. Again, a visitor to his laboratory touched a lumbar nerve of the animal while an electrical machine was activated. Galvani assured himself by further experiments that the twitching was, in fact, related to the electrical action. He also elicited twitching

without the aid of the electrostatic machine by pressing a copper hook into a frog's spinal cord and hanging the hook on an iron railing. Although twitching could occur during a lightning storm or with the aid of an electrostatic machine, it also occurred with only a metallic contact between leg muscles and nerves leading to them. A metallic arc connecting the two tissues could therefore be a substitute for the electrostatic machine.

Galvani delayed the announcement of his findings until 1791, when he published his essay *De Viribus Electricitatis in Motu Musculari Commentarius* (*Commentary on the Effect of Electricity on Muscular Motion*, 1953). He concluded that animal tissue contained a heretofore neglected innate, vital force, which he termed "animal electricity," which activated nerve and muscle when spanned by metal probes. He believed that this new force was a form of electricity in addition to the "natural" form that is produced by lightning or by the electric eel and torpedo ray and to the "artificial" form that is produced by friction (i.e., static electricity). He considered the brain to be the most important organ for the secretion of this "electric fluid" and the nerves to be conductors of the fluid to the nerve and muscle, the tissues of which act as did the outer and inner surfaces of the Leyden jar. The flow of this electric fluid provided a stimulus for the irritable muscle fibres, according to his explanation.

Galvani's scientific colleagues generally accepted his views, but Alessandro Volta, the outstanding professor of physics at the University of Pavia, was not convinced by the analogy between the muscle and the Leyden jar. Deciding that the frog's legs served only as an indicating electroscope, he held that the contact of dissimilar metals was the true source of stimulation; he referred to the electricity so generated as "metallic electricity" and decided that the muscle, by contracting when touched by metal, resembled the action of an electroscope. Furthermore, Volta said that if two dissimilar metals in contact both touched a muscle, agitation would also occur and increase with the dissimilarity of the metals. Galvani refuted this by obtaining muscular action with two pieces of the same material. Thus Volta rejected the idea of an "animal electric fluid," replying that the frog's legs responded to differences in metal temper, composition, and bulk. But the ensuing controversy was without personal animosity; Galvani's gentle nature and Volta's high principles precluded any harshness between them. Volta, who coined the term galvanism, said of Galvani's work that "it contains one of the most beautiful and most surprising discoveries." Nevertheless, partisan groups rallied to both sides. Giovanni Aldini, Galvani's nephew, wrote many answers to Volta's challenges.

In retrospect, Galvani and Volta are both seen to have been partly right and partly wrong. Galvani was correct in attributing muscular contractions to an electrical

stimulus but wrong in identifying it as an "animal electricity." Volta correctly denied the existence of an "animal electricity" but was wrong in implying that every electrophysiological effect requires two different metals as sources of current. Galvani, shrinking from the controversy over his discovery, continued his work as teacher, obstetrician, and surgeon, treating both wealthy and needy without regard to fee. In 1794 he offered a defense of his position in an anonymous book, *Dell'Uso e dell'Attività dell'Arco Conduttore nella Contrazione dei Muscoli*, the supplement of which described muscular contraction without the need of any metal. He caused a muscle to contract by touching the exposed muscle of one frog with a nerve of another and thus established for the first time that bioelectric forces exist within living tissue.

On June 30, 1790, Galvani's devoted wife and companion died, childless, at the age of 47. In the last years of his life, Galvani refused to swear allegiance to the new Cisalpine Republic established by Napoleon. Thereupon he was dropped from the faculty rolls, and his salary was terminated. Rejecting help and much saddened, he moved into the old Galvani home in which his brother was living. Soon, however, the politicians recanted, and the professorship was again offered to Galvani without the requirement of an oath. But this welcome step was short-lived because the affront had cut short his days.

Galvani provided the major stimulus for Volta to discover a source of constant current electricity; this was the voltaic pile, or a battery, with its principles of operation combined from chemistry and physics. This discovery led to the subsequent age of electric power. Moreover, Galvani opened the way to new research in the physiology of muscle and nerve, and the entire subject of electrophysiology. Galvani died in the house of his birth on December 4, 1798, at age 61, at a time when the world was on the threshold of the great electrical revolution.

**BIBLIOGRAPHY.** LUIGI GALVANI, *Opere edite ed inedite del professore Luigi Galvani* (1841) and *Aggiunta*, ed. by SILVESTRO GHERARDI (1842), comprise a prime reference; *Memorie ed esperimenti inediti di Luigi Galvani* (1937), Galvani's laboratory notes; *Commentary on the Effect of Electricity on Muscular Motion* (1953), an English translation of Galvani's *De Viribus Electricitatis in Motu Musculari Commentarius* (1791), with facsimile of the Latin text, an introduction by I. BERNARD COHEN, and an extensive bibliography; c. MESINI, *Luigi Galvani* (1958), a clear and scholarly modern study (in Italian).

(B.Di.)

## Gama, Vasco da

Vasco da Gama, a Portuguese navigator of the late 15th and early 16th centuries, led the Portuguese expedition of 1497–99 that opened the sea route between Europe and India by way of the Cape of Good Hope.

The third son of Estêvão da Gama, a nobleman who was commander of the fortress of Sines on the coast of Alentejo province in southwest Portugal, Vasco was born in about 1460. Little is known of his early life; he may have studied at the inland town of Évora—somewhere he learned mathematics and navigation. In 1492 King John II of Portugal sent him to the port of Setúbal, south of Lisbon, and to the Algarve, Portugal's southernmost province, to seize French ships in retaliation for French peacetime depredations against Portuguese shipping—a task that Vasco rapidly and effectively performed.

In accordance with the policy of Prince Henry the Navigator, King John was planning to send a Portuguese fleet to India to open the sea route to Asia and to outflank the Muslims, who had hitherto enjoyed a monopoly of trade with India and other eastern states. Estêvão da Gama was chosen to lead the expedition, but after his death Vasco took his place. Accounts of his appointment differ; whether he was chosen by King John and this choice confirmed by King Manuel, who ascended the throne in 1495, or whether it was King Manuel who first chose him, remains unclear. According to one version, the appointment was first offered to his eldest brother Paulo, who declined because of ill health.

*The first voyage.* Da Gama sailed from Lisbon on July 8, 1497, with a fleet of four vessels—two *naos* (medium-sized three-masted sailing ships), each of about 120 tons, named the "São Gabriel" and the "São Rafael"; a 50-ton caravel, named the "Berrio"; and a 200-ton storeship. They were accompanied to the Cape Verde Islands by another ship commanded by Bartolomeu Dias, the Portuguese navigator who had discovered the Cape of Good Hope a few years earlier and who was en route to the West African castle of São Jorge da Mina on the Gold Coast (now Ghana). With da Gama's fleet went three interpreters—two Arabic speakers and one who spoke several Bantu dialects. The fleet also carried *padroes* (stone pillars) to set up as marks of discovery and overlordship.

Passing the Canary Islands on July 15, the fleet reached the São Tiago in the Cape Verde Islands on the 26th, remaining there until August 3. Then, to avoid the currents of the Gulf of Guinea, da Gama took a circular course through the South Atlantic to the Cape of Good Hope, reaching Santa Helena Bay (in modern South Africa) on November 7. The expedition departed on November 16, but unfavourable winds delayed their rounding of the Cape of Good Hope until November 22. Three days later da Gama anchored in Mossel Bay, erected a *padrão* on an island, and ordered the storeship to be broken up. Sailing again on December 8, the fleet reached the coast of Natal on Christmas Day. On January 11, 1498, it anchored for five days near the mouth of a small river between Natal and Mozambique, which they called the Rio do Cobre (Copper River). On January 25, in what is now Mozambique, they reached the Quelimane River, which they called the Rio dos Bons Sinais (the River of Good Omens), and erected another *padrão*. By this time many of the crews were sick with scurvy; the expedition rested a month while the ships were repaired.

On March 2 the fleet reached the island of Mozambique, the inhabitants of which believed the Portuguese to be Muslims like themselves. Da Gama learned that they traded with Arab merchants and that four Arab vessels laden with gold, jewels, silver, and spices were then in port; he was also told that Prester John, the long-sought Christian ruler, lived in the interior but held many coastal cities. The Sultan of Mozambique supplied da Gama with two pilots, one of whom deserted when he discovered that the Portuguese were Christians.

The expedition reached Mombasa (now in Kenya) on April 7 and dropped anchor at Malindi (also now in Kenya) on April 14, where a pilot who knew the route to

Calicut, on the southwest coast of India, was taken aboard. After a 23-day run across the Indian Ocean, the Ghâts mountains of India were sighted, and Calicut was reached on May 20. There da Gama erected a *padrão* to prove he had reached India. Welcomed by the Zamorin, the Hindu ruler, of Calicut (then the most important trading centre of southern India), he failed, however, to conclude a treaty—partly because of the hostility of Muslim merchants and partly because the trumpery presents and cheap trade goods that he had brought, while suited to the West African trade, were hardly in demand in India.

After tension between da Gama's expedition and the Zamorin of Calicut increased, da Gama left at the end of August, taking with him five or six Hindus so that King Manuel might learn about their customs. He visited Anjdiv Island (near Goa) before sailing for Malindi, which he reached on January 8, 1499. Unfavourable winds caused the expedition to take nearly three months crossing the Arabian Sea, and many of the crew died of scurvy. At Malindi, because of greatly reduced numbers, da Gama ordered the "São Rafael" to be burned; there he also erected a *padrão*. Mozambique, where he set up his last *padrão*, was reached on February 1. On March 20 the "São Gabriel" and "Berrio" rounded the Cape together but a month later were parted by a storm; the "Berrio" reached the Tagus River in Portugal on July 10. Da Gama, in the "São Gabriel," continued to Terceira Island in the Azores, whence he is said to have dispatched his flagship to Lisbon. He himself reached Lisbon on September 9 and made his triumphal entry nine days later, spending the interval mourning his brother Paulo, who had died on Terceira. Manuel I granted Vasco the title of *dom* (equivalent to the English "sir"), an annual pension of 1,000 cruzados, and estates.

*The second voyage.* To further da Gama's achievement, Manuel I dispatched the Portuguese navigator Pedro Álvares Cabral to Calicut with a fleet of 13 ships. Later, the Hindus, incited by the Muslims, rose in arms and massacred the Portuguese whom Cabral had left behind. To avenge this deed a new fleet was fitted out in Lisbon to be sent against Calicut and to establish Portuguese hegemony in the Indian Ocean. At first the command was to be given to Cabral, but it was later transferred to da Gama, who in January 1502 was given the rank of admiral. Da Gama himself commanded ten ships, which were in turn supported by two flotillas of five ships each; each flotilla being under the command of one of his relations. Sailing in February 1502, the fleet called at the Cape Verdes, reaching the port of Sofala in East Africa on June 14. After calling briefly at Mozambique, the Portuguese expedition sailed to Kilwa, in what is now Tanzania. The ruler of Kilwa, the emir Ibrāhīm, had been unfriendly to Cabral; da Gama threatened to burn Kilwa if the Emir did not submit to the Portuguese and swear loyalty to King Manuel, which he then did.

Coasting southern Arabia, da Gama then called at Goa (later the focus of Portuguese power in India) before proceeding to Cannanore, a port in southwest India to the north of Calicut, where he lay in wait for Arab shipping. After several days an Arab ship arrived with merchandise and between 200 and 400 passengers, including women and children. After seizing the cargo, da Gama shut up the passengers aboard the captured ship and set it afire, killing all on board, the cruelest act of his career.

After da Gama formed an alliance with the ruler of Cannanore, an enemy of the Zamorin, the fleet sailed to Calicut. The Zamorin offered friendship, but da Gama rejected the offer and presented an ultimatum that the Muslims be banished from the port. To show that he meant what he threatened, da Gama bombarded the port and seized and massacred 38 Hindu fishermen who had sailed out to his ships to sell their wares; their bodies were then thrown overboard, to be washed ashore. The Portuguese then sailed south to the port of Cochin, with whose ruler (an enemy of the Zamorin) they formed an alliance. After an invitation to da Gama from the Zamorin had proved to be an attempt to entrap him, the Portuguese had a brief fight with Arab ships off Calicut but put them to full flight. On February 20, 1503, the

Arrival  
in Calicut

Last  
years

fleet left Cannanore for Mozambique on the first stage of their return voyage, reaching the Tagus on October 11.

*The third voyage.* Obscurity surrounds the reception of da Gama on his return by King Manuel. Da Gama seemingly felt himself inadequately recompensed for his pains. Controversy broke out between the Admiral and the Order (*i.e.*, religious association) of São Tiago over the ownership of the town of Sines, which the Admiral had been promised but which the order refused to yield. Da Gama had married a lady of good family, Caterina de Ataíde—perhaps in 1500 after his return from his first voyage—and he then appears to have retired to the town of Évora. He was later granted additional privileges and revenues, and his wife bore him six sons. Until 1505 he continued to advise the King on Indian matters, and he was created count of Vidigueira in 1519. Not until after King Manuel died, was he again sent overseas; King John III nominated him in 1524 as Portuguese viceroy in India.

Arriving in Goa in September, da Gama immediately set himself to correct the many administrative abuses that had crept in under his predecessors. Whether from overwork or other causes, he soon fell ill and died in Cochín on December 24, 1524. In 1538 his body was taken back to Portugal. Vasco da Gama's fame rests primarily upon his opening of the sea route from western Europe to the East, thus ushering in a new era in world history. He also helped to make Portugal a world power.

**BIBLIOGRAPHY.** There is no autobiography of Vasco da Gama. Portuguese chroniclers wrote at length about his voyage of 1497–99, and some of them must have had access to secret documents since destroyed. The only one translated into English is that of GASPAR CORREA (*c.* 1490–1565) from his *Lendas da Índia*; see *The Three Voyages of Vasco da Gama, and His Viceroyalty*, ed. by LORD STANLEY OF ALDERLEY (1869, reprinted 1963). The only firsthand account of the first voyage has also been printed in English in E.G. RAVENSTEIN (ed.), *A Journal [by an Unknown Writer] of the First Voyage of Vasco da Gama, 1497–1499* (1898, reprinted 1963). A later and more definitive edition has been printed in Portuguese in ABEL FONTOURA DA COSTA (ed.), *Roteiro da Primeira Viagem de Vasco da Gama, 1497–1499 por Alvaro Velho*, 3rd ed. (1969). The story of the voyage of 1497–99 is breezily told in HENRY H. HART, *Sea Road to the Indies* (1950). An outstanding synthesis of the background of Vasco da Gama's achievements is found in JOHN H. PARRY, *The Age of Reconnaissance: Discovery, Exploration and Settlement, 1450–1650*, 2nd ed. (1966). For brief accounts together with English translations of extracts from early documents, see JOHN H. PARRY (ed.), *The European Reconnaissance: Selected Documents* (1968). The unique manuscript copy of the three *Roteiros* (sailing directions) of Vasco da Gama's Arab pilot, Ahmad ibn Mâdjid, has not been fully translated and printed in English, but see A.G.R. TIBBETTS, *Arab Navigation in the Indian Ocean Before the Coming of the Portuguese* (1971). For the definitive Portuguese translation of the Arab text, see T.A. CHUMOVSKY (ed.), *Três Roteiros desconhecidos de Ahmad ibn Mâdjid* (1960).

## Gambetta, Léon

A leading 19th-century French republican statesman, Léon Gambetta played a prominent part in directing the defense of France during the Franco-Prussian war of 1870–71. In helping to found the Third Republic, he made three essential contributions: first, by his speeches and articles, he converted many Frenchmen to the ideals of moderate democratic republicanism. Second, by his political influence and personal social contacts, he gathered support for an elective democratic political party, the Republican Union. Finally, by backing Adolphe Thiers, who was elected provisional head of government by the National Assembly of 1871, against royalists and Bonapartists, he helped transform the new regime into a parliamentary republic.

Gambetta was born at Cahors, in the southwest of France, on April 2, 1838. His mother was from Gascony; his father was an Italian who had emigrated to Cahors and had opened a grocery store there. A successful pupil at the local high school, ambitious and naturally eloquent, young Gambetta refused to stay in a provincial town with no other prospect than to work in his father's

Gambetta, photograph by Étienne Carjat. In the Bibliothèque Nationale, Paris.

store. Against his father's will, he went to Paris to study law.

Gambetta professed very strongly republican opinions, and his exuberant and generous nature soon made him highly popular among the Paris students. In 1859 he was called to the bar, but he was unsuccessful as a lawyer until 1868, when a political case known as the *Affaire Baudin* made him suddenly famous. Jean-Baptiste Baudin, a deputy (legislator) killed resisting Napoleon III's coup d'état of 1851, had become a republican martyr, and eight journalists were being prosecuted for attempting to have a monument erected in his memory. As counsel of one of the accused, Gambetta delivered an extremely forceful speech in which he indicted the imperial regime, its origin, and its policy.

The  
Affaire  
Baudin

Press reports of his speech made his political fortune, and almost overnight Gambetta became an acknowledged leader of the Republican Party. In 1869 he was elected to the Legislative Assembly. He opposed the steps that led to the outbreak of the Franco-German War in July 1870, but, once it had begun, he urged the quickest possible victory over the Germans. After the disastrous defeat of the French at Sedan, in which Napoleon III was captured on September 1, 1870, Gambetta played a principal role in proclaiming the republic and forming a provisional government of national defense. He became minister of the interior.

The most pressing problem of the provisional government was the defense of Paris, which was besieged by the enemy. Most members of the government stayed in the city, but Gambetta, as their delegate, left Paris in a balloon on October 17, 1870, floating over the German lines. Establishing himself at Tours, he began to arouse unoccupied France for the defense of the entire country. He became war minister as well, assuming virtually unlimited powers.

Of the two main French armies, one had been captured at Sedan, and the other was besieged at Metz and soon forced to surrender. Gambetta, as always enthusiastic and indefatigable, succeeded in raising new armies, which were trained and supplied with arms. These achieved some local successes but were more often defeated.

When Tours was threatened, Gambetta left for Bordeaux. Though he wished to continue fighting, the country was tired of war, and the provisional government signed an armistice on January 18, 1871.

The armistice convention provided for the election of a National Assembly, which met at Bordeaux in March 1871 to ratify the peace terms. Gambetta was elected a deputy for Strasbourg, in Alsace, but, after the ratification of the peace, which yielded most of Alsace and Lorraine to Germany, he lost his seat and retired for a short time to Spain.

In by-elections in July 1871 he was elected by the *dé-*

Formation  
of the  
Third  
Republic

partement of the Seine. The assembly was to determine whether France would remain a republic or restore the monarchy. The majority of the deputies were monarchists. There were, however, two candidates to the throne, the heads, respectively, of the elder and the younger branch of the Bourbons, and they were unable to reach agreement. With supreme skill, Gambetta managed to push ratification of the republic through the weary assembly. The republican constitution of 1875 formed the basis of the republic until 1940.

Parliamentary intrigue prevented Gambetta from being elected president of the republic, but he became president of the Chamber of Deputies, a position in which he exercised great power. He attempted to promote a tolerant republic, an "Athenian republic," as he described it. In spite of his corpulence, dishevelled beard, and badly groomed appearance, his natural warmth, generosity, and liberalism made him highly popular.

Jules Grévy, the president, disliked Gambetta and for a long time refused to ask him to form a government. After he at last was appointed premier, in November 1881, he pursued, in foreign affairs, a policy of establishing a closer relationship with Great Britain and, in domestic affairs, an ambitious program of domestic reform. He was overthrown in January 1882, before achieving either goal.

In 1872 he began a liaison with Léonie Léon, a pretty, well-educated woman, and, after his resignation, he settled with her outside Paris, with the intention of marrying her. While handling a revolver, he shot himself in the arm, and, as his health was very poor, the wound healed slowly. During his convalescence, he was stricken with appendicitis, but the doctors did not operate. He died on December 31, 1882, at the age of 44.

Assess-  
ment

He was honoured with a national funeral. His reputation has remained largely undiminished; there is hardly a town in France without a street bearing his name. Yet his fame rests on what he achieved in his long years of opposition and during the Franco-German War rather than during the two terms—totalling three years—in which he exercised power. He was a fervent advocate both of fully modern democracy—universal suffrage, freedom of the press, right of meeting, trial by jury for political offenses, separation of church and state—and of national unity. For the sake of the latter, he occasionally struck bargains with his political opponents, thus gaining an undeserved reputation as an opportunist. Undoubtedly, he was largely responsible for the consolidation of parliamentary democracy in France, but his compromises resulted in a fragile party system that served to weaken democratic government.

(J.C. de C.)

## Gambia, The

The Gambia, a West African republic, is a small state with a total area of 4,467 square miles (11,569 square kilometres). The country is a narrow enclave, from 15 to 30 miles (25 to 50 kilometres) wide and 295 miles (475 kilometres) long, stretching inland from the Atlantic Ocean and surrounded (except on its short coastal side) by Senegal. Essentially, The Gambia is a strip of land on either bank of the Gambia River. The unusual shape and size of the former British colony are attributable to arbitrary territorial compromises arising from 19th-century Anglo-French rivalry in West Africa. Its capital is Banjul (formerly Bathurst).

The Gambia, which had a population of about 524,000 in 1975, and which obtained independence from the

United Kingdom on February 18, 1965 (retaining membership in the Commonwealth of Nations), is one of the poorest countries on the continent, economically dependent on a single crop, peanuts (groundnuts). With its river, the finest waterway in West Africa, it has the potential to develop into a flourishing corridor in the heart of the West African hinterland. Because The Gambia and Senegal remain politically and economically divided, however, development of the river basin is prevented by lack of coordination between the two states. The Gambian government, for example, fears that the building of an international bridge over the river might deprive The Gambia of ferry tolls, or that river traffic might be reduced in consequence, and is unwilling to forgo such immediate benefits for the sake of long-term advantages to be gained from the development of the river basin.

For an account of The Gambia's major physical feature, see GAMBIA RIVER; for historical aspects, see WEST AFRICA, HISTORY OF.

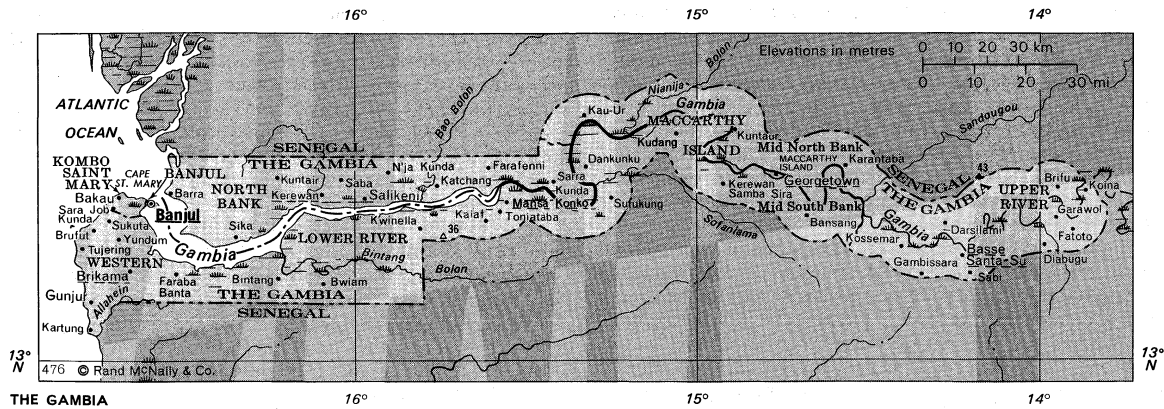

**Geomorphology.** The Gambia River is the country's dominant feature, flowing across a plateau of Tertiary sandstone, compacted sediment composed predominantly of quartz grains formed from 65,000,000 to 6,500,000 years ago. The landscape is generally flat, dissected terrain, with gentle slopes of not more than three degrees. In the east, narrow valleys are separated by broad interfluvies or flattish hills. In the west, lower and smaller sand hills alternate with depressions up to three miles wide filled in with sand so that a flat plain is formed.

**Climate.** The climate is of the drier tropical type, characterized by a short and intense rainy season, occurring some time between June and October, and a longer dry season. Near the coast the rainy season lasts longer and the rainfall is heavier, diminishing eastward. At Yundum, in the west, the average annual rainfall is about 51 inches (1,300 millimetres) and the mean monthly temperature 77° F (25° C), while at Basse Santa Su, about 270 miles inland, the comparable figures are 43 inches (1,100 millimetres) and 82° F (28° C). The relative humidity is high, particularly from July to December, but drops from December to April, when the dry north-eastern winds known as the harmattan are dominant. The vegetation cover of The Gambia is savanna (grassland) on the uplands, while various kinds of swamps cover the lowlying areas.

**People and population.** The river basin has in the past acted as a focal point for migrating groups of people from adjacent parts of West Africa, and The Gambia is consequently populated by diverse ethnic groups. About 42 percent of the population is Malinke (Mandingo), followed by Fulani, Wolof, Dyola (Yola), and Soninke (Seraculeh). There are also smaller groups of Senegalese, other African, and non-African peoples. The population (which is predominantly Muslim) at the 1973 census was 493,000, about 100,000 more persons than expected from estimates based on the 1963 census. A peculiar characteristic of the national population is its seasonal variation, caused by the influx of up to 20,000 Senegalese farm workers, most of them between ages 15 and 34.

The population density is quite high, with an average of 148 persons per square mile of dry land (57 per square kilometre), although distribution is uneven, with lower densities nearer the coast and higher densities inland. Patterns of settlement in The Gambia reflect three regions, expressed on both banks of the river, consisting of (1) the swamps adjacent to the river (and not extending above Kau-Ur); (2) the riverine flats, known as *banto faros* (from a Mandingo word meaning "beyond the swamp"); and (3) the sandstone uplands. Most rural settlement is concentrated on the uplands, which have better drained soils and are more healthful than the flooded swamps and estuarine *banto faros*. In the *banto faros* on the middle course of the river, however, where valleys are deeper and there is less danger of flooding, the number of village settlements increases. Many of the villages are built on the boundary between the uplands and the riverine flats.

Principal  
ethnic  
groups

The rate of urban growth has been slow. Banjul, the capital, had a population of about 39,500 in 1973, while the area around Sara Job Kunda (conventionally called Serrekunda), the next largest urban area (comprising several smaller settlements), had a population of about 25,500. Only seven other settlements had as many as 3,000 inhabitants, only 66 had more than 1,000, and the rest were villages.

**The national economy.** The Gambia is primarily agricultural, with both men and women engaged in cultivation. On the *banto faros* of the river's middle course, fields are created by enclosing selected areas with embankments made of mud and reeds, which are cultivated by women, who grow rice, garden crops, and some peanuts. On the sandy uplands the men grow peanuts, sorghum, and millet and practice the rotation of crops. The average size of cultivated plots is 2½ acres for a man and 1¼ acres for a woman (about one and 0.5 hectare, respectively). In addition to the main cereal crops, the women also grow such subsistence crops as lentils, cassava, yams, eggplant, tomatoes, peppers, and okra. Fruit trees are also maintained.

The Gambian economy, as noted above, is based primarily on the production of peanuts for export. Grown on the upland soils, peanuts have been the main cash crop for virtually all Gambian farmers and the source of the largest share of governmental revenue. Sown in June and July, the crop is harvested in October and November. Production has increased steadily with the help of seasonal migrants from Senegal and Guinea and with the wider use of fertilizers and ox-drawn equipment, as well as the introduction of better seed varieties. The annual output of peanuts in shell now totals around 140,000 tons. In an effort to diversify the economy, the production of palm kernels, a secondary export crop, has been encouraged since the mid-1960s, when a pilot scheme for the cultivation of oil palms was begun, using improved varieties of seed from Nigeria. Experimental cotton growing was encouraging enough for 100 acres (40 hectares) to be planted in the early 1970s.

Processing, rather than manufacturing, industries are important. Peanuts are sold unshelled to traders and

agents of the Gambia Oilseeds Marketing Board, which fixes the season's price in advance, pays the producers in cash, and sells overseas. The agents arrange for the transportation of the peanuts to Banjul or to Kau-Ur, where the nuts are shelled before being shipped. After shelling, a large proportion of the crop is pressed at oil mills. Exports include nuts, oil, and cattle cake, the residue after the oil has been extracted.

The ocean off The Gambia has great potential for inshore and deep-sea fishing, but little public revenue has been derived from fisheries because of inadequate equipment to replace traditional techniques, which confine the fishermen to estuarial or coastal waters. Some development has nevertheless taken place, with the government lending money to encourage the use of motorized fishing boats and the construction of traditional types of smoke huts for processing fish, particularly bonga (shad, or West African herring), which is exported to West African countries. A potential European market for shrimp and prawns remains to be exploited.

**Trade and finance.** The Gambia has a large volume of trade for its small size, the total annual value in the mid-1970s amounting to about \$200 U.S. (£ 100) per person. Exports go mainly to the United Kingdom (about 40 percent), The Netherlands, Portugal, and France. For the decade 1965–75, however, the country had an adverse balance of trade.

**Transport.** The navigability of the Gambia River has discouraged the development of good roadways, total mileage being only 1,155 miles (1,858 kilometres), less than 300 miles of which is hard-surfaced. There are no railways and no internal air services. The one good port is Banjul, and there is a small international airport nearby at Yundum. Banjul offers easy access to shipping and has good road and river connections. Improvements are planned for both the port and Yundum Airport. Prospects for tourism and trade in Banjul are good, but the remainder of the country suffers from a lack of services.

**Administration and social conditions.** The Gambia is an independent republic. The government is headed by a president, whose term of office is linked to the unicameral parliament, the House of Representatives. Elections are held every five years. The vice president and Cabinet members are appointed by the president from the 32 elected members of the house. There are also four house members elected by the chiefs in assembly, three nominated members who are without votes, and the attorney general, who is nominated and has a vote. The People's Progressive Party (PPP) holds about seven-eighths of the elected seats. Local administration in each of the 35 districts into which The Gambia is divided is the responsibility of the local chief, who is assisted by village heads and advisers. The 35 districts are also grouped into eight local government areas, seven of which are administered by councils consisting of a majority of elected members and the chiefs of the district. Banjul is administered by a city council.

The government provides such social services as it can afford from revenues primarily obtained from the tax on peanut exports. There are two large trade unions in existence, as well as some smaller specialized unions.

Marine resources

Importance of peanuts in the economy

The Gambia, Area and Population			
	area*		population
	sq mi	sq km	1973 census
<b>Division</b>			
<b>Local government area</b>			
Banjul	5	12	39,000
Kombo St. Mary	29	76	39,000
Lower River	625	1,618	43,000
MacCarthy Island			
Mid North Bank	566	1,467	47,000
Mid South Bank	551	1,428	53,000
North Bank	871	2,256	94,000
Upper River	799	2,070	87,000

Total The Gambia	4,127	10,689†	493,000
	4,467	11,569	

\*First total includes dry land and so-called "wet" lands; second total includes water; total dry land only is 3,325 sq mi (8,613 sq km).

†Detail does not add to total given because of rounding.

Source: Official government figures.

**Defense.** While The Gambia has no standing army, as a member of the Commonwealth of Nations it is tacitly understood it may expect defense cooperation from other Commonwealth countries. It has a 200-man para-military "field force," which is part of the 600-man police force and is concerned with internal security. A special agreement on defense and security has also been concluded with Senegal.

**Education.** Only 20 percent of the school-age population was enrolled in 1967. Education is mostly at the primary level, although there are some secondary schools and one teacher-training college. Gambian students seeking higher education usually travel to Sierra Leone, the United Kingdom, or the United States.

**Health.** There are two general hospitals and a number of health centres and dispensaries. Mosquito-control units are active, and there is a leprosy-control clinic.

**Cultural life.** The different tribal groups are the focus of cultural life. An official newspaper is published three times a week, and Radio Gambia, a government station, broadcasts each evening.

**Prospects for the future.** The Gambia can achieve prosperity only through coordinating its development with that of neighbouring states, such as Senegal and Mali. Such coordinated development might permit the growth of the port of Banjul and lessen The Gambia's present dependency upon the state of the world peanut market. Meanwhile port facilities at Banjul are being improved with assistance from the World Bank. Until political obstacles are overcome, however, the Gambia River must remain economically isolated from its natural hinterland, with its potentialities largely unused.

## Gambia River

The Gambia River, 700 miles (1,120 kilometres) long, is one of the finest waterways in Africa and the only West African river easily accessible to oceangoing shipping. The river, which flows westward from the Republic of Guinea to empty into the Atlantic Ocean, constitutes a unifying factor for the independent state of Gambia, which consists of a narrow strip of land along both banks of the river. The political separation between Gambia and Senegal has, however, hindered the development of the resources of the river and its basin. (For detailed coverage of the state of Gambia, see the article GAMBIA, THE).

**Geomorphology.** From its source in the Fouta Djallon Highlands in the Republic of Guinea (*q.v.*), the Gambia follows a winding course to its mouth, which is a ria, or drowned estuary. The dividing and reuniting of river channels—a phenomenon known as braiding—has created several islands along the river's middle course, of which the two largest are Elephant Island and MacCarthy Island. The river is joined by numerous creeks called *bolons*, the largest of these being Bintang Bolon, which flows into it from the south.

The width of the river valley varies considerably along its course. At its mouth, Cape Saint Mary, it is about 12 miles (19.3 kilometres) wide. Immediately to the east it narrows like an hour glass, being a mere three miles (5 kilometres) wide between Banjul (formerly Bathurst), the capital of Gambia, on the left bank, and Barra on the opposite bank. South of Banjul it widens again until it is about seven miles (11 kilometres) across, thereafter narrowing gradually upstream to the source. Just east of Elephant Island, about 80 miles (129 kilometres) from Bathurst, it is only one mile (1.6 kilometres) wide.

The river valley is cut into a plateau of sandstone from

the Tertiary Period (compacted sediment composed predominantly of quartz grains, formed from 65,000,000 to 7,000,000 years ago). For 80 miles (129 kilometres) inland from the mouth the river banks are low, consisting mainly of soft mud. Above Elephant Island, low cliffs of red ironstone (a clayey rock, heavily loaded with iron oxide) occur, interspersed with sections of swampland. Above MacCarthy Island, further upstream, the cliffs become higher, varying between 20 and 50 feet (6 and 15 metres) in height, and the valley becomes narrower.

**Vegetation and animal life.** Dense mangrove swamps fringe the lower river for 60 miles (97 kilometres) inland; after which freshwater swamps and salt flats on low-lying stretches alternate with dense clumps of small trees and shrubs that line the cliffs. On the higher slopes of the riverbank, swamps and shrubs give place to parkland and tall grass. The wild oil palm grows in small clumps in low swampy areas along the valley bottom.

The vegetation of the river and of its creeks provides a favourable habitat for insects, animals, and birds. The swamps encourage mosquitoes and tsetse flies to breed. The river abounds in fish, and river creatures, including the hippopotamus and the crocodile. There is a great variety of bird life. Among the 400 known species that have been recorded are the kingfisher, the cuckoo, the swallow, the heron, the dove, the sunbird, the hawk, and the grass warbler.

**Climate and soils.** The river lies in a tropical climatic region that has a distinct rainy season from June to October and a distinct dry season from December to April. Three regions are associated with the river, extending from the river banks northward and southward, parallel to its flow. Closest to the river is the swamp region, which lies on deposits of clayey alluvium. Backing the swamps are grass-covered river flats known locally as *banto faros* (meaning "beyond the swamp" in the Mande language). The soils of these flats are clayey in the estuarine section of the river and become flooded with salt water during the rainy season. In the *banto faros* upstream, the soils are lighter loams (natural mixtures of sand and clay together with organic matter) that are also flooded during the rainy season, but with fresh water. Higher up the valley sides, beyond the *banto faros*, lies the sandstone plateau. Its soils are well drained, light, and relatively less fertile, supporting a vegetation of coarse tall grass and scattered trees such as the baobab and the locust bean tree (which bears pods in bunches).

**Human settlement.** The swampy region closest to the river, with its dense masses of mangrove trees, often growing more than 100 feet (30 metres) high, abounds in wild life but has been of little use for either agriculture or human settlement. The *banto faros* of the lower river are rendered useless for cultivation by the salt water which periodically inundates them, and settlements on them are few. The flats of the middle and upper river are of some agricultural value, however. Much of the grassland is regularly cleared, and the light soils are easily cultivable. The annual flooding of the fertile alluvial loams of the middle flats makes them especially suitable for intensive rice cultivation. On the light sandy and well-drained soils of the higher slopes, groundnuts (peanuts) grow particularly well. Cultivation and settlement have therefore taken place in the middle flats and on the higher slopes, with many villages being located on the borderline between the flats and the plateau, thus avoiding both the flooding of the lower slopes and the increasing aridity of the higher terrain.

**Hydrology.** In 1970 there was still little information available relating to the river's rate of flow. Flooding is more extreme upriver than it is nearer the mouth. To the east, a rise of 40 feet (12 metres) in the level of the water has been reported when the river is in flood. Nearer the estuary the wide valleys also become flooded, but due to the high degree of permeability of their sandy soils, the water drains rapidly. Apart from seasonal fluctuations in the water level, variations also occur at shorter intervals due to the tidal nature of the river.

**Navigation.** The Gambia is one of the most navigable of African rivers. Although there is a sandbar at the sea-

Mangrove swamps

Rice growing

Silting  
of the  
channel

ward end of the estuary, there are depths of 26 feet (8 metres) of water, so that it can be crossed by ships at any tide. Thus, while oceangoing shipping is subjected to restraints on other West African rivers, ships of 2,000 to 3,000 tons can sail 150 miles (240 kilometres) up the Gambia from Bathurst to Kuntaur, while smaller vessels can penetrate 176 miles (283 kilometres) to Georgetown. Until recently small steamers, sailing cutters, lighters towed by tug boats, and other craft sailed as far upstream as the eastern boundary between Gambia and Senegal, which coincides with the river's tidal limit. Beyond this point there is sufficient draft for launches only in the rainy season. The upper river channel, however, became silted in recent years, as a result of accelerating soil erosion caused by increasing clearance for cultivation of slopes on the riverbanks. By 1970 steamers, which formerly sailed to Fatoto, 288 miles (463 kilometres) upstream from Bathurst, had to stop at Basse Santa Su, 20 miles (32 kilometres) further down. The lower channel was also affected through the rapid erosion of the low lateritic cliffs (formed of red iron-bearing soil) bordering it, and silting of the channel necessitated the removal of the groundnut decorticating (husking) mills at Kuntaur to Kau-ur, 30 miles (48 kilometres) downstream as the crow flies, in order that larger vessels transporting the groundnut crop overseas could be accommodated.

**Transport.** The chief value of the river has been its transportation function. As the main artery of the state of Gambia, it is the principal means of transporting passengers, freight, and mail in the territory. North-south river crossings are provided by ferries such as those plying between Barra and Bathurst, Banni and Kerewan, Farafenni and Yelitenda, and Kau-ur and Jessadi. Out of the eight crossings in operation in 1968, only four were served by motorized craft.

**Prospects for the future.** Because of the political boundaries of the state of Gambia, inherited from the colonial era, the full development of the Gambia River has not yet been achieved. Until now the river, because of its navigability, has proved a boon to the state of Gambia. Without extensive dredging of the river bed, however, its navigability will deteriorate. The economic development of the river basin will, however, necessitate cooperation with the state of Senegal, whose territory entirely surrounds that of Gambia. The Gambian administration has, however, opposed such things as the construction of a bridge to carry trans-Gambian traffic, since this would deprive it of the revenue now obtained from the ferry service, and also because the bridge would restrict the movement of large ships to the first few miles of the estuary only. A proposed dam, while providing water for irrigation in the upper provinces, as well as for the generation of electricity, is also opposed because it would affect streamflow and navigability. Until a way is found to break such impasses, the greater potential for economic growth of the Gambia River will remain unrealized.

**BIBLIOGRAPHY.** R.J. HARRISON CHURCH, "The Gambia: A Riverine Enclave," in *West Africa*, 6th ed. (1968), includes a description of the Gambia River.

(E.R.A.F.)

## Gambling

Gambling is the betting or staking of something of value, with consciousness of risk and hope of gain, on the outcome of a game, a contest, or an uncertain event the result of which may be determined by chance or accident or have an unexpected result by reason of the bettor's miscalculation.

Many activities involve elements of risk and hope of gain and may depend on the outcome of an uncertain event or events—business ventures, buying and selling stock, military strategies, and foreign relations, for example; and, indeed, participation in such enterprises is often referred to as gambling or taking a chance. This article, however, is intended to cover specifically those activities associated with gambling. The words gambling, gaming, and game are derived from the Anglo-Saxon *gamen*, *gamon* ("sport" or "play").

Gambling games may vary in complexity from betting on the outcome of the toss of a coin, in which the winner claims the coin the side of which he correctly guesses, to betting on cards dealt in a game such as Poker, in which strategy also applies. The outcomes of gambling games may be determined by chance alone, as in the purely random activity of a tossed pair of dice or of the ivory ball on a Roulette wheel, or by physical skill, training, or prowess in athletic contests or, again, by a combination of strategy and chance. The rules by which gambling games are played sometimes serve to confuse the relationship between the components of the game, which depend on skill and chance, so that some players may be able to manipulate the game to serve their own interests. Thus, knowledge of the game is useful to the Poker player or the horse-race gambler but is of very little use to the purchaser of a lottery ticket or to a slot-machine player.

A gambler may participate in the game itself while betting on its outcome (card games, Craps), or he may be prevented from any active participation in an event in which he has a stake (professional athletics, lotteries). Some games are dull or nearly meaningless without the accompanying betting activity and are rarely played unless wagering occurs (coin tossing, Poker, dice games, lotteries). In other games, betting is not intrinsically part of the game, and the association is merely conventional and not necessary to the performance of the game itself (horse racing, football pools). Commercial establishments may organize gambling when a portion of the money wagered by patrons can be easily acquired by participation as a favoured party in the game, by rental of space, or by withdrawing a portion of the betting pool. Some activities of very large scale (horse racing, lotteries) usually require commercial and professional organization to present and maintain them efficiently.

## HISTORY OF GAMBLING

Archaeologists have found artifacts used in games of chance in Egypt dating from as early as 3500 BC. Figurines, paintings in tombs, and drawings on pottery provide many illustrations of people or gods tossing astragali (astragalus, a small bone in the ankle under the talus or heel bone of a sheep or dog; often called knuckle-bones) and using counting boards to record the totals of play. In many excavations of prehistoric sites of even earlier periods, astragali have been discovered in large numbers; perhaps as long ago as 40,000 years, people were tossing these bones in games of chance—but of course the rules and patterns of play are not fully known today. An astragalus is an uneven, four-sided (two sides are round) bone, each side of which was probably assigned a different value in games in which it was used. Greek and Roman adults and children played games using astragali and even made copies of them in stone and metal embellished with incised figures. The astragali are still used by some Arab and American Indian tribes. Other artifacts that might also have been used in games included "throwing-sticks" of wood or ivory (about three inches long, square or elliptical in cross section, and marked in various stylized ways); such sticks were found in ancient Britain, Greece, Rome, Egypt, and in America among the Mayans.

The six-sided die had evolved long before the birth of Christ. Some dice were carved from astragali, but more uniform cubes were manufactured of pottery and wood. The earliest dice, from Iraq and India, date from about 3000 BC. Somewhere about 1400 BC the arrangement of the points still used today (opposite sides always total seven) was developed.

It is likely that astragali, throwing-sticks, and dice may have been used either in gaming or in divination of the future by the casting of lots, or sortilege. Numerous references are found in the Bible to the casting of lots, and probably astragali were used on many of the occasions to which it refers. It is important to note that those occasions were not regarded as games; lots were cast as means of ending disputes, dividing or distributing property, or otherwise divining God's will. (For example, all four of

Early  
archae-  
ological  
evidence

The  
casting of  
lots

the New Testament Gospels describe the casting of lots to determine the disposition of the clothes of the crucified Jesus.) None of the denunciations of the prophets against vices of the Israelites included references to games of chance, nor is there any evidence that the Jews gambled before they came under the influence of Greek and Roman civilizations after the 4th century BC. Significantly, the Talmudic word for gambling is *qubbiyya*, borrowed from the Greek *kybeia*, "dice playing."

Thus, it is known that dice were used in the casting of lots, but they also were used in games of chance. As an example, the Aryan invaders of India in the 2nd millennium BC loved to gamble; and dice games with *vibhī-daka* nuts were popular among all classes except the very religious. The Rgveda, a collection of Vedic hymns, includes a poem, the "Gamester's Lament," one stanza of which quotes the god Savitr: "Don't play with dice, but plow your furrow! Delight in your property, prize it highly! Look to your cattle and look to your wife, you gambler!" Thus noble Savitr tells me."

In the *Mahābhārata*, the Hindu epic probably written in the 1st century BC, gambling with dice is frequently and prominently described; the world itself is conceived of as a gambling game.

Tacitus describes the gambling of property and people among the early Germans. Tribal battles were occasionally concluded with a game of chance.

**The evidence of ethnography and folklore.** A U.S. anthropologist, A.L. Kroeber, tried to discover whether or not gambling was distributed among the cultures of the world in systematic patterns that might reveal a general association between gambling and other cultural traits. He found that the stricter sects of puritanical religions, like those of Protestantism, Buddhism, and Islām, might accept many types of athletics and games but reject gambling because, he thought, of an aversion to the emotional involvement that comes with playing for stakes of money or property. Apart from religious controls, however, the reasons why a people accept or reject gambling was a puzzle about which he could only speculate. His list of nongambling societies included the aboriginal Australians, who are indifferent to property, and also the Papuan Melanesians, who spend much time and effort in acquiring property. Other nongamblers were the Polynesians, Micronesians, some of the peoples of Indonesia, the more remote tribes of India, most of the Siberians, many East Africans, and South Americans, except for the natives of Peru, highland Bolivia, Chile, Argentina, and Paraguay. Kroeber suggested that the areas of gambling and nongambling peoples were both large and compact so that the distributions of favourable or hostile attitudes were the products of "consistent diffusion" or the transmission of attitudes about the desirability or undesirability of gambling among cultures having mutual contact. The mechanics and techniques of gambling are so simple that theories of diffusion could not account for their distribution. He could find no consistent association between gambling and characteristics of the economy, the system of wealth, or type of religion.

More recently anthropologist John Roberts demonstrated that a useful threefold division could be made of games (but not necessarily gambling games) played by tribes that had been investigated in sufficient detail. These were games of physical skill (which might or might not include strategy or chance), games of strategy (without physical skill but perhaps with chance), and games of chance alone. A study of 50 tribes from all parts of the world revealed that 43 played games of physical skill, 20 played games of chance, and 19, games of strategy. Games seem to be expressive of the themes and patterns of basic ideas of a culture, and they also are models of various cultural activities; thus, they may simulate combat, hunting, chasing, divining, or coercing. It was found that cultures in which games of chance were played usually had religious beliefs in gods or spirits that were benevolent and could be coerced—that games of chance were linked to the mastery of the supernatural. Games of strategy, on the other hand, were associated with the learning of social roles (socialization) or mastery of the

social system, whereas games of physical skill were associated with mastery of both the self and the environment. Although the study did not distinguish between gambling and nongambling games, it illustrated that games of the sort that had been the objects of betting were linked predictably with other aspects of culture. Social scientists are continuing the attempt to reveal these relationships.

Scores of references to gambling have been found in folktales from cultures around the world. Greek and Roman myths refer to a god of gambling, or luck; the Irish and Scots have tales about extraordinary stakes, or stakes not claimed by winners; but the most abundant supply of dramatic stories about gambling is found in the folk literature of Asia, extending into Southeast Asia, Japan, the Philippines, and India. The Asians have dozens of folk stories about men gambling—using their wives, sisters, daughters, their own bodies, or parts of bodies as stakes. Some of these folktales have an ancient heritage; some include gambling with gods, whereas others are entirely secular. North America is another continent with an abundance of folk material on gambling. Of all the world's societies whose cultures have been studied sufficiently to know, and who play games of chance, half are North American Indians.

**Efforts to suppress gambling.** Class distinctions in laws relating to the suppression of gambling have an early origin. Roman emperors were fond of dicing games and played them frequently, especially Augustus and Claudius, but Roman common people were forbidden to play except during certain seasons. Throughout the Middle Ages churchmen and kings continually made efforts to suppress gambling, and their failure to do so serves as testimony to the abiding strength of the gambling fervor. A list of the bishops of the church who sermonized against gambling goes from St. Cyprian of Carthage (c. AD 240) to St. Bernardino of Siena in 1423. In 1232 Frederick II issued an edict against dice playing, and Louis IX in 1255 made the manufacture of dice illegal. Most of the gaming during this long period must have been with knucklebones and dice; cards were not common until 1350. But these prohibitions were directed not at the games as much as at the vices that seemed to accompany them. The church was more concerned with the drinking and swearing brought on by, or manifested in, gaming, and the state was more concerned with idleness, thriftlessness, cheating, and crime—which may have been characteristic of conspicuous gambling. That games of chance were not in themselves thought to be evil is indicated by the invention in 960 of a clerical version of dice by Bishop Wibold of Cambray, whose intention was not to stamp out gaming but to convert it to good. English monarchs beginning with Edward III promulgated a series of prohibitory laws designed to protect manly sports and the military arts. Henry VIII, though he himself gambled, pronounced gaming houses to be unlawful because they distracted young men from the practice of archery and military preparation. Henry's stand against "common gaming houses" was to survive in England for about 400 years, until the 1960s.

#### MATHEMATICAL THEORY UNDERLYING GAMBLING GAMES

**Background.** With all the evidence of the popularity of dice playing by most classes of people during several thousand years before the 15th century, it is notable that no record has been found of the idea of statistical ratios and a theory of probability. A 13th-century French humanist, Richard de Fournival, is credited with having written a Latin poem that included a passage giving the first known calculation of the number of ways of throwing three dice (there are 216). Earlier, however, the game mentioned above as invented by Wibold in 960 listed 56 virtues that the player of his clerical dice game was supposed to practice according to the ways three dice can be thrown, irrespective of order (the number of such combinations of three dice is indeed 56). Neither Wibold nor Fournival, however, attempted to determine the relative probabilities of the separate combinations. An Italian mathematician-physician-astrologer, Gerolamo Cardano,

gamblers'  
needs

is believed to have written the first mathematical analysis of the cast of dice in 1526. He proposed by use of theoretical argument—and his own considerable familiarity with dice games—a probability theory from which he issued advice to his students on how to wager. Galileo took up the analysis of dice playing in the late 16th century, as did Pascal in 1654—both at the requests of gamblers who had been troubled by disappointing and costly experiences with dice. Galileo's calculations were exactly those that would be used by mathematicians today, and the modern science of probability was on its way at last. The greatest advance in theory came in the middle of the 17th century with a manuscript by Christiaan Huygens, *De Ratiociniis in Ludo Aleae* ("On Ratiocination in Dice Games"). The history of the science of probability, then, is adequately shown to owe its start to the lowly problems of games of chance.

Before the time of the Reformation, people generally believed that every event of any kind was determined by the will of God or, if not by God, by some other supernatural force or personalized entity. Such beliefs have persisted among many, perhaps most, people to the present day. In a time when they were practically universal, however, a mathematical theory based on a contrasting notion that certain events might be random (controlled by pure chance, undirected, nonpurposive) had great difficulty in becoming expressed and established. Mathematician M.G. Kendall has pointed out that

It seems to have taken humanity several hundred years to accustom itself to a world wherein some events were without cause . . . or were determined by a causality so remote that they could be accurately represented by a non-causal model.

The idea of purely random activity is basic to the comprehension of the relationship between chance and probability.

**Chances, probabilities, and odds.** Events or outcomes that are equally probable have an equal chance of occurring in each instance. In games of pure chance, each instance is a completely independent one; that is, each play has the same probability as each of the others of producing a given outcome. Probability statements apply in practice to a long series of events but not to individual ones. The "law of large numbers" is an expression of the fact that the ratios predicted by probability statements are increasingly accurate as the number of events increases; but the absolute number of outcomes of a particular type departs from expectation with increasing frequency as the number of repetitions increases. It is the ratios that are accurately predictable, not the individual events or precise totals.

The probability of a favourable outcome among all possibilities can be expressed: probability ( $p$ ) equals the total number of favourable outcomes ( $f$ ) divided by the total number of possibilities ( $t$ ), or  $p = f/t$ . But this holds only in situations governed by chance alone. In a game of tossing two dice, for example, the total number of possible outcomes is 36 (each of six sides of one die combined with each of six sides of the other), and the number of "ways to make," say, a seven are six (made by throwing 1 and 6, 2 and 5, 3 and 4, 4 and 3, 5 and 2, or 6 and 1); therefore, the probability of throwing a seven is  $6/36$ , or  $1/6$  (or approximately .167).

In most gambling games it is customary to express the idea of probability in terms of "odds against winning." This is simply the ratio of the unfavourable possibilities to the favourable ones. If the probability of throwing a seven is  $1/6$ , then in every six throws, "on the average," one throw would be favourable and five would not; the odds against throwing a seven are therefore 5 to 1. The probability of getting "heads" in a toss of a coin is one-half; the odds are 1 to 1, called "even." Care must be used in interpreting the phrase "on the average." Again it applies most accurately to a large number of cases and is not useful in individual instances. A common gamblers' fallacy called "the doctrine of the maturity of the chances" (or "Monte Carlo fallacy") falsely assumes that each play in a game of chance is not independent of the others and that a series of outcomes of one sort should be balanced in the short run by the other possibilities. A

number of "systems" have been invented by gamblers based largely on this fallacy; casino operators are happy to encourage the use of such systems and to exploit any gambler's neglect of the strict rules of probability and independent plays.

In some games an advantage may go to the dealer, banker (the individual who collects and redistributes the stakes), or some other participant. Therefore, not all players have equal chances to win or equal payoffs. This inequality may be corrected by rotating the players among the positions in the game. Commercial gambling operators, however, usually make their profits by regularly occupying advantaged positions; or they may charge money for the opportunity to play or subtract a proportion of money from the bank on each play. In the dice game of Craps the casino returns to winners from  $\frac{3}{4}$  of 1 percent to 27 percent less than the correct odds, depending on the type of bet made. The house percentage in Roulette in U.S. casinos is  $5\frac{1}{19}$  percent to  $7\frac{1}{19}$  percent, and in European casinos it is  $1\frac{13}{37}$  percent to  $2\frac{26}{37}$  percent. The house must always win in the long run. Some casinos also add rules that enhance their profits, especially rules that limit the amounts that may be staked under certain circumstances.

Many gambling games include elements of physical skill or strategy as well as of chance. The game of Poker, like most other card games, is a mixture of chance and strategy. Betting on horse racing or athletic contests involves the assessment of physical capacity and the use of other skills. In order to assure that chance is allowed to play a major role in determining the outcomes of such games, weights, handicaps, or other correctives may be introduced to give the contestants approximately equal opportunities to win, and adjustments may be made in the payoffs so that the probabilities of success and the magnitudes of the payoffs are put in inverse proportion to each other. Pari-mutuel pools in horse-race betting, for example, reflect the chances of various horses as anticipated by the players. The individual payoffs are large for those bettors whose winning horses are backed by relatively few people and small if the winners are backed by a relatively large proportion of the bettors; the more popular the choice, the lower the individual payoff. The same holds true for betting with bookmakers on athletic contests (illegal in most of the United States but legal in England). Bookmakers ordinarily accept bets on the outcome of what is regarded as an uneven match by requiring the side more likely to win to score more than a simple majority of points. In a game of United States or Canadian football, for example, the more highly regarded team would have to win by, say, more than ten points to yield an even payoff to its backers.

Unhappily, these procedures for maintaining the influence of chance can be interfered with; cheating is possible and reasonably easy in most gambling games. Much of the stigma attached to gambling has resulted from the dishonesty of its promoters, and a large proportion of modern gambling legislation is written to control cheating. More laws have been oriented, however, to efforts by governments to derive tax revenues from gambling than to control cheating. (Taxes can be levied against the incomes of the promoters or players, or of the turnover [bank, pool] itself.)

#### GAMBLING AND ITS CONTROL IN VARIOUS NATIONS

**Prevalence of principal forms.** The world's most enthusiastic gamblers are probably the Chinese and other Southeast Asians. In the years before the Communist revolution, in some provinces of China, Burma, and Thailand as much as one-third of the average farm family's income went to pay gambling debts. Before World War I most of Thailand's state revenue was derived from state-licensed gambling establishments.

Horse-racing gambling exists in many countries, including Canada, the United States, Argentina, Colombia, Mexico, Puerto Rico, Venezuela, Australia, Indonesia, Japan, the Philippines, Denmark, Great Britain, France, West Germany, Ireland, Italy, Norway, Sweden, Poland, and the Soviet Union.

Casino gaming is forbidden in Switzerland, Spain, and Scandinavia. In 1960 there were fewer than a dozen casinos in England, but by 1968 approximately 1,000 had managed to find a loophole in the written law; this led to a new system of licensing and control, which by the early 1970s reduced the number to 120. In the rest of Europe there were about 180 casinos in the 1970s, some of them very large and famous houses (at Monte Carlo, Bad Homburg, Baden-Baden), others small and unpretentious. France had 80 percent of this total, Germany about 7 percent, and Italy less than 5 percent. A few of the Communist bloc countries have experimented with casinos, some of which are financed by foreign entrepreneurs. In most of the countries of Europe (and several other areas) that have casinos, local citizens are not permitted to gamble in them, but visitors from distant cities within the country and from foreign states are permitted, even encouraged, to do so. The purpose of this two-class system is to protect people from the temptations of over-indulgence at accessible casinos and also to prevent the outflow of currency to other nations. This system prevails in Monaco, for example, where gambling in the casino at Monte Carlo is the backbone of the tourist industry and provides an important share of the national income. In some parts of the Caribbean area, too, casinos form the basis of tourist industries that constitute a chief source of foreign exchange and revenue.

Among the games played regularly at casinos, Roulette, which is one of the principal gambling games in France, is played throughout the world. Crap shooting is the principal game at most American casinos. Chuck-a-luck, once a standard dice game at North and Central American casinos, has, since the 1940s, largely faded out of the picture. Slot machines are a mainstay of casinos in the United States and also are found in thousands of private clubs, restaurants, and other establishments; they are common in other countries, including Australia, where they are known as Poker machines, and in Great Britain, where they are called fruit machines. Among the card games played at casinos, Baccarat, in its popular form Chemin de fer, has remained a principal gambling game in Great Britain and in the continental casinos most often patronized by the English at Deauville, Biarritz, and the Riviera resorts. Faro, at one time the principal gambling game in the United States, has, since the ascendancy of Craps, become almost obsolete. Poker is offered at many establishments, but Blackjack has been the principal card game in U.S. casinos. The French card game Trente et Quarante (or Rouge et Noire) is played at Monte Carlo and other continental casinos.

State-licensed or state-operated lotteries are widely distributed about most of the world (see the article LOTTERY). Soccer-pool companies can be found in Great Britain, Sweden, Australia, and a few African nations.

In the United States, Nevada is the only state that permits almost all common forms of gambling (that state collected \$41,000,000 in tax revenues from gambling in 1970). About half of the states permit horse racing. In 1939 all horse-race gambling was limited by law to pari-mutuel betting, the system under which bets are pooled by the track management and redistributed to the winners after taxes and revenues are deducted. A large but unknown amount of illegal betting with bookmakers has persisted, however, and in 1971 New York became the first state other than Nevada to legalize off-track betting on horse racing (see HORSE RACING).

**Legislation and control.** In countries in which gambling is legal, legislation and control usually are directed primarily toward ensuring that the state receives its full share of gambling revenue and toward preventing the gambler from cheating or being cheated. In countries in which some or all forms of gambling are illegal, legislation and control are more complex and subject to change. In the United States, for example, although Nevada is the only state to have legalized casino gambling, several states repeatedly have considered and reconsidered doing so. Illegal gaming houses and illegal numbers rackets exist and are generally held to be responsible for large incomes to organized criminal syndicates. A few states

have laws making it possible for local governments to legalize particular card games. Also, many states permit casino gaming in private clubs and charitable enterprises and for certain special occasions. Some churches and service clubs have offered Bingo sessions as a means of raising money, and raffles for a prize are a commonly exploited technique for raising money or publicizing a product or occasion. State and local ordinances are often quite inconsistent, as are law enforcement practices. In many localities certain forms of gambling and gambling devices, the operation of slot machines by private clubs, for example, although illegal, are tolerated. The federal law is quite definite about prohibiting materials concerning gambling to be transmitted in interstate commerce, but again law enforcement inconsistencies, smuggling, and changing legal definitions compromise the effectiveness of the law.

In 1951 the British Royal Commission on Betting, Lotteries, and Gaming issued a report that stands as a landmark in official thought concerning gambling legislation. The commission argued that legislation designed only to prohibit or restrict participation in particular forms of gambling would be likely to fail because it is difficult to enforce; it frequently becomes out-of-date; it leads to class distinctions; and it fails to provide for the ingenuity of those who would profit from promoting gambling. The commission recommended that there should be strict control over the provision of commercial gambling, including the licensing or registration of all promoters and operators. It also recommended that the law be made to apply fairly to all sections of the society and that the public be continually informed about the extent and character of gambling. The principle concerning fair application is often subverted by repressive gambling laws because the rich are able to afford many ways of indulging their risk-taking whims through such activities as stock-market speculation, travel to distant resort areas and casinos, placing bets with bookmakers with whom a line of credit has been established, and so on. The British Parliament, in its revisions of the Gaming Act, has been guided to some extent by the commission report, which, in general, takes the view that gambling is an activity that "citizens may properly indulge in moderation, but . . . that there are grave dangers in uncontrolled indulgence."

This willingness to tolerate gambling in moderation is more difficult to find in the United States, where opinion surveys and political elections have indicated that both the public and its legislative representatives are strongly divided on questions relating to the legalization of gambling. Nevertheless, there appears to be a trend toward legalizing certain forms of gambling—particularly lotteries and off-track bookmaking. Among the gains that could be realized by legalization, it has been argued, are: the state could exert more control over gambling promoters so that cheating might be reduced, tax revenues obtained, and professional operators kept from unnecessarily promoting gambling among those to whom it might be addictive. If, as is sometimes claimed, the "criminalization" of gambling (defining it as illegal) produces a tendency for professional gamblers to try to bribe law enforcement officers, then the legalization of gambling might remove a need for corrupting officials. On the other hand, legalization of gambling might increase the total volume of gambling, encourage some citizens to gamble who would otherwise not do so, and display the state's indifference to certain moral traditions and styles of life of its people.

## Games, History of

The history of games is a part of the history of man as a social animal: his interrelations with other individuals and groups, his civilization and culture, and especially his play. The particular games that are the subject of this article are those more-or-less active games that adults in different parts of the world have enjoyed sufficiently in their early forms to develop for them uniform codes of rules and specifications, and to organize them for competitive play. The ones that are cited as examples are mostly those now played with a ball between opposing sides (e.g., tennis, billiards, football, baseball, cricket). The article covers the early history of such games and their functions as physical outlets, displays of skill, entertainment for spectators, and pastimes bringing men and women together socially. Separate sections deal with the period of greatest growth of games in schools and clubs, their national and international organization, and the paradoxical decline of games at a time of their increasing world-wide promotion and coverage by press and television. Because the term games is given a limited definition here, it is notable, particularly when reasons for playing specified games are being inferred, that there are probably other recreational ways of achieving some of the same satisfactions. A few will be indicated as the opportunity occurs.

Readers, particularly American ones, desiring to know more about the wider subject of man's love and need of recreation are referred to Foster Rea Dulles' book, *A History of Recreation: America Learns to Play*, in which the author tells of the ways a young nation, brought up to believe "that all idle pursuits were a Satanic trap to lure the godly from the path of duty," nevertheless found itself incapable of observing what is now known to be an unnatural and harmful injunction. Man must play or pay a heavy penalty. The reader is also referred to other articles in *Encyclopædia Britannica*: see ATHLETIC GAMES AND CONTESTS; CHILDREN'S SPORTS AND GAMES; SPORTS, AMATEUR AND PROFESSIONAL; and to the historical sections of the separate articles on individual games.

For that category of nonactive games, which have provided both men and women with much pleasant pastime, amusement, intellectual stimulation, social intercourse, and—especially when played for stakes—excitement, see BOARD AND TILE GAMES; CARDS AND CARD GAMES; DICE GAMES; NUMBER GAMES AND MATHEMATICAL RECREATIONS; and WORD AND LETTER GAMES. See also BRIDGE; CHESS; CRIBBAGE; POKER; ROULETTE; and RUMMY GAMES.

### EARLY HISTORY

The organization of games for competitive play and the codifying of each game's rules for general acceptance followed the improvement of communications in the 19th century and the growth of towns. Better roads, the railroads, the automobile, and the airplane have fostered national and international association. The towns growing progressively larger, sometimes into conurbations, denied the space for natural play to millions and substituted spectator games. But old ways died hard, particularly in European countries, and it was possible in the 1970s either to find games still being enjoyed that had no

more than local significance, or codified games being played with local rules.

The metamorphosis of games from being unorganized, undisciplined amusements in villages and small towns into what they became in the second half of the 19th and in the 20th centuries—sophisticated occupations for thousands and mass amusement for millions—was relatively swift. It followed the pace set by the Industrial Revolution. Before that series of economic and social changes took place, games were simple alternatives to country pursuits. Contests, particularly on holy days, were occasionally arranged between different communities as social occasions or as excuses for violence. In the country, games generally were spontaneous affairs, indulged in on the spur of the moment for an unspecified time. Gambling, of course, was an exception; matches between cocks and even cricketers were arranged for that.

**Importance of the ball.** The most significant fact in the history of games was the early appearance of the ball. The observation that animals enjoy gambols with playthings as much as humans suggests that there may never have been a time in man's evolution when a ball substitute was not chased, batted, or thrown. In historical times the ball has always been present. The Egyptians, Greeks, Persians, and Romans were all familiar with it. The Romans had a special room set aside for ball play in their public baths. Mostly, however, the ancient world played forms of catch, as other people have done in every country ever since.

For centuries the manufacture of balls hardly changed. They were made of strips of leather sewn together and stuffed with hair, feathers, or cloth. Sometimes air-filled bladders were an alternative, and for kicking there was always a stone, the precursor of the tin can. Only in the history of the Aztec Indians and others in the same geographical area are there references to rubber balls before the 18th century: travellers to the New World reported seeing them there at the end of the 15th century. The rubber ball was used in Spain in *pelota vasca* (jai alai [q.v.]) before its introduction in other parts of Europe.

Those who most enjoyed playing with a ball soon found ways of hitting it farther and harder with bats or clubs of various kinds. The variety of clubs shown on friezes and urns has made it possible for the enthusiastic historian of an individual game to claim—with some truth—ancient lineage for his own. Certainly there were stick games played by the Persians, Greeks, and American Indians. Polo, a word of Tibetan origin, was apparently well known in some form to the Persians at the time of Darius I (reigned 522 to 486 bc). Golf, though claimed by Scotland in its modern form, had respectable antecedents in Roman times and in many European countries. The word golf comes, it is widely believed, from the Dutch *kolf*.

**Playing areas.** Another important factor in the early development of ball games was the nature of available playing areas. It was easy to appreciate the advantages of the flat surface of a courtyard, for example, and even the smallest boy could understand that a ball thrown against a relatively large and smooth wall could be made to bounce back to him. Because the bound of the leather ball was low, only a small space was needed. Many European church walls provided the opportunity, and by using them, handball games were invented. If the wall was supported by a buttress, an angle was provided for a more elaborate game (see HANDBALL AND FIVES).

Nobles and courtiers found the same kind of opportunity within the walls of castles. The original game of tennis, or *jeu de paume* ("palm of the hand game"), now known as court tennis in the United States and sometimes as royal or real tennis in England, was played as a recognized pastime in the courtyards of noble establishments in France as early as the 13th century. Played over a fringed or tassled string or a net, the game made use of the irregularities of the walls surrounding it. Some of these irregularities were carefully reproduced in courts built expressly for the game in later centuries: they had become an integral part of the game (see TENNIS AND ALLIED COURT GAMES).

Historically the game was important because through

Games as simple alternatives to country pursuits

The influence of available playing areas

its story could be traced the origin of several court games and to some extent the evolution of the racket. Nurtured in France, tennis spread to Holland, England, and Scotland. Because it was a gentleman's game played by courtiers and enjoyed by the ladies, who were able to watch from their rooms in the towers, it was one of the first ball games to be subject to some organization. Games of tennis are reported to have been played for the amusement of Queen Elizabeth I when on tour. The degree of organization is suggested by John Webster's metaphor:

We are merely the stars' tennis balls, struck and bandied  
Which way please them.

Evolution  
of the  
tennis  
racket

In the earlier centuries it was played with the hand only, probably with several players on each side of the net. Later the hand was bound with thongs and cords, and finally a stick was inserted in the cords to make a primitive racket. But it is hard to write positively about the evolution of the racket. For example, a picture of a most elegantly dressed lady of the 14th century, described as playing *jeu de paume*, shows her obviously about to serve the ball with the help of an implement resembling a baseball bat. By the early 17th century, the highborn Prince James, duke of York, was portrayed in a tennis court holding what appears to be a strung table tennis racket. This short-handled bat was in general use by that date.

The game reached the peak of its popularity in the 16th and 17th centuries. Henry VIII's love for it is well documented. He was a good player and built himself a court, still used four centuries later, at Hampton Court Palace. Long before that, however, the populace of England and France were being forbidden to play many games because they supposedly wasted time and caused gambling.

The game the populace played was probably like fives or handball, a simple use of walls wherever they were to be found. They would also play the open-air game of tennis (called *la longue paume*) in which teams of two or more would oppose each other on different sides of a line stretched across the centre of a flat area with no boundary walls. The suggestion of modern lawn tennis was there.

Meanwhile, thousands of miles across the sea from Europe and long before the landing of Columbus, Indians in North America had taught themselves to string a racket-like implement and to play a game the refined modern descendant of which is lacrosse.

**Social structure and games.** The social structure of European society in the eight centuries before 1800 determined which recreations prospered and which did not. Tennis was a gentleman's game, the only outdoor ball game that was. It was played in the seclusion of a courtyard and later in private covered courts; it soon had recognized rules for match play. Football was a game not played by gentlemen, a rabble game, which it remained, in spite of its universality and popularity, until the 19th century when the age of the common man began. The exception to the rule might easily be golf. Something like it was played across open countryside from Roman times to the 19th century. It was played by gentlemen, as occasional references showed, and was played by others no doubt, but it was an unsatisfying game with a ball stuffed with feathers. Still, clubs flourished from the 18th century onward to be ready, as it turned out, for the revolution in popularity that followed the invention of the gutta-percha ball in 1845.

Social  
relation-  
ship  
of games

Joseph Strutt in his book *The Sports and Pastimes of the People of England*, first published in 1801, indicated clearly the social relationships of games by the arrangement of his material. He divided his work into four books and each book into several chapters: book I, "Rural Exercises Practised by Persons of Rank"; book II, "Rural Exercises Generally Practised"; book III, "Pastimes Usually Exercised in Towns and Cities or Places Adjoining to Them"; and book IV, "Domestic Amusements of Various Kinds and Pastimes Appropriate to Particular Seasons."

The rural exercises of book I were hunting, hawking, and horse racing, a chapter each to those pursuits which, until modern times, were denied to everyone except the land-owning classes. Practically all the ball games noticed in this article were to be found in book II. In book III,

however, there was one game, bowls (lawn bowling), deserving of attention because its acceptance by persons of rank meant that, like tennis, it reached a developed form earlier than the games of physical contact that were unthinkable for gentlemen.

**Bowls and bowling.** Sir Francis Drake found time to finish his game of bowls before sailing to meet the Spanish Armada in 1588. By Drake's time, the game had reached such sophistication that it was already played with biassed woods or bowls made to curve. In its simpler form, with ordinary balls, it had been played for centuries and enjoyed great popularity. A similar game, boccie, had long been played in the Piedmont.

The general idea of placing one bowl as near as possible to another stationary one, or jack, and, if necessary, of knocking one's opponents' bowls out of the way in order to do so, made the game virtually the same as the one children played with marbles or adults enjoyed on ice when curling. But the bias of the bowl and the introduction of sweeping for curling, both 16th century developments, heightened the skill and increased the competitive fascination of both games. The Dutch and the Scots were fond of both, and the Dutch made bowls a popular recreation in New Amsterdam in North America.

Bowling, or tenpins, has been regarded as a modern American game, and indeed it reached its highest organizational and technological development there. Derived from skittles, or ninepins, however, it was in essence one of the oldest forms of amusement. The Germans were the first to popularize it, but by late medieval times there were alleys everywhere in Europe. Henry VIII was again the man to give bowling final respectability in England. He added a bowling alley to one of his residences. It remained a tavern game, however, and, like shovelboard, was a recreation popular also with nobility, but rarely played together or in the same place.

**Billiards.** The only other ball game that found its way into gentlemen's houses in the 16th century was billiards. Quite how this came about is unknown, but billiards swiftly grew in popularity, and by the end of the 17th century it was an expected diversion in country houses. It was clearly related to a tavern game, and for a time wooden obstacles on the table were a common feature. The modern game dates from 1800. Its main features, however, were established long before that. English encyclopaedist Ephraim Chambers (1738) described it as "an ingenious kind of game played on an oblong table, covered with green cloth, . . . with little ivory or wooden balls. . . ."

#### THE FUNCTIONS OF GAMES

Looking backward over the centuries, it would seem that there have been three functions for games. The first was to rid the participant of animal spirits and excess emotions by playing rough, strenuous, and what are now called physical-contact games. The second was to excite admiration and to give pleasure to the individual and others by demonstrating skill. These objects were achieved in the display games. The third was to offer emotional outlets to large numbers of people by arranging spectacles—the spectator games—compensating for the lack of opportunity for taking part and also satisfying man's undoubted enjoyment in being, on occasion, one of a crowd. To these three functions there was added for a brief period a fourth, the function of bringing men and women together in a social situation. Common to all four but in varying degrees and dependent on the individual natures of the participants was the spirit of competition.

The functions did not remain static. From time to time they were modified as social pressures changed. Often the games served more than one purpose. Association football (soccer), universally the most popular game of the 19th and 20th centuries, moved into the spectator category after several hundred years of usefulness as an outlet for physical exuberance. In consequence, British players, the acknowledged masters for half a century, found themselves left behind in the 1950s by the artistry of the Hungarians, Spaniards, and Latin Americans. They were

Changing  
functions  
and  
growth of  
spectator  
sports

forced to alter their style, as they did successfully. Nevertheless, as late as the 1970s they could still be criticized for their overly physical performances.

Baseball, too, in the United States left the quieter environment of amateur display to become towards the end of the 19th century the national, professional spectator sport. Professionalism, except for coaching, was linked with spectator sports and emphasized the point of play that most excited a crowd.

In other parts of the world, notably Australia, India, and the West Indies, cricket, much to English surprise, followed suit. In this game, in the late 20th century, it was not so much the style of play that changed as the conditions under which a match was fought. Matches confined to a few hours were preferred by the crowds to the leisurely contests of former times spread over days. There was more excitement and more spectator interest and appeal.

**Physical outlets.** The chief physical games have been all forms of football, perhaps most of all American football, and such others as hockey, polo, hurling, and lacrosse, all of which involved chasing a ball vigorously with a stick. Most of them were played in the West in the early days by young men who were denied the pleasure of the hunt by the hierarchical structure of the feudal system. In violent play, the ball took on the attributes of the quarry. There were at first no written rules but possibly a few local ones. The games ranged from casual affairs arranged on the spur of the moment to traditional battles between two villages or two sides of a town. At the conclusion the contestants were battered and exhausted.

The authorities were constantly worried by these games. They counted the damage and deplored the waste of time when something more useful might be done like practising archery at the butts. However, in spite of laws prohibiting games and puritanical repression at a later date, it is hard to believe that some did not appreciate how essential violent play was for the young. As the poet Alfred Cochrane expressed the idea:

I once admitted—to my shame—  
That football was a brutal game  
Because she hates it.

Two popular sports or games that are equally brutal and were always performed partly for display and partly as spectacles are boxing (fighting) and wrestling. They both date from earliest times, were part of the athletic games and contests of ancient Greece, and have been enthusiastically enjoyed at all periods and in all countries. Of the two wrestling had the higher reputation, gathering the crowds in towns and rural areas from Japan to Europe for thousands of years. The attraction was the skill exhibited and the display of violence. For some men and women in every age boxing and wrestling have been a compelling catharsis.

**Displays of skill.** Until recent times cricket was the most remarkable of the display games. Indigenous to England from the 17th century and played only in Holland on the European continent, cricket was exported by the English to all countries of the British Empire. It failed to take hold in the United States, perhaps because it was colonial or too unexciting for pioneering temperaments, but elsewhere, if there was a British colony, cricket was enjoyed.

For two centuries the enjoyment was predominantly in the display. A spectator who watched only a period of a three-day match or sat awhile in a field watching a village game was less concerned with the result or the prospect of excitement than with the skill of the batsman, bowler, or fieldsman. The players, too, were concerned chiefly with their own skills: if a batsman, how to master the bowler's pace or spin and to play the appropriate stroke; if a bowler, how to beat the bat by showing superior skill to the player holding it. If wrestling aroused, cricket soothed.

By the last third of the 20th century, only the games emphasizing individual performances were left to recall the once-admired virtues of display. Sometimes the artistry of a footballer or a cricketer could arouse admiration of a crowd, but generally that was regarded as a

bonus, and team games were by then assumed primarily to provide excitement. It was the diver in lonely concentration on the top board, the gymnast, the figure skater or pair, the skier, or the athlete preparing to make his jump or throw whose skillful performance mattered more than any points advantage to be gained. There was a physical or technical beauty to be achieved in display that, at the moment of performance, transcended all other aims.

**Spectator entertainment.** The growth of urban living promoted the advance of spectator games. Proportionately fewer and fewer people had the opportunity satisfactorily to organize their own leisure. The country way of life, which intermingled sport and work, had little in common with an industrialized society whose recreational needs were starved and needed, as it turned out, a new industry to satisfy them.

In the ancient world the usual spectator games were athletic, to which were added chariot races, wrestling, boxing, and gladiatorial contests. There was also theatre. The medieval citizen got his occasional spectator fun from fairs, jousts, and dramatic performances. He was very fond of the drama, often associated with religion, as in the mystery plays, and his audience participation was accepted and expected.

The puritanical attitudes of the 17th century reduced the amount of fun in Europe and America, and by the time their influence had waned, the shadows of the Industrial Revolution were beginning to close in. In the United States the shooting matches and the tavern games were supplemented by dances and visits to the theatre. Real freedom to enjoy oneself as one wished was a long time coming, and when it did games did not at first play much part.

It was a different story in the 19th century. Along with Barnum's American Museum and his travelling exhibitions, horse races, regattas, and athletics drew the crowds. By mid-century in the United States, baseball had begun to grip the public's imagination. For the first time in history a ball game was on its way to becoming a major spectator sport. Elsewhere it was association football, the only game ever known to attract week after week, in one part of the world or another, millions of watchers.

The attraction and worth of spectator games to an urban community too poor to be mobile were obvious. They provided excitement, interest, and romance. Cynically the games could be described as Karl Marx described religion, as "the opium of the people"; charitably they could be regarded as a logical development of man's enthusiasm for games when precluded from taking part himself. Mostly, at the beginning, the impetus came from private enthusiasm, although it proved by no means easy to turn large stadiums into successful business enterprises.

**Social games.** The fourth function of games—social—was at its peak short-lived. Four games at least and one other form of exercise, bicycling, owed their immense popularity between 1870 and 1914 to the opportunities they gave to men and women for sunlit dalliance and more serious flirtation. After World War I they remained enjoyable but no longer necessary, for the age of chaperones was past. The games were archery, croquet, lawn tennis, and roller skating. Men and women played them together, and it was part of the emancipation of women from Victorian bonds that they were allowed to do so. In places where the climate made it possible, ice skating performed the same function.

After World War I only lawn tennis continued as a popular mixed game, and it survived as such for another 20 years. Although its function as a social game declined, it continued to be enjoyed as a club game, as did badminton and squash rackets in the winter; and, with the rise of professional tennis in the 1960s and 1970s and the construction of numerous indoor courts, tennis achieved a strong position as both a participant and a spectator sport.

Although the social games were short-lived, the elderly in the 1970s looked back on them with nostalgia. For a section of society they symbolized an era of domestic stability and charm unknown before and unlikely to be

Recreational needs in an industrialized society

repeated. When the majority had automobiles, the world changed.

#### THE GREAT BALL-PLAYING ERA

The great ball-game-playing period began around 1850 and continued until 1939. It began in the United States and England and spread rapidly throughout the world. For some undiscoverable reason the Anglo-Saxons had a penchant for games. Some regarded it as a virtue; others, as a fault. On the continent of Europe only the Dutch shared the Anglo-Saxon passion for games, and their contribution was to encourage ice sports.

**Growth in schools and clubs.** In England in the 19th century the stimulus for playing ball games came from the reformed public (private) boarding schools. Except for a few poor scholars, these schools in that century were strictly for the children of the ruling and landed classes. The laxity of morals and the wildness of behaviour among the leaders of society at the end of the 18th century and the beginning of the 19th had been reflected in these schools. They had become barbaric. When the pupils were not being flogged by often incompetent teachers, they were committing the most outrageous pranks or sins. For Victorian England these schools were a scandal, and few, if any, in a much more serious society doubted the need for reform.

One of the obvious areas of reform was the use of leisure time. So lax was the discipline in most of these schools that boys, except when actually in their classrooms, were left to their own devices. They were punished for their evil ways, but little or nothing was done to provide alternative employment. Games, organized games, were a solution. They were adopted with speed. *Mens sana in corpore sano* ("a healthy mind in a healthy body") became the watchwords. Long before the end of the century the schools had become production plants for Christian gentlemen, and their training came as much from the playing field as from the classroom. Some, including the popular author Rudyard Kipling, thought it went too far.

Then ye returned to your trinkets; then ye contented your souls,  
With the flannelled fools at the wicket or the muddled oafs  
at the goals.

Although cricket, rugby, association football, and rowing were the chief recreations encouraged, other games found a seasonal place: swimming in the summer, rackets and fives in the newly built courts in the winter. Matches were soon being played against nearby clubs and other schools. Although transport was still slow, unless two schools were on the same railroad, quite long distances were covered. Soon, it appeared, it was more important for a boy to win his school colours at a major game or to get a "blue" at Oxford or Cambridge than it was to win a classical or literary prize or get a first class degree in his final examination.

It was not, however, only a time for school reform; it was a time of social reform. Many were sickened by the existences led by the industrial poor; many longed to make the lives of children healthier and happier. Games for them seemed an equally good idea, particularly to those social workers brought up in the public (private) schools. Football and cricket teams were formed everywhere—out of Sunday schools, out of boys' clubs, out of factories, villages, and towns. Toward the end of the century, local authorities provided playing spaces in public parks and recreation grounds. Playing leagues at all levels were formed: the great playing era had begun.

This period was the beginning of the age of professionalism, which was to reach its peak much later. Cricket had long had a few professionals: wagering matches had been played between them as early as the 18th century. Soon very few spectator games could hold out against the tide of professionalism as old-fashioned people wanted, although the amateur tradition died hard.

In the United States the rise of organized games on the East Coast came about the same time as it did in England. The fashions for lawn tennis, croquet, roller skating, and athletics swept the area. This was all the more

surprising because before the 1860s, hardly anyone had been interested in playing organized outside games. The concern for health, an American preoccupation ever since, was a contributory factor, but primarily it was the result of the United States being one of the first to be caught up in a world-wide convention.

Cricket, even in the United States, had been an exception to the absence of organized games before 1850, but baseball was also starting on its road of popularity before that date through the formation of the Knickerbocker Baseball Club in the 1840s. Baseball soon ousted cricket from popular esteem, and after the Civil War the organization of the game with professional players began in earnest.

**National and international organizations.** As the playing of games spread throughout the world, national organization was followed by international. Soon the automobile, the ship, and finally the airplane were carrying teams everywhere. The Imperial Cricket Conference was founded in 1909, although the first international match between England and Australia had been played as early as 1877. The international organizing body for association football, the Fédération Internationale de Football Association, began in 1904 with headquarters in Switzerland. The International Lawn Tennis Federation was founded in 1912. Some national games such as the immensely popular baseball and American football, however, remained curiously isolated from international competition.

**Gambling and betting.** Games have been associated throughout their history with gambling and betting. Playing ball games for money stakes has been very limited and is associated chiefly with pioneering days and in Europe with the wild behaviour of the 18th century. Once games were organized they were remarkably free from influence likely to have a bad effect on the games themselves.

The money that is made out of betting on the results of games, however, is a different matter. In Great Britain, association football (soccer) pools have come to resemble national lotteries in terms of the numbers of bettors and the amounts bet. Instead of buying a number, however, the bettor selects winning or other teams. There is much betting on the outcomes of baseball, football, and basketball games in the United States, including both professional and college football and basketball pools—all of it illegal. The popularity of the games has decreed that they should be used in this way.

#### DECLINE OF GAMES

In spite of the great boost given by the airplane to international and professional spectator and exhibition play, there was a steady decline in game playing and watching after World War II. Even the women who had played many games enthusiastically between the wars no longer found in a new generation the same compulsions that had seemed so strong in the 1920s and 30s. The facts of the situation were concealed by the enormous coverage given by the press and television to the best teams and the most important matches. It was possible therefore, to have an intimate knowledge of the performances of celebrated players and clubs without ever participating as a player or a spectator. There was still an immense following for games, but largely they had become gladiatorial contests viewed on television screens in the afternoons and evenings.

**Large clubs vs. small.** So the very large clubs prospered, supported by television rights and the great number of people who will always go to see the best. In Europe there was no end to this kind of entertainment in the association football season. If there was no international match to be watched, there were plenty of international meetings between clubs of different countries playing one another in one of the many competitions started since World War II. Soon armchair spectators knew almost as much of players in other countries as they did of their own.

Meanwhile, the smaller clubs lost members and could hardly recall the days when they played before a sizable

Role of

public  
schools

Focus on  
best teams  
and most  
important  
matches

Beginnings  
of profes-  
sionalism

crowd. Many were in serious financial trouble and were struggling to continue in the leagues. It was not hard to discover where the players and spectators had gone. Masses of them were watching star-class players and teams. In addition, relative affluence and the automobile meant for millions of others a new interest in going places. The richer half of the world was on wheels for the day or for the weekend. And if they were not on wheels, they were in the skies visiting foreign countries as a matter of course. London, Paris, Athens, Rome, New York, San Francisco, and Tokyo were available to more people than the available hotels and campsites could accommodate. Youth, too, was mobile as never before; they had something better to do, they thought, than to play games.

**The game-conscious world.** Nevertheless, several games enjoyed greater popularity in the second half of the 20th century than ever before. Chief among these was golf. Aided by the television cameras to promote interest in the game, the new wealth, the social side in the club house, the individual as well as the team spirit, the fact that the handicapping system made it practically never too late to learn or a player too old to continue, the possibility of a wife and husband belonging to the same club and having something to do in early retirement—all these in aggregate made it possible for golf to meet the needs of a large number of people. Moreover, the professionals, when they were followed on the course, were watched by the most experienced and most willing-to-learn crowd in history.

And for many there was still the winter and what to do with the long hours of darkness. Basketball and bowling gained players and spectators. Skiing and other winter sports attracted new millions. Badminton, squash rackets, and table tennis continued to appeal to millions for keeping fit, making social contacts, and defeating boredom. Just as association football had swept Latin-American countries as well as all Europe, so the games of table tennis and badminton appealed strongly to millions in China, Malaysia, Indonesia, and Japan. All the world was games conscious in the last quarter of the 20th century, but all the world was not playing so enthusiastically as 50 years before.

**BIBLIOGRAPHY.** No books deal specifically with the area covered in the above article; see the bibliographies of individual games for up-to-date historical surveys. F.R. DULLES, *America Learns to Play* (1959), is a unique account of one nation's recreational history. Similarly, J. STRUTT, *Sports and Pastimes of the People of England . . .* (1801 and later editions), provides the most comprehensive description of games played in England before 1800. For background including pictorial reference, G.M. TREVELYAN, *Illustrated English Social History*, 4 vol. (1949), should be consulted. C.B. Fry's *Magazine of Sports and Outdoor Life* (1904-17), recaptures at its height the enthusiasm for games at the beginning of the 20th century. Of the many distinguished books on the histories of individual games, M.D. WHITMAN, *Tennis Origins and Mysteries* (1932), packs a good deal of information into a small compass.

(J.Ar.)

## Gandhi, Mahatma

Mohandas Karamchand Gandhi, the preeminent leader of Indian nationalism and the prophet of nonviolence in the 20th century, was born, the youngest child of his father's fourth wife, on October 2, 1869, at Porbandar, the capital of a small principality in Gujarāt in western India under British suzerainty. His father, Karamchand Gandhi, who was the dewan (chief minister) of Porbandar, did not have much in the way of a formal education but was an able administrator who knew how to steer his way between the capricious princes, their long suffering subjects, and the headstrong British political officers in power.

Gandhi's mother, Putlibai, was completely absorbed in religion, did not care much for finery and jewelry, divided her time between her home and the temple, fasted frequently, and wore herself out in days and nights of nursing whenever there was sickness in the family. Mohandas grew up in a home steeped in Vaiṣṇavism—wor-

ship of the Hindu god Viṣṇu (Vishnu)—with a strong tinge of Jainism, a morally rigorous Indian religion, whose chief tenets are nonviolence and the belief that everything in the universe is eternal. Thus he took for granted *ahimsā* (noninjury to all living beings), vegetarianism, fasting for self-purification, and mutual tolerance between adherents of various creeds and sects.

Margaret Bourke-White, LIFE MAGAZINE © TIME INC.

Gandhi, 1946.

**Youth.** The educational facilities at Porbandar were rudimentary; in the primary school that Mohandas attended the children wrote the alphabet in the dust with their fingers. Luckily for him, his father became dewan of Rājkot, another princely state. Though he occasionally won prizes and scholarships at the local schools, his record was on the whole mediocre. One of the terminal reports rated him as "good at English, fair in Arithmetic and weak in Geography; conduct very good, bad handwriting." A diffident child, he was married at the age of 13 and thus lost a year at school. He shone neither in the classroom nor on the playing field. He loved to go out on long solitary walks when he was not nursing his by now ailing father or helping his mother with her household chores.

Education

He had learned, in his words, "to carry out the orders of the elders, not to scan them." With such extreme passivity, it is not surprising that he should have gone through a phase of adolescent rebellion, marked by secret atheism, petty thefts, furtive smoking—and most shocking of all for a boy born in a Vaiṣṇava family—meat eating. His adolescence was probably no stormier than that of most children of his age and class. What was extraordinary was the way his youthful transgressions ended.

"Never again," was his promise to himself after each escapade. And he kept his promise. Beneath an unprepossessing exterior he concealed a burning passion for self-improvement that led him to take even the heroes of Hindu mythology, such as Prahlāda and Hariścandra—legendary embodiments of truthfulness and sacrifice—as living models.

In 1887 Mohandas scraped through the matriculation examination of the University of Bombay and joined Samaldas College in Bhavnagar (Bhaunagar). As he had suddenly to switch from his native language—Gujarati—to English, he found it rather difficult to follow the lectures.

Meanwhile, his family was debating his future. Left to himself, he would have liked to be a doctor. But besides the Vaiṣṇava prejudice against vivisection, it was clear that if he was to keep up the family tradition of holding high office in one of the states in Gujarāt, he would have to qualify as a barrister. This meant a visit to England, and Mohandas, who was not too happy at Samaldas College, jumped at the proposal. His youthful imagination

conceived England as "a land of philosophers and poets, the very centre of civilization." But there were several hurdles to be crossed before the visit to England could be realized. His father had left very little property; moreover, his mother was reluctant to expose her youngest child to unknown temptations and dangers in a distant land. But Mohandas was determined to visit England. One of his brothers succeeded in raising the necessary money, and his mother's doubts were allayed when he took a vow that while away from home, he would not touch wine, women, or meat. Mohandas disregarded the last obstacle, the decree of the leaders of the Medh Bania caste, to which the Gandhis belonged, who forbade his trip to England as a violation of the Hindu religion, and sailed in September 1888. Ten days after his arrival he joined the Inner Temple, one of the four London law colleges.

Law  
studies

**England.** Gandhi took his studies seriously and tried to brush up on his English and Latin by taking the London University matriculation examination. But during the three years he spent in England, his main preoccupation was with personal and moral issues rather than with academic ambitions. The transition from the half-rural atmosphere of Rājkot to the cosmopolitan life of London was not easy for him. As he struggled painfully to adapt himself to Western food, dress, and etiquette, he felt awkward. His vegetarianism became a continual source of embarrassment to him; his friends warned him that it would wreck his studies as well as his health. Fortunately for him he came across a vegetarian restaurant as well as a book providing a reasoned defense of vegetarianism, which henceforth became a matter of conviction for him, not merely a legacy of his Vaiṣṇava background. The missionary zeal he developed for vegetarianism helped to draw the pitifully shy youth out of his shell and gave him a new poise. He became a member of the executive committee of the London Vegetarian Society, attending its conferences and contributing articles to its journal.

In the vegetarian restaurants and boarding houses of England, Gandhi met not only food faddists but some earnest men and women to whom he owed his introduction to the Bible, and the *Bhagavadgītā*, the most popular expression of Hinduism in the form of a philosophical poem, which he read for the first time in its English translation by Sir Edwin Arnold. The English vegetarians were a motley crowd. They included socialists and humanitarians like Edward Carpenter, "the British Thoreau"; Fabians like George Bernard Shaw; and Theosophists like Annie Besant. Most of them were idealists, quite a few were rebels who rejected the prevailing values of the late Victorian Establishment, denounced the evils of the capitalist and industrial society, preached the cult of the simple life, and stressed the superiority of moral over material values and of cooperation over conflict. These ideas were to contribute substantially to the shaping of Gandhi's personality and, eventually, to his politics.

Return to  
India

Painful surprises were in store for Gandhi when he returned to India in July 1891. His mother had died in his absence, and he discovered to his dismay that the barrister's degree was not an open sesame to a lucrative career. The legal profession was already beginning to be overcrowded, and Gandhi was much too diffident to elbow his way into it. In the very first brief he argued in a Bombay court, he cut a sorry figure. Turned down even for the part-time job of a teacher in a Bombay high school, he returned to Rājkot to make a modest living by drafting petitions for litigants. Even this employment was closed to him when he incurred the displeasure of a local British officer. It was, therefore, with some relief that he accepted the none-too-attractive offer of a year's contract from an Indian firm in Natal, South Africa.

**South Africa.** Africa was to present to Gandhi challenges and opportunities that he could hardly have conceived. In a Durban court, he was asked by the European magistrate to take off his turban; he refused, and left the courtroom. A few days later, while travelling to Pretoria, he was unceremoniously thrown out of a first-class railway compartment and left shivering and brooding at

Reaction  
to  
segregation

Pietermaritzburg Station; in the further course of the journey he was beaten up by the white driver of a stage-coach because he would not travel on the footboard to make room for a European passenger; and finally he was barred from hotels reserved "for Europeans only." These humiliations were the daily lot of Indian traders and labourers in Natal who had learned to pocket them with the same resignation with which they pocketed their meagre earnings. What was new was not Gandhi's experience, but his reaction. He had so far not been conspicuous for self-assertion or aggressiveness. But something happened to him as he smarted under the insults heaped upon him. In retrospect the journey from Durban to Pretoria struck him as one of the most creative experiences of his life; it was his moment of truth. Henceforth he would not accept injustice as part of the natural or unnatural order in South Africa; he would defend his dignity as an Indian and as a man.

While in Pretoria, Gandhi studied the conditions in which his countrymen lived and tried to educate them on their rights and duties, but he had no intention of staying on in South Africa. Indeed, in June 1894, as his year's contract drew to a close, he was back in Durban, ready to sail for India. At a farewell party given in his honour he happened to glance through the *Natal Mercury* and learned that the Natal Legislative Assembly was considering a bill to deprive Indians of the right to vote. "This is the first nail in our coffin," Gandhi told his hosts. They professed their inability to oppose the bill, and indeed their ignorance of the politics of the colony, and begged him to take up the fight on their behalf.

Until the age of 18, Gandhi had hardly ever read a newspaper. Neither as a student in England nor as a budding barrister in India had he evinced much interest in politics. Indeed, he was overcome by a terrifying stage fright whenever he stood up to read a speech at a social gathering or to defend a client in court. Nevertheless, in July 1894, when he was barely 25, he blossomed almost overnight into a proficient political campaigner. He drafted petitions to the Natal legislature and the British government and had them signed by hundreds of his compatriots. He could not prevent the passage of the bill but succeeded in drawing the attention of the public and the press in Natal, India, and England to the Natal Indians' grievances. He was persuaded to settle down in Durban to practice law and to organize the Indian community. In 1894, he founded the Natal Indian Congress of which he himself became the indefatigable secretary. Through this common political organization, he infused a spirit of solidarity in the heterogeneous Indian community. He flooded the government, the legislature, and the press with closely reasoned statements of Indian grievances. Finally, he exposed to the view of the outside world the skeleton in the imperial cupboard, the discrimination practiced against the Indian subjects of Queen Victoria in one of her own colonies in Africa. It was a measure of his success as a publicist that such important newspapers as *The Times* of London and the *Statesman* and *Englishman* of Calcutta editorially commented on the Natal Indians' grievances.

In 1896 Gandhi went to India to fetch his wife Kasturbai and their children and to canvass support for the Indians overseas. He met prominent leaders and persuaded them to address public meetings in the country's principal cities. Unfortunately for him, garbled versions of his activities and utterances reached Natal and inflamed its European population. On landing at Durban in January 1897, he was assaulted and nearly lynched by a white mob. Joseph Chamberlain, the colonial secretary in the British Cabinet, cabled the government of Natal to bring the guilty men to book, but Gandhi refused to prosecute his assailants. It was, he said, a principle with him not to seek redress of a personal wrong in a court of law.

Gandhi was not the man to nurse a grudge. On the outbreak of the Boer War in 1899, he argued that the Indians, who claimed the full rights of citizenship in the British crown colony of Natal, were in duty bound to defend it. He raised an ambulance corps of 1,100 volunteers, out of whom 300 were free Indians and the rest in-

War

dentured labourers. It was a motley crowd: barristers and accountants, artisans and labourers. It was Gandhi's task to instill in them a spirit of service to those whom they regarded as their oppressors. The editor of the *Pretoria News* has left a fascinating pen portrait of Gandhi in the battle zone:

After a night's work which had shattered men with much bigger frames, I came across Gandhi in the early morning sitting by the roadside eating a regulation army biscuit. Every man in (General) Buller's force was dull and depressed, and damnation was heartily invoked on everything. But Gandhi was stoical in his bearing, cheerful and confident in his conversation and had a kindly eye.

The British victory in the Boer War brought little relief to the Indians in South Africa. The new regime in South Africa was to blossom into a partnership, but only between Boers and Britons. Gandhi saw that, with the exception of a few Christian missionaries and youthful idealists, he had been unable to make a perceptible impression upon the South African Europeans. In 1906 the Transvaal government published a particularly humiliating ordinance for the registration of its Indian population. The Indians held a mass protest meeting at Johannesburg in September 1906 and, under Gandhi's leadership, took a pledge to defy the ordinance if it became law in the teeth of their opposition, and to suffer all the penalties resulting from their defiance. Thus was born Satyagraha ("firmness in truth"), a new technique for redressing wrongs through inviting, rather than inflicting, suffering, for resisting the adversary without rancour and fighting him without violence.

The Satyagraha struggle in South Africa lasted for more than seven years. It had its ups and downs, but under Gandhi's leadership, the small Indian minority kept up its resistance against heavy odds. Hundreds of Indians chose to sacrifice their livelihood and liberty rather than submit to laws repugnant to their conscience and self-respect. In the final phase of the movement in 1913, hundreds of Indians, including women, went to jail, and thousands of Indian workers who had struck work in the mines bravely faced imprisonment, flogging, and even shooting. It was a terrible ordeal for the Indians, but it was also the worst possible advertisement for the South African government, which, under pressure from the governments of Britain and India, accepted a compromise negotiated by Gandhi on the one hand and the South African statesman General Jan Christiaan Smuts on the other.

"The saint has left our shores," Smuts wrote to a friend on Gandhi's departure from South Africa for India, in July 1914, "I hope for ever." Twenty-five years later, he wrote that it had been his "fate to be the antagonist of a man for whom even then I had the highest respect." Once, during his not infrequent stays in jail, Gandhi had prepared a pair of sandals for Smuts, who recalled that there was no hatred and personal ill-feeling between them, and when the fight was over, "there was the atmosphere in which a decent peace could be concluded."

As later events were to show, Gandhi's work did not provide an enduring solution for the Indian problem in South Africa. What he did to South Africa was indeed less important than what South Africa did to him. It had not treated him kindly, but by drawing him into the vortex of its racial problem, it had provided him with the ideal setting in which his peculiar talents could unfold themselves.

**The religious quest.** Gandhi's religious quest dated back to his childhood, the influence of his mother and of his home at Porbandar and Rajkot, but it received a great impetus after his arrival in South Africa. His Quaker friends in Pretoria failed to convert him to Christianity, but they quickened his appetite for religious studies. He was fascinated by Tolstoy's writings on Christianity, read the Qu'rān in translation, and delved into Hindu scriptures and philosophy. The study of comparative religion, talks with scholars, and his own reading of theological works brought him to the conclusion that all religions were true and yet every one of them was imperfect because they were "interpreted with poor intel-

lects, sometimes with poor hearts, and more often misinterpreted."

Rajchandra, a brilliant young philosopher who became Gandhi's spiritual mentor, convinced him of "the subtlety and profundity" of Hinduism, the religion of his birth. And it was the *Bhagavadgītā*, which Gandhi had first read in London, that became his "spiritual dictionary" and exercised probably the greatest single influence on his life. Two Sanskrit words in the *Gītā* particularly fascinated him. One was *aparigraha* (nonpossession), which implied that man had to jettison the material goods that cramped the life of the spirit and to shake off the bonds of money and property. The other was *samabhava* (equability), which enjoined him to remain unruffled by pain or pleasure, victory or defeat, and work without hope of success or fear of failure.

These were not merely counsels of perfection. In the civil case that had brought him to South Africa in 1893, he had persuaded the antagonists to settle their differences out of court. The true function of a lawyer seemed to him "to unite parties riven asunder." He soon regarded his clients not as purchasers of his services but as friends; they consulted him not only on legal issues, but on such matters as the best way of weaning a baby or balancing the family budget. When an associate protested that clients came even on Sundays, Gandhi replied: "A man in distress cannot have Sunday rest."

Gandhi's legal earnings reached a peak figure of £5,000 a year, but he had little interest in money making and his savings were often sunk in his public activities. In Durban, and later in Johannesburg, he kept an open table; his house was a virtual hostel for younger colleagues and political co-workers. This was something of an ordeal for his wife, without whose extraordinary patience, endurance, and self-effacement, Gandhi could hardly have devoted himself to public causes. As he broke through the conventional bonds of family and property, their life tended to shade into a community life.

Gandhi felt an irresistible attraction to a life of simplicity, manual labour, and austerity. In 1904, after reading John Ruskin's *Unto This Last*, a critique of capitalism, he set up a farm at Phoenix near Durban where he and his friends could literally live by the sweat of their brow. Six years later another colony grew up under Gandhi's fostering care near Johannesburg; it was named Tolstoy Farm after the Russian writer and moralist, whom Gandhi admired and corresponded with. Those two settlements were the precursors of the more famous *āśrāmas* in India, at Sabarmati near Ahmedabad (Ahmadābād), and at Sevagram near Wardha.

South Africa had not only prompted Gandhi to evolve a novel technique for political action but also transformed him into a leader of men by freeing him from bonds that make cowards of most men. "Persons in power," Professor Gilbert Murray prophetically wrote about Gandhi in the *Hibbert Journal* in 1918, "should be very careful how they deal with a man who cares nothing for sensual pleasure, nothing for riches, nothing for comfort or praise, or promotion, but is simply determined to do what he believes to be right. He is a dangerous and uncomfortable enemy, because his body which you can always conquer gives you so little purchase upon his soul."

**Emergence as leader of nationalist India.** From 1915 to 1918, Gandhi seemed to hover uncertainly on the periphery of Indian politics, declining to join any political agitation, supporting the British war-effort in World War I, and even recruiting soldiers for the British Indian Army. At the same time, he did not flinch from criticizing the British officials for any acts of high-handedness or from taking up the grievances of the long-suffering peasantry in Bihār and Gujarāt. Not until February 1919, provoked by the British insistence on pushing through the Rowlatt Bills, which empowered the authorities to imprison without trial those suspected of sedition, in the teeth of Indian opposition, did Gandhi reveal a sense of estrangement from the British Raj. He announced a Satyagraha struggle. The result was a virtual political earthquake that shook the subcontinent in the spring of

at  
Amritsar

1919. The violent outbreaks that followed—leading, among other incidents, to the killing by British soldiers of nearly 400 Indians attending a meeting at Amritsar in the Punjab (Pañjāb) and the enactment of martial law—prompted him to stay his hand. But within a year he was again in a militant mood, having in the meantime been irrevocably alienated by British insensitiveness to Indian feeling on the Punjab tragedy and Muslim resentment on the peace terms offered to Turkey following World War I.

By the autumn of 1920, Gandhi was the dominant figure on the political stage, commanding an influence never attained by any political leader in India or perhaps in any other country. He refashioned the 35-year-old Indian National Congress into an effective political instrument of Indian nationalism: from a three-day Christmas week picnic of the upper middle-class in one of the principal cities of India, it became a mass organization with its roots in small towns and villages. Gandhi's message was simple; it was not British guns but imperfections of Indians themselves that kept their country in bondage. His program of nonviolent noncooperation with the British government included boycott not only of British manufactures but of institutions operated or aided by the British in India: legislatures, courts, offices, schools. This program electrified the country, broke the spell of fear of foreign rule, and led to arrests of thousands of Satyagrahis, who defied laws and cheerfully lined up for prison. In February 1922, the movement seemed to be on the crest of a rising wave, but alarmed by a violent outbreak in Chauri Chaura, a remote village in eastern India, Gandhi decided to call off mass civil disobedience. This was a blow to many of his followers who feared that his self-imposed restraints and scruples would reduce the nationalist struggle to pious futility. Gandhi himself was arrested on March 10, 1922, tried for sedition, and sentenced to six years' imprisonment. He was released in February 1924, after an operation for appendicitis. The political landscape had changed in his absence. The Congress party had split into two factions, one under Chitta Ranjan Das and Motilal Nehru (the father of Jawaharlal Nehru, India's first prime minister) favouring the entry of the party into legislatures, and the other, under C. Rajagopalachari and Vallabhbhai Jhaverbhai Patel, opposing it. Worst of all, the unity between Hindus and Muslims of the heyday of the noncooperation movement of 1920–22 had dissolved. Gandhi tried to draw the warring communities out of their suspicion and fanaticism by reasoning and persuasion. And finally, after a serious communal outbreak, he undertook a three weeks' fast in the autumn of 1924 to arouse the people into following the path of nonviolence.

During the mid-'twenties Gandhi took little interest in active politics and was considered a spent force. But in 1927, the British government appointed a constitutional reform commission under Sir John Simon, a prominent English lawyer and politician, that did not contain a single Indian. When the Congress and other parties boycotted the commission, the political tempo rose. After the Calcutta Congress in December 1928, where Gandhi moved the crucial resolution demanding dominion status from the British government within a year under threat of a nation-wide nonviolent campaign for complete independence, Gandhi was back at the helm of the Congress Party. In March 1930, he launched the Satyagraha against the tax on salt, which affected the poorest section of the community. One of the most spectacular and successful campaigns in Gandhi's nonviolent war against the British Raj, it resulted in the imprisonment of more than 60,000 persons. A year later, after talks with Lord Irwin, Gandhi accepted a truce, called off civil disobedience, and agreed to attend the Round Table Conference in London as the sole representative of the Indian National Congress. The conference, which concentrated on the problem of the Indian minorities rather than on the transfer of power from the British, was a great disappointment to the Indian nationalists. Moreover, when Gandhi returned to India in December 1931 he found his party facing an all-out offensive from Lord Irwin's successor, Lord Willingdon, who unleashed the sternest repression in the his-

tory of the nationalist movement against it. Gandhi was once more imprisoned, and the government tried to insulate him from the outside world and to destroy his influence. This was not an easy task. Gandhi soon regained the initiative; in September 1932, while still a prisoner, he embarked on a fast to protest against the British government's decision to segregate the untouchables (the depressed classes) by allotting them separate electorates in the new constitution. The fast produced an emotional upheaval in the country; an alternative electoral arrangement was jointly and speedily devised by the leaders of the Hindu community and the untouchables and endorsed by the British government. The fast became the starting point of a vigorous campaign for the removal of the disabilities of the untouchables whom Gandhi renamed Harijans, "the children of God."

In 1934 Gandhi resigned not only as the leader but also as a member of the Congress Party. He had come to believe that its leading members had adopted nonviolence as a political expedient and not as the fundamental creed it was for him. In place of political activity he now concentrated on his "constructive programme" of building the nation "from the bottom up"—educating rural India, which accounted for 85 percent of the population; continuing his fight against untouchability; promoting hand-spinning, weaving, and other cottage industries to supplement the earnings of the underemployed peasantry; and evolving a system of education best suited to the needs of the people. Gandhi himself went to live at Sevagram, a village in central India, which became the centre of his program of social and economic uplift.

**The last phase.** With the outbreak of World War II, the nationalist struggle in India entered its last crucial phase. Gandhi hated fascism and all it stood for, but he also hated war. The Indian National Congress, on the other hand, was not committed to pacifism and was prepared to support the British war effort if Indian self-government was assured. Once more Gandhi became politically active. The failure of the mission of Sir Stafford Cripps, a British cabinet minister, who came to India in March 1942 with an offer that Gandhi found unacceptable, the British equivocation on the transfer of power to Indian hands, and the encouragement given by high British officials to conservative and communal forces promoting discord between Muslims and Hindus impelled him to demand in the summer of 1942 an immediate British withdrawal from India. The war against the Axis, particularly Japan, was in a critical phase; the British reacted sharply by imprisoning the entire Congress leadership and set out to crush the party once for all. The popular reaction was one of shock and indignation; there were violent outbreaks that were sternly suppressed; the gulf between Britain and India became wider than ever.

A new chapter in Indo-British relations opened with the victory of the Labour Party in 1945. During the next two years, there were prolonged triangular negotiations between leaders of the Congress and the Muslim League under M.A. Jinnah and the British government culminating in the Mountbatten Plan of June 3, 1947, and the formation of the two new dominions of India and Pakistan in mid-August 1947.

It was one of the greatest disappointments of Gandhi's life that Indian freedom was realized without Indian unity. Muslim separatism had received a great boost while Gandhi and his colleagues were in jail, and in 1946–47, as the final constitutional arrangements were being negotiated, the outbreak of communal riots between Hindus and Muslims unhappily created a climate in which Gandhi's appeals to reason and justice, tolerance and trust had little chance. When partition of the subcontinent was accepted—against his advice—he threw himself heart and soul into the task of healing the scars of the communal conflict, toured the riot-torn areas in Bengal and Bihār, admonished the bigots, consoled the victims, and tried to rehabilitate the refugees. In the atmosphere of that period, surcharged with suspicion and hatred, this was a difficult and heart-breaking task. Gandhi was blamed by partisans of both the communities.

Return to  
party  
leadership

Partition  
of British  
India

When persuasion failed, he went on a fast. He won at least two spectacular triumphs; in September 1947 his fasting stopped the rioting in Calcutta, and in January 1948, he shamed the city of Delhi into a communal truce. A few days later, on January 30, while he was on his way to his evening prayer meeting in Delhi, he was shot down by a young Hindu fanatic.

**Place in history.** The British attitude to Gandhi was one of mingled admiration, amusement, bewilderment, suspicion, and resentment. Except for a tiny minority of Christian missionaries and radical socialists, the British tended to see in him at best a utopian visionary, at worst a cunning hypocrite, whose professions of friendship for the British race were a mask for subversion of the British Raj. Gandhi was conscious of the existence of this wall of prejudice, and it was part of the strategy of Satyagraha to penetrate it.

His three major campaigns in 1920–22, 1930–34, and 1940–42 were well designed to engender that process of self-doubt and questioning that was to undermine the moral defences of his adversaries, and to contribute, together with the objective realities of the post-war world, to produce the grant of dominion status in 1947. The British abdication in India was the first step in the liquidation of the British Empire on the continents of Asia and Africa. Gandhi's image as an archrebel died hard but, as it had done to the memory of Washington, Britain, in 1969, the centenary year of Gandhi's birth, erected a statue to his memory.

Gandhi had critics in his own country, and indeed in his own party. The liberal leaders protested that he was going too fast; the young radicals complained that he was not going fast enough; left-wing politicians alleged that he was not serious about evicting the British or liquidating such vested Indian interests as princes and landlords; the leaders of the untouchables doubted his good faith as a social reformer; and Muslim leaders accused him of partiality to his own community.

Recent research has established Gandhi's role as a great mediator and reconciler. His talents in this direction were applied to conflicts between the older moderate politicians and the young radicals, the political terrorists and the parliamentarians, the urban intelligentsia and the rural masses, the traditionalists and the modernists, the caste Hindus and the untouchables, the Hindus and the Muslims, and the Indians and the British.

It was inevitable that Gandhi's role as a political leader should loom larger in public imagination, but the main-springs of his life lay in religion, not in politics. And religion for him did not mean formalism, dogma, ritual, or sectarianism. "What I have been striving and pining to achieve these thirty years," he wrote in his autobiography, "is to see God face to face." His deepest strivings were spiritual, but unlike many of his countrymen with such aspirations, he did not retire to a cave in the Himalayas to meditate on the Absolute; he carried his cave, as he once said, within him. For him truth was not something to be discovered in the privacy of one's personal life; it had to be upheld in the challenging contexts of social and political life.

In the eyes of millions of his countrymen, he was the Mahatma (the great soul). The unthinking adoration of the huge crowds that gathered to see him all along his route made his tours a severe ordeal; he could hardly work during the day or rest at night. "The woes of the Mahatmas," he wrote, "are known only to the Mahatmas."

Gandhi won the affection and loyalty of gifted men and women, old and young, with vastly dissimilar talents and temperaments; of Europeans of every religious persuasion; and of Indians of almost every political line. Few of his political colleagues went all the way with him and accepted nonviolence as a creed; fewer still shared his food fads, his interest in mudpacks and nature cure, or his prescription of *brahmacharya*, complete renunciation of the pleasures of the flesh.

Gandhi's ideas on sex may sound quaint and unscientific. His early marriage at the age of 13 seems to have complicated his attitude to sex and charged it with feelings

of guilt, but it is important to remember that total sublimation, according to the best tradition of Hindu thought, is indispensable for those who seek self-realization, and *brahmacharya* was for Gandhi part of a larger discipline in food, sleep, thought, prayer, and daily activity designed to equip himself for service of the causes to which he was totally committed. What he failed to see was that his own unique experience was no guide for the common run of mankind.

It is probably too early to judge Gandhi's place in history. He was the catalyst if not the initiator of three of the major revolutions of the 20th century: the revolutions against colonialism, racism, and violence. He wrote copiously; the collected edition of his writings may run to 80 volumes.

Much of what he wrote was in response to the needs of his co-workers and disciples and the exigencies of the political situation, but on fundamentals, he maintained a remarkable consistency, as is evident from the *Hind Swaraj* ("Indian Home Rule") published in South Africa in 1909. The strictures on Western materialism and colonialism, the reservations about industrialism and urbanization, the distrust of the modern state, and the total rejection of violence that was expressed in this book seemed romantic, if not reactionary, to the pre-World War I generation in India and the West, which had not known the shocks of two global wars, experienced the phenomenon of Hitler, and the trauma of the atom bomb. Prime Minister Jawaharlal Nehru's objective of promoting a just and egalitarian order at home, and nonalignment with military blocs abroad doubtless owed much to Gandhi, but neither he nor his colleagues in the Indian nationalist movement wholly accepted the Gandhian models in politics and economics.

In recent years Gandhi's name has been invoked by the organizers of numerous demonstrations and movements, but with a few outstanding exceptions—such as those of his disciple the land reformer Vinoba Bhave in India and the black civil rights leader Martin Luther King, Jr., in the United States—these movements have been a travesty of the ideas of Gandhi.

Yet Gandhi will probably never lack champions. Erik H. Erikson, a distinguished American psychoanalyst, in his recent work on Gandhi senses "an affinity between Gandhi's truth and the insights of modern psychology." One of the greatest admirers of Gandhi was Albert Einstein, who saw in Gandhi's nonviolence a possible antidote to the massive violence unleashed by the fission of the atom. And Gunnar Myrdal, the Swedish economist, after his survey of the socio-economic problems of the underdeveloped world, has pronounced Gandhi "in practically all fields an enlightened liberal." In a time of deepening crisis in the underdeveloped world, of social malaise in the affluent societies, of the shadow of unbridled technology and the precarious peace of nuclear terror, it seems likely that Gandhi's ideas and techniques will become increasingly relevant.

**BIBLIOGRAPHY.** Gandhi's autobiography, *The Story of My Experiments with Truth*, 2 vol. (1927–29), tells the story of his life up to 1921; "Satyagraha in South Africa," a pamphlet issued by the Ministry of Information and Broadcasting of India (1928), illuminates the formative two decades he spent in South Africa. The *Collected Works of Mahatma Gandhi*, 40 vol. (1958– ), covers the period up to May 1929, and will eventually include all his writings, speeches, and letters.

A biography by PYARELAL, Gandhi's former Secretary, *Mahatma Gandhi*, 2nd ed., 2 vol. (1965–66), provides a richly documented chronicle of Gandhi's early and last years. D.G. TENDULKAR, *Mahatma*, rev. ed., 8 vol. (1960–63), tells the story of Gandhi's life mostly in Gandhi's own words extracted from his published writings. LOUIS FISCHER, *The Life of Mahatma Gandhi* (1950), is based largely on printed sources but includes the author's vivid personal impressions of Gandhi and India in the 1940s; B.R. NANDA, *Mahatma Gandhi: A Biography* (1958), a story of Gandhi's life as well as a critique of his thought, makes use of unpublished government records and correspondence of Gandhi. H.S.L. POLAK, H.M. BRAILSFORD, and LORD PETHICK-LAWRENCE, *Mahatma Gandhi* (1949), is a good introduction for western readers. HORACE ALEXANDER, *Gandhi Through Western Eyes* (1969);

and GEOFFREY ASHE, *Gandhi: A Study in Revolution* (1968), are sympathetic and analytical studies. ROBERT PAYNE, *The Life and Death of Mahatma Gandhi* (1969), is a readable account, with emphasis on the personal rather than political aspect.

CHANDRAN D.S. DEVANESON, *The Making of the Mahatma* (1969), covers Gandhi's childhood and youth in detail. A vivid glimpse of Gandhi in his late thirties may be found in J.J. DOKE, *M.K. Gandhi: An Indian Patriot in South Africa* (1909, reprinted 1967). E.H. ERIKSON, *Gandhi's Truth: On the Origins of Militant Nonviolence* (1969), illuminates Gandhi's life and technique by bringing to bear on them the insights of psychoanalysis.

Among the books containing reminiscences of Gandhi, the more important are: M.G. POLAK, *Mr. Gandhi: The Man* (1931); JAWAHARLAL NEHRU, *An Autobiography* (1936); S. RADHAKRISHNAN (ed.), *Mahatma Gandhi: Essays and Reflections of his Life and Work*, 2nd ed. (1949); CHANDRASHANKER SHUKLA (ed.), *Incidents of Gandhiji's Life* (1949); NIRMAL KUMAR BOSE, *My Days with Gandhi* (1953); E.S. JONES, *Mahatma Gandhi: An Interpretation* (1948); and VINCENT SHEEAN, *Lead, Kindly Light* (1949).

Among the books highly critical of Gandhi may be mentioned: B.R. AMBEDKAR, *What Congress and Gandhi Have Done to the Untouchables* (1945); SIR SANKARAN NAIR, *Gandhi and Anarchy* (1922); and I. YAJNIK, *Gandhi As I Know Him*, rev. ed. (1943).

There are numerous anthologies of Gandhi's writings. *Selected Writings of Mahatma Gandhi* (1951), by RONALD DUNCAN; and *All Men Are Brothers* (1959), published by UNESCO, are judicious selections for the general reader.

(B.R.N.)

## Ganges River

The great river of the North Indian plains is officially as well as popularly called the Ganga, both in Hindi and in other Indian languages. Internationally, however, it is known by its anglicized name, the Ganges. From time immemorial it has been the holy river of the Hindus. For most of its course it is a wide and sluggish stream, flowing through one of the most fertile and densely populated tracts of territory in the world. Despite its importance, its length of 1,557 miles (2,506 kilometres) makes it only the 15th longest river in Asia, and the 39th longest river in the world.

Rising in the Himalayas and emptying into the Bay of Bengal, it drains a quarter of the territory of India, while its basin supports a concentration of about 300,000,000 people, a population larger than that of any state on earth with the exceptions of China and India. The Gangetic Plain, across which it flows, is the heartland of the region known as Hindustān and has been the cradle of successive civilizations from the Kingdom of Aśoka in the 3rd century BC, down to the Mughul Empire, founded in the 16th century.

For most of its course the Ganges flows through Indian territory, although its large delta in the Bengal area, lies mostly in Bangladesh. The general direction of the river's flow is from north-northwest to southeast. At its delta, the flow is generally southward.

**Physiography.** The Ganges rises in the southern Himalayas on the Indian side of the Tibet border. Its five headstreams—the Bhāgirathi, the Alaknanda, the Mandakini, the Dhāuli Ganga, and the Pindar—all rise in the Uttarkhand division of the state of Uttar Pradesh. Of these, the two main headstreams are the Alaknanda (the longer of the two), which rises about 30 miles north of the Himalayan peak of Nanda Devi, and the Bhāgirathi, which originates about 10,000 feet above sea level in an ice cave at the foot of the Himalayan glacier known as Gangotri. Gangotri itself is a sacred place for Hindu pilgrimage. The true source of the Ganges, however, is considered to be at Gaumukh, about 13 miles south of Gangotri.

After the Alaknanda and Bhāgirathi unite at Devaprayāg, they form a main stream known as the Ganga, which cuts through the outer (southern) Himalayas to emerge from the mountains at Rishikesh. It then flows onto the plain at Hardwār, a place that is held sacred by the Hindus.

Although there is a seasonal variation in the river's flow, its volume increases markedly as it receives more tribu-

taries and enters a region of heavier rainfall. From April to June the melting Himalayan snows feed the river, while in the rainy season from July to September the rain-bearing monsoon winds cause floods. Within the state of Uttar Pradesh, the principal right bank tributaries are the Jumna (Yamuna) River that flows past Delhi, the capital of India, to join the Ganges near Allahābād and the Tons that descends from the Vindhya Range in the state of Madhya Pradesh and joins it soon after. The left bank tributaries in Uttar Pradesh are the Rāmghanga, the Gomati, and the Ghāghara.

The Ganges next enters the state of Bihār, where its main tributaries from the Himalayan region to the north are the Gandak, the Burhi Gandak, the Ghugri, and the Kosi and its most important southern tributary is the Son. In West Bengal, the last Indian state that the Ganges enters, the Mahānanda joins it from the north. (Throughout West Bengal in India, as well as in Bangladesh, the Ganges is locally called the Padma). The river then skirts the Rājmahāl Hills to the south, and flows southeast to Farakka, at the apex of the delta. The westernmost distributary of the delta is the Hooghly, on the east bank of which stands the city of Calcutta. The Hooghly itself is joined by two tributaries flowing in from the west, the Dāmodar and the Rupnarayan. In Bangladesh, the Ganges is joined by the mighty Brahmaputra (which for about 150 miles before the junction is called Yamuna) near Goalundo Ghāt. The combined stream, now called the Padma, joins with the Meghna River above Chandpur. The waters then flow to the Bay of Bengal through innumerable channels, the largest of which is known as the Meghna Estuary.

Dacca, the principal city of Bangladesh, stands on the Burhi Ganga, a tributary of the Dhaleswari. Apart from the Hooghly and the Meghna, the other distributary streams which form the Ganges Delta are: in West Bengal, the Jalangi; and in Bangladesh, the Matabhanga, the Bhairab, the Kobadak, the Gorai (Madhumati), and the Ariāl Khān.

The lengths of the major tributaries of the Ganges, in miles, are as follows: the Jumna (860), the Rāmghanga (428), the Ghāghara (600), the Son (487), the Gandak (263), the Burhi Gandak (378), the Kosi (450), the Mahānanda (180), the Dāmodar (368), and the Brahmaputra (1,800).

**The delta.** The Ganges, as well as its tributaries and distributaries, is constantly vulnerable to changes in its course in the delta region. Such changes have occurred in comparatively recent times, especially since 1750. In 1785, the Brahmaputra flowed past the city of Mymensingh; it now flows more than 40 miles west of it before joining the Ganges.

The delta, the seaward prolongation of silt deposits from the Ganges and Brahmaputra river valleys, covers an area of about 22,000 square miles and is composed of repeated alternations of clays, sands, and marls, with recurring layers of peat, lignite, and beds of what were once forests. The new deposits of the delta, known in Hindi and Urdu as the *khadar*, naturally occur in the vicinity of the present channels.

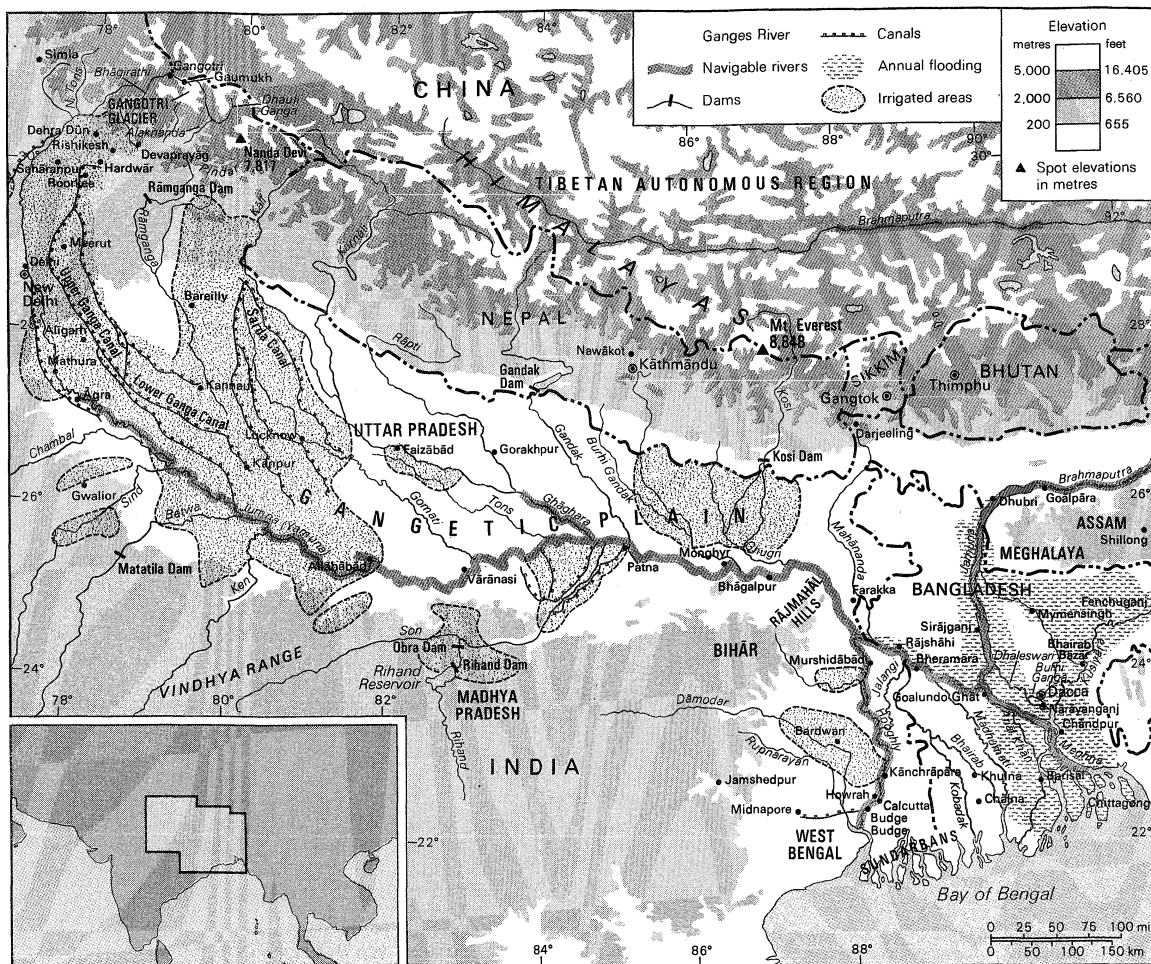

The southern surface of the Ganges Delta has been formed by the rapid and comparatively recent deposition of enormous loads of silt. To the east, the seaward side of the delta is being changed at a rapid rate by the formation of new lands, known as *chārs*, and new islands. So much silt is deposited here that the 100 fathom line lies much farther out to sea than it does, for example, off the mouth of the Indus in the Arabian Sea. The western coastline of the delta has, however, remained practically unchanged since the 18th century.

The rivers in the West Bengal area, being sluggish, have been described as dead or dying; little water passes down them to the sea. In the Bangladesh delta region, the rivers are broad and active, carrying plentiful water; they are connected by innumerable creeks. During the rains, from June to October, the greater part of the region is flooded to a depth of several feet, leaving the villages and homesteads, which are built on artificially raised land, isolated above the flood waters. Communication between

Silt deposits in the delta

The Himalayan head-streams

The Ganges River Basin.

Irrigation data from L. Cantor, *A World Geography of Irrigation*; Edinburgh, Oliver and Boyd, 1967; flooding data from R. Rawson, *The Monsoon Lands of Asia*

settlements during this season can be accomplished only by boat.

To the seaward side of the delta as a whole there is a vast stretch of tidal forests and swampland. The forests, which are called Sundarbans (Sanskrit meaning "beautiful forest"), are protected by India and Bangladesh. For conservation purposes, no permanent settlement is permitted in them.

In certain parts of the delta, there occur layers of peat, composed of forest vegetation and rice plants. In many natural depressions, known as *bil*, peat, still in the process of formation, is used as a fertilizer by local farmers. In recent years, it also has been dried and used as a domestic and industrial fuel.

**Climate and hydrography.** The Ganges Basin contains the largest river system on the subcontinent. The water supply is dependent partly on the rains brought by the monsoon winds from July to October, as well as on the flow from melting Himalayan snows, in the hot season from April to June. Precipitation in the river basin accompanies the southwest monsoon winds, but is also related to cyclones that originate in the Bay of Bengal between June and October. Only a small amount of rainfall occurs in December and January. The average annual rainfall varies from 30 inches at the western end of the basin to over 90 inches at the eastern end. (In the Upper Gangetic Plain in Uttar Pradesh rainfall averages about 30 to 40 inches, in the Middle Plain of Bihār from 40 to 60 inches, and in the delta region between 60 and 100 inches.) The delta region experiences strong cyclonic storms both before the commencement of the monsoon season, from March to May, and at the end of it, from September to October. Some of these storms result in much loss of life and destruction of homes, crops, and livestock. One such storm, which occurred in November

1970, was of catastrophic proportions, resulting in deaths of at least 200,000 people.

Since there is little variation in relief over the entire surface of the Gangetic Plain, the river's rate of flow is slow. Between the Jumna River at Delhi and the Bay of Bengal, a distance of nearly 1,000 miles, the elevation drops nearly 700 feet. Altogether the Ganges-Brahmaputra plains extend over an area of 300,000 square miles. The alluvial mantle of the plain, which in some places is more than 6,000 feet thick, is possibly not more than 10,000 years old.

**Vegetation, animals, and birds.** The Ganges-Jamuna area was once densely forested; historical writings indicate that in the 16th and 17th centuries wild elephants, buffalo, bison, rhinoceroses, lions, and tigers were hunted there. Most of the original natural vegetation has disappeared from the Gangetic Basin as a whole, and the land is now intensely cultivated to meet the needs of an ever-growing population. Wild animals are few, except for deer, boars, and wildcats, and some wolves, jackals, and foxes. Only in the Sundarban area of the delta are some Bengal tigers, crocodiles, and marsh deer still found. Fish abound in all the rivers; especially in the delta area where they form an important item of diet. Many varieties of birds are found, such as mynah birds, parrots, crows, kites, partridges, and fowls. In winter, duck and snipe migrate south across the high Himalayas, settling in large numbers in water-covered areas. In the Bengal area common fish include featherbacks (Notopteridae), barbs (Cyprinidae), walking catfish, gouramis (Anabantidae), and milkfish (Channidae).

**The people of the Gangetic Plain.** Ethnically, the people of the Ganges Basin are of mixed origin. In the west and centre of the basin they were originally descended from Aryan ancestors. Later, Turks, Mongols,

Disappearance of original vegetation

Afghans, Persians, and Arabs came from the west and intermingled with them. To the east and south, largely in the Bengal area, an admixture of Tibetan, Burmese, and miscellaneous hill people has also occurred. The Europeans, arriving still later, did not settle or intermarry to any extent.

Historically the Gangetic Plain has constituted the heartland of Hindustān and has cradled its successive civilizations. The centre of the pre-Christian empire of Aśoka was Patna (Pāṭaliputra), standing on the banks of the Ganges in Bihār. The centres of the great Mughal Empire were at Delhi and Āgra, on the western peripheries of the Gangetic Basin. Kannauj on the Ganges, north of Kānpur, was the centre of the feudatory Empire of Harṣa, which covered most of North India in the middle of the 7th century. During the Muslim era, which began in the 12th century, Muslim rule extended not only over the plain, but over all of Bengal as well. Dacca and Murshidābād in the delta region were centres of Muslim power.

The British, having founded Calcutta on the banks of the Hooghly in the late 17th century, gradually advanced up the valley of the Ganges, reaching Delhi in the mid-19th century.

A great number of cities have been built on the Gangetic Plain. Among the most notable are Roorkee, Sahāranpur, Meerut, Āgra (the city of the famous Tāj Mahal mausoleum), Mathura (esteemed as the birthplace of the Hindu god Kṛṣṇa), Aligarh, Kānpur, Bareilly, Lucknow, Allāhābād, Vārānasi (Benares; the holy city of the Hindus), Patna, Bhāgalpur, Rājshāhi, Murshidābād, Bardwan, Calcutta, Howrah, Dacca, Khulna, and Barisāl.

In the delta, the area down the Bhāgirathi-Hooghly Channel was urbanized even before the arrival of the British; subsequent growth of commerce and industry resulted in further urbanization. The aggregate population of Calcutta and its 37 satellite towns, known as the Calcutta Metropolitan District, exceeds 7,000,000. Stretching along both banks of the Hooghly for about 50 miles, the urban-industrial conglomeration extends from Kānchrāpāra-Kalyāni in the north to Budge Budge in the south.

The religious importance of the Ganges may exceed that of any other river in the world. It has been revered from the earliest times, and today is regarded as the holiest of rivers by about 350,000,000 Hindus. While places of Hindu pilgrimage, called *tīrath*, are located throughout the subcontinent, those that are situated on the Ganges have particular significance. Among these are the confluence of the Ganges and the Jumna at Allāhābād, where a bathing festival, or *melā*, is held in January and February, during which about 400,000 persons immerse themselves in the river. Other holy places for immersion are at Vārānasi (Benares), or Kāśī, and at Hardwār.

The Hooghly River at Calcutta is also regarded as holy. The places of pilgrimage on the Ganges also include Gangotri and the junction of the Alaknanda and Bhāgirathi headstreams. The Hindus cast their dead upon the river, believing that they will thus go straight to heaven, and cremation ghats (temples at the summit of riverside steps) for burning the dead have been built in many places on the banks of the Ganges.

**Irrigation.** Use of the Ganges water for irrigation, either when the river is in flood, or by means of gravity canals, has been common since early times. Such irrigation is described in scriptures and mythological books written long before the Christian era. Megasthenes, a Greek ambassador who was in India, recorded the use of irrigation in the 4th century bc. Irrigation was highly developed during the period of Muslim rule from the 12th century onward, and the Mughal kings later constructed several canals. The canal system was further extended by the British.

The cultivated area of the Ganges Valley in Uttar Pradesh and Bihār benefits from a system of irrigation canals which have increased the production of such cash crops as sugarcane, cotton, and oilseeds. The older canals are mainly in the Ganges-Jumna Doab, a word which

means "land between two rivers." The Upper Ganga Canal (which with its distributaries is 5,950 miles long), which begins at Hardwār, was opened in 1856; the Lower Ganga Canal (5,120 miles with distributaries), opened in 1880, begins at Naraura. The Sarda Canal irrigates about 1,000,000 acres of land in Oudh, in Uttar Pradesh. The land north of the Ganges, being higher, is difficult to irrigate by canal, and water in the subsoil must be pumped to the surface by electricity. The expansion of irrigation into this area has, therefore, depended on the availability of power in the northern part of Uttar Pradesh. Large areas in Uttar Pradesh and in Bihār are also irrigated by channels running from hand-dug wells.

The Ganges-Kobadak scheme in Bangladesh, largely an irrigation plan, covers parts of the districts of Khulna, Jessore, and Kushtia, lying within the moribund part of the delta where the rivers are choked with silt and vegetational overgrowth.

Total annual rainfall in this region is generally below 60 inches, and winters are comparatively dry. The system of irrigation is based on both gravity canals and lifting devices. Power is provided by a thermal plant situated at Bheramara, on the Ganges in the Kushtia District. The first part of the scheme, already in operation, diverts the Ganges water through a 60-mile canal into the moribund Kobadak River, a distributary of the Ganges, in order to irrigate 100,000 acres. A large-scale dredging of the Kobadak in the Khulna District is planned as the next stage.

**Navigation.** In ancient times the Ganges and some of its tributaries, especially in the east, were navigable. According to the Greek Megasthenes, navigation took place on the Ganges and its main tributaries in the 4th century bc. In the 14th century, inland river navigation in the Ganges Basin was still flourishing. In the 19th century, irrigation-cum-navigation canals formed the main arteries of the water-transport system. The advent of paddlesteamers revolutionized inland transport, stimulating the growth of the indigo industry in Bihār and Bengal. Regular steamer services ran from Calcutta up the Ganges to Allāhābād and far beyond, as well as to Āgra on the Jumna, and up the Brahmaputra River. Altogether, these services covered about 5,000 miles of waterways; they are still continued today under governmental auspices in both India and Pakistan. Much of the inland water traffic is carried on by various types of rural rivercraft.

The decline of large-scale water transport began with the construction of railways during the mid-19th century. The increasing withdrawal of water for irrigation has also affected navigation. Today, the river traffic is insignificant beyond the middle Ganges Basin around Allāhābād.

West Bengal and Bangladesh, however, continue to rely on the waterways to transport jute, tea, grain, and other agricultural and rural products. Principal river ports are Chālina, Khulna, Barisāl, Chāndpur, Nārāyanganj, Goalundo Ghāt, Sirājganj, Bhairab Bāzār, and Fenchuganj, in Bangladesh; and in India, Calcutta, Goālpāra, Dhubri, and Dibrugarh. The partition of India and Pakistan in 1947 produced far-reaching changes, virtually halting the large trade in tea and jute formerly carried to Calcutta from Assam by inland waterway.

In Bangladesh, inland water transport is the responsibility of the Inland Water Transport Authority (IwTA). In India, the comparable authority is the Ganga Brahmaputra Water Transport Board.

The construction of the Farakka Barrage at the head of the delta, just inside Indian territory in West Bengal, was a bone of contention between India and Pakistan (Bangladesh was, before 1971, the province of East Pakistan).

According to the Indian view, the port of Calcutta was deteriorating due to the deposit of silt and the intrusion of saline seawater. In order to ameliorate the condition of Calcutta by flushing away the seawater and raising the water level, it was proposed that quantities of freshwater be diverted from the Ganges at the site of the Farakka Barrage which was partially opened in 1972.

Chandhuri, *Power Resources in India* (1970); International Commission on Large Dams, *World Register of Dams* (1965).

The water is carried by means of a large canal into the Bhāgirathi River, which joins the Hooghly River, on the banks of which stands Calcutta.

According to Pakistan, all riparian countries should exercise joint control over the waters of international rivers for the sake of mutual prosperity. The Ganges waters are also vital to irrigation, to navigation, and to the prevention of saline incursions in Bangladesh. Pakistan maintained that the Farakka Barrage would deprive East Pakistan (now Bangladesh) of a valuable source of water upon which its prosperity depends. Agreement on the Ganges waters dispute was reached between India and Bangladesh after the creation of the latter as an independent state in 1971.

**Hydroelectric power.** The largest number of streams in the Ganges Basin originate in the Himalayas. Power generation from these rivers depends upon the extent to which, by using water storage, the river flows can be regulated.

The hydroelectric potential of the Ganges Basin has been estimated at about 4,800,000 kilowatts, representing an annual output of 25,400,000,000 kilowatt hours.

**Future prospects.** The Ganges Basin is one of the world's most populous areas. It is predominantly agricultural and produces a wide range of food and cash crops including wheat, sugarcane, oilseeds, cotton, and millet in the upper basin; rice, sugarcane, and tobacco in the middle basin; and jute, sugarcane, and tobacco in the lower basin.

In recent years, modern industry has also been established in many places, based on local raw materials and on the availability of power. A network of roads and railways serves the entire basin. Future prospects, however, depend upon the improvement and modernization of agriculture, as well as on the growth of large and medium-sized industry based on the availability of cheap energy. The expansion of irrigation and an increase in the generation of cheap hydroelectric power therefore hold the key to meeting the challenge of an increasing population and to future prosperity.

## García Lorca, Federico

Poet and dramatist alike, Federico García Lorca is the most celebrated of 20th-century Spanish writers. He was the outstanding member of a group of writers who might have brought about a new Golden Age for Spanish literature had it not been for the Civil War, during which many died and others were scattered into exile. Lorca's work is at once both intensely Spanish and universal, traditional and innovative. His plays and much of his poetry are deeply rooted in Andalusia—its cities, Córdoba, Granada, Seville; its landscapes, its gypsies and peasants, its Civil Guard, its saints, its ancient code of honour. Yet he also wrote about the Negroes of Harlem and about Walt Whitman.

No matter how localized the subject of his work, the recurrent themes that appear in them are universal: love and lust, death, motherhood, a brotherly compassion for the poor and humble, and, above all, cruelty, violence, and death resulting when primordial passions are frustrated by convention. The elemental passion in Lorca's poetry is expressed largely through concrete, voluptuous, sulfurous, vibrating, sometimes surrealistically juxtaposed images and symbols. He is a poet who, as he says, has "fire in my hands."

Federico García Lorca was born on June 5, 1898, at Fuente Vaqueros, a village in the province of Granada. His father was a farmer, his mother a schoolteacher. Struck by his musical gifts, his mother became his first piano teacher.

## Early life

When the family moved to the city of Granada, Lorca attended a Jesuit school there. At his father's urging, he then read law at the University of Granada but soon abandoned law to study literature, painting, and music. A precocious composer and excellent performer, he was "the musician" to his friends. To their surprise, in 1918 he published *Impresiones y paisajes* ("Impressions and Landscapes"), a book of prose inspired by a trip he had taken into Castile. The book suggested that Lorca soon might become known as "the writer."

In 1919 he entered the *residencia de estudiantes* (residence of scholars) at the University of Madrid, a large university that had become the cultural centre of the Spanish capital. There he became friends with artists and writers of his own generation, including the painter Salvador Dalí, the film maker Luis Buñuel, and the poet Rafael Alberti; there he also met well-known older figures such as the poet Juan Ramón Jiménez.

During his first two years at the *residencia*, Lorca's poetry became known in literary circles throughout the whole of Spain. Yet he had published hardly any of his work. "Verse is made to be recited," he said, "in a book it is dead." And so, at the *residencia* and elsewhere in Madrid, like a medieval troubador, he read his poetry and plays. Thus, throughout his career, his works were often composed and passed on by word of mouth long before they were published.

At the same time that he was composing the experimental poems that would later be published as *Libro de poemas* (1921; "Book of Poems"); *Primeras canciones* (1936; "First Songs"); and *Canciones* (1927; "Songs"). He was also writing his first play, *El maleficio de la mariposa* (*Butterfly's Evil Spell*), which opened in 1920 at the Eslava Theater in Madrid. A disastrous failure, it closed after the first night.

Lorca found the true bent of his genius when he collaborated with the distinguished composer Manuel de Falla on the folk music festival *Fiesta de cante Jondo* at Granada in 1922. In the traditions of folk and gypsy music, Lorca seemed to find a resolution of his musical, poetical, and spiritual impulses. *Poema del cante jondo* (written 1922, published 1931; "Poem of the Cante Jondo") and *Romancero gitano* (written 1924–27, published 1928; *The Gypsy Ballads*) were to be the lyrical expression of this resolution.

In the 18 poems of *Gypsy Ballads* Lorca combined the ancient magic of a traditional literary form—the Spanish ballad (*romance*)—with startling new images. The description, for example, in "The Ballad of the Spanish Civil Guard," of the Guard riding ominously toward a gypsy village:

Los caballos negros son.  
Las herraduras son negras.  
Sobre las capas relucen  
manchas de tinta y de cera.  
Tienen, por eso no lloran,  
de plomo las calaveras.  
Con el alma de charol  
vienen por la carretera.  
Black are the horses.  
The horseshoes are black.  
On the dark capes glisten  
stains of ink and of wax.  
Their skulls are leaden,  
which is why they don't weep.  
With their patent-leather souls  
they come down the street.

(Federico García Lorca, *Selected Poems*, translated by A.L. Lloyd. Copyright 1955 by New Directions Publishing Corporation. Reprinted by permission of New Directions Publishing Corporation.)

While Lorca was writing *Gypsy Ballads*, he was also writing plays. His first dramatic success came in 1927 with the Barcelona production of *Mariana Pineda*, a poetic and romantic verse drama, with scenery by Salvador Dalí. The same year and the same city also saw the first public exhibition of Lorca's drawings.

The publication of *Gypsy Ballads* in 1928 brought Lorca sudden international fame but little happiness. Dis-

pleased about the creation of what he called "the myth of my gypsy-hood" and tormented by an emotional crisis that he described as "one of the most painful states I have had in my life," he sought relief and a new source of inspiration in the United States and Cuba in 1929–1930.

The trip inspired *Poeta en Nueva York* (*Poet in New York*), published posthumously in 1940. In this work, Lorca's horror at what he saw as the death in life of a mechanized civilization is conveyed by the surrealistic juxtaposition of brutal, tortured images:

Con una cuchara  
arrancaba los ojos a los cocodrilos  
y golpeaba el trasero de los monos.  
Con una cuchara.

With a spoon  
he gouged out the crocodile's eyes  
and thumped on the monkey-rumps,  
with a spoon.

("The King of Harlem," in Federico García Lorca, *Poet in New York*, translated by Ben Belitt. Copyright 1955 by Ben Belitt. Reprinted by permission of New Directions Publishing Corporation.)

By 1931 Lorca was back in Spain where he began the poems to be published as *Diván del Tamarit* (1936; "Divan of Tamarit") and again wrote for the theatre. Expressing the passionate enthusiasm for marionettes that he had had since childhood, he wrote two puppet plays: *Los títeres de cachiporra* (*The Billy Club Puppets*) and *Retablo de Don Cristóbal* (*The Puppet Play of Don Cristóbal*). Even these puppet farces were clouded by melancholy.

The advent of the Republic in Spain made it possible for Lorca to plunge fully into the theatre. The Ministry of National Education subsidized La Barraca, a troupe of students who, from 1932 to 1935, brought masterpieces of the classical theatre to uneducated workers and peasants. Founder, driving spirit, director, and musician for La Barraca, Lorca staged Lope de Vega, Calderón de la Barca, and Cervantes, thereby acquiring immense theatrical experience.

The result was the first of a trilogy of folk dramas, *Bodas de sangre* (*Blood Wedding*), staged in 1933. The theme was inspired by a news item: a bride had fled on her wedding day with the man whom she secretly loved, and the rivals had killed each other. In Lorca's play the characters become pawns in a tragedy of fate. They are trapped in a conflict between primitive passions and civilization's unyielding code of honour—a conflict that ends in death.

In 1934 the goring and subsequent death of a bullfighter who had been Lorca's friend inspired "Llanto por Ignacio Sánchez Mejía" (published 1935; "Lament for Ignacio Mejías"). Lorca's greatest poem, the finest elegy in modern Spanish literature and one of the finest in all literature, it beats with the hollow, haunting, dirgelike refrain, repeated over and over again: "A las cinco de la tarde" ("At five in the afternoon"):

A las cinco de la tarde.  
Eran las cinco en punto de la tarde.  
Un niño trajo la blanca sábana  
a las cinco de la tarde.  
Una espuerta de cal ya prevenida.  
a las cinco de la tarde.  
Lo demás era muerte y sólo muerte  
a las cinco de la tarde.  
At five in the afternoon.  
It was exactly five in the afternoon.  
A boy brought the white sheet  
at five in the afternoon.  
A frail of lime ready prepared  
at five in the afternoon.  
The rest was death, and death alone  
at five in the afternoon.

Later in 1934, *Yerma*—the second of Lorca's folk drama trilogy and, along with *Blood Wedding*, one of the few successful poetic tragedies of the 20th century—was produced. The play—"a tragic poem"—is about the torment of a woman who, despairing over her childless

Bringing  
classical  
theatre  
to the  
unedu-  
cated

Gypsy  
Ballads

state, kills her sterile husband. On an evening in June 1936, at the home of friends, Lorca read the final play of the trilogy, *La casa de Bernarda Alba* (*The House of Bernarda Alba*). Almost entirely in prose, the play is about four daughters who, shut up by their tyrannical mother in a house of mourning, burn with hatred and lust.

In July, alarmed by the outbreak of the Civil War, Lorca left Madrid for Granada. But his fate fulfilled the premonition of violent death that haunts his works. In Granada, Lorca, one of the century's great poets, was shot without trial by the Nationalists in the night of August 19–20, 1936. Lo demás era muerte y sólo muerte ("The rest was death, and death alone").

#### MAJOR WORKS

**POETRY:** *Canciones* (1927); *Romancero gitano* (1928; *The Gypsy Ballads*, 1953); *Poema del cante jondo* (1931); *Poeta en Nueva York* (posthumously published 1940; *The Poet in New York*, 1940); "Llanto por Ignacio Sánchez Mejías" (1935; trans. in *Lament for the Death of a Bullfighter, and Other Poems*, 1937).

**PLAYS:** *Bodas de sangre* (1933; *Blood Wedding*, 1939); *Yerma* (1934; Eng. trans., 1941); *La casa de Bernarda Alba* (1936; *The House of Bernarda Alba*). These three plays were all translated in *Three Tragedies of Federico García Lorca* (1947). Also, *Doña Rosita la soltera* (1935; *Doña Rosita, the Spinster*, 1941).

**BIBLIOGRAPHY.** MARCELLE AUCLAIR, *Enfances et mort de García Lorca* (1968), the only complete study of Lorca published to date; ARTURO BAREA, *Lorca: The Poet and His People* (1944), an analysis of the poet and his work by a Spaniard of Lorca's generation; ROBERT LIMA, *The Theatre of García Lorca* (1963), the plays viewed historically, critically, and biographically, with an extensive bibliography of Lorca's theatre that includes adaptations of texts for operas and ballets; JOHN B. TREND, *Lorca and the Spanish Poetic Tradition* (1956), contains an informative chapter on Lorca by an English hispanist who knew him at the start of his poetic career; HOWARD T. YOUNG, *The Victorious Expression: A Study of Four Contemporary Spanish Poets* (1964), has an intelligent study of the poet that includes an annotated list of English translations of his work; JOSE A. BALBONTIN, *Tres poetas de España* (1957; Eng. trans., *Three Spanish Poets*, 1961), traces Lorca's development and includes a number of his poems in translation; MANUEL DURAN (ed.), *Lorca: A Collection of Critical Essays* (1962), articles on both Lorca's poetry and theatre by a heterogeneous group of scholars, poets, and critics; three works that are interesting but present variously one-sided views of Lorca are: CARL W. COBB, *Federico García Lorca* (1967); EDWIN HONIG, *García Lorca*, rev. ed. (1968); and ROY CAMPBELL, *Lorca: An Appreciation of His Poetry* (1952), which also contains translations by Campbell that make Lorca's poetry sound unduly English.

(M.A.)

## Garden and Landscape Design

Garden and landscape design are a substantial part but by no means all of the work of the profession of landscape architecture. Defined as "the art of arranging land and the objects upon it for human use and enjoyment," landscape architecture includes also site planning, land planning, master planning, urban design, and environmental planning. Site planning involves plans for specific developments in which precise arrangements of buildings, roadways, utilities, landscape elements, topography, water features, and vegetation are shown. Land planning is for larger scale developments involving subdivision into several or many parcels, including analyses of land and landscape, feasibility studies for economic, social, political, technical, and ecological constraints, and detailed site plans as needed. Master planning is for land use, conservation, and development at still larger scales, involving comprehensive areas or units of landscape topography or comprehensive systems such as open space, park-recreation, water and drainage, transportation, or utilities. Urban design is the planning and design of the open-space components of urbanized areas; it involves working with architects on the building patterns, engineers on the traffic and utility patterns, graphic and industrial designers on street furniture, signs, and lighting, planners on overall land use and circulation, economists on economic feasibility, and sociologists on social feasi-

bility, needs, and desires. Environmental planning is for natural or urbanized regions or substantial areas within them, in which the impact of development upon land and natural systems, their capacity to carry and sustain development, or their needs for preservation and conservation are analyzed exhaustively and developed as constraints upon urban design, master, land, and site planning. Within this framework of comprehensive survey, study, analysis, planning, and design of the continuous natural and humanized environment, garden and landscape design represent the final, detailed, precise, intensive refinement and implementation of all previous plans.

Ideally all of these planning and design phases follow one another closely in a continuous sequential process, but this rarely happens. Various levels of planning and design are performed by different people at different times; often the more comprehensive phases are not performed at all or in an over-simplified manner. The wise gardener, therefore, always begins with a careful analysis of conditions surrounding his project.

Garden and landscape design deals with the treatment of land areas not covered by buildings, when those areas are considered important to visual experience, with or without utilitarian function. Typically, these land areas are of four types: those closely related to single buildings, such as front yards, side yards, and backyards, or more extensive grounds; those around and between groups of buildings, such as campuses, civic and cultural centres, commercial and industrial complexes; those bordering and paralleling transportation and utility corridors, such as parkways, freeways, waterways, power easements; and park-recreation open-space areas and systems. These areas may be of any size, from small urban courtyards and suburban gardens to many thousands of acres of regional, state, or national parks. Although usually conceived as vegetated green spaces on natural ground, they can include also playgrounds, urban plazas, covered malls, roof gardens, and decks, which may be almost entirely formed by construction and paving.

Garden and landscape design, therefore, works with a wide range of natural and processed materials capable of holding up well in the specific local climatic conditions of the site. These materials include earth, rock, water, and plants, either existing on the site or brought in; and construction materials such as concrete, stone, brick, wood, tile, metal, and glass.

Garden and landscape design is uniquely concerned with direct relations among art, science, and nature. It operates exactly at the frontier between man and nature, developing transitional connecting zones between the outside limits of buildings and engineering structures and the natural forms and processes that surround them. This is true for large houses and gardens in the country, for regional parks at the edges of cities, for urban and suburban gardens, for urban plazas and roof decks; it is true wherever soil exists to be treated, wherever it may be brought in to fill containers, wherever open spaces are exposed to the weather.

If garden and landscape design is concerned with the relations between man and nature, it is also largely determined by one or the other of the conflicting philosophies about how man does or should relate to nature. Man knows that biologically and physiologically he is the product of natural evolution, that his organic system is similar to that of the animals. Yet man's great technological accomplishments lead him to feel that he is above, beyond, or outside nature, that he has conquered and dominated the wilderness and has it now within his power to remake the world into complete synthetic environments. Every work of garden and landscape design reflects one or the other of these conflicting attitudes. The Japanese garden, for example, is inspired by the notion of man as a part of nature; the Renaissance garden, by the idea that man is nature's master. Garden and landscape design thus reveals much about a culture and a period.

Garden and landscape design is an art insofar as it creates for people experiences that uplift their spirits, expand their vision, and invigorate their lives. It is a science insofar as it develops precise knowledge of its pro-

Function of garden and landscape design

Components of landscape architecture

cesses and materials. And it is directly related to and expressive of nature insofar as it incorporates natural materials and scenes without major change in their character. When the preservation of natural landscape is primary, as in a regional park, art and science appear in the skill and sensitivity with which necessary facilities and changes are related to the natural landscape. At the other extreme, in an urban plaza, trees in boxes or openings in the paving may be the only natural elements; art and science then appear in the design and construction of the total plaza, including its display of trees as symbols of nature, as pleasing forms, and as sources of shade.

Art, science, and nature become most intimately interlocked in certain aspects of horticulture expressed in designed gardens and landscapes: in improved varieties of herbaceous and woody plants; in the cultural practices that stimulate their maximum contributions to the scene; and in the techniques and skills for directing and reshaping the forms of plants—in a range from trimmed hedges and topiary (careful sculptural cutting), through espaliered (trained to grow flat against a wall or trellis) and pollarded (cut back to the trunk to promote a dense head of foliage) trees, to ultimate refinements such as the Japanese practice of removing individual needles from pine trees.

No doubt much art recognizes, expresses, or symbolizes nature in some way. Only the arts of garden and landscape, however, produce works in which nature participates directly in varying degrees of integration with more processed forms and materials.

Functional  
and  
technical  
aspects

As in most other arts, garden and landscape design must solve not only aesthetic but also technical and functional problems. Gardens are for horticulture as well as for viewing, parks are for active recreation as well as for passive relaxation. The surface of the earth must be covered to prevent erosion, dust in summer, and mud in winter. Water persists in running downhill, and even light garden structures must have adequate footings.

This does not mean, however, that there is an inherent or inevitable conflict between utility and beauty. Such conflicts usually develop either because the designer tries to carry out an aesthetic concept that ignores the technical and functional requirements of the problem or because the program is so demanding technically, functionally, or economically that it eliminates aesthetic considerations from the design process. In most garden and landscape design situations it is necessary first to evaluate the technical conditions and functional demands and then to derive from them design concepts that resolve them.

The vegetated landscape that covered most of the earth's continents before man began to build still surrounds and penetrates even his largest metropolises. All of man's efforts to design gardens and to preserve and develop green open space in and around his cities are efforts to maintain contact with this original pastoral, rural landscape. Designed gardens and landscapes, by filling the open areas in cities, create a kind of continuity in space between man's structural urban landscapes and the open rural landscapes beyond.

Designed gardens and landscapes have a special kind of continuity in time. Buildings, paintings, and sculpture may survive longer than specific plants, but the constant cyclical growth and change in plants provide a continuous time dimension that static structures and sculpture can never achieve. From the annual flower to the redwood that began, so the story goes, when Christ was crucified, planting has a regular continuity and annual seasonal expression that measure for men the stages and generations of their lives.

This article will discuss the aesthetic and physical components of design, the various kinds of private and public design, and the role and development of gardening in the history of man. It is divided into the following sections:

- I. Design components
  - Aesthetic components
  - Elements
  - Principles
  - The design process

- Physical components
  - Natural components
  - Structural components
- II. Kinds of design
  - Private or residential design
  - Public design
- III. Historical development
  - Western
    - Antiquity
    - Middle Ages
    - Renaissance to modern: 15th to 20th centuries
    - Modern
  - Non-Western
    - Chinese
    - Japanese
    - Indian
    - African, Oceanic, and pre-Columbian

## I. Design components

### AESTHETIC COMPONENTS

**Elements.** The traditional elements of design are space, mass, line, or outline; colour, tone, light, and shade; texture; scent; and time, as related to climate, natural light, season, and growth factors.

**Space.** Space is air or atmospheric volume defined by physical elements and man's visual imagination. Space has floors: earth, rock, grass, low planting, concrete, asphalt, stone, brick, wood, carpet, tile, linoleum. It has sides or walls: topography, rock, vegetation, vertical structures. And it has ceilings: treetops, structural coverage, or the sky. The most easily understood spaces are the rooms, terraces, patios, and gardens of private residences. A room is defined precisely and unavoidably by floor, walls, and ceiling, particularly with doors closed and windows draped. Beyond these rooms there are the streets, squares, plazas, parks, and public buildings of the city. An urban plaza surrounded by major buildings likewise has positive floors and walls, with sky for ceiling. The fields, meadows, orchards, groves, forests, plains, lakes, river and stream valleys, hills, and mountains of the wider landscape have less precise and regular enclosures. Patios may have fences and walls, gardens hedges and trellises, but in parks there are loose spaces of many soft sizes and forms, defined by trees, ground forms, and shrubbery masses. And in the open landscape there are many different apparent space scales, from the intimate, small farming scenes of New England, Portugal, or Japan to the almost limitless panoramas of the Great Plains, Southwest deserts, or Rocky Mountains. In all of these, space is defined by ground or floor surfaces below, obstacles that block vision horizontally or terminate it at the horizon, and sky overhead. Man's sense of space in all of them results partly from what he actually sees and partly from his imaginative extension, interpretation, and structuring of what he actually sees. Thus, a sand dune, a rock, and a cactus may become a "room" in the desert, while the entire Yosemite Valley is a great room housing thousands of people.

**Mass.** Mass is the opposite of space. They define each other and depend upon each other for visual existence. Mass may be topographical earth forms, rock outcrops and boulders, trees and shrub groups, buildings, and water forms—streams, lakes, or waterfalls. These are masses in the larger landscape, even though they also incorporate spaces within themselves. Trees, shrubs, and buildings have multiple spaces within them, even though they read as masses from outside. Water forms contain spaces for divers and aquatic life, but of a different density.

**Line.** Line in the landscape may be the sharp edge of paving, structure, or rock; the boundary between two different surface materials, as grass and ivy; the edge of a shadow; or the silhouette outline of any three-dimensional form, such as a rock, plant, or building. Whatever its source, a line in the landscape plays an important role in the way man sees, interprets, and relates to the scene. A line may lead the eye into the distance, around a corner and out of the scene, or around the scene and back again, holding the viewer within it. It is similar to the role of lines in a painting, holding the viewer within

Lines in  
painting  
and  
landscape  
compared

or leading him out of the composition. In a landscape, however, the function of lines is vastly more complicated and difficult to predict. The pattern—that is, the form created by lines—is three-dimensional in any given scene that is viewed. It is four-dimensional in that a spectator continues to move through the landscape over periods of time. The pattern changes throughout each day because of the changing light and shade patterns produced by the movement of the earth around the sun. And the pattern is never exactly the same on one day as on any previous day, because of changes in the weather, the seasons, and the elements of the landscape. Buildings, topography, and rocks may be maintained almost the same for substantial periods of time; but vegetation changes constantly, with both seasonal adjustments and annual growth. That is one reason why landscapes without vegetation seem static, lifeless, and monotonous.

**Colour.** Colour gives physical landscapes that final dimension of real life, definition, and interest. Spring blossoms and fresh green leaves, after the cold barrenness of winter, herald a new season of vitality and fun. After the deep and stable green of summer, fall colours mark a last resurgence of liveliness before the winter barrenness sets in again. The apparent sizes and forms of landscape spaces change with each such seasonal change: bright colours advance, dull colours recede, changing apparent distances.

Structural colours, too, affect the apparent sizes and forms of landscape spaces. Most obvious is the negative effect of bright billboards upon quiet landscapes. To most people billboards seem destructive and arbitrary intrusions; they do not grow out of the scene but are forced onto it. Yet man-made forms—even billboards—can be made to appear to be a part of nature to the extent that they are designed to harmonize with the existing scene.

The aim of the garden and landscape designer is to combine the strong, artificial colours of paint and structure with the softer and more subdued grays, greens, browns, and blues of nature as well as with seasonal outbursts of the purest and truest colours in the world.

Colour  
variations

Colour varies by hue, the actual colours from the colour wheel; by value, the strength of the colours, bright or pale; the tone or grayness, how pure they are or how grayed by admixture with other colours; by the way that light and shade play on them; and by the texture, smooth or rough, of the surface they are on. All of these factors are taken into account by the garden and landscape designer.

**Light and shade.** Because the sun—and, to a lesser extent, the moon, stars, fire, and artificial lighting—has the property of casting shadows, landscape design, in

placing trees, structures, and other elements on the land, must always take into consideration the light and shade resulting from such placement.

Light and shade are not the same in all parts of a country or the world. Light is welcome in cool, gray, northern climates, shade in hot, bright, desert or tropical regions. In the clear air of unspoiled deserts, man sees so far that he loses all sense of size, scale, and distance; in the foggy humidity of the western coasts of Europe and North America distances seen and objects perceived change from day to day, sometimes from hour to hour, so that one lives with a continuing sense of mystery and variety. Landscape design must, ideally, remain sensitive to and work carefully with the light and shade relations that are most desirable in each different region or sub-region.

**Texture.** Texture—the smoothness or roughness of surfaces—is another element of landscape design. It is perceived primarily by feeling, although through vision one approximates the textures of different surfaces and imagines how they would feel. The surface texture of the earth may vary from fine sand or silt to coarse clods, gravel, or boulders. The texture of plant coverage may vary from fine bent grasses through coarser meadow grasses to brush, ivy, or cactus. Wall surfaces range from the smoothness of glass and plaster to the roughness of brick, stone, or rough-sawn lumber.

Felt textures must be intimate to be experienced. Visual textures may be experienced at any distance. Farther away, larger elements participate in texture effects; at medium distances the foliage of trees and the size of rocks create textural qualities; from an airplane or hill-top the size and arrangement of buildings, topographic forms, masses of vegetation, or water create textural effects.

**Scent.** Scent is a delicate and subtle element in landscape experience, often lost to 20th-century man because of widespread pollution of the air with foul-smelling exhaust and waste gases. The fragrance of flower and fruit is one of the traditional delights of garden and park, still attainable through sensitive selection and arrangement of plants.

**Time, climate, and season.** Unlike the static continuity of architectural and urban monuments, garden and landscape spaces are dependent on maintenance, which determines whether the form envisioned by the original designers will endure or change over decades or centuries. The Saihō-ji garden and many others in Japan continue today in much the same form as they began because of continuing maintenance. On the other hand, the inadequate maintenance of the Renaissance gardens—designed as geometric architectural abstractions, to which

plant forms were made to conform by clipping and trimming—has allowed many of the larger plants to resume their natural forms. The results, however pleasant, are not what the designers envisioned. Instead of hundreds of years, the typical suburban garden in the United States has a predictable life of about five years. Ownership or tenancy tends to change in that cycle, with unpredictable results in the garden.

Time and climate are closely interrelated in their effects on garden and landscape spaces. Because relations between temperature and moisture, light and shade, change daily throughout the year, every region and locality on earth—in fact, every building site—has its own climate, unlike any other. Therefore, garden and landscape design for every region, locality, and site may be expected to be different. Nevertheless, climates can be generalized in certain broad categories that are similar, though not identical, over large areas of the earth.

Climatic factors having major impact on garden and landscape design are temperature range (hot to cold), precipitation range (high to low, rain to snow), their combinations (hot, wet summers; hot, dry summers; cold, wet winters; cold, dry winters; and so on), growing season (year around in the tropics, a few weeks in the Arctic), atmospheric humidity (clear air or clouds, fog, mist) and its effects on visibility and light-shade patterns, air movement (winds, breezes) and its effect on the other factors (cooling in hot weather, chilling in cold, moving clouds and fog).

The combination of all of these factors affects how one sees the landscape (bright, clear desert distances; soft, mysterious, changeable foggy landscapes), what one expects from design (shade from the sun, protection from the wind, shelter from rain and snow), and how one designs gardens and landscapes. The patios, cloisters, and oases of Mediterranean and Middle East regions, the romantic naturalistic parks of Europe, China, and eastern North America, the esoteric garden abstractions of Japan—all of these different approaches to design were inspired partly by the particular qualities of the landscape climate in which they developed.

Time and natural light are, of course, intimately interlocked in the daily cycle of night and day, in the seasonal cycles (light is different in summer and winter because of differences in temperature and humidity), and in the annual cycles (long days in summer, short days in winter).

Time, climate, light, and season are all reflected in garden and landscape in the growth and change of plants. In the tropics, growth is constant, taken for granted, a problem of control. As growing seasons become shorter in the north and south or at higher elevations, they become more precious. In far northern and southern latitudes the short summer is a period of rejoicing and outdoor activity. A tree that will mature in five to ten years in Southern California or Florida will require 30 to 40 years in the North Central states. Spring blossoms, fall colour, the change from summer green to winter's exposed branch structures, all of these mark the seasonal changes clearly and strongly in the Eastern United States, in Europe, and in other temperate areas.

**Principles.** The traditional principles of design deal with the arrangement or organization of the elements, as expressed in specific materials, on a specific site. The site—a piece of land, with surface form and internal content—may in itself require reshaping. On it will be placed—or may already exist—buildings, roads, minor structures, trees, shrubs, ground-cover planting, water elements, rocks.

The elements of design are contained in these individual components and in specific relations that may develop among them on a particular site. The principles of design—which deal with overall relations—are unity and variety, rhythm and balance, accent and contrast, scale and proportion, and composite three-dimensional spatial form.

**Unity and variety.** Unity and variety are derived from the number of elements, or kinds of material, within a given visual area and from the way they are combined. A brick building or a rose garden is unified by concentration on one material. The difficulty of achieving a sense of unity increases as the number of elements, or kinds of material, increase. A building of six materials or a garden of 30 kinds of plants, for example, will have more variety but unity can be achieved only by careful organization and arrangement. At a certain point, which varies with the situation and the skill of the designer, it becomes impossible to establish unity. Variety then dominates.

**Rhythm and balance.** Rhythm and balance result from the three-dimensional arrangement of elements and materials on the site. Rhythm is a sequence or repetition of similar elements—as a double row of trees. It tends to emphasize direction and movement, as along an allée toward a viewpoint or terminus. Balance is the sense one

Rapho Guillumette

gets, looking in any direction, that the elements to one's left balance those to one's right and the feeling one has that the views one has just experienced are in equilibrium with what one sees now. The most obvious examples of balance are the symmetrical axial Renaissance gardens of Europe, but these are not the only or even the most interesting ways to achieve balance.

**Accent and contrast.** Accent and contrast enliven arrangements that may be so balanced, orderly, and harmonious as to be dull. An accent is an element that differs from everything around it, as silver-gray foliage against dark-green conifers, but is limited in quantity in relation to surrounding elements. Contrast is stronger: two different elements may be juxtaposed in almost equal quantity to emphasize the special qualities of each. Well-known examples are the formal palace in the informal park, the green park in the densely built-up city. Accent and contrast are more difficult to handle successfully than straightforward, simple, harmonious design. An example of the failure to handle it successfully is the common practice of lining a street with alternate specimens of two quite different trees, as pines and cherries, which merely cancel each other out.

**Scale and proportion.** Scale refers to the apparent (not the actual) size of a landscape space or of the elements within it. Proportion is the determined relations among the sizes of all the parts within an element and of all the elements within a space. Thus, the proportionate sizes of the legs, arms, and back of a garden bench, for example, determine the scale of the seat. And the overall size of the seat, in proportionate relation to walk width, arbor height, lawn area, tree size, and so on, helps to determine the scale of the garden.

**Composite three-dimensional spatial form.** Composite three-dimensional spatial form results from the delineation of a block of air by physical elements, which enclose and enframe the space and establish its relations with neighbouring spaces, distant views, and so on. A patio with paved floor and walled enclosure (with perhaps a grilled outlook) and sheltered by trees or pergola structures (arbor or trellis) is an obvious example of this form.

**The design process.** The design process has been called in the past modes of composition and style or period selection. In the first quarter of the 20th century, the arts, including architectural, garden, and landscape design, were dominated by traditional, eclectic, preconceived systems of form and approach called the Beaux Arts system, after the famous school in Paris. In essence, these systems told designers what to design and where. Their only choice and their only skill lay in how to adapt preconceived systems—such as formal and informal gardens—to the particular problem at hand. Innovation consisted of timid new relationships among traditional elements.

In the first quarter of the century there also occurred what is called the modern revolt. Beginning in painting and sculpture, it soon swept through architecture and reached garden and landscape design toward the end of the quarter in Europe, reaching the United States in about 1935.

The essence of the modern revolt was the rejection of preconceived or traditional styles, periods, rules, regulations, or systems governing design. In place of these, systems and processes developed for analyzing problems and situations in their own terms and in terms of the modern resources available for solving them. Basic to the new theories was the idea that designed forms should arise from and express each specific situation and the contemporary, industrial culture around it. By the 1970s all fields of design seemed to be dominated by these theories; but, although submerged, traditional Beaux Arts design continues to surface regularly in strange new combinations with modern forms. A form of this eclecticism emerged in the early 1970s, when architects once again designed symmetrical monumental buildings with little functional or structural expression, and traditional formal-informal concepts in garden and landscape design began to reappear.

## PHYSICAL COMPONENTS

**Natural components.** Natural components of garden and landscape design include earth, rock, water, and plants.

**Earth.** As a base for design, earth is the floor of landscape spaces, the root medium in which half of every plant lives, the foundation for structures, the vehicle for surface and subsurface drainage of excess water, and a sculptural material in its own right.

As a floor, earth can be seen as an abstract surface. If apparently level, with just enough slope for drainage, it is ready to be covered with paving, grass, ground cover, or other planting, which is necessary to avoid dust in dry weather and mud in wet weather; if sloping or irregular, earthwork may be necessary to conform to new construction or to the design plan, to provide adequate drainage, or in order to relate properly to neighbouring topography and views.

As a root medium for plants, earth must be understood as soil. One must know the type and depth of soil before planning a garden or landscape. Soil occurs in layers: topsoil, in which there is a high percentage of organic humus and micro-organisms; subsoil, which is more sterile as it gets deeper; and bedrock, which is not yet broken up. There are many variations in these layers. In the mountains there may be only a few inches of soil over rock; in old valleys the soil may be hundreds of feet deep. Most plants require one to six feet of topsoil, with good drainage, but there are plants that will grow in rock, sand, sterile soil, boggy land, shallow water, or plain water. If the soil is not adequate for the planting desired or if the form of the earth is to be changed, then new soil conditions adequate for planting must be created.

As a foundation for structures, earth must be dry and firm. Although structures can be built in almost any soil conditions, they become more and more expensive as the earth becomes less dry and firm. Desirable foundation conditions, the exact opposite of the loose, moist soil that is best for most plants, create many technical problems in the relations between structures and plant areas.

As a drainage vehicle, earth absorbs a high percentage of the water that falls on its surface. This absorbed water may be stored below ground, or it may move horizontally through sloping soil patterns. Surface water that is not absorbed, either because the soil is saturated or because the slope of the ground makes it run off too fast, must drain away on the surface. This creates many technical problems, especially if the surface is not covered to prevent erosion or if a great deal of land is covered by roofed structures or paved surfaces, which increase the amount of water running off because none is absorbed.

As a sculptural material, earth can be contoured to conform with functional and maintenance demands. Rolling natural hills and golf-course earth forms demonstrate the potential. Slopes must not be too steep for planting to hold, unless they are structurally retained.

**Rock.** Rock is a major factor in some regions, minor in others, nonexistent in some. It varies in size from sand through pebbles, cobbles, boulders, and fixed outcrops to solid-rock mountains. It varies in form from square or jagged, newly cut or broken to rounded forms produced by the action of water. It varies also in colour and in texture. It can be used as a ground cover, dry or in cement; in vertical structures with various degrees of cutting and finishing; to simulate natural rock formations; and in sculptural groupings that emphasize the natural form of the rocks, as the Japanese do so well.

**Water.** Water is essential to all gardens and landscapes, even in the desert, although amounts vary considerably. As a design element, water contributes coolness, moisture, sparkle, lightness, depth, serenity, the possibility of aquatic plants and animals, and recreation. It may run through natural stream and river channels and collect in natural ponds, lakes, and seas, or it may be kept in structural channels and pools, recirculated to avoid waste. In some soil conditions it may be necessary to seal the bottoms of natural-appearing streams and

ponds to hold the water. Under natural conditions water runs downhill through naturally formed channels and collects in low spots or bowls of firm form. Water also may be pumped uphill or thrown into the air in jets and fountains. Water is used increasingly throughout countries with technically complex artificial irrigation systems, which become distinctive landscape elements.

**Plants.** Plants are considered the primary material of gardens and landscapes, by contrast with the concentration of structures in cities. They may be grouped and organized for design purposes in several ways: by size (trees, shrubs, low plants, grass); by form (vertical, horizontal, round, irregular); by texture (size, shape, and arrangement of foliage and structure); by colour (flowers, fruit, foliage, structure); by rate of growth (fast, medium, slow); by seasonal effect (spring, summer, fall, winter); by fragrance (flowers, fruit, foliage); by environmental requirements (soil, drainage, sun-shade, temperature range, pests and diseases, pruning needs). All of these properties affect the selection, arrangement, and maintenance of plants in designed landscapes.

Animals are also important in designed landscapes, particularly, of course, in zoos and agricultural scenes. The incompatibility of dogs and well-maintained gardens, however, is well-known.

Finally, people are prime elements in garden and landscape design, not only as clients and users but also as a visual component that brings life to landscape spaces and validates the success or failure of the design.

**Structural components.** Structural components of garden and landscape include structures closely related to the earth, enclosure structures, shelter structures, engineering structures, and special buildings.

**Earth-related structures.** Earth-related structures include paving (walks, roads, terraces, patios) and change-of-level structures (retaining walls, steps, ramps, bridges), which must be made of materials that will resist decay, such as brick, stone, concrete, asphalt. These structures provide the connections for movement and circulation and the areas for intensive gathering, social use, or active recreation. They embody a substantial and complex technology.

**Enclosure structures.** Enclosure structures, such as walls and fences, are designed to control vision or movement or both. They may be of various heights, three to ten feet (one to three metres) or more, and of many materials: brick, stone, or concrete masonry; wood; metal; sheet materials such as glass, plastic, asbestos, pressed boards. Because they are at eye level and extend and connect buildings, they are very important in intimate visual design.

**Shelter structures.** Shelter structures, designed to protect from sun, rain, or wind, may incorporate enclosure elements at the sides with overhead elements, which may

be open framework pergolas or arbors carrying vines or solid opaque or translucent roofs. Among such structures are gazebos, pavilions, garden temples, summer houses, hermit huts, follies, ruins, and grottoes.

**Engineering structures.** Engineering structures tend to appear unexpectedly, because incongruously, in gardens and landscapes. They are usually mechanical or electrical transformers, vents, valves, siphons, drains, culverts, headwalls, dams, and many other nameless and mysterious forms. In a good landscape design, these structures are integrated into the overall plan.

**Special buildings.** Special buildings include many that are nearly as complete as the fully enclosed buildings that are the province of the architect: greenhouses, conservatories, orangeries, tool sheds, dovecotes and pigeon houses, icehouses, root houses, bathhouses, playhouses, and many more. These are usually auxiliary in scale and detail in relation to the main house or other buildings but relate to them in character and detail.

Shelter structures, engineering structures, and special buildings are important in garden and landscape because they introduce precise geometric forms intermediate in scale between main buildings and landscape. If scattered or designed indiscriminately, they can destroy a pleasant landscape; carefully designed, they can be so grouped or arranged as to create rhythmic connections and patterns within the overall architectural-landscape design concept.

**Sculptural components and outdoor furnishings.** Sculptural components of garden and landscape have traditionally been predictable forms and types: figurative sculpture, decorative urns and plaques, fountains, sundials, birdbaths, cisterns, and wells. All of these continue to appear as elements of the persistent underground Beaux Arts vocabulary. In contemporary design, however, they are eliminated or take on new forms derived from modern sculpture. The possibility now exists for the production of gardens and landscapes so completely sculptured that one cannot tell where design stops and sculpture begins.

Outdoor furnishings and equipment include all of those fixed and movable elements that tend to appear in garden or landscape after the plans are done and installed and therefore without benefit of design control. In the garden they are seats, tables, barbecues, umbrellas, plant containers, supports, and guards, as well as lights and light systems. In the public landscape they include these garden elements and many more: signs, trash containers, alarm boxes, mailboxes, newsstands, kiosks, service elements, telephone stands. If all of these elements are not predicted insofar as possible in the original design plans, incorporated in them, and carefully controlled thereafter, they can destroy carefully planned landscapes. One red oil drum for trash can dominate the visual experience of a large, pastoral picnic area.

Importance of structures and buildings in design

## II. Kinds of design

The landscape is everything one sees from wherever one is, still or moving. The landscape as a work of individual art is any garden or estate space designed, developed, and maintained for the private experience of an individual or family, a space not accessible to others either physically or visually. The landscape as a work of collective art is everything beyond this private range: everything seen beyond the confines of private gardens or estates, all borrowed landscapes, all streetscapes, all city, metropolitan, and regional landscapes, and their accumulation in national, continental, hemispheric, and world landscapes. This collective art may be good or bad depending on whether it results from the accidental accumulation of individual and conflicting efforts or from controlled and planned efforts.

### PRIVATE OR RESIDENTIAL DESIGN

The history of landscape design is largely the history of landscape as a work of private, individual art. Plazas (structural public open spaces, not dominated by foliage), throughout classical, medieval, and Renaissance history, were the concessions of the ruling class to the need for public meeting places; but it was not until Central Park was developed in New York City in the mid-19th century that this need reached the level of designed public green spaces. During most of its history, landscape design was of three kinds: private utilitarian farms and gardens; private gardens in which the enhancement of the quality of living was paramount; and private gardens designed to express the power and benevolence of the ruling or upper classes. The expansion in scale of private gardens beyond the needs of private living led inexorably, first, to the dedication of such spaces to public use and then to the development of public gardens and parks designed for public use.

The private garden, however, has remained the centre for private fantasy and a means of escape from the grinding and difficult world of reality. The most important aspect of the private garden is its privacy: from the physical world, by means of distance and enclosure; from the social world, by separation and exclusion. Space and greenery are also important. The space may be very small, perhaps a tiny courtyard, and greenery limited to one or two plants, but these make possible that private world of fantasy that may make the difference between sanity and lunacy. The 20th-century mass migration to the suburbs is the latest expression of this need.

Generally, the private garden occupies a space some-

where between 20 feet square and one quarter of an acre (100 feet square). The forms of private gardens range from the formalism of pure geometry or the artistic representation of natural processes through the variations of standard gardening techniques and the informalism of letting nature take its course to various manifestations of literary, poetic, historic, and subjective concepts.

When housing moves from single-family, detached buildings on private lots to higher density variations—duplexes, semidetached villas, town houses, clusters, condominiums, low- and high-rise apartments—new relationships between private and public design develop. As population density increases, private design shrinks, and public design increases. Somewhere between the extremes of the single-family dwelling with minimum public space and the high-rise apartment with minimum private space there is an optimum relationship in which the real needs for both private and public space and facilities can be expressed. Perhaps the best potential lies in town-house, cluster-house, and condominium developments, in which there is a flexible relationship between public and private space and facilities.

### PUBLIC DESIGN

Because of fixation on the notion that the original resource of land and landscape, continuous from sea to shining sea, is best organized for private or public use by gridiron subdivision into innumerable separate parcels, public landscape design begins at the level of single buildings on single lots, with frontyards and backyards. The buildings may be government offices, quasi-public companies, or private corporations, but all tend to be designed in terms of public and private spaces, as though they were private residences for the groups involved.

Campus design begins when publicly accessible buildings grow into complexes of two or more, for religious, commercial, industrial, governmental, or educational use. Instead of or in addition to simple frontyard and backyard design, there are more complex systems of spaces between buildings, which vary from courtyards and quadrangles of varying forms and dimensions to passageways connecting them in varying widths and degrees of overhead coverage. The open spaces range in character from paved architectural courtyards and cloisters to open playing fields and parklike spaces. Campus design makes possible the richest, most complex and rewarding range of relationships between architectural and landscape design. Perhaps the best examples of campus design, in which the sequential experience of

indoor and outdoor space approaches the maximum, are the religious, educational, and civic complexes of Europe, developed before the idea of gridiron subdivision fragmented environmental design. There are also many fine examples in the United States of similar institutions that have transcended or resisted subdivision.

In the broader area of urban design, which deals with whole communities or sectors of urban areas, landscape architecture deals with such open-space components as public gardens, parks and playgrounds, plazas, squares, and malls. In these urban spaces, the designer attempts to meet the need for community, for play and recreation, for refreshment and relaxation, for individual withdrawal in a gregarious atmosphere. While in quantity they may be inadequate in comparison, say, to Europe, qualitatively the United States has many fine examples of public open spaces.

Towns, cities, and metropolitan areas may be said to have three basic components: buildings, designed by architects or builders; open spaces, designed by landscape architects or technicians; and circulation-utility corridors—the street, highway, railway, and rapid-transit systems—which are usually planned and designed by engineers.

The basic structure of urban areas consists of the open spaces together with corridors comprising a total open-space system, defined by and connecting the buildings. The corridors have usually been considered merely a utilitarian framework, connecting and servicing buildings and quality open spaces, channelling traffic and utilities throughout urban areas, and connecting them with the open country around. Modern urban thinking has begun to go beyond this concept, to see the total open-space-corridor system as the major qualitative structure of the city, which, when viewed in conjunction with overall building design, is seen to establish the city's basic character.

From this point of view the role of landscape architecture, once limited to tasteful planting of corridors designed by engineers, begins to expand. Some urban plan-

ners would expand it even further, believing that open-space corridors should be designed throughout primarily as social spaces for people and only secondarily as utilitarian passages for vehicles.

Commemorative sites—cemeteries, historic spots, battlefields—are important to man because they memorialize and symbolize important events in personal, local, national, or world history. Wherever they occur—in urban, rural, or primeval areas—these sites or areas are marked with stone or bronze memorials and often dramatized with more elaborately designed developments. The designs tend to follow traditional and conservative precedents, often impressive but seldom imaginative. It is still difficult to equal Asplund's Forest Crematorium (1940) in Stockholm or the Fosse Ardeatine memorial in Rome. (G.Ec.)

### III. Historical development

#### WESTERN

**Antiquity.** *Egyptian.* The earliest surviving detailed garden plan, dating from about 1400 BC, is of a garden belonging to an Egyptian high court official at Thebes. The main entrance is aligned on a pergola (trellis-bordered) walk of vines leading directly to the dwelling. The rest of the garden is laid out with tree-lined avenues, four rectangular ponds containing waterfowl, and two garden pavilions. Although rigidly symmetrical, the garden is divided into self-contained, walled enclosures, so that the symmetry of the whole could not have been apparent to the viewer. Such a highly developed pattern argues a considerable incubation period, and it is likely that similar enclosed pleasure gardens had been designed as early as 2800 BC.

*Assyrian, Babylonian, and Persian.* The gardens of Assyria, Babylon, and Persia were of three kinds: large, enclosed game reserves such as the garden of Eden described by the Hebrews in the Old Testament; pleasure gardens, which were essentially places where shade and cool water could be privately enjoyed; and sacred enclosures rising in man-made terraces, planted with trees

and shrubs, forming an artificial hill such as the Hanging Garden of Babylon.

**Greek and Hellenistic.** The urban life of ancient Greece led to the development of houses built around central, private courtyards. Lined with colonnades that gave access to the rooms of the house, the courtyard, or peristyle, was open to the sky and insulated from the street. In the peristyle was a garden consisting of a water supply and potted plants. Much of life, however, was lived in public. The sports grounds, where exercise was taken, became popular gathering places and developed into the original academy and lyceum, which included the exercise ground, seats for spectators, porticoes for bad weather, statues of honored athletes, and groves of shade trees. These public recreation grounds (academies and lyceums) set the type for the later classical Roman villa garden and the 19th-century European public park. A third type of garden familiar to the Greeks was the sacred landscape, such as the Vale of Tempe or the mountain sanctuary of Delphi.

The relatively austere Greek taste was transformed in the Hellenistic Age (c. 323 BC–30 BC) by the influence of the East. Luxurious pleasure grounds were made, especially at colonies such as Alexandria and Syracuse. These gardens were conspicuously luxurious in their display of precious materials, and artificial in their use of hydraulic automata.

**Roman.** Roman gardens derived from the Greek, those in the seaside resorts of Pompeii and Herculaneum (1st century BC) following the Hellenistic pattern. These small, enclosed town gardens were visually extended by landscapes painted on the walls. Throughout the imperial period, the more ambitious villa gardens flourished in many forms on sites carefully chosen for climate and aspect.

The most elaborate was that of Nero's Golden House, which covered over 300 acres (120 hectares) in the middle of Rome and included an artificial lake (where the Colosseum now stands) and a theatrically pastoral landscape of plowland, vineyard, pasture, and wood. More influential in later times was the vast garden complex of Hadrian's Villa, of which extensive ruins can still be found near Tivoli.

**Middle Ages.** The barbarian invasions of the 4th and 5th centuries AD destroyed Roman civilization and with it the gardens of western Europe. The Eastern Empire, centred on Constantinople, retained its hold on Greece and much of Asia Minor for another millennium; and Byzantine gardens persisted in the Hellenistic tradition, laying more emphasis on wonder-provoking apparatus than on aesthetic values. A recurrent feature of these gardens was a tree of gold or silver equipped with birds that flapped their wings and sang and branches that sprayed wine or perfume.

**Islāmic.** Beginning in the 7th century, the Arabs progressively captured much of western Asia, Egypt, the whole of the North African coast, and Spain; in the process, they spread features of Persian and Byzantine gardens across the Mediterranean as far as the Iberian Peninsula. Most characteristic of these gardens was the use of water—the ultimate luxury to desert dwellers, who appreciated it not only because it allowed plants to grow but also because it cooled the air and gratified the ear with the sound of its movement. It was commonly used in regularly shaped, often rectangular, pools. The

water was kept moving by simply designed fountains and fed by narrow canals resembling agricultural irrigation channels. Because water was rarely abundant, the pools were shallow but increased in apparent depth by a blue tile lining.

These pools of water graced Islāmic gardens—such as those of the Alhambra in Granada—that resembled the Hellenistic colonnaded courtyard. The gardens provided shade, excluded hot winds, and created the sense of being in a jewelled private world, insulated from normal pressures. Expanses of water mirroring the sky gave an impression of spaciousness and introduced lightness, brightness, and an air of unreality to the enclosed space. In the Moorish Caliphate of Cordoba in Spain, in the valley of the Guadalquivir, there were said to have been 50,000 villas, all of which probably had such garden courts.

The greatest period of garden making in the Islāmic world was the 14th century. In the vicinity of the conqueror Timur Lenk's capital of Samarkand, the names of 11 royal gardens are recorded, and there were probably others belonging to his nobles. Whereas gardens of the Alhambra type were architecturally conceived within the total plan of a building, some of the more extensive Timurid gardens and their derivatives, the Mughal gardens of India, were pleasantries of water, meadow, trees, and flowers, in which buildings took a subordinate place. Although these garden buildings were permanent, their subordinate role and the lightness and luxuriating frivolity of their design mark them as heirs of the casually positioned tents seasonally erected in hunting parks. There were also gardens of strictly architectural design—huge walled enclosures with corner towers, a central palace, regularly disposed avenues, and tanks of water. Deer and pheasants were kept in these gardens, which combined the quality of hunting park and of *hortus conclusus*, or closed garden. Trees were planted sometimes in regular quincuncial patterns (one in the middle and one at each corner of a square or rectangle) but more often freely. In all types of Islāmic gardens, flowers were lavishly used. Their presence was even simulated in

garden carpets and in the woven hangings that were used as temporary screens.

Influential on later Western practice were the parks made by the Saracen emirs of Sicily. The Normans who conquered the Saracens in the 11th century adopted the manner of life of those they had overthrown, and thus the emirs' gardens survived their makers. A large area of the Conca d'Oro, the great natural amphitheatre behind Palermo, was taken up with pleasure grounds—walled enclosures large enough to contain woods and hills, canals, artificial lakes, groves of oranges and lemons, fountains, water stairways, and wild creatures running free.

*Western European.* In Europe, beyond the limits of the Islāmic conquest, the destruction of civilized society by the barbarian tribes had been nearly complete; but the physical remains of the past shaped the reviving future: the peristyle gardens of Roman villas became the cloisters of Christian basilicas. Security and leisure existed only in the monastic system, which also preserved some of the traditional skills of cultivation. For some time the only type of garden was the cloister, with its well, herbs, pot plants, and shaded walk. Then secular gardens began to appear, but they were usually of limited extent, confined within the fortifications of a castle and often raised well above ground level on a battlemented turret. These Gothic gardens were rectangular, with the traditional division into four parts by paths, the quarters again subdivided according to the amount of ground available and the convenience of cultivation. At the point of principle intersection was a well, which, when elaborated, became the vertical feature of the garden. Seats—often of turf—were constructed in the walls. Many flowers were grown, but their season was short; after June and often earlier, the beds were flowerless. More extensive and elaborate gardens were rare.

In 13th-century Italy, through the influence of the Holy Roman emperor Frederick II, who had spent much of his youth in Sicily, the example of the Saracen emirs was felt in Apulia and Naples. The *Triumph of Death*, painted by the Florentine artist Andrea Orcagna (Pisa, Campo Santo), shows a garden of considerably greater

extent than the cloister or battlement type. Gardens like this existed also in Lombardy, where the court of Gian Galeazzo Visconti, the founder of the great walled park of Pavia, cultivated the arts of civilized life. In describing the Royal Gardens at Naples, the writer and poet Giovanni Boccaccio speaks of statues disposed regularly around a lawn, interspersed with marble seats. Such a garden suggests that Frederick II's classicizing influence extended into the mid-14th century. Also significant was the garden of Hesdin in Picardy, which became famous throughout France for its automata and water tricks. It was made by a crusader who, having returned to France by way of Palermo in 1270, no doubt incorporated in his garden what he had seen of Saracenic gardens there and in Syria. In northern Europe, Hesdin was an exotic creation without parallel for several centuries.

**Renaissance to modern: 15th to 20th centuries. Italian.** The increasing prosperity of western Europe and man's increasing confidence in himself and in his capacity to impose order on the external world was reflected in the gardens of Italy by the mid-15th century. The change began near Florence, where the old medieval enclosures began to open up. The rectangles, which had been dissociated, were now sited one behind the other, thus prolonging the main axis, which was now aligned on the centre of the dwelling. This change inevitably introduced the idea that house and garden were a coherent, complementary whole. And, because villas were increasingly sited for amenity rather than defense, gardens became less enclosed, more susceptible first to visual, then to actual extension.

The unity of house and garden, together with the need for physical adjustment to the sloping sites favoured by classical precedent, threw the planning of the new Renaissance garden into the hands of architects. Most influential was the garden courtyard designed by Donato Bramante at the Vatican to link the Papal palace with the Villa Belvedere; the uneven site and the disparity in bulk of the two buildings was overcome with terraces and stairways. It remained an enclosed garden but one far removed from the earlier cloistral courtyards. The garden of the Belvedere combined the function of an open-air room with that of an outdoor sculpture gallery.

The ingredients of the Renaissance garden thus separately established were united in varying proportions. The typical evolved garden of the period was characterized by some openness of aspect, axial development, a tendency to prolongation, unity of concept between house and garden emphasized by a considerable "built"

element of stone, lavish employment of statuary (often in the form of fountains), and the proliferation of such classical accents as grottoes, nymphaea (Roman buildings with a fountain, plants, and sculpture), urns, and inscriptions. There is no adequate evidence that this type of garden had an exact equivalent in the classical period, although there is evidence that each of its elements existed.

The variation in style among Italian gardens is considerable and is due not only to the date they were made, the exigencies of the site, and regional variation but also to their social function. The scale of the garden compartments at the back of the Villa Gamberaia at Settignano (1610), for example, is small in contrast with the extensive view over Florence from the front and thus suggests intimate use by members of a small household. The more extensive parterre garden (an ornamental garden with paths between the beds) of the Villa Lante at Bagnaia (begun 1564) is designed neither for solitary enjoyment nor for a crowd but for a select, discerning company—as is the garden of the far more splendid Villa Farnese at Caprarola (completed 1587). The most remarkable mid-16th-century garden, that of the Villa d'Este at Tivoli (1550), is situated on a steep slope of the Sabine hills. The river that plunges down this slope is harnessed to an astonishing variety of fountains, including a "water organ." Although the garden is designed around a central axis, the stream is not used centrally but is led about the garden in order to take maximum advantage of its force. Unlike the less copious stream of the Villa Lante garden, which quietly emphasizes the central axis, the Tivoli stream is ostentatious. The Villa d'Este is, in fact, a spectacular permanent theatrical performance meant to astonish and impress the multitude. A different impression is given by the Boboli Gardens of the Pitti Palace at Florence (1550). Though, like the Villa d'Este gardens, they were designed for a crowd—specifically, for state functions—they are not dramatic in themselves. Unless used ceremonially, they are lifeless and arid. The ruined garden associated with, though detached from, the Orsini Castle at Bomarzo is a remarkable aberration. Its original layout probably consisted of a grove in which were concealed the stone giants and strange monsters that now astonish visitors. The garden reflects the strained individualism of the mid-16th-century style termed Mannerist.

Flowers were extensively used in most Italian gardens, but because of the shortness of their season they could not be the principle feature. Beds were divided into decorative geometric compartments by trimmed herbs, rosemary, lavender, or box. In general, more emphasis was

given to evergreens; ilex, cypress, laurel, and ivy gave shade and were an enduring contrast to stonework.

**17th- and 18th-century French.** The French invasions of Italy in the last quarter of the 16th and first quarter of the 17th centuries introduced to France the idioms of the Italian garden. The first garden coordinated with dwelling appeared at the Château of Anet (1547–56) and was designed by the architect Philibert Delorme; but, despite its evident sophistication, it remained an inward-looking, essentially medieval garden. The first sign of prolongation and calculated extension of vision beyond the garden proper appeared in the grounds of Dampierre. Here the moat that formerly surrounded French castles became an ornamental body of water on one side and a decorative canal on the other. Both aspects of the new garden design—coordination with the dwelling and extension along a central axis—were united at the château of Richelieu (1631) and later at Vaux-le-Vicomte (completed 1661),

the château of Nicolas Fouquet, the minister of finance. On Fouquet's fall in the mid-17th century, his team of artists—which included the landscape designer André Le Nôtre—was taken over by the young Louis XIV, and the gardens of Versailles were begun.

The French version of the Italian garden was created in the plain of north France, which largely conditioned the manner of its development. The array of steep terraces linked by stairways, which characterized the Villa d'Este and many others, was predominant in France only at St. Germain-en-Laye, where the steep site permitted it. Elsewhere, grandeur on the scale that competitive pride demanded was achieved by extraordinary extension: an axial development suggesting a domain coextensive with the world. The French 17th-century garden, a manifestation of Baroque taste, required variety as well as unlimited vista and achieved it with fountains, parterres, and lesser gardens disposed within the boscaiges (wooded enclosures) that flanked the central axis. These hidden gardens were the successors of the *giardini segreti* of the Italians but had a different function; they were not retreats for private contemplation or intimate conversation but the setting for ingenious theatrical entr'actes. Distinctively French was the unified and elaborate treatment of the compartmentalized garden beds, which the Italians had made in a variety of forms. These *compartiments de broderie* were arabesques, sometimes of box edging and flowers but more often of coloured stones and sand. The Persians had copied their flower gardens on carpets and taken them indoors; the French laid out their grounds in the form of carpets. The French garden was marked by a ruthlessly logical extension of practices that had been empirically evolved in Italy.

French cultural dominance of Europe in the early 18th century led to an almost universal adoption of Versailles as the model for palatial gardens. Even at Naples, where the gardens of Poggio Reale had astonished the invading French in the late 15th century, a vast layout inspired by the axial extent of Versailles was developed at Caserta; and, as far away as Peter the Great's Peterhof in Russia, a pseudo-Versailles was laid out by the French gardener Alexandre-Jean-Baptiste Le Blond. Impressive exercises in the same manner were carried out in Germany and Austria. In Holland, also, the example of the French garden was irresistible, although local conditions as well as

national temperament led to regional variation. Because Dutch canals were busy highways, they generally flanked gardens rather than constituted the main axis. No luxury in Holland, water was less extravagantly used than in drier, hotter climates. Moreover, fountains were less common because the absence of high ground required that they be power driven. Finally, because stone was scarce, terraces were usually held by turf banks rather than by retaining walls, and sculpture was often of lead. Another kind of sculpture typical of the Dutch garden was topiary: trees and shrubs were trained, cut, and trimmed into sculptural, ornamental shapes. Social conditions made the apparent extension of a geometric garden scheme easy, for a man-made landscape already existed in the intensively cultivated Netherlands. In Spain, aridity as well as Islāmic tradition perpetuated the patio garden, a room of air and shade in the tradition of the Greek peristyle. Although a famous layout in the French style was made on high ground at La Granja, where the cooler air and an ample head of water made it acceptable, the classical extension garden remained basically alien to the Iberian Peninsula.

*17th- and 18th-century English.* The Italian pronouncement "things planted should reflect the shape of

things built" had ensured that gardens were essentially open-air buildings and the making of them the province of architects. Before the 18th century, geometric regularity had been applied in great details of design and in small. England was committed to a version of the French geometric extension garden but with an emphasis on characteristic English grass lawns and gravel walks. Whereas the typical French vista was along the main axis, with subordinate vistas at right angles to it, in the two most influential gardens in England, St. James's and Hampton Court, the vistas sprang like the rays of the sun from a semi-circle. With the accession of William and Mary (1689–1702), Dutch influence led to widespread use of topiaried yew and box.

In 18th-century England, man became increasingly aware of the natural world of which he was a part. Rather than imposing his man-made geometric order on the natural world, he began to consider adjusting his own life to it. Literary men, notably Alexander Pope and Joseph Addison, began to question the propriety of trees being carved into artificial shapes as substitutes for masonry and to advocate the restoration of free forms.

The man who led the revolt against the "artificial," symmetrical garden style was the painter and architect William Kent, the factotum of the Earl of Burlington. Together Burlington and Kent created at Chiswick House (1734) a garden with a meandering stream and an "irregular" path. As the writer Horatio Walpole put it, Kent's "principle was that nature abhors a straight line." The process of relaxing the garden's architectural discipline advanced with speed. At Stowe, Buckinghamshire, the original enclosed, geometrical garden was amended over the years until a totally different, "irregular" formality was achieved. Trees, for example, were allowed to assume their natural forms, and a large expanse of water was redesigned into two irregularly shaped lakes.

The use of the ha-ha, or sunken fence, to create and at the same time conceal the physical division between garden and contiguous park grounds (a division needed to keep grazing animals out of the garden) was a major step in the creation of the new, "natural" garden. Walpole explains the purpose of the visual unification:

The contiguous ground of the park without the sunk fence was to be harmonized with the lawn within; and the garden in its turn was to be set free from its prime regularity, that it might assort with the wilder country without.

The face of the "country without" was altered by the rage that afflicted the English nobility for planting vast areas of trees. Much of England was covered with new parks, traversed by rides and avenues that primarily were conceived as visual extensions of the garden paths. The

unification of park and garden was virtually completed by Lancelot “Capability” Brown (1715–83) by the simple expedient of making the garden into a park. “Capability” (so-called because he always spoke of a place as having “capabilities of improvement”) developed the current aesthetic that an undulating line was “natural” and that it was the “line of beauty” by using little statuary and few buildings and concentrating on designing landscapes according to nature’s harmonies and gradients. His landscapes consist of expanses of grass, irregularly shaped bodies of water, and trees placed singly and in clumps.

Although the adherents of the new English school of garden design were in agreement in their abhorrence of the straight, classical line and the geometrically ordered garden, they did not agree on what the natural garden should be. Unlike Brown, for example, the taste for the romantic and the literary led many to seek inspiration in the dramatic and the bizarre, in the remote past, and in remote, exotic places. The Brownian style was strongly challenged, for example, by the “Picturesque” school, led by Sir Uvedale Price and the artist-parson William Gilpin, who argued, quite correctly, that the “naturalism” of the Brownians was no less unnatural than the geometric regularity of Le Nôtre’s Versailles and that sudden declivities, rocky chasms, and rotting tree trunks (all deliberately designed) were more proper for the natural garden than were enormous, undulating meadows accented with tight clumps of thickly planted trees. Another school of opinion created what might be called the English garden of poetic bric-a-brac. The aim in this garden was to create an air of accident and surprise and to arouse varied sensations (solemnity, sublimity, terror) in the viewer—sensations evoked by associations with the remote in time and space. Wandering through the grounds one came upon classical statues, urns, and temples; Gothic ruins, ivy-covered and inhabited by owls; or Chinese pagodas and bridges. After Horatio Walpole recorded the first appearance of chinoiserie at Wroxton in 1753 (a garden no doubt laid out some years before), “Chinese” and Gothic details were featured, together with classic temples, in most fashionable grounds.

By 1760 the enthusiasm for this style had diminished in

England; but in Europe the poetic bric-a-brac garden (*le jardin anglo-chinois*, or *le jardin anglais*, as the French called it) was almost as widely emulated as Versailles had been. In Italy, for example, Renaissance gardens were destroyed to make way for the new fashion, as at the Villa Mansi near Lucca. In France, the sculpted group of “Apollo Attended by the Nymphs” was removed from the classical “Grotto of Thetis” on the terrace of Versailles to a secluded boscage garden, where it was housed under ornamental “Turkish” tents; eventually it was moved from there to a simulated rocky cavern in the *jardin anglais* of the Petit Trianon. The *jardin anglais* was to be found even at Queluz in Portugal and in the Potsdam garden of Frederick the Great of Prussia.

**19th century.** Increasing world trade and travel brought to late-18th-century Europe a flood of exotic plants whose period of flowering greatly extended the potential season of the flower garden. Although the emphasis in Italian Renaissance gardens, in the classical Baroque gardens of France, in the lawns and gravelled walks of 17th-century England, and in the Brownian park garden was upon design, they had rarely been totally without flowers. In most gardens flowers were grown, sometimes in great numbers and variety; but flower gardens in the modern sense were limited to cottages, to small town gardens, and to relatively small enclosures within larger gardens. The accessibility of new plants, together with avidity for new experience and a high-minded concern with natural science, not only gave renewed life to the flower garden but was the first step toward the evolution of the garden from work of art to museum of plants. A compromise between the new flower garden and the Brownian park was effected by Humphry Repton. He was largely responsible for popularizing the open terrace overlooking the park, which frankly admitted the different functions of park and garden and also emphasized their stylistic disharmony. The plant collectors’ garden, or “gardenesque” style, was most strongly advanced by J.C. Loudon in the mid-19th century. Loudon urged that garden making be taken out of the hands of the architect, the painter, and the cultivated dilettante and left to the professional plantsman.

English  
influence  
on  
European  
gardens

The undiscerning use of the new palette that importation and plant breeding had made available was so patently an aesthetic disaster that by the end of the 19th century attempts were made to break its hold. The architect Sir Reginald Blomfield advocated a return to the formal garden, but to this, insofar as it required dressed stonework, there were economic objections. More successful and more in tune with the escapist needs of the increasing number of urban dwellers were the teaching and practice of William Robinson, who attacked both the old ceremonial garden and the collectors' garden with equal vigour and preached that botany was a science, but gardening was an art. Under his leadership a more critical awareness was brought to the planning and planting of gardens. His own garden at Gravetye Manor demonstrated that plants look best where they grow best and that they should be allowed to develop their natural forms. Adapting Robinson's principles, Gertrude Jekyll applied the cult of free forms over a substructure of concealed architectural regularity, bringing the art of the flower garden to its highest point.

In North America, where for a long time most men were preoccupied with making a world, not a garden, ornamental gardens were slow to take hold. In the gardens that did exist, the rectilinear style popular in late-17th- and early-18th-century Europe persisted well into the 18th century—perhaps because it met man's psychological need to feel he could master a world that was still largely untamed. The town gardens of Williamsburg (begun in 1698) were typical of the Anglo-Dutch urban gardens that were being attacked everywhere in 18th-century Europe except Holland. And Belmont, in Pennsylvania, was laid out as late as the 1870s with mazes, topiary, and statues, in a style that would have been popular in England about two centuries before.

Although garden improvers set up in business in the United States, there is no evidence that they prospered until the 19th century, when one hears of André Parmentier, a Frenchman, who worked on Hosack's estate at Hyde Park and then of A.J. Downing, a successful protagonist of the gardenesque, who was succeeded by Calvert Vaux and Frederick Law Olmstead (the latter the originator of the title and profession of landscape architect), the planners of Central Park in New York (begun 1857) and of public parks throughout the country.

The eclecticism of the 19th century was universal in the Western world. Besides the gardens that were fundamentally Reptonian—that is, an attempted compromise between the Brownian park garden and the Loudonian flower garden—gardens of almost every conceivable style

were copied; designing teams such as Sir Charles Barry, the architect, and William Eden Nesfield, the painter, in England, for example, produced Italianate parterres as well as winding paths through thickets.

**Modern.** A sense of history still plays a part in 20th-century gardening. The desire to maintain and reproduce old gardens, such as the reconstruction of the 16th-century gardens of Villandry in France and the colonial gardens of Williamsburg in the United States, is not peculiarly modern (similar things were done in the 19th century); but, as man increasingly needs the reassurance of the past, it is likely to be, within limits, an accelerating process. Attempts to create a distinctive modern idiom are rare. Gardens large by modern standards are still made, in styles that vary from a version of the grand early-18th-century manner at Anglesey Abbey in Cambridgeshire to an inflated Jekyllism crossed with gardenesque at Bodnant near Conway. An air either of controlled wilderness or of slightly run-to-seed orderliness is preferred. Modern public gardens, which have evolved from the large private gardens of the past, seek instant popular applause for the quantity and brightness of their flowers. In Brazil Roberto Burle Marx uses tropical materials to give an air of contemporaneity to traditional modes of design. Gardens frequently reflect Japanese influence, particularly in America.

Most characteristic of the 20th century is functional planning, in which landscape architects concentrate upon the arrangement of open spaces surrounding factories, offices, communal dwellings, and arterial roads. The aim of such planning has been to provide, at best, a satisfactory setting for the practical aspects of living. It is gardening only in the negative, "tidying up" sense, with little concern for the traditional garden purpose of awakening delight. So starved has the spirit of those living in heavily populated regions become, however, that demands grow more and more insistent for gardening in the positive sense—for environmental planning with a chief goal not of facilitating man's economic activities but of refreshing his spirit.

Functional  
planning

#### NON-WESTERN

**Chinese.** Western gardens for many centuries were architectural, functioning as open-air rooms and demonstrating Western man's insistence on physical control of his environment. Because of a different philosophical approach, Oriental gardens are of a totally different type.

China—which is to Eastern civilization what Egypt, Greece, and Rome are to Western—practiced at the beginning of its history an animist form of religion. The

States

sky, mountains, seas, rivers, and rocks were thought to be the materialization of spirits whom men regarded as their fellow inhabitants in a crowded world. Such a belief emphasized the importance of good manners toward the world of nature as well as toward the world of men. Against this background the Chinese philosopher Lao-tzu taught the quietist philosophy of Taoism, which held that one should integrate oneself with the rhythms of life; Confucius preached moderation as a means of attaining spiritual calm; and the teaching of Buddha elevated the attainment of calm to a mystical plane.

Such a history of thought led the Chinese to take keen pleasure in the calm landscape of the remote countryside. Because of the physical difficulty of frequent visits to the sources of such delight, the Chinese recorded them in landscape paintings and made three-dimensional imitations of them near at hand. Their gardens were therefore representational, sometimes direct but more often by substitution, making use of similar means to recreate the emotions that choice natural landscapes evoked. The kind of landscape that appealed was generally of a balanced sort; for the Chinese had discovered the principle of complementary forms, of male and female, of upright and recumbent, rough and smooth, mountain and plain, rocks and water, from which the classic harmonies were created. The principle of scroll painting, whereby the landscape is exposed not in one but in a continual succession of views, was applied also in gardens; and grounds were arranged so that one passed pleasantly from viewpoint to viewpoint, each calculated to give a different pleasure appropriate to its situation. A refined and expectant aestheticism, which their philosophy had inculcated, taught the Chinese to ignore nothing that would prepare the mind for the reception of such experiences, and every turn of path and slope of ground was carefully calculated to induce the suitable attitude. As the garden was in effect a complex of linked, related, but distinct sensations, seats and shelters were situated at chosen spots so that the pleasures that had been meticulously prepared for could be quietly savoured. Kiosks and pavilions were built at places where the dawn could best be watched or where the moonlight shone on the water or where autumn foliage was seen to advantage or where the wind made music in the bamboos. Such gardens were intended not for displays of wealth and magnificence to impress the multitude but for the delectation of the owner, who felt his own character enhanced by his capacity for refined sensation and sensitive perception and who chose friends

to share these pleasures with the same discernment as he planned his garden.

Based on natural scenery, Chinese gardens avoided symmetry. Rather than dominating the landscape, the many buildings in the garden "grew up" as the land dictated. A fanciful variety of design, curving roof lines, and absence of walls on one or on all sides brought these structures into harmony with the trees around them. Sometimes they were given the rustic representational character of a fisherman's hut or hermit's retreat. Bridges were often copied from the most primitive rough timber or stone-slab raised pathways. Rocks gathered from great distances became a universal decorative feature, and a high connoisseurship developed in connection with their colour, shape, and placement.

Although the troubled 20th century has largely destroyed the old gardens, paintings and detailed descriptions of them dating from the Sung dynasty (AD 960–1279) reveal a remarkable historical consistency. Nearly all the characteristic features of the classic Chinese garden—man-made hills, carefully chosen and placed rocks, meanders and cascades of water, the island and the bridge—were present from the earliest times.

Chinese gardens were made known to the West by Marco Polo, who described the palace grounds of the last Sung emperors, during whose reign the arts were at their most refined. Other accounts reached Europe from time to time but had little immediate effect except at Bomarzo, the Mannerist Italian garden that had no successors. In the 17th century, the English diplomat and essayist Sir William Temple, sufficiently familiar with travellers' tales to describe the Chinese principle of irregularity and hidden symmetry, helped prepare the English mind for the revolution in garden design of the second quarter of the 18th century. Chinese example was not the sole or the most important source of the new English garden; but the account of Father Attiret, a Jesuit at the Manchu court, published in France in 1747 and in England five years later, promoted the use of Chinese ornament in such gardens as Kew and Wroxton and hastened the "irregularizing" of grounds. The famous *Dissertation on Oriental Gardening* by the English architect Sir William Chambers (1772) was a fanciful account intended to further the current revolt in England against the almost universal Brownian park garden. Influence of the West on Chinese gardens was slight. Elaborate fountain works, Baroque garden pavilions, and mazes—all of which the Jesuits made for the imperial garden at Yüan Ming

Yüan—took no root in Chinese culture. Not until the 20th century did European regularity occasionally become evident near the Chinese dwelling; at the same time, improved Western hybrids of plant species that had originated in the East appeared in China.

**Japanese.** Chinese culture permeated the Far East and, by way of Korea, infiltrated Japan. By the year AD 1000 Japan was already developing a distinctive national art best described as a stylized, ritualistic version of the Chinese. The typical early Japanese garden lay to the south of the dwelling and consisted of a narrow pond or lake orientated through its longer axis and containing an

William G. Froelich, Jr.

island. At the north end of the pond was an artificial hill from which a secondary stream descended in a cascade. These stereotyped gardens of the Heian period (AD 794–1185) show by their careful reproduction of magical detail that they derive from a single prototype—certainly Chinese. Variation entered only through the compulsion of the site and the detailed handling of stones and trees.

Creativity began to replace imitation in the Kamakura period (1192–1333). Although there were many subsidiary styles, gardens were broadly classified, according to terrain, as either hill or flat. The hill garden, consisting of hills and ponds, came to be associated with Mt. Fuji, the mountain of ideal form. The flat garden represented a surface of water—lake or sea—with its adjacent shores and islands. Since the scale was so small—a heap of earth 30 feet (nine metres) high representing a mountain and a half-acre (0.2-hectare) pond, an arm of the sea—the intention was to reproduce the spirit rather than the features of the chosen landscape. Association and symbolism thus played a major role in the creation and appreciation of these gardens.

The scaling down of landscapes to garden size was logically continued to the point where miniature gardens were made in trays as small as a foot square containing lakes, streams, islands, hills, bridges, garden houses, and real trees painstakingly cultivated to an appropriate scale. These small, portable gardens reflected the extreme of the picturesque tradition of Oriental gardening.

Two characteristic Japanese styles are the abstract garden and the tea garden. The most famous example of the

former is the garden of the Ryōan-ji in Kyōto, where an area about the size of a tennis court is covered with raked sand and set with 15 stones divided into five groups. If anything is represented here, it is some rocky islets in a sea, but the appeal of the garden lies essentially in the charm of its relationships. The Japanese tea garden grew out of an esoteric ritual originated in China and connected with the taking of tea. The tea cult, which flourished from the 14th to the end of the 16th centuries, was calculated to instill humility, restraint, sensibility, and other cognate virtues. The gardens through which the guests approached the teahouse were governed by severe rules of design intended to create an appropriate spiritual atmosphere, such as the “lonely precincts of a secluded mountain shrine” or “a landscape in clouded moonlight, with a half-gloom between the trees” or any mood “in harmony with the spirit of tea.” Even the precise number and arrangement of nails in the teahouse door were specified.

The Japanese fondness for systematization led them to classify garden treatment as well as subject. Three standard treatments were recognized: the elaborate, the moderate, and the modest. Once the degree of finish was determined, certain rules were followed to preserve consistency. The Taoist doctrine of complementary forms was at the root of much Japanese design, but the cult of stones is also central to Japanese gardening. The nine stones, five standing and four recumbent, used in Buddhist gardens were symbols of the nine spirits of the Buddhist pantheon; the shapes and postures chosen were presumed to have a relationship with the character and history of the persons represented. Sacred associations played a part in profane gardens as well. It was regarded as inauspicious, for example, if three stones, the “Guardian Stone,” the “Stone of Adoration,” and the “Stone of the Two Deities” (or the “Stone of Completeness”), were not present. In addition to the sacred symbols, a whole armoury of poetic associations and symbols grew up, and stones, according to their shape and use, acquired such names as “Torrentbreaking Stone,” “Recumbent Ox Stone,” “Propitious Cloud Stone,” and “Seagull-resting Stone.” Beyond what they represented, stones were part of an aesthetic design and had to be placed so that their positions appeared natural and their relationships harmonious. The concentration of the interest on such detail as the shape of a rock or the moss on a stone lantern led at times to an overemphatic picturesqueness and an accumulation of minor features that, to Occidental eyes accustomed to a more general survey, may seem cluttered and restless. Nevertheless, Japanese gardening has had and continues to have an influence on the gardens of the West, particularly in the United States. The influence appears not so much in direct imitation of Japanese themes as in the selection and presentation of detail.

**Indian.** The influence of Chinese culture throughout the East was such that other indigenous cultures usually succumbed to it; but India was an exception. Western garden styles were introduced into northern India first through contact with Iranian culture, then by the invasion of Alexander the Great and the subsequent Hellenistic influence, and, finally, by the invading Mughals, who introduced the Islāmic garden. In southern India and in Ceylon elaborate gardens existed before the birth of the Buddha (563? BC). In such a garden—containing baths, lotus-covered pools, trees, and beds of flowers—the Buddha himself was born beneath a tree. Anciently worshipped by the Hindus, trees thus acquired an additional sanctity. Buddhist temples were associated with gardens whose purpose was to promote contemplation and whose preferred sites were therefore away from cities.

**African, Oceanic, and pre-Columbian.** The African cultures beyond European and Asiatic influence did not evolve pleasure gardens, although in their more settled societies a beginning had perhaps been made. Nor is more than a love of flowers and a casual cultivation of decorative plants recorded of the Oceanic peoples; but of the Aztecs of Mexico and the Incas of Peru the conquistadors reported elaborate gardens with terraced hills, groves, fountains, and ornamental ponds that were es-

entially royal pleasure grounds, reflecting a need for private solace and public display not unlike contemporary gardens in the West. (D.P.Cl.)

**BIBLIOGRAPHY.** The 19th and 20th centuries have seen a spate of gardening literature, both of the how-to-do-it variety and of specialized studies of national types. General works include DEREK CLIFFORD, *A History of Garden Design*, 2nd ed. (1966), an attempt to relate garden design to cultural history; and MARIE LUISE GÖTHEIN, *A History of Garden Art*, 2 vol., trans. from the German by MRS. ARCHER-HIND (1928), the most valuable detailed general history.

*National Studies:* (America): WILLIAM COBBETT, *The American Gardener* (1821); A.J. DOWNING, *A Treatise on the Theory and Practice of Landscape Gardening* (1841); C.L. OLMSTEAD, *Forty Years of Landscape Architecture*, 2 vol. (1922-28; reprinted in 1 vol., 1970), (Brazil): P.M. BARDI, *The Tropical Gardens of Burle Marx* (1964). (China): OSVALD SIREN, *Gardens of China* (1949). (Great Britain): ALICIA AMHERST, *A History of Gardening in England*, 3rd ed. (1910); SIR REGINALD BLOMFIELD and F. INIGO THOMAS, *The Formal Garden in England*, 3rd ed. (1901, reprinted 1936); M. HADFIELD, *Gardening in Britain* (1960); CHRISTOPHER HUSSEY, *English Gardens and Landscapes, 1700-1750* (1967); EDWARD S. HYAMS, *The English Garden* (1964), a well informed guide book. (India): C.M. VILLIERS-STUART, *Gardens of the Great Mughals* (1913). (Italy): J.C. SHEPHERD and GEOFFREY JELICOE, *Italian Gardens of the Renaissance*, 3rd ed. (1966), the best book; GEORGINA MASSON, *Italian Gardens*, new ed. (1966), a well informed but not always accurate guide book that lacks historical coherence; INIGO TRIGG, *The Art of Garden Design in Italy* (1906), the source of many 20th-century reproductions of Italian gardens; EDITH WHARTON, *Italian Villas and Their Gardens* (1904), still worth attention. (Japan): LORRAINE E. KUCK, *The World of the Japanese Garden* (1968), the best book; J. CONDOR, *Landscape Gardening in Japan* (1893); J. HARADA, *The Gardens of Japan* (1928). (Persia): DONALD N. WILBER, *Persian Gardens and Garden Pavilions* (1962). (Spain): C.M. VILLIERS-STUART, *Spanish Gardens: Their History, Types and Features*, (1929).

## Gardening

Gardening belongs both to art and to science: to art in that it deals with the grouping of plants in harmonious or pleasing arrangements in the landscape; to science in that it is concerned with the techniques of cultivating plants and producing satisfactory growth.

The personal value of, and interest in, gardening obviously derives as much from the relaxation that the practice provides as from the appreciation of the garden itself. The home garden—like the Roman atrium or the Spanish patio—can be a place of repose and seclusion: it can offer a protected corner from the winds of nature as well as from the winds of everyday concern. The therapeutic effect of gardening has been expounded by many; it has a salutary value not only because it requires physical work but also because it fosters a hopeful and anticipatory mood conducive to contentment.

### GENERAL FEATURES

**Definitions.** Horticulture includes the growing of flowers, fruits, and vegetables as crops for profit, as in market gardening, or truck farming; the growing of plants for sale, as in nursery gardening; and the cultivation of a plot of ground for the growing of flowers, fruits, and vegetables for private enjoyment or consumption. In this last sense, only is horticulture equivalent to gardening in its popular and unqualified meaning.

Nursery gardening is a business of considerable current investment. Plant nurseries and seedsmen provide an expanding list of cultivated and improved varieties of garden plants, and an annually increasing volume of plant material is shipped and sold throughout the world to satisfy the demand now put upon such businesses by the growing number of home gardeners. Other horticultural enterprises include the raising of flowers for the cut-flower market and landscape architecture and design (see the articles HORTICULTURE; and GARDEN AND

The business of gardening

LANDSCAPE DESIGN). Since plants in gardens often are grown in conditions very different from their natural environment, and often have been highly selected or bred through many generations to develop larger flowers or fruits than are found in the wild plants, it is necessary to protect them from competition with other more-vigorous plants by weeding and by other garden operations and to apply to their cultivation principles derived from plant physiology, chemistry, and botany, often modified by the experience of the planter. Although the basic principles involved in growing plants are the same in all parts of the world, the practice naturally needs much adaptation to local conditions.

**Historical background.** *Early history.* Of the earliest recorded garden, the garden of Eden, there are no details. It has sometimes been placed in Mesopotamia (now Iraq). The hanging gardens of Babylon may have been terraces arranged around a steep hill. Some of the early Egyptian wall paintings show boats gliding through pools of water lilies and lotuses, some of which may have been cultivated; and a picture in one of the tombs in the Valley of the Kings shows a gardener tying vines to a trellis. Minoan frescoes taken from the Palace of Knossos in Crete, probably of one of the Middle Minoan periods (c. 2200–1600 BC), show lilies, irises, rockroses, and possibly saffron crocus. The garden of Alcinoos, which was probably in Corfu, and the enclosed gardens, vineyards, and fruit trees at Ithaca described nostalgically by Odysseus in the *Odyssey* probably date from about 1250 BC.

In the earliest times, as today in the Middle East, shade was the first requisite of any garden, and so the garden of Cyrus II the Great was a garden of trees and orchards. In classical Rome, the record shows fully and clearly that the Romans enjoyed their gardens, which were mainly enclosed courts with some emphasis on herbal plants. The rose was then one of the favourites, and topiary art was practiced with box shrubs.

In China plant knowledge and gardening developed very early. The first Chinese work about plants may have been the classical herbal of Shen Nung, said to have reigned about 2800 BC, but it was not put into writing until the 1st century AD, and most of it is now lost except for a few excerpts in later works.

Medieval gardening revolved largely around the monasteries. There may have been many other gardens as well, but probably the scribes at the monasteries kept better records. The garden was still essentially a small enclosed area, and the plants grown were mainly herbs for medicinal purposes, vegetables for food, vines, and fruit.

Gardens, however, were reborn all over Europe during the Renaissance, with most activity in the south, especially in Italy. Such flowers as lilies, roses, carnations (gillyflowers), and many others, appear in the backgrounds of many pictures and tapestries. The garden remained an enclosed area, the proverbial haven of quiet and peace in a troubled world. The earliest Renaissance herbals show knowledge of a great variety of plants, and the information given was in most cases derived from original observations of the living plants rather than from tradition and hearsay, but copying from other works was also fairly common, and the same wood blocks were passed on for illustrations from book to book.

The earliest specifically English book devoted to gardening is probably one by a Mayster (Master) Ian Gardener, *The Feate of Gardening*, a practical little work said to be a copy made about 1440 of a work originally written about 40 years earlier.

*17th and 18th century.* The range of garden plants growing at the end of the 16th and early in the 17th centuries in the Netherlands is well shown by the delightful engravings in the various herbals of the time.

The earliest botanic garden was that of Pisa (1543), closely followed by Padua (1545). The first English botanic garden, that of Oxford, was founded in 1621, followed by the great one at Edinburgh in 1667. Kew was founded almost a century later, in 1759. These botanic

gardens contributed substantially to the art and science of horticulture and still do, as demonstrations of diverse plants and as diffusers of plants to other gardens and of knowledge (see also BOTANICAL GARDEN).

In the 17th century both the range of plants available and interest in gardens increased considerably. It was during this time that the royal gardens and estate gardens were prominent. In the mid-17th century began the extensive development of majestic park gardens in France. These were laid out on an immense scale with elaborate waterworks and borders of pleached trees, but one of their principles was that the main feature of the layout should be clear and easily seen from one central point, generally the terrace of the château.

The influence of French gardens spread to England in the 18th century, where it found expression in gentle, parklike landscape gardens. Again, these were not gardens of flowers but parks for the delectation of the owner and his household retinue and friends. The English gardens relied for their effect on clever adaptations of the landscape with lakes, gentle slopes, and clumps of trees as well as most carefully placed temples in the Roman style. Sometimes, a romantic but sham ruin was created as a focal point for the eye, and artificial grottoes were constructed. Literally, small armies of labourers must have been used in shifting the soil.

Gardens in North America were smaller, trimmer, and neater, with box edgings and pleached trees, like those of Williamsburg in Virginia, so lovingly and carefully reconstructed in the 20th century. In the late 18th and early 19th centuries, a more intensive interest in the individual plant and its beauty was exemplified by the great flower books of the period, illustrated by well-known artists of the time, and by the *Botanical Magazine* (founded in 1787 and published in the mid-20th century as *Curtis's Botanical Magazine*) with its fine-coloured plates. Gardening became an international art, and such books were circulated over Europe as were also the prized plants that they portrayed. In addition to large parks, smaller gardens were just beginning to be developed.

*From the 19th century.* Smaller gardens became widespread in the 19th century; a floral retreat was no longer the sole property of the rich. Many good gardening features were undoubtedly swept away in the making of the great landscape gardens of the 18th century, with their emphasis on naturalism and curves and their abhorrence of a straight line. Much that was good in those landscape gardens unfortunately was later elaborated and filled in with intricate bedding schemes and fussy detail in the 19th century. It was a complete contrast from earlier styles. The craft of gardening, rather than the art, was in the ascendant; but it was a more widely spread craft, extending from the manor down to the small suburban garden. In this century began the rise of societies of horticulture and botany, which played a great part in the encouragement of horticulture thereafter.

A passion for masses of brightly coloured flowers, in place of the softer greens of the grass and trees of the landscape garden, became the ruling theme, but with this change came interest also in the individual plant, in the making of large collections of different plants, and in the superb cultivation of outstanding specimens for competition and exhibition. It was the beginning of the age of specialization in plants. It was also the beginning of the age of the great plant collectors, of plant introduction, selection of plants, and plant breeding (see PLANT BREEDING).

In the winter, gardening was entirely an indoor enjoyment in the elaborate conservatories and supporting greenhouses, except for a few enlightened estate owners who began to plant arboretums, based especially on the North American conifers that were then just introduced. Expeditions of many botanist-explorers returned with a wealth of exotic plant material. The flood of plants was so large that it could not be contained in the trim Victorian or Edwardian gardens, nor did such introductions as rhododendrons, lilies, and other plants fit well into

The rise of the small home garden

The Renaissance garden

Indoor gardening

such ordered schemes. But they did fit well into the woodlands, which were then thinned, cleaned up, and opened out to become part of the garden.

New plants brought new gardening habits, which continued into the second half of the 20th century and were exemplified by the great woodland gardens of the first half of the 20th century. It was an exciting time in gardens when so much new was flowering. The system of awards given to plants by the horticultural societies increased enthusiasm for new plants and also for better varieties of old plants, and the demand for these stimulated the nurserymen to grow and supply them.

While the shortage and high cost of labour in mid-20th century limited the size and content of privately as opposed to publicly maintained gardens, the enthusiasm for horticulture was greater and more widespread than ever before over all the temperate and tropical world, and the number of gardens increased. Labour-saving tools, more natural as opposed to more formal methods of growing plants, and the great discoveries of plant physiology and pest control made possible the spread of horticulture, both as a profession and as a hobby and relaxation from other work. Combined with this, a specialist interest by certain gardeners in one particular genus or group of plants rather than a diffused interest in a large range of plants brought with it a great upsurge of plant breeding in the 1920s, which enriched gardens with an increasing supply of floral novelties.

#### THE HOME GARDEN

**Common aspects of gardens.** To apartment dwellers, as well as to homeowners, the hobby of gardening can be a source of much pleasure. An outdoor space—no matter how small—can be a garden, an area tended for a spot of beauty or for food. Even a window box, or pots on a window sill, can support a succession of blossoms and some easily grown herbs or vegetables.

The grounds about a house are an extension of the home itself and can add greatly to its attractiveness. Portions may be set aside for privacy, for recreation, for utility, and for an aesthetic setting for the house. Such home gardens have certain features in common: (1) A boundary or visual limit, within which the garden is framed, usually a hedge, shrub border, fence, wall, or other screen as background. (2) Provision for enjoying and utilizing the garden by way of paths, vistas, seating, and separation of areas. (3) Focal points, including unusual or favoured plants, sculpture, or some other dramatic feature such as a pool, waterfall, entryway, etc. (4) A pattern, or major theme—as formal or informal, traditional or contemporary, natural or exotic, subdued or stimulating, etc.

These features are the basic elements of a home-garden plan and can help in creating a unified, overall garden scheme that will provide seasonal development of a planting in relation to the house and other existing features of more or less permanent nature, such as large trees and topographical features.

Styles in  
gardens

Styles in gardens vary from formal and ordered—in which symmetrical balance and a rather regular grouping of plants is evident—to informal and natural, in which the design is basically that found in nature and only subtly modified, if at all. The distinction admittedly is difficult to maintain, for each of these features may be blended in a garden. Traditional gardens, classic in the arrangement of borders and beds, are often contrasted with contemporary gardens, in which design elements are usually conspicuous and exhibit clearly the influence of man. Eastern gardens, especially the Japanese gardens, are classic and quite traditional in their own countries but are strikingly different elsewhere; in Western countries, therefore, such gardens are often considered contemporary and novel. Gardens, of course, can be anything the gardener wants: wild or ordered, utilitarian (a vegetable patch or cut-flower plot) or aesthetic—geometrical or free form. (An account of the styles popular historically, with description of famous gardens, is given in the article GARDEN AND LANDSCAPE DESIGN.)

**Permanent elements.** The more or less permanent plants considered in the garden plan are the lawn and turf areas, ground covers, shrubs and vines, and trees. More transitory and therefore requiring continued concern are the herbaceous plants, such as the short-lived annual (one season) and biennials (two season), and the perennials and bulbous plants, which resume growth each year.

**Lawns and ground covers.** Areas of turf, or lawn, provide the green expanse that links all other garden plantings together. They usually consist of grasses—thousands to the square metre—kept shorn close to the ground to provide a green carpet. But grasses are not the only plants suitable for such cover. Lawns can be of almost any low-growing plant that spreads rapidly to clothe the ground. Such nongrass covers are called ground covers and include a variety of creeping plants.

The main grasses used in cool areas for fine-textured lawns are fescues (*Festuca* species), bluegrasses (*Poa* species), and bents (*Agrostis* species), often in mixtures. A rougher lawn mixture may contain ryegrass (*Lolium* species). In drier tropical and subtropical regions, Bermuda grass (*Cynodon dactylon*) is frequently used, but it does not make nearly so fine a lawn as those seen in temperate regions of higher rainfall.

Ground covers are perennial plants used as grass substitutes in regions where grasses do poorly or are sometimes combined with grassy areas to produce a desired design. The deep greens, bronzes, and other colours that ground-cover plants can provide offer pleasing contrasts to the green of a turf. Ground covers, however, are not so durable as lawns and do not sustain themselves as well under foot traffic and other activities. Among the better known plants used as ground covers are Japanese spurge (*Pachysandra terminalis*), common periwinkle (*Vinca minor*), lily of the valley (*Convallaria majalis*), ajuga or bugleweed (*Ajuga reptans*), bishop's weed or goutweed (*Aegopodium podagraria*), many stonecrops (*Sedum* species), dichondra (*Dichondra repens*), and many ivies (*Hedera* species).

**Shrubs and vines.** Smaller woody plants, such as shrubs and bushes, have several stems arising from the base. These plants attain heights up to about six metres (about 20 feet). They often form the largest part of modern gardens since their cultivation requires less labour than that of herbaceous plants, and some flowering shrubs have extended blooming periods. Among the popular garden shrubs are lilac (*Syringa vulgaris*), privet (*Ligustrum* species), spirea (*Spiraea* species), honeysuckle (*Lonicera* species), forsythia (*Forsythia* species), mock orange (*Philadelphus* species), and hydrangea (*Hydrangea* species).

Bushlike azaleas (*Azalea* species) and rhododendrons (*Rhododendron* species) provide colourful blossoms in shady spots where other shrubs find it difficult to grow.

Vines are often useful in softening the sharp lines of buildings, fences, and other structures. They can provide shade as an awning or cover on an arbour or garden house. Some species are also useful as ground covers on steep slopes and terraces. Among the many woody perennial vines for the garden are the ivies, trumpet vine (*Bignonia*, or *Campsis, radicans*), clematis (*Clematis* species), wisteria (*Wisteria chinensis*), climbing roses, annual herbaceous vines such as morning glory (*Ipomoea* species) and ornamental gourds, the last of which can provide rapid but temporary coverage of unsightly objects.

**Trees.** Trees are the most permanent features of a garden plan. Since they form the structural foundation of the home garden, care should be taken to choose trees that, when mature, fit the site where they were planted. The range of tree sizes, shapes, and colours is vast enough to suit almost any gardening scheme, from shrubby dwarf trees to giant shade trees, from slow to rapid growers, from all shades of green to bronzes, reds, yellows, and purples. A balance between evergreen trees, such as pines and spruces, and deciduous trees, such as oaks, maples, and beeches, can provide protection and visual interest year around (see TREE).

Lawn  
grasses

**Transitory elements.** *Herbaceous plants.* Herbaceous plants, which die down annually and have no woody stem above ground, are readily divided into three categories, as mentioned earlier: (1) Annuals, plants that complete their life cycle in one year, are usually grown from seed sown in the spring either in the place they are to flower or in separate containers, from which they are subsequently moved into their final position. Annuals flower in summer and die down in winter after setting seed. Many brilliantly coloured ornamental plants as well as many weeds belong in this category. (2) Biennials are plants sown from seed one year, generally during the summer. They flower the second season and then die. (3) Herbaceous perennials are those that die down to the ground each year but whose roots remain alive and send up new top growth each year. They are an important group in horticulture, whether grown as individual plants or in the assembly of the herbaceous border.

*Bulbous plants.* For horticultural purposes, bulbous plants are defined to include those plants that have true bulbs, corms, and a few with tubers or rhizomes. A bulb is defined as a modified shoot with a disklike basal plate and above it a number of fleshy scales that take the place of leaves and contain foods such as starch, sugar, and some proteins. Each year a new stem arises from the centre. A corm consists of the swollen base of a stem, generally rounded or flattened at the top and covered with a membranous tunic in which reserve food materials are stored. A tuber or rhizome is not the base of the stem but rather a swollen part of an underground stem; it is often knobby.

All such plants have evolved in places where they can survive in a semidormant state over a long unfavourable season, either cold, mountain winters or long, summer droughts.

#### KINDS OF GARDENS

**Flower gardens.** Though flower gardens may vary in different countries in the different plants that are grown, the basic planning and principles are nearly the same, whether the gardens are formal or informal. Trees and shrubs are the mainstay of a well-designed flower garden. In designing a garden, these permanent features are usually considered first, and the spaces for herbaceous plants, annuals, and bulbs are arranged around them. The range of flowering trees and shrubs is enormous. It is important, however, that such plants be appropriate to the areas they will occupy when mature. Thus it is little use planting a forest tree that will grow to 100 feet high and 50 feet across in a small suburban front garden 30 feet square, but a narrow flowering cherry or redbud tree would be quite suitable. Bare-rooted trees and shrubs are best set in the garden while they are dormant. Plants rooted in a ball of soil or in a container, however, can be planted at any time.

Blending and contrast of colour as well as of forms are important aspects to consider in planning a garden. The older type of herbaceous border was designed to give a maximum display of colour in summer, but many gardeners now prefer arranging for some flowers during the early spring as well, at the expense of some bare patches later. This is often done by planting early-flowering bulbs in groups toward the front. Mixed borders of flowering shrubs combined with herbaceous plants are also popular and do not require quite so much maintenance as the completely herbaceous border. Borders of annuals are brilliant with colour during the summer, but sowing, thinning, supporting, and planting out half-hardy plants requires extensive labour if the border is large.

Groups of half-hardy annuals may be planted at the end of spring to fill gaps left by the spring-flowering bulbs. The perpetual-flowering roses and some of the larger shrub roses look well toward the back of such a border, but the hybrid tea roses and the floribunda and polyantha roses are usually grown in separate rose beds or in a rose garden by themselves.

**Woodland gardens.** The informal woodland garden is the natural descendant of the shrubby "wilderness" of

earlier times. The essence of the woodland garden is informality and naturalness. Paths curve rather than run straight and are of mulch or grass rather than pavement. Trees are thinned to allow enough light, particularly in the glades, but irregular groups may be left, and any mature tree of character can be a focal point. Plants are chosen largely from those that are woodlanders in their native countries: rhododendron, magnolia, pieris, and maple among the trees and shrubs; lily, daffodil, and snowdrops among the bulbs; primrose, hellebore, Saint-John's-wort, epimedium, and many others among the herbs.

A woodland garden is a labour-saving way of gardening; it need not be kept very neat and tidy.

**Rock gardens.** Rock gardens are designed to look as if they are a natural part of a rocky hillside or slope. If rocks are added, they are generally laid on their larger edges, as in natural strata. A few large boulders usually look better than a number of small rocks. In a well-designed rock garden, rocks are arranged so that there are various exposures for sun-tolerant plants such as rock-roses and for shade-tolerant plants such as primulas, which often do better in a cool, north-facing aspect. Many smaller perennial plants are available for filling plants in vertical cracks among the rock faces.

The main rocks from which rock gardens are constructed are sandstone and limestone. Sandstone, less irregular and pitted generally, looks more restful and natural, but there are certain plants, notably most of the dianthus, which do best in limestone. Granite is generally regarded as too hard and unsuitable for the rock garden since it weathers very slowly.

**Water gardens.** The water garden represents one of the oldest forms of gardening. There are records and pictures of water lilies made by the Egyptians as far back as 2000 BC. The Japanese have also made water gardens to their own particular and beautiful patterns for many centuries. In the centre is often a Japanese lantern of stone and perhaps a flat trellis roof of wisteria extending out over the water. In Europe and North America, water gardens range from formal pools with rectangular or circular outline, sometimes with fountains in the centre and often without plants or with just one or two water lilies (*Nymphaea*), to informal pools of irregular outline planted with water lilies and other water plants and surrounded by boggy or damp parts where moisture-tolerant plants can be grown. Unless the pool contains suitable oxygenating plants, the water will not keep clear nor will any introduced fish live. Most water plants, including even the large water lilies, do well in still water  $\frac{3}{4}$  to 1½ metres deep (2–5 feet). Water lilies may be planted in baskets let down to the bottom or directly in the mud of the bottom. In the case of new plantings, water is added gradually as the plants grow until full depth is achieved. Temperate water lilies are all-day bloomers, but many of the tropical and subtropical ones open their flowers only in the evenings.

In temperate countries, water gardens can also be made under glass and the pools kept heated. In such cases, more tropical plants, such as the great *Victoria amazonica* (*V. regia*) or the lotus (*Nelumbo nucifera*), may be grown together with papyrus reeds at the edge. The range of moisture-loving plants for damp places at the edge of the pool is very great and includes many very beautiful plants such as the candelabra primulas, calthas, irises, and osmunda ferns.

**Herb and vegetable gardens.** Most of the medieval gardens and the first botanic gardens were largely herb gardens containing plants used for medicinal purposes or herbs such as thyme, parsley, rosemary, fennel, marjoram and dill for savouring foods. A small herb garden planted near the kitchen door can be both decorative and useful, or a group of herbs can be planted together in a convenient place. The term herb garden is usually used now to denote a garden of herbs used for cooking, and the medicinal aspect is rarely considered. A herb garden needs a sunny position since the majority of the plants grown are native to warm, dry regions.

The planting of vegetables is a part of many gardens,

A miniature "wilderness"

The old-fashioned garden

# The French potager

although as gardens get smaller and labour for gardens more expensive, this is the part of the garden on which many tend to economize.

The vegetable garden requires an open and sunny location. Good cultivation and preparation of the ground is important for successful vegetable growing, and it is also desirable to practice a rotation of crops as in farming. The usual period of rotation for vegetables is three years; this also helps to prevent the carry-over from season to season of certain pests and diseases.

The old French *potager*, the prized vegetable garden, was grown to be decorative as well as useful; the short rows with little hedges around and the high standard of cultivation represent a model of the art of vegetable growing. The elaborate parterre vegetable garden at the Château de Villandry is perhaps the finest example in Europe of a decorative vegetable garden.

Growing vegetables for exhibition is a separate craft that requires techniques more thorough than the usual vegetable gardener will manage, but the increase in size that can be obtained is considerable.

**Specialty gardens.** *Roof gardens.* The modern tendency in architecture for flat roofs has made possible the development of attractive roof gardens in urban areas above private houses and commercial buildings such as big department stores. These gardens follow the same principles as others except that the depth of soil is less because of the weight and therefore limits the size of plants to be used. The plants are generally set in tubs or other containers, but elaborate roof gardens have been made with small pools and beds. Beds of flowering plants are suitable, among which may be stood tubs of specimen plants to produce a desired effect.

*Indoor plants and window boxes.* The growing of houseplants is a very popular feature of horticulture. It has been found that many plants of tropical forests, such as the aroids and some of the figs—particularly *Ficus elastica*—and herbs such as African violets (*Saint-paulia*) grow well in centrally heated houses provided with adequate moisture; they do not require high intensity of light. The modern picture window, however, with its wide expanse of undivided glass, combines particularly well with large houseplants, and specimens up to six feet or more may be grown if space permits; alternatively, the plants may be kept to a modest size by constant pruning, but correct choice of plants is important. The range of houseplants is very large, and large specialist nurseries supply them.

*Scented gardens.* Scent is one of the characters that many people appreciate highly in flowers. Gardens in which scent from both leaves and flowers is the main criterion for inclusion of a plant have been established for the benefit of blind people in some parks and can give much pleasure. Many plants with highly scented flowers or leaves do not have very decorative or brilliantly coloured flowers, but this is of no consequence to a blind person. For such a garden, the plants must be made easy to touch, and thus they are usually grown in raised beds. Many of these scented plants must be bruised or rubbed to yield their fragrance; others become strongly scented in full sun.

## THE PRINCIPLES OF GARDENING

**Soil requirements.** Soil is obviously the basic factor in the cultivation of all plants, although in a few specialized instances soilless cultivation in water, gravel, or sand enriched with suitable chemicals (hydroponics) has been quite successful.

Soil consists of particles, mainly mineral, derived from the breakdown of rocks and other substances but also including organic matter. In the pore spaces between the particles, both soil water containing dissolved salts and air circulate. This air contains more carbon dioxide and less oxygen than the atmosphere. It and the soil water also contain immense quantities of minute living organisms, many so small that they cannot be seen even with a microscope. For plant roots, this pore space into which they must penetrate and from which they obtain much of their nourishment is very important, as are the prop-

erties of the surfaces of the soil particles, which vary in different kinds of soils.

Soils can be roughly divided into three main types on the basis of their usefulness horticulturally, but many areas contain a mixture.

*Clays.* Clays, in which the particles are very fine, are called in horticulture heavy soils, since it is hard work to turn them over with a spade. They can be very fertile but tend to be lacking in good drainage, holding their water closely adhered to the soil particles; therefore, they cannot be worked when wet, and under pressure they tend to compact down tightly, driving out the air. During drought they tend to become hard and even to develop large cracks so that they cannot be worked satisfactorily. Clay soils can be lightened with as much humus as can be dug into them.

*Sands and gravels.* Sands and gravels are opposite in properties to clay. The soil particles are large, and the soils are called light because they are easy to work and turn in nearly all weather. Since their water-holding capacity is very low, however, they tend to dry out quickly. They are "hungry" soils requiring great quantities of manures, humus, and fertilizers to keep them prolific.

*Peats and heaths.* Peats and heaths are usually very acid and ill drained. They result where conditions have prevented the complete breakdown of old vegetable matter into humus, generally because of poor aeration and surplus acid bog water. Much peat is derived from the decaying roots of sphagnum moss, useful for mulching in the garden. A heath soil is generally less fertile, consisting of a large mixture of sand with the peat and tending to be very low in mineral content and in water-retaining capacity.

The ideal garden soil is a medium loam consisting of a mixture of clay and sand, fairly rich in humus and easily worked, and not forming large clods when dry. The consistency of the soil is important, for a porous, properly tilled soil provides a medium through which roots can penetrate readily and rapidly. Another factor of importance in soils is the acidity or alkalinity, which is generally expressed chemically as a "pH number" that can be ascertained by a simple test with litmus paper. The neutral point is pH 7; numbers below this are acid and above it alkaline. Soil alkalinity is usually derived from free calcium carbonate or a similar alkaline salt.

**Feeding; fertilizing and watering.** Maximum return can be obtained only from soil that contains an ample supply of the elements necessary for plant growth, combined with sufficient moisture to enable them to be dissolved and then absorbed through the plant hairs. The three main elements required for plant growth are nitrogen, potassium, and phosphorus, which are taken up by the plant in the form of salts; but a number of trace elements—magnesium, sulfur, iron, manganese, copper, zinc, boron, molybdenum, chlorine, and sodium—are also required in much smaller amounts.

Manuring with farmyard manure or garden compost can supply the majority of these requirements. These manures, however, are scarce and expensive in many areas, and so it is often necessary to use mineral fertilizers as well as organic ones. The soil, however, is such a complex substance with so many interrelated factors contributing to its fertility that all fertilizers must be applied both in moderation and in balance with each other according to the deficiencies of the soil and the requirements of the particular crop. Different crops have very different fertilizer requirements. Compost, decayed organic matter from vegetable wastes such as kitchen scraps, grass clippings, and leaves, is of benefit in providing nutrients and humus to soils.

Manures are generally best dug into the ground in autumn in most temperate countries, but they may also be used as mulches in the spring to control weeds. The mulches are then dug into the ground in the autumn.

Watering of newly placed plants and of all plants during periods of drought is an essential gardening chore. Proper (*i.e.*, deep and thorough) watering—not simply sprinkling the soil surface—can result in greatly improved growth. Water is essential in itself, but it also

Manures and composts

makes minerals available to plants in solution, the only form usable by plants. All plants benefit from watering during drought. About 2½ centimetres (one inch) of water applied weekly to the soil surface will percolate down about 15 centimetres (about six inches); this is a minimal subsistence amount for many herbaceous garden plants, and small trees and shrubs require more. Thorough and deep watering once a week is beneficial to plants by encouraging deep penetration of roots, which in turn enables plants to survive dry surface conditions.

**Protection.** Practically all plants have a definite figure of tolerance to cold, below which temperature they are killed. Many plants from tropical or subtropical regions cannot survive frost and are killed by temperatures below 32° F (0° C). Others, called half-hardy, can withstand a few degrees of frost. Fortunately, many of the best garden plants are completely hardy and will withstand any low temperatures that are likely to be reached in the temperate regions. Tolerance of cold depends considerably on the state of the plant at the time of exposure. A dormant plant, for example, can withstand much lower temperatures than one in active growth in which the vessels of the stem are full of sap. A plant in dry soil can usually withstand lower temperatures than one in moist soil. Many plants have an adaptation for enduring winter conditions: annuals by seeding; bulbous plants by dying back to an underground storage organ; herbaceous perennials by dying back to ground level.

The simplest form of protection for a plant is a wrapping to keep warmer air around it—a mulch (leaves, soil, ashes, etc.) placed in winter over the crown of a slightly tender plant, or sacking placed around it. This last method is particularly useful for plants that lose their leaves and become dormant seasonally; it is not, therefore, so suitable for evergreens, which utilize their leaves year round.

Glass structures such as greenhouses or outdoor frames can provide additional protection for tender plants. Such structures can be heated and the temperature regulated by a thermostat to any required degree. Thus in temperate regions, orchids and other tropical plants can be grown so that they flower throughout the winter, many "forced" to flower earlier than their normal season by the higher temperature. Greenhouses are roughly divided by gardeners into four categories: (1) The cold house, in which there is no supplementary heating and which is only suitable for plants that will not be killed by a few degrees of frost, such as alpine, or bulbous plants, such as daffodils in pots. The exclusion of wind and the heat from the sun will keep such a house appreciably warmer than the temperature outside. (2) The coolhouse, in which the minimum temperature is kept to 45° F (7° C). Most amateurs' greenhouses fall into this class and a very large range of plants can be grown in them. (3) The intermediate house, in which the minimum temperature is kept at 55° or 60° F (13° or 16° C) is suitable for a wide range of orchids. (4) The stove house, or hothouse, in which the minimum temperature is kept above 60° F (16° C) and in which tropical plants such as anthuriums and cat-leyas can be grown.

**Pruning.** Pruning, which consists of restricting plants to a desired shape, is one of the most important of horticultural arts. Where trees and shrubs are left to grow naturally, they often become much too large for their space in the garden. Also they may grow lanky and misshapen and have much dead growth. Where a branch or shoot is cut, it will often be induced to make a number of young shoots from below the cut, and these are likely to flower more freely than the older branches. Fruit trees in particular when pruned annually often give fruit of finer quality, larger in size, freer of disease, and of better colour. Many shrubs benefit from the cutting out of all weak or dead wood and the shortening of strong shoots each winter. Hard pruning, or "heading back," cutting to within a few inches of the base of the shoot, is often used to rejuvenate shrubs that have become too large or that flower poorly. Pruning, started when the plant is young, obviates the need of drastic and risky remedial pruning later of a large, old, or misshapen bush or tree.

Pruning implements must be kept sharp for making clean cuts that lessen infection. The removal of a heavy branch often is done in stages to avoid tearing the bark below the final cut. Large cuts are generally painted over with a preservative.

**Propagation.** The production, or propagation, of new individuals is either from seed, in which case there is likely to be some variation in the progeny, or vegetatively, by division, cuttings, grafting, budding, or layering. In all these latter cases, the progeny are literally parts of the parent plant and so do not vary from it. A group of such plants is known as a clone. Often, as with cereals and flower seeds of annuals, seedsmen have been able, by continual breeding and weeding out, to introduce pure strains that breed true and without perceptible variation. They still, however, may carry genetic variation.

Seeds are usually sown in the spring either in the open ground, as in the case of most vegetables and hardy annuals, or in containers indoors as in the case of half-hardy annuals. A few seeds, however, especially those of alpine and other cold-adapted plants, require a period of freezing before they will germinate, as indeed happens in their own environment.

Propagation by cuttings is used for many shrubs. This is done generally toward midsummer in most cases, but the exact season will vary in accordance with the state of ripening of the wood. Young shoots of the current season are usually the most successful for rooting. Roses are usually propagated by budding, in which a bud from the rose desired is inserted in rootstock just above ground level. Fruit trees are usually propagated by grafting, in which a young shoot is inserted in the stock. Layering is a method by which a young shoot is pegged down in the ground with the end twisted upward almost at right angles; the lower side of the wood just before the twist is wounded so as to induce rooting. When this takes place, the layer is severed from the parent.

**Control of weeds.** This is a basic, and probably the most arduous, factor of cultivation and has been carried on from the time the earliest nomads settled down to an agricultural life. It has always been necessary to free the chosen crops of competition from other plants. For smaller weeds hoeing is practicable. The weeds are cut off by the action of the hoe and left to wither on the surface. Hand weeding, by pulling out individual weeds, is often necessary in gardens, particularly the rock garden, in seed boxes, and often in the herbaceous border or among annuals. Chemical and biological control of weeds developed greatly after World War II, and has made much mechanical cultivation unnecessary (see WEED CONTROL).

**Control of pests and diseases.** Damage to plants is most often caused by pests such as insects, mites, eelworms, and other small creatures but may also be caused by mammals and rodents such as deer, rabbits, and mice. Damage by disease is that caused by fungi, bacteria, and viruses.

Prevention is generally better than cure, and constant vigilance is necessary to prevent a pest infestation or a disease outbreak. Control can be obtained by the use of chemical sprays, dusts, and fumigants, but some of these are so potent that they should be used only by the experienced operator. Considerable evidence is available regarding the possible harmful long-term effects on the biological chain of excessive use of some of these noxious chemicals, particularly the hydrocarbons (see CONSERVATION OF NATURAL RESOURCES). Some control can be obtained through good garden practices: clearing up all dead and diseased material and burning it; pruning and thinning so that a reasonable circulation of air is obtained through the plants; and crop rotation. Some control may also be obtained through the natural biological predators, but even allowing for all these factors, the absence of chemical control would diminish food crops by a considerable percentage. The breeding of plants immune to certain pests and diseases is also a valuable means of control (see PEST CONTROL; DISEASES OF PLANTS).

**Mechanical aids.** Mechanical devices to aid the gardener include tillers, lawn mowers, hedge cutters, sprin-

Pest  
control  
through  
vigilance

"Forcing"  
flowers

klers, and a variety of more esoteric equipment that has made gardening an easier pursuit. Such machines are not a substitute for good judgment and technique in the garden, however, nor will they give anyone a completely labour-free garden. They will enable a considerably larger area to be cultivated and maintained than if all labour had to be by hand.

#### HORTICULTURAL REGIONS

**Temperate zones.** These zones for horticulture cannot be defined exactly by lines of latitude or longitude but are usually regarded as including those areas where frost in winter occurs, even though this may be rare. Thus most parts of Europe, North America, and north Asia are included, though some parts of the United States, such as southern California and Florida, are considered subtropical. A few parts of the north coast of the Mediterranean and the Mediterranean islands are also subtropical. In the Southern Hemisphere, practically all of New Zealand, a few parts of Australia, and the southern part of South America have temperate climates. For horticultural purposes altitude is also a factor: the lower slopes of great mountain ranges such as the Himalayas and the Andes, for example, are included. Thus the temperate zones are very wide and the range of plants which can be grown there is enormous, probably greater than in either the subtropical or tropical zone. In the temperate zone are the great coniferous and deciduous forests: pine, spruce, fir, most of the cypresses, the deciduous oaks (but excluding many of the evergreen ones), ash birch, and lime (linden).

The temperate zones are also the areas of the grasses—the finest lawns particularly are in the regions of moderate or high rainfall—and of the great cereal crops. Rice is excluded as being tropical, but wheat, barley, corn (maize), and rye grow well in the temperate zones.

The winter  
rest

A great asset for plants in the temperate zones is the winter resting season, which clearly differentiates them from tropical plants, which tend to grow continuously. Thus bulbs, annuals, herbaceous perennials, and the deciduous habit in trees are means by which temperate-zone plants pass the resting season undamaged. Another influence is the varying length of darkness and light throughout the year, so that many, such as chrysanthemums, have a strong photoperiodism. The chrysanthemum flowers only in short daylight periods, although artificial simulation can produce flowers the year round.

Most of the great gardens of the world have been developed in temperate zones. Particular features such as rose gardens, herbaceous borders, annual borders, woodland gardens, and rock gardens are also those of temperate-zone gardens. Nearly all depend for their success on the winter resting period.

**Tropical zones.** There is no sharp line of demarcation between the tropics and the subtropics. Just as many tropical plants may be cultivated in the subtropics, so also many subtropical and even temperate plants may be grown satisfactorily in the tropics, especially at high elevations. As an example, the scarlet runner bean, a common plant in temperate regions, grows, flowers, and develops pods normally on the high slopes of Mt. Meru in Africa near the Equator; it will not, however, set pods in Hong Kong, a subtropical situation a little south of the Tropic of Cancer but at a low elevation. In addition to elevation, another determinant is the annual distribution of rainfall. Plants that will grow and flower in the monsoon areas, as in India, will not succeed where the climate is uniformly wet, as in Bougainville in the Solomon Islands. Another factor is the length of day, the number of hours the sun is above the horizon; some plants will only flower if the day is long, others make their growth during the long days and flower when the day is short. Certain cosmos strains are so sensitive that, where the day is always about 12 hours, as near the Equator, they will flower when only a few inches high; whereas if grown near the Tropics of Cancer or Capricorn, they will attain a height of several feet, if the seeds are sown in the spring, before flowering in the short days of autumn and winter. Poinsettia is a short-day plant that may be seen

in flower in Singapore on any day of the year, while in Trinidad it is a blaze of glory only at Christmas.

In the tropics of Asia and parts of Central and South America, where more exotic plants have been established and distributed, the dominant features of the gardens are flowering trees, shrubs, and climbers. Herbaceous plants are relatively few, but many kinds of orchids can be grown.

Vegetable crops vary in kind and quality with the presence or absence of periodic dry seasons. In the uniformly wet tropics, the choice is limited to certain root crops and still fewer greens. Sweet potatoes will grow and bear good crops where the average monthly rainfall, throughout the year, exceeds ten inches; they grow even better where there is a dry season. The same can be said of taro, yams, and cassava. Tropical greens from Malaya are not as good as those grown in South China, the Hawaiian Islands, or Puerto Rico. They include several spinaches, of which Chinese spinach or amaranth is the best; several cabbages; Chinese onions and chives; several gourds, cucumbers, and, where there is a dry season, watermelons. Brinjals or eggplants, peppers, and okra are widely cultivated. Many kinds of bean can be grown successfully, including the French bean from the American subtropics, the many varieties of the African cowpea, and yard-long bean. The yam bean, a native of tropical America, is grown for its edible tuber. In the drier areas the pigeon pea, the soybean, the peanut, and the Tientsin green bean are important crops. Miscellaneous crops include watercress, ginger, lotus, and bamboo.

**BIBLIOGRAPHY.** Practically all governments now support agencies that conduct horticultural research and publish bulletins relating to the cultivation of fruits, vegetables, and ornamental plants. Similarly, many academic institutions and horticultural organizations provide courses of study and publish gardening information. The references that follow are only a sample of the numerous books available on all aspects of gardening. Many of them have additional references for further reading on particular topics in gardening.

**History:** The history of gardening may be found in many of the large works on gardening and particularly in the historical section in *Curtis's Botanical Magazine Index* (1956); E. HYAMS, *Of Gardens and Gardeners* (1969); J. VON MIKLOS and E. FIORE, *The History, the Beauty, the Riches of the Gardener's World* (1969).

**General:** J.U. CROCKETT, *The Time-Life Encyclopedia of Gardening* (1971– ), a series of several volumes, highly readable and lavishly illustrated; D.M. REID, *Botany for the Gardener* (1967), a presentation of the principles underlying the practice of gardening; R. PAGE, *The Education of a Gardener* (1962), a work helpful in planning a garden; KAREL CAPEK, *Gardener's Year* (Eng. trans. 1931, reprinted 1963), a delightful record of an annual cycle by this famous Romanian playwright; T.H. EVERETT, *Gardening Handbook* (1970); D.J. EDWARDS, *Gardening Explained* (1969); CARLTON B. LEES, *Gardens, Plants, and Man* (1970), a popular account of the significance of gardens. The following works are substantial and detailed books of a more difficult level: G.H. PRESTON (ed.), *The Complete Book of Gardening*, rev. ed. (1954); ROYAL HORTICULTURAL SOCIETY, *Dictionary of Gardening*, 2nd ed., 4 vol. (1951) and *Supplement* (1969); R. HAY and P.M. SYNGE, *The Dictionary of Garden Plants in Colour* (1969); L.H. BAILEY, *Manual of Cultivated Plants Most Commonly Grown in the Continental United States and Canada*, rev. ed. (1949); *Hortus Second* (1951); J.W. STEPHENSON, *Gardener's Directory* (1960); N. TAYLOR (ed.), *Encyclopedia of Gardening*, 4th ed. (1961); M.B. CRANE and W.J.C. LAWRENCE, *The Genetics of Garden Plants*, 4th ed. (1952); *Practical Plant Breeding*, rev. 3rd ed. (1952).

## Garibaldi, Giuseppe

Giuseppe Garibaldi, the most distinguished soldier of the Risorgimento, the movement that united Italy, was known in his day as a great revolutionary, a patron of protest movements all over Europe and the Americas, and was one of the most skillful guerrilla generals of all time. First widely known for his military exploits in South America, his name became a household word in 1849 with his unsuccessful defense of Rome against the French and Austrians. Of all his successes, the most remarkable was an expedition of "the Thousand" in 1860, when an invading force under his command landed in Sicily, defeated the larger army of the King of Naples, and ended by conquering half of Italy, and playing a key role in the country's unification.

Garibaldi, 1866.  
Deutsche Fotothek, Dresden

Garibaldi was born on July 4, 1807, in the French town of Nice, which was largely settled by people of Italian stock. His family was one of fishermen and coastal traders, and for over ten years he himself was a sailor on the

Mediterranean and the Black Sea. In 1832 he acquired a master's certificate as a merchant captain. By 1833–34, when he served in the navy of the kingdom of Piedmont-Sardinia, he had come under the influence of Giuseppe Mazzini, the great prophet of Italian nationalism, and the French Socialist thinker, the Comte de Saint-Simon. Under Mazzini's inspiration, Garibaldi, in 1834, took part in a mutiny intended to provoke a republican revolution in Piedmont, but the plot failed; he himself escaped to France and in his absence was condemned to death by a Genoese court.

**Exile in South America.** From 1836 to 1848 Garibaldi lived in South America as an exile, and these years of turmoil and revolution in that continent strongly influenced his career. He volunteered to serve the Rio Grande do Sul republic as a naval captain in the unsuccessful attempt by that small state to break free from the Brazilian empire. Actually, he did little more than prey on Brazilian shipping. In the course of often harrowing adventures on land and sea, he managed to elope with Anna Maria Ribeiro da Silva (known as Anita), a married woman, who remained his companion in arms until her death. After a succession of victories by the Brazilians in 1839–40, he finally decided to leave the service of Rio Grande. Driving a herd of cattle, he made the long trek to Montevideo with Anita and their son. There he tried his hand as commercial traveller and teacher but could not accustom himself to civilian life. In 1842 he was put in charge of the tiny Uruguayan navy in another liberation war—this time against Juan Manuel de Rosas, the dictator of Argentina. The following year, again in the service of Uruguay, he took command of a newly formed Italian Legion at Montevideo; these men formed the first of the "Redshirts," with whom his name henceforth became associated. After he won a small but heroic engagement at the Battle of Sant'Antonio in 1846, his fame reached even to Europe, and in Italy a sword of honour, paid for by subscriptions, was donated to him. For a short time in 1847 he was in charge of the defense of Montevideo. On this occasion he first came to the attention of Alexandre Dumas père, who later did much to foster his reputation. He also greatly impressed other foreign observers as an honest and able man. His South American experiences gave him invaluable training in the techniques of guerrilla warfare that he was later to use with great effect against French and Austrian armies, which had not been taught how to counter them. And these first exploits in the cause of freedom cast him in the mold of a professional rebel, an indomitable individualist who all his life continued to wear the gaucho costume of the pampas and to act as if life were a perpetual battle for liberty.

**War of liberation.** In April 1848 Garibaldi led 60 members of his Italian Legion back to Italy to fight for the Risorgimento, or resurrection, of Italy in the war of independence against the Austrians. He first offered to fight for Pope Pius IX, and—when his offer was refused—for Charles Albert, the king of Piedmont-Sardinia. The King, too, rebuffed him, for Garibaldi's conviction as a rebel in 1834 was still remembered; moreover, the regular army despised this self-taught guerrilla leader. Garibaldi went, therefore, to the aid of the city of Milan, where Mazzini had already arrived and had given the war of liberation a more republican and radical turn. Charles Albert, after his defeat at the hands of the Austrians at Custoza, agreed to an armistice, but Garibaldi continued in the name of Milan what had become his private war, and emerged creditably from two engagements with the Austrians at Luino and Morazzone. But at the end of August, heavily outnumbered, he had to retreat across the frontier to Switzerland.

For a time Garibaldi settled down at Nice with Anita (whom he had married in 1842) and their three children, but his resolve to help free Italy from foreign rule was now stronger than ever. He was confirmed in his purpose by his belief—which he and only a handful of others shared with Mazzini—that the many Italian states, though often engaged in internecine warfare, could nonetheless be unified into a single state. When Pius IX, threatened by liberal forces within the papal states, fled

marriage

Champion  
of Milan

from Rome toward the end of 1848, Garibaldi led a group of volunteers to that city. There, in February 1849, he was elected a deputy in the Roman Assembly, and it was he who proposed that Rome should become an independent republic. In April a French army arrived to restore papal government, and Garibaldi was the chief inspiration of a spirited defense that repulsed a French attack on the Janiculum Hill. In May he defeated a Neapolitan army outside Rome at Velletri, and in June he was the leading figure in the defense of Rome against a French siege. There was no chance at all of holding the city, but the gallantry of the resistance became one of the most inspiring stories of the *Risorgimento*.

Refusing to accept defeat, in July 1849 Garibaldi led a few thousand men out of Rome and through central Italy, manoeuvring to avoid French and Austrian armies, until he reached neutral territory in the republic of San Marino.

**Retreat.** There he found himself surrounded and decided to disband his men. Soon afterward, he himself was pursued by the Austrians on land and sea as he tried to escape. Although Anita died during this escape, Garibaldi successfully crossed the Apennines to the Tuscan coast. The retreat through central Italy, coming after the defense of Rome, made Garibaldi a well-known figure wherever newspapers were read. From then on he was the "hero of two worlds." Some people criticized his military skill in this campaign; but his qualities as a leader had proved to be extraordinary, and his courage and determination not to surrender were a lesson in patriotism to his fellow countrymen. Many Italians who until then had never heard the word Italy found their lives changed as a result of what he had done. The Italian cause had, for the moment, been defeated, but Garibaldi had ensured that nationalism would in the end emerge stronger than ever.

The Piedmontese monarchy, however, was too frightened to let this rebel return to his mother and his children, and soon he was in exile a second time, first at Tangier, then on Staten Island, then in Peru, where he returned to his original trade as a ship's captain. Only in 1854 was he allowed to return to Italy; Conte di Cavour, the prime minister of Piedmont, believed that by this act he could pry Garibaldi away from the republican Mazzini. In the following year Garibaldi bought part of the island of Capraia off the Sardinian coast, which remained his home for the rest of his life. In 1856 he tried to lead an expedition to release political prisoners held by the Bourbon kings of Naples, but it came to nothing. In 1858 he received an invitation from the Conte di Cavour to help prepare for another war against Austria. His task was to lead an army of volunteers collected from other provinces of Italy, and for this purpose he was given the rank of major general in the Piedmontese army. When war broke out in April 1859, he led his *Cacciatori delle Alpi* ("Alpine huntsmen") in the capture of Varese and Como and reached the frontier of the south Tirol. This war ended with the acquisition of Lombardy by Piedmont.

In September 1859, after peace had returned to northern Italy, Garibaldi transferred his attention to central Italy where a revolutionary government had established itself at Florence. There, on several occasions, he had private meetings with King Victor Emanuel II of Piedmont-Sardinia, when it was agreed that he should prepare to invade the papal states; the King would support his venture if it succeeded or disown him if it failed. At the last moment, however, the King realized that this was too dangerous and asked him to give up the idea. Garibaldi agreed, though reluctantly. He was ready at any moment to revive this kind of unwritten agreement with Victor Emanuel, but it became increasingly clear that their aims were not entirely identical. Though both men were patriots, Garibaldi was already working for the unification of Italy; the King was more prudent and was concerned rather with expanding Piedmont as far as seemed feasible. Garibaldi was especially furious when, early in 1860, Cavour and Victor Emanuel gave his home town of Nice back to France (it had become Piedmontese in

1814), and he made one of his rare appearances in Parliament to protest this violation of the national principle. In January 1860 he married Giuseppina, the daughter of the Marchese Raimondi, but abandoned her, within hours of the marriage, when he discovered she almost certainly was five months pregnant by one of his own officers. Twenty years later, he was able to obtain the decree of nullity that enabled him to legitimize his children by Francesca Armosino, who became his third wife.

**Conquest of Sicily and Naples.** In May 1860 Garibaldi set out on the greatest venture of his life, which was to result in the conquest of Sicily and Naples. This time he had no government backing, but Cavour and Victor Emanuel did not dare to stop him, for he had already become a popular hero. They stood ready to assist, but only if he proved successful; and he accepted this unwritten arrangement, confident that he could thus force Cavour to support a new move toward the unification of the Italian peninsula. Sailing from near Genoa on May 6 with 1,000 men, he reached Marsala in Sicily on the 11th and in the name of Victor Emanuel proclaimed himself dictator. A popular revolution in Sicily gave him considerable help, for his personal charm was irresistible and many of the peasants thought him a god come to deliver them from slavery and feudalism. The decisive moment for his forces was a small engagement at Calatafimi, when he gave convincing proof that he could defeat the regular soldiers of the King of Naples' army. Immediately there was a great popular movement in his support; and this helped him, at the end of May, to enter and capture Palermo, the capital of the island.

The seizure of Palermo was one of Garibaldi's most remarkable military successes, and it convinced Cavour that this volunteer army should now be strongly, if still secretly, supported by Piedmont. Moving across the island, Garibaldi won the Battle of Milazzo in July, helped by reinforcements from northern Italy. On August 18–19 he crossed over the Strait of Messina and landed on the mainland in Calabria. As always, his strategy was to deny the enemy a moment's pause. After a lightning campaign, he moved up through Calabria and on September 7, 1860, entered Naples, Italy's largest city, where he proclaimed himself "Dictator of the Two Sicilies" (the name of the territories of the King of Naples, comprising most of southern Italy and Sicily). He then fought another battle on the Volturno River north of Naples. This was the biggest battle of his career, Garibaldi commanding about 30,000 men. After his victory he held plebiscites in Sicily and Naples, which allowed him to hand over the whole of southern Italy to King Victor Emanuel. When the two met, he was the first person to hail Victor Emanuel as king of a united Italy. The King made a triumphal entry into Naples on November 7, and Garibaldi sat beside him in the royal carriage. But immediately afterward the former dictator returned to Capraia, refusing all the rewards thrust on him. He had asked for only one thing—to be allowed to continue governing Naples as the King's viceroy until conditions returned to normal; but this was refused him, for in the eyes of the conservatives he was still a dangerous radical: an anticlerical who moreover professed to hold advanced ideas on social reform. He was also a man who was known to want to reconquer Rome from the pope and make it into Italy's capital. This was too dangerous a scheme for Victor Emanuel, for there was a French garrison defending the papal temporal power in Rome. There was also another, more insidious danger: Garibaldi was more popular than the King himself. Furthermore, the regular army of Piedmont was deeply jealous of his successes and determined that he should not be permitted to score fresh ones. Finally, it was feared that Mazzini and the republicans might recapture Garibaldi's allegiance and make him desert the monarchical cause.

**Kingdom of Italy.** In 1861 a new kingdom of Italy came into existence, but from the start it found Garibaldi virtually in opposition. Many people regarded him as an embarrassment. He opposed Cavour in Parliament; he accused the government of shabby treatment of the volunteer soldiers who had conquered half the country and

Garibaldi  
and  
Lincoln

given it to the King; he condemned the harsh and inefficient administration of the provinces that he had conquered and for which he felt especially responsible. In many ways he showed that he considered himself almost an independent power in his own right, both in his dealings with his own government and with foreign powers. So much admired was he outside the country that President Lincoln in July 1861 offered him a command in the U.S. Civil War; the offer was declined, partly because Lincoln would not make a sweeping enough condemnation of slavery, but also because he would not give Garibaldi supreme command of the Federal troops. Another sign of Garibaldi's international reputation was the rapturous reception that he later received in England in April 1864. Perhaps never before in history had there been such a large spontaneous gathering as the one that cheered him through the streets of London, and the aristocratic houses of the city vied with each other to do him honour.

**Last campaigns.** Early in 1862 Victor Emanuel again persuaded Garibaldi to lead a revolutionary expedition, this time to attack Austria in the Balkans. He was allowed to recruit another volunteer army, and munitions were collected for him in Sicily; but he then decided to use this army to attack the papal states. The Italian government did not want to jeopardize its relations with the French, who garrisoned the papal states, and at this point ordered its own forces to stop Garibaldi. At the ensuing Battle of Aspromonte he was badly wounded and taken prisoner. He was quickly freed, however, and now the King's complicity with him could no longer be denied. His wound left him badly lamed, but this did not prevent the government from using him more openly when war broke out with Austria in 1866. He was given an almost independent command in the Tirol, and once again he emerged from the war with a good deal more credit than any of the regular soldiers. This war led to the acquisition of Venice. In 1867 Garibaldi led another private expedition of his own into the papal states. This, too, was secretly subsidized by the government, though, of course, the King pretended otherwise; but political mismanagement of the whole incident forced the French to intervene, and French troops defeated Garibaldi's volunteers at Mentana. Once more he was arrested by the Italian government in order to cover up its complicity, but he was soon released and taken back to Caprera. Garibaldi led one final campaign in 1870–71 when he went to assist the French republic against Prussia. Again he distinguished himself, though on a small scale, and he was subsequently elected a member of the French National Assembly at Bordeaux.

Death

Garibaldi died at Caprera on June 2, 1882. During the last decade of his life he was severely crippled by rheumatism and by his many wounds. Though he had become something of a recluse on his island, he kept abreast of affairs through the numerous visitors and deputations that called on him, and he habitually made pronouncements on affairs of the day. Toward the end he called himself a Socialist, but both Marx and the Communist anarchist Mikhail Bakunin disowned him. He also became something of a pacifist, for his own experience had taught him that wars were seldom either righteous or effective in achieving their ends. He was a recognized champion of the rights of labour and of women's emancipation. He also showed himself a religious freethinker and ahead of his time in believing in racial equality and the abolition of capital punishment.

**Assessment.** Garibaldi was responsible for most of the military victories of the Risorgimento, not least because he was one of the great masters of guerrilla warfare. Almost equally important was his contribution as a propagandist to the unification of Italy. Himself a man of the common people, he knew far better than Cavour or Mazzini how to reach the masses with the new message of patriotism. A man of immense personal fascination and courage, he possessed an instinctive authority that made others ready to lay down their lives for the causes he espoused. Furthermore, the fact that he used his military and political gifts for liberal or nationalist causes coin-

cided well with current fashion and brought him great acclaim. In addition, he attracted support by being a truly honest man who asked little for himself. His very eccentricities appealed to public opinion. Living on barren Caprera, he grew his own food, made many of his own clothes, and seemed to have little regard for the ordinary comforts and conventionalities of life.

But his forthright innocence coloured his politics. Not interested in power for himself, he believed in dictatorship because of his South American experiences. He distrusted Parliaments because he saw them to be ineffective and corrupt. Actually, his own dictatorship of southern Italy in 1860, though much criticized, compares surprisingly well with the subsequent administration by the kingdom of Italy. Yet it was easy to regard him as a dangerous man for he saw everything too much in black and white. There was little of the intellectual about Garibaldi; he was, above all, a true believer and an orator. Yet his simpleminded radicalism for the first time created some kind of political awareness in many of his fellow countrymen and brought home to them what nationality signified. His realism and common sense may well have been chiefly responsible for inducing the radical Left to support the conservative monarchy of Victor Emanuel, and without his support the unification of Italy could not have taken place when it did. It is equally true that he repeatedly forced the conservatives into a more active espousal of patriotism than they would have liked, and this, too, had lasting results. Finally, it was he, more than anyone else, who compelled foreign countries to look with sympathy on what was happening in Italy. Notwithstanding his turn toward Socialism, he remained primarily a nationalist—but the object of his nationalism was always the liberation of peoples and not patriotic aggrandizement. To his embodiment of this aim he owes his eminent place in Italian history.

**BIBLIOGRAPHY.** Garibaldi's memoirs are most easily available in the 2-volume edition by A. WERNER, *Autobiography of Giuseppe Garibaldi* (1889), with an interesting supplementary volume about him by his friend JESSIE WHITE MARIO. Another version of the memoirs was partially ghosted by ALEXANDRE DUMAS, trans. by R.S. GARNETT, *The Memoirs of Garibaldi* (1931). Some other of Garibaldi's writings, and many comments on him by contemporaries, may be found in *Garibaldi*, ed. by D. MACK SMITH (1969). Three excellent studies are G.M. TREVELYAN, *Garibaldi's Defense of the Roman Republic* (1907), *Garibaldi and the Thousand* (1909), and *Garibaldi and the Making of Italy* (1911). The shortest modern biography is D. MACK SMITH, *Garibaldi: A Great Life in Brief* (1956); more substantial is JOHN PARRIS, *The Lion of Caprera* (1962). On his private life, by friends of his, there should be noted MARIE ESPERANCE VON SCHWARTZ, *Garibaldi: Recollections of his Public and Private Life* (1887); and AUGUSTO VECCHI, *Garibaldi at Caprera*, with a preface by MRS. GASKELL (1862).

(De.M.S.)

## Garrick, David

David Garrick, actor, producer, dramatist, and poet, revolutionized the style of acting in England, replacing French fustian with a natural ease and a new emphasis on interpretation of character; he made notable innovations in production methods and stage techniques; and by a sincere if sometimes ill-advised devotion to Shakespeare, made the poet's plays accessible to 18th-century audiences.

**Early years.** Garrick was of French and Irish descent, the son of Peter Garrick, a captain in the English army, and Arabella Clough, the daughter of a vicar choral at Lichfield Cathedral who was of Irish extraction. David was born on February 19, 1717, at Hereford, where his father was on recruiting duty. In the family home at Lichfield, the seven children were reared on the highest moral principles in conditions of strict economy. To obtain full pay, after several years on half pay, Captain Garrick joined an infantry regiment at Gibraltar; and David, then 14, as eldest son at home, reported family progress in lively letters that, on the whole, did credit to Lichfield grammar school. In 1736 Gilbert Walmesley, registrar of the ecclesiastical court of Lichfield, who lived in the bishop's palace and lent his prem-

Johnson

ises for private theatricals organized by his young protégé, advised that "Little Davy" should be sent to the academy opened in that year by Samuel Johnson at Edial, near Lichfield. This venture lasted only a few months, and on March 2, 1737, Johnson and Garrick set out for London; according to Johnson, he had two-pence-halfpenny in his pocket and David three halfpence.

Garrick entered his name as a law student at Lincoln's Inn and prepared to study with a friend of Walmesley's at Rochester, Kent; but his father's death in March 1737 and a legacy of £1,000 from an uncle made possible a change of plan. David had spent some months at Lisbon as apprentice to his uncle, a vintner, and, as he and his elder brother were interested in the wine trade, they set up as Garrick & Co., wine merchants—Peter at Lichfield and David in London, in Durham Yard, off the Strand. His business took him into places of entertainment, where he soon had a large acquaintance, including the actor Charles ("Wicked Charlie") Macklin, with whom he conferred on modern theories of acting, and the elegant but unreliable Charles Fleetwood, manager of Drury Lane Theatre, one of the two theatres authorized by the 1737 Licensing Act, the other being Covent Garden. In April 1740, Drury Lane produced Garrick's first comedy, *Lethe, or Esop in the Shades*.

**Beginning of career as an actor.** Garrick entered the acting profession anonymously, in a mask. In March 1741, upon the illness of the actor billed to take the part, he dashed onto the stage as Harlequin at a small, unlicensed theatre in Goodman's Fields. Soon afterward the proprietor took a company to Ipswich for the summer season, and Garrick appeared there in Thomas Southerne's *Oroonoko* as Aboan, a noble savage, with his face blackened, and later played Captain Duretête, in George Farquhar's *The Inconstant*. He was thereafter well received in several parts, but when he applied at Drury Lane and Covent Garden, neither Fleetwood nor old John Rich, manager of Covent Garden, wanted him. He had to return to Goodman's Fields. His mother had died in 1740, but he still dared not tell his family that he had entered a profession then generally held in low esteem. Not until the night after his astounding first appearance as Richard III in 1741 did he break the news to Peter.

First  
success

The instant success of a young, unknown actor in a major tragic Shakespearean part remains one of the romances of theatrical history. The Garrick legend was founded in a single night. Audiences, weary of the pompous recitative and stately attitudinizing imposed by French tradition, were ready for the naturalistic new style, and they soon perceived that this bright young man could do anything. He was equally good in *Pamela*, a dramatization of Samuel Richardson's novel; in Thom-

as Otway's *The Orphan and Venice Preserv'd*; in Colley Cibber's *Love Makes a Man*; or, *The Fop's Fortune*; in *King Lear*; and in a farce he himself wrote, *The Lying Valet*. He wrote to Peter: "Mr. Pit, who is reckon'd ye Greatest Orator in the house of Commons, said I was ye best actor ye English stage had produc'd." Alexander Pope had pronounced: "That young man never had his equal an actor, and he will never have a rival." Thomas Gray wrote to Horace Walpole that a dozen dukes a night attended Goodman's Fields. So much adulation, so easily won, might have demoralized a less stable character, but Garrick, though highly strung and sensitive, had a strong vein of common sense and remarkable staying power.

Fleetwood was now eager to secure him for Drury Lane and offered a salary larger than ever proposed to any performer. Before the season of 1742–43 Garrick went over to Dublin where he played at the theatre in Smock Alley with the captivating Peg Woffington, with whom he was already in love, and whom he hoped to marry. There, his success was tremendous, and he continued to triumph at Drury Lane from 1742–45, playing such diverse roles as Hamlet; the simple-minded Abel Drugger in Ben Jonson's *The Alchemist*; and the voluble Francis Archer in George Farquhar's *The Beaux' Stratagem*. But Fleetwood's patent of the theatre was running out, and he was a ruined man. In 1743 Garrick sued him for £600 arrears of salary and led an actor's strike against him, one side effect of which was a quarrel with Macklin. A reconciliation was arranged in 1747, but Macklin's senile mutterings, noted down by his biographer, became the fountainhead of the anti-Garrick legends of vanity, avarice, meanness, and arrogance.

In the winter of 1745–46 Garrick was in Dublin, sharing with Thomas Sheridan, the playwright and actor-manager, in the direction of the Theatre Royal. During this time negotiations began for Garrick to become part owner and manager of Drury Lane Theatre. In the season of 1746–47 Garrick made his only appearances at Covent Garden. John Rich had also secured James Quin, the outstanding exponent of the old style of acting, and the season became a duel between them.

**Reforms of Drury Lane Theatre.** In April of 1747 friends in the city helped Garrick to raise £8,000, his share of the purchase money for the lease and furnishings of Drury Lane Theatre and renewal of the patent, in partnership with one James Lacy, a failed actor with a flair for the entertainment trade, who had been stage manager at Covent Garden. Garrick was to perform and to choose plays and players; Lacy, assisted by a weakish, devoted younger Garrick, "Brother George," dealt with the business side. Drury Lane, redecorated, reopened in September 1747 with Macklin as Shylock and a prologue by Johnson that set forth Garrick's principles, as a producer, of devotion to Shakespeare and reform of plays and players and ending with the famous appeal:

The drama's laws the drama's patrons give,  
For we, who live to please, must please to live.  
... 'Tis yours this night to bid the reign commence  
Of rescued nature and reviving sense.

Garrick was unwell, however. He had endured many minor ailments, indicative of overstrain, in the past months, during which he had never acted more poignantly. The infidelities and extravagance of Peg Woffington had convinced him that they had better not marry. He had announced to his brilliant new troupe that they would find his rule stricter than any to which they were accustomed. Among his stars were Macklin, Woffington, and Kitty Clive, the only actress of whom he was said to be afraid, but one who was to become a dear friend.

He had made plans for reforming audiences as well as actors. He was going to try refusing admittance behind the scenes and on the stage and discontinuing the practice of reduced entry fees for those who left early or came late. He planned to bring down the orchestra from the gallery and to enlarge the auditorium. The apron, a forestage in front of the curtain onto which players marched, struck an attitude, and took up their stances for lengthy soliloquies, became obsolete with the new,

## Repertoire

natural style of acting. Garrick hoped to introduce new lighting, but not until 1765 did he get his footlights and sidelights, which were oil lamps with reflectors.

Most important was to be his choice of plays and manner of production. He was going to produce much more Shakespeare, purged of the coarse language and effects of Restoration drama: the name of Garrick should be remembered with that of Shakespeare. He would add a death scene between Romeo and Juliet but restore much of the original text lost in adaptations by the Restoration playwrights, Thomas Otway and Colley Cibber. He would present Nahum Tate's 1681 adaptation of *King Lear*, without the Fool and with a happy ending, and give *The Fairies* (*A Midsummer Night's Dream*) without the clownish artisans and *Hamlet* without the gravediggers and the tragic fate of Ophelia. *Florizel and Perdita* (adapted from *The Winter's Tale*) and Dryden's version of *The Tempest* would make charming light operas. He would rewrite *The Taming of the Shrew*, adapting the role of Katherina for Kitty Clive. In general, his audiences, accustomed to rewritings of Shakespeare, accepted his "improvements" with docility: they at least had the merit of keeping the plays on the stage by suiting them to the taste of the time. Moreover, Garrick's acting and casting often succeeded in interpreting character in a way closer to Shakespeare and new to the audience.

On June 22, 1749, Garrick married Eva Maria Veigel, a Viennese opera dancer who spoke little English and was a devout Roman Catholic. Under the stage name of La Violette, she had enchanted audiences at the Opera House in the Haymarket in 1746, and, although she had refused to dance for Garrick at Drury Lane in 1748, the following year she consented to retire and thereafter to attempt only one role, that of Mrs. Garrick. The marriage, though childless, was happy, and the Garricks' hospitality became famous.

**Successes and setbacks.** At Drury Lane, Garrick went from strength to strength. He had already appeared in most of the parts in which he was best liked, and he realized with good humour that, as he was slightly below middle height and had put on weight, he had better give up youthful characters and add to his fame in the more mature roles—Abel Drugger, *King Lear*, *Macbeth*, Richard III. His mobile features, dark complexion, and eyes—widely praised for their lustre, expressiveness, and piercing brilliance—were famous on and off stage. In search of "copy," he frequented the law courts and House of Commons and would even visit the scene of a family tragedy. Critics disagreed as to whether he excelled in tragedy or comedy. He himself once told a young aspirant that comedy called for the greater skill.

## Reputation

Though he raised Drury Lane Theatre from penury to astounding financial success and, by his improvements in 1747–48 and 1762 and by the acting of his company, had made it London's most flourishing theatre, he had his setbacks. He burdened his players with some deadly historical and classical tragedies. He could turn disaster to success, however. When his theatre was wrecked by hooligans in November 1755, he faced a hostile house with courage. When in 1769 preternaturally wet weather washed out his cherished Shakespeare Jubilee at Stratford-on-Avon, he refurbished both costumes and script for London, played *The Jubilee* to packed houses, and emerged with a profit. He was accused of avarice—though his inconspicuous charities were many—and was laughed at for his vanity and love of staying at great houses. He was involved in a succession of "paper wars" with touchy and even slanderous disappointed writers and players, such as Charles Churchill, who praised and attacked him, and Samuel Foote, who ridiculed the extravagant Shakespeare Jubilee. Garrick's caricatures of fellow actors in the Duke of Buckingham's *The Rehearsal* in his early days gave wide offense. His rivalry with Rich, at Covent Garden, was sometimes acrimonious; sometimes it led to new success. Rich had prided himself on his Christmas pantomimes; Garrick's, with superb effects and lighting by Philip James de Loutherbourg, a young expert in scenic design of Polish descent, far surpassed them. For his own spectacular "Christmas gam-

bol," *Harlequin's Invasion* (1759), with music by William Boyce, he wrote the patriotic song, "Heart of Oak."

Though "Heart of Oak" is perhaps the only poem by which he is remembered, his quality as a poet is shown by songs added to plays and by verses to Peg Woffington (the early ones those of a young man deeply in love; the bitter "Epistle to Mrs. Woffington" of 1745 exposing "the naked truth") and to his wife. As a dramatist (he wrote more than 20 plays and "entertainments" and adapted many more), he suffers from having written for a particular company and audience; and his farces and burlesques, though lively, have not held the stage. Only *The Clandestine Marriage* (1766), written with George Colman the Elder, is still successfully revived. His letters, however, have lasting interest. All of his life a prolific letter writer, he wrote as he acted, with ease, spontaneity, and versatility. His letters are a valuable source for the details of his busy life, the tangled theatrical history of his time, and his character and outlook.

**Last Years.** In 1763 the Garricks departed for a continental tour. They enjoyed sightseeing in Italy in aristocratic company, but Mrs. Garrick suffered agonies from what was, apparently, a slipped disk, and Garrick contracted typhoid in Venice and nearly died in Munich. They wintered in Paris, where Garrick enlarged his acquaintance with French literary and theatrical celebrities, Shakespearean enthusiasts, and the philosophes. After returning (spring 1765), he appeared in no new parts, but ten years passed before he prepared to sell his share of the Drury Lane patent. A series of farewell performances included four Shakespearean parts: Benedick, Hamlet, Richard III, and Lear; Abel Drugger; Sir John Brute from Sir John Vanbrugh's *The Provok'd Wife*; Archer from *The Beaux' Stratagem*; and, for his last performance, Don Felix from Susannah Centlivre's *The Wonder: A Woman Keeps a Secret*.

Garrick's retirement was happy. In London he was a member of Johnson's Literary Club and Brooks's. At Hampton he had his duties as squire, his library and garden, his dogs, and his nieces and nephews. All of his life a sufferer from kidney trouble, he was taken ill while staying with his old friends Lord and Lady Spencer at Althorp Park, Northamptonshire, for the New Year, 1779, and died on January 20 at his house in Adelphi Terrace. Mrs. Garrick survived him until 1822.

Garrick was buried in the Poets' Corner, Westminster Abbey; a monument in Lichfield Cathedral bears Johnson's famous "I am disappointed by that stroke of death that has eclipsed the gaiety of nations, and impoverished the public stock of harmless pleasure." He left property reckoned at more than £100,000.

## MAJOR WORKS

*Lethé; or, Esop in the Shades* (1740); *The Lying Valet* (1741); *Miss in Her Teens; or, The Medley of Lovers* (1747); *Lilliput* (1756); *The Male Coquette; or, Seventeen Fifty Seven* (1757); *The Guardian* (1759); *Harlequin's Invasion* (1759); *The Enchanter; or, Love and Magic* (1760); *The Farmer's Return from London* (1762); *The Clandestine Marriage* (1766; with George Colman the Elder); *Neck or Nothing* (1766); *Cymon* (1767); *Linco's Travels* (1767); *A Peep Behind the Curtain; or The New Rehearsal* (1767); *The Jubilee* (1769); *The Irish Widow* (1772); *A Christmas Tale* (1773); *The Meeting of the Company; or, Bayes's Art of Acting* (1774); *Bon Ton; or, High Life Above Stairs* (1775); *The Theatrical Candidates* (1775); *May-Day; or, The Little Gypsy* (1775).

**BIBLIOGRAPHY.** For Garrick's life the chief source other than contemporary accounts is his own correspondence: *The Letters of David Garrick*, ed. by DAVID M. LITTLE and GEORGE M. KAHL, 3 vol. (1963), which also includes an excellent short biography by Kahrl. These volumes quite outdate JAMES BOADEN, *The Private Correspondence of David Garrick, with the Most Celebrated Persons of His Times*, 2 vol. (1831–32). Early biographies include THOMAS DAVIES, *Memoirs of the Life of David Garrick*, 2 vol. (1780; rev. ed., 1808), a solemn but popular study by a man who knew Garrick; ARTHUR MURPHY, *The Life of David Garrick*, 2 vol. (1801), a racy and anecdotal study; and PERCY FITZGERALD, *The Life of David Garrick*, 2 vol. (1868, reprinted 1971). CAROLA OMAN, *David Garrick* (1958), is a full-length biography containing the latest information available. GEORGE PIERCE BAKER and DAVID MASON LITTLE edited, separately over 100 unpublished

Farewell  
performances  
and  
retirement

letters, in 1907 and 1930; and R.C. ALEXANDER in 1928, the long missing Paris 1751 *Diary of David Garrick*.

## Garrison, William Lloyd

The figure of William Lloyd Garrison, if not his program for abolishing slavery in the United States, dominated the 30-year Abolitionist crusade that ended successfully in 1865 with the adoption of the 13th Amendment to the Constitution of the United States. Neither an effective organizer nor a political strategist, Garrison first achieved notoriety and, finally, acclaim as the editorial voice of the antislavery conscience, denouncing slavery as a national sin and demanding immediate and unconditional emancipation. "On this subject," he promised in the first issue of his Abolitionist newspaper, *The Liberator*, in 1831, "I do not wish to think, or speak, or write, with moderation. . . . I am in earnest—I will not equivocate—I will not excuse—I will not retreat a single inch—AND I WILL BE HEARD." When he stopped publishing *The Liberator* in 1865, he had come to personify for millions of Americans the moral fervour and tenacity that had sustained the Abolitionist cause.

Garrison.

### Early life

Born on December 12 (or 10), 1805, in Newburyport, Massachusetts, the son of an itinerant seaman who subsequently deserted his family, Garrison grew up in an atmosphere of declining New England Federalism and lively Christian benevolence—twin sources of the Abolitionist movement, which he joined at the age of 25. As editor of the *National Philanthropist* (Boston) in 1828 and the *Journal of the Times* (Bennington, Vermont) in 1828–29, he served his apprenticeship in the moral reform cause. In 1829, with a pioneer Abolitionist, Benjamin Lundy, in Baltimore, he became coeditor of the *Genius of Universal Emancipation*; he also served a short term in jail for libelling a Newburyport merchant who was engaged in the coastal slave trade. Released in June 1830, Garrison returned to Boston and, a year later, established *The Liberator*, which became known as the most uncompromising of American antislavery journals.

Like most of the Abolitionists he recruited, Garrison was a convert from the American Colonization Society, which advocated the return of free blacks to Africa, to the principle of "immediate emancipation," borrowed from English Abolitionists. "Immediatism," however variously it was interpreted by American reformers, condemned slavery as a national sin, called for emancipation at the earliest possible moment, and proposed schemes for incorporating the freedmen into American society. Through *The Liberator*, which circulated widely both in England and the United States, Garrison soon achieved recognition as the most radical of American antislavery advocates. In 1832 he founded the New England Anti-Slavery Society, the first immediatist society in the country, and in 1833 he helped organize the Amer-

ican Anti-Slavery Society, writing its Declaration of Sentiments and serving as its first corresponding secretary. It was primarily as an editorialist, however, excoriating slaveowners and their moderate opponents alike, that he became known and feared. "If those who deserve the lash feel it and wince at it," he wrote in explaining his refusal to alter his harsh tone, "I shall be assured that I am striking the right persons in the right place."

In 1837, in the wake of financial panic and the failure of Abolitionist campaigns to gain support in the North, Garrison renounced church and state and embraced doctrines of Christian "perfectionism," which combined abolition, women's rights, and nonresistance, in the biblical injunction to "come out" from a corrupt society by refusing to obey its laws and support its institutions. From this blend of pacifism and anarchism came the Garrisonian principle of "No Union With Slaveholders," formulated in 1844 as a demand for peaceful Northern secession from a slaveholding South.

By 1840 Garrison's increasingly personal definition of the slavery problem had precipitated a crisis within the American Anti-Slavery Society, a majority of whose members disapproved of both the participation of women and Garrison's no-government theories. Dissension reached a climax in 1840, when the Garrisonians voted a series of resolutions admitting women and thus forced their conservative opponents to secede and form the rival American and Foreign Anti-Slavery Society. Later that year a group of politically minded Abolitionists also deserted Garrison's standard and founded the Liberty Party. Thus, 1840 witnessed the disruption of the national organization and left Garrison in control of a relative handful of followers loyal to his "come-outer" doctrine but deprived of the support of new antislavery converts and of the Northern reform community at large.

In the two decades between the schism of 1840 and the Civil War, Garrison's influence waned as his radicalism increased. The decade before the war saw his opposition to slavery and to the federal government reach its peak: *The Liberator* denounced the Compromise of 1850, condemned the Kansas-Nebraska Act, damned the Dred Scott decision, and hailed John Brown's Raid as "God's method of dealing retribution upon the head of the tyrant." In 1854 Garrison publicly burned a copy of the Constitution at an Abolitionist rally in Framingham, Massachusetts. Three years later he held an abortive secessionist convention in Worcester, Massachusetts.

The Civil War forced Garrison to choose between his pacifist beliefs and emancipation. Placing freedom for the slave foremost, he supported Abraham Lincoln faithfully and in 1863 welcomed the Emancipation Proclamation as the fulfillment of all his hopes. Emancipation brought to the surface the latent conservatism in his program for the freedmen, whose political rights he was not prepared to guarantee immediately. In 1865 he attempted without success to dissolve the American Anti-Slavery Society and then resigned. In December 1865 he published the last issue of *The Liberator* and announced that "my vocation as an abolitionist is ended." He spent his last 14 years in retirement from public affairs, regularly supporting the Republican Party and continuing to champion temperance, women's rights, pacifism, and free trade. "It is enough for me," he explained in justifying his refusal to participate in radical equalitarian politics, "that every yoke is broken, and every bondman set free." He died in New York City on May 24, 1879.

**BIBLIOGRAPHY.** The standard biography is WENDELL P. and FRANCIS J. GARRISON, *William Lloyd Garrison, 1805–1879: The Story of His Life Told by His Children*, 4 vol. (1885–89). Still useful are two contemporary accounts: OLIVER JOHNSON, *William Lloyd Garrison and His Times* (1879); and SAMUEL J. MAY, *Some Recollections of Our Antislavery Conflict* (1869); as well as the sympathetic neo-abolitionist essay by JOHN JAY CHAPMAN, *William Lloyd Garrison* (1913). For more recent estimates, see RUSSELL B. NYE, *William Lloyd Garrison and the Humanitarian Reformers* (1955); WALTER M. MERRILL, *Against Wind and Tide: A Biography of William Lloyd Garrison* (1963); and JOHN L. THOMAS, *The Liberator, William Lloyd Garrison* (1963).

## Gaseous State

A gas is one of the three major states, or phases, of matter, the others being liquid and solid; less clearly definable, but also referred to as states of matter, are plasma, colloids, and amorphous conditions, such as glass. Each state of matter has properties that distinguish it from the others and that are, therefore, independent of the particular substance being studied. Thus, the gaseous state has properties simply as a gas, and if any substance in a gaseous state is condensed to the liquid state, the identical substance will have the distinctly different properties of a liquid. The most familiar example is water, whose properties as ice, liquid, and vapour (gas) are dramatically different within the temperature and pressure ranges of everyday experience.

### GENERAL PROPERTIES

All matter consists of atoms or molecules or mixtures of these in constant motion, whether it is through space, called translational motion, or motion in one place, called vibrational motion. In the gaseous state, each particle moves about in three dimensions almost independently of the influence of nearby particles, whereas in liquids and solids the motion of the same atoms and molecules is subordinated to the forces exerted on them by their neighbours. The freely moving atoms and molecules of a gas are constantly colliding with one another and rebounding to produce a pressure that is transmitted throughout the bulk of the gas and against the walls of the container; thus, one of the most obvious properties of the gaseous state is that a gas fills completely whatever container it is put in. The earth's atmosphere, consisting of a mixture of gases, reveals many of the properties of the gaseous state to simple observation. For example, a gas can be compressed, as with a bicycle pump. When a gas is heated, it expands and rises, as over a hot radiator; if a gas is cooled enough, it condenses to a liquid, as with breath on a cold window. The earth's weather is largely the result of changes in the gaseous properties of air, the most important change being that of temperature, which leads, among other things, to pressure changes and to the amount of water vapour the mixture can absorb; all clouds, precipitation, storms, winds, and clear skies are phenomena that can be explained in terms of the properties of gases. The compressibility and expansion properties of the gaseous state are utilized in all sorts of ways in industry and in everyday life. For example, whatever fuel is used, the internal-combustion engine, steam engine, jet engine, rocket, and guns are all designed to utilize the properties of the gaseous state. This is also true of the arts of cooking, welding steel, and deep-sea diving, of the performance of aircraft, the operation of windmills, and so on. It is the gaseous properties of oxygen that have determined the evolution of lungs, organs that can handle only gases, not liquids or solids.

It would seem, therefore, that a great deal must have been learned about gases long ago, even by primitive man, but this is not the case. Although gases have been studied experimentally and theoretically since antiquity, any systematic discussion of gases is based upon experimental data collected during the last two centuries and upon theories that began to develop only during the 19th century and that are still evolving. The fact is that it is exceedingly difficult and often impossible to explain the behaviour of gases in terms that allow precise predictions to be made concerning gaseous behaviour under various known conditions.

There are two distinct ways of discussing the gaseous state. First, there is the laboratory description of the behaviour of a bulk volume of gas trapped in a container. This is a macroscopic view, independent of the atomic theory of matter, since it deals with properties, easy to measure, of a vast number of particles, such as the pressure they exert all together on the walls of their container or their temperature as measured by a thermometer. Description in terms of bulk measurable properties is called (phenomenological) thermodynamics and trans-

port theory. Second, there is the particle description of a gas; this is a microscopic view that deals with the individual properties of the particles and how these properties collectively give rise to the observed behaviour of a gas when studied in the laboratory. Description in these terms is called statistical thermodynamics and kinetic theory. During the last 150 years, increasingly successful attempts have been made to develop a complete theory that will coordinate these two distinct descriptions.

### THERMODYNAMIC APPROACH TO GASES

Gases range from simple gases, whose particles are single atoms (monatomic), such as neon or helium, to the complex multi-atom (polyatomic) gases, such as the hydrocarbons, obtained in the petroleum industry. The cost of determining all the physical and chemical properties of every gas is prohibitive in terms of time and money, and any procedure that allows predictions to be made of some properties in lieu of actual measurements is of great value. The science of thermodynamics provides general rules that relate some of the behaviour of all gases on the basis of limited data. Of particular importance is the relationship among the pressure, volume, and temperature of a gas, since these are the three properties usually easiest to measure. For example, low pressures are measured by balancing the pressure of the contained gas through a tube against a vertical column of mercury (the height of the column gives an accurate measure of the pressure the mercury exerts on the gas), while for gases at high pressure a free-piston gauge is used, the pressure of the gas being balanced by applying an external force, such as weights of known value, to the piston. Temperature can be measured by a variety of devices, including gas or liquid thermometers, resistance thermometers, and thermocouples. The relationship among pressure, volume, and temperature is called the thermal equation of state. The relationship may be expressed as a precise mathematical equation or as a collection of graphs or tables. The thermodynamics of gases is concerned with the two-fold problem of determining the thermal equation of state (see below *Thermal equation of state*) of just a few gases and attempting to predict values for all other gases using the equation; thereafter, the prediction of all of the other properties of a gas can be made in terms of its pressure, volume, and temperature.

**The simple gas laws.** The relationships between the volume of a gas and its temperature and pressure embody easily measured, basic properties of all gases. These relationships have been deduced and put in the form of equations called the gas laws. The first gas law, discovered by the English physicist Robert Boyle and named after him (in France the law is named after Edme Mariotte), states that the volume of a given quantity of gas varies inversely with the pressure exerted on it. That is, if a gas is compressed to half its volume, the pressure it will exert on its container will be twice as much, or, if the pressure on a gas is doubled, the volume will be reduced by one-half; a limiting factor is that the temperature must not change, for, if it does, the pressure-volume relationship will not hold. In symbols, Boyle's law is written:  $V$  varies as (or  $\propto$ )  $1/P$ ,  $V$  being the volume and  $P$  the pressure. This can be stated as an equation by introducing a constant (depending on the units of volume and pressure used and on the amount of gas) that has been found experimentally:  $V = k_1 1/P$ ; that is, the volume equals the product of the constant and the reciprocal of the pressure. The second gas law was worked out (1787) by the French physicist Jacques-Alexandre-César Charles and named after him and also after Joseph-Louis Gay-Lussac, a French chemist who repeated Charles' experiments and published his results in 1802. It states that the volume of gas varies directly as its absolute temperature (see below *Thermal equation of state*), if the pressure is kept constant. That is to say, if the temperature of a gas is increased the volume will increase proportionately, as long as the pressure within the gas does not change. In symbols,  $V$  varies as (or  $\propto$ )  $T$ ,  $T$  being the absolute temperature. In equation form, the relationship is  $V = k_2 T$ ,  $k_2$  being a constant determined through experiment. In

scopic and  
micro-  
scopic  
descrip-  
tions

words, then, the volume of a specified amount of any gas expands whether with a rise in temperature or with a reduction in pressure, and the gas contracts if it is cooled or if the pressure is increased, and the changes can be calculated by using one or the other of the two gas laws.

**Thermal equation of state.** If both pressure and temperature are changed at the same time, both equations must be used to calculate the change in volume, pressure, or temperature that is obtained when the other factors are changed. A single equation can be derived from Boyle's and Charles' laws: the product of the pressure and the volume equals the product of the temperature and a constant,  $R$ , called the universal gas constant. In symbols the equation is written:  $P\bar{V} = RT$ ,  $P$  being the pressure,  $T$  the absolute temperature, and  $\bar{V}$  the volume of one mole of gas. A mole is a quantity of substance such that its weight in grams is numerically the same as the molecular weight of the substance; e.g., the molecular weight of oxygen ( $O_2$ ) is 32; therefore, one mole of oxygen is that quantity that weighs 32 grams. The universal gas constant,  $R$ , is 1.987 calories per mole degree, a figure found by experiment. The absolute-temperature scale was devised (1848) by the English physicist William Thomson, later Lord Kelvin, on the basis of his work with heat. Charles had already found that all gases shrank  $\frac{1}{273}$  of their volume when they were cooled  $1^\circ C$ , and Kelvin reasoned that if a gas could be cooled  $273^\circ$  below  $0^\circ C$ , the energy of its molecules would become zero. This hypothetical temperature was given the name absolute zero, and the scale of temperatures built on absolute zero, in which each degree was equivalent to a degree on the Celsius thermometer, was called the absolute scale of temperature. Recently, this has been changed to the Kelvin scale and is written  $^\circ K$ , but  $0^\circ K$ , which is equal by definition to  $-273.15^\circ C$ , is still called absolute zero.

The equation is called the thermal equation of state, and it is the most important of the mathematical descriptions worked out for gases, since by simply measuring any two of the unknowns, the third can be calculated. It is applicable to a large variety of gaseous conditions in industry and science, including astronomy.

**General shortcomings.** The thermal equation of state, however, is not applicable to all gases under all conditions. It is an approximation, however, that is certainly accurate for most gases at pressures of less than a few atmospheres and at temperatures between room temperature and several hundred degrees higher.

**Ideal gas.** Because of this common behaviour pattern, a hypothetical gas, called the ideal, or perfect, gas, has been proposed that obeys the equation exactly under all conditions. The importance of the concept is twofold. First, it provides a criterion of behaviour that most real (as opposed to ideal) gases approach; and, second, there is an exact particle theory for such a gas. The difference between the ideal gas and any real gas is due to several factors, the most obvious being that every molecule has a real volume, and the total volume of the molecules in a container is, therefore, a significant figure when the space occupied by the gas (the  $\bar{V}$  in the equation) becomes relatively small; the physical volume of the gas molecules is not taken into account in the equation. Much more important factors that also are excluded concern forces of interaction among atoms and molecules that come into play under various conditions, especially near condensation; at condensation the phenomenon of latent heat (see below *Discrepancies between observed behaviour and the equation of state*) is not taken into account; and, of course, the fact that molecules have different shapes and that their collisions would be affected by these distinct shapes is also not part of the calculations that can be made using  $P\bar{V} = RT$ . Still another factor enters when the temperature is raised sufficiently to ionize the molecules and then decompose them and, finally, to strip atoms of all their electrons. Such a gas, consisting only of positively charged nuclei and electrons, is called plasma, and its properties, since each particle has an electric charge, differ altogether from those of a normal gas, whose particles are electrically neutral. In passing from normal gaseous state to plasma, therefore,

the changes cannot be predicted by the thermal equation of state. The simple gas laws would be absolutely correct for a gas if each molecule were simply a mathematical point in space.

In addition to pressure, volume, and temperature, another important thermodynamic property of a gas is its energy. The change in energy with changing volume of any gas that is kept at a constant temperature can be calculated from thermodynamic theory, using the same thermal equation of state. The dependence of the energy on temperature is known as the heat capacity of a gas, and this must be determined experimentally when the gas is held at constant volume or pressure. A knowledge of the thermal equation of state and the heat capacity allows all of the other thermodynamic properties of many gases to be deduced without further measurement.

It took centuries for these principles to be discovered. Historical highlights were the speculations of Francis Bacon (1620) that heat was not an indestructible fluid called caloric, which everyone believed could enter or leave a gas, but rather that heat was some form of motion of particles. Boyle and Charles developed the concept of the thermal equation of state, while Joseph Black, an English chemist, established (1770) the idea of a heat capacity and energy of a gas in his studies of gas calorimetry. The American Benjamin Thompson, later Count von Rumford (1798), and the Englishman James Prescott Joule (1845) finally disproved the caloric theory of heat. The laws of thermodynamics, which interrelate these properties, were discovered and formulated during the 19th century.

**Discrepancies between observed behaviour and the equation of state.** If a graph is plotted of the mutual changes in pressure, volume, and temperature of a gas, then a three-dimensional surface is obtained. Such a graph for any laboratory gas being manipulated in a container shows that, for a certain pressure and temperature, the gas will change its phase; i.e., the substance can appear as a gas or a liquid or a solid. It is not easy to picture a three-dimensional surface, and it is usual to make two-dimensional projections of this surface onto a piece of paper. There are three such projections, and the most important one is the graph of pressure against volume. This will be a family of curves such that each member of the family will be a graph of pressure versus volume for a gas kept at constant temperature. Historically, laboratory experiments showed that for some gases, like oxygen and nitrogen, if the temperature were kept at room temperature, then no matter how much the gas pressure was increased (and the volume thereby decreased), the gas never condensed into a liquid; i.e., the pressure-versus-volume curve was a smooth one, with no sharp jumps or kinks in it. On the other hand, for many gases kept at room temperature, as the pressure was increased, a discontinuity in behaviour occurred, and the gas started to condense into a liquid. During condensation, the pressure and the temperature remained constant, while the volume of the mixture of gas and liquid decreased until all of the gas had turned to liquid. Thereafter, a further increase in pressure (still maintaining a constant temperature) resulted in a slight decrease in the volume of the liquid. In addition, as the gas condensed, it released energy, even though its temperature remained constant. This is the phenomenon called the latent heat of condensation, which was discovered by Black (1757) and studied systematically by Black and a colleague (1764), in the case of water vapour condensing into liquid water.

In spite of these early studies of condensation, prior to the work of the Irish physical chemist Thomas Andrews (1869), the conditions necessary to liquefy a gas by compressing it at constant temperature were not clear. Andrews established the existence of a critical-temperature curve, the significance of which was that if the actual temperature of the gas being compressed were greater than this critical temperature, then no amount of compression would liquefy the gas. If, however, the gas were compressed at a constant temperature below the critical temperature, condensation would always occur. If the temperature of the gas is kept just below the critical

Early  
specula-  
tions

Absolute  
zero

Critical  
point

temperature as the gas is compressed, then the volume change during condensation is small, while, if the gas being compressed is kept at just the critical temperature, then the gas passes directly into the liquid without any change in volume at all. The name critical point is given to that point on the constant critical-temperature curve that represents the termination of any observable distinction between the gaseous and liquid phases. Neither vaporization nor liquefaction, in the sense of boiling or droplet condensation, occur in substances having a temperature greater than the critical temperature.

An important problem that arises as a gas is compressed at constant temperature is whether the gas obeys the thermally perfect equation of state. In general, this equation is found to hold to within 1 percent as the gas density (which is the mass of gas contained in a fixed volume or, more importantly, the actual number of gas particles in a fixed volume) rises from the density of the gas at room temperature and pressure up to about 100 times this value. Thereafter, deviations from the predictions of the thermally perfect gas equation of state appear, until eventually the equation becomes completely wrong when the gas starts to condense, since during condensation the pressure and temperature remain constant, and the volume decreases.

**Empirical equations for specific gases.** The problem of determining the thermal equations of state of a real gas (as opposed to the hypothetical thermally perfect gas) is an old one. The first serious attempt was made by the Dutch physicist Johannes Diderik van der Waals (1873), who formulated a thermal equation of state containing two adjustable parameters (arbitrary constants that characterize certain variable factors in a system) that could be found by comparing experimental values of pressure, volume, and temperature measured in the laboratory with theoretical values containing the adjustable parameters predicted by his equation of state. There are now well over 100 empirical thermal equations of state available for a whole range of gases. Of the two best known, one contains five adjustable parameters, and the other contains eight adjustable parameters. These complicated equations can reproduce the complete range of observed pressure, volume, and temperature behaviour from the gas phase through condensation into liquid phase for a very wide range of gases. They are very useful for interpolation—*i.e.*, predicting values intermediate between measured values—but they suffer, as do all other empirical thermal equations of state, in that the adjustable parameters are not related directly to any aspect of the particle behaviour of the gas.

**Virial equation of state.** The particles of any real gas are surrounded by fields of force, so that the particles interact with each other, even when separated in the gaseous phase. These interparticle forces (called intermolecular forces) are the whole essence of real-gas behaviour, and any thermal equation of state must allow for these forces. Intermolecular forces do not include gravitational force, because, for the small masses of gas that occur in containers of laboratory or industrial size, gravitational force between particles is negligible. Gravitational effects in gases are important only when discussing the structure of the earth's atmosphere or of interstellar events.

There is only one way of writing the thermal equation of state of a real gas that will both fit laboratory data and also show the effect of intermolecular forces. This is called the virial equation of state, and it is derived from the thermal equation of state for an ideal gas by taking into account the attraction or repulsion between the molecules. It is written as a mathematical series with a very large number of terms:

$$\frac{P\bar{V}}{RT} = 1 + \frac{B(T)}{\bar{V}} + \frac{C(T)}{\bar{V}^2} + \frac{D(T)}{\bar{V}^3} + \dots$$

The quantities  $B(T)$ ,  $C(T)$ ,  $D(T)$ , etc., are called the second, third, and fourth virial coefficients, the first virial coefficient being unity. They are all independent of the gas pressure and density and depend only on the temperature. Viewed as a purely empirical thermal equation

of state, the virial equation is not particularly convenient, because, at moderately high gas densities, many terms must be added up, and, at very high densities, such as those that occur when the gas is condensing into a liquid, the equation may actually diverge and, therefore, be useless. In spite of this, the virial equation is of the utmost importance, because it forms a link between purely macroscopic (*i.e.*, bulk) properties, such as pressure, volume, and temperature, and microscopic properties, such as the intermolecular forces between the particles.

Because of difficulties associated with the virial equation of state for the case of dense gases during condensation, empirical thermal equations of state are still used today. Of particular value is the principle of corresponding states or phases, a law stating that all substances obey the same thermal equation of state, provided the equation is written in reduced variables; *i.e.*,

$$\frac{P\bar{V}}{RT} = \text{Function} \left( \frac{P}{P_{\text{crit}}}, \frac{T}{T_{\text{crit}}} \right).$$

This means that the product of pressure and volume, divided by the product of the universal gas constant and the absolute temperature, equals not unity, as would be the case with an ideal gas, but some mathematical function that should be the same for all substances. The reason why the actual pressure and temperature of the gas (on the right-hand side, which corrects the discrepancy between ideal and real gas) are divided by the critical pressure ( $P_{\text{crit}}$ ) and critical temperature ( $T_{\text{crit}}$ ) is that, as already noted, the critical-point values are unique for every substance, and, therefore, they represent a reference point closely related to the condensation of a gas.

#### THE PARTICLE-DESCRIPTION APPROACH TO GASES

Although thermodynamics provides a very general and very powerful discipline for determining the interrelationships among the many physical and chemical properties of gases, it is quite unable to predict the actual numerical value of these properties. It can predict, for example, the relationship between the constant-pressure heat capacity and constant-volume heat capacity of all gases in terms of the thermal equation of state, but it cannot predict the numerical value of either heat capacity of any gas. Calculations of the numerical values of the properties of gases require a microscopic theory based on the fact that all gases are composed of particles that may be single (monatomic) atoms or complicated polyatomic molecules. For the normal range of temperatures encountered in industrial applications (but not aerospace applications), all atoms may be regarded as particles possessing no internal structure; *i.e.*, they are considered to be solid particles. When atoms are bound together into polyatomic molecules, however, these molecules do possess internal structure; for example, the simplest polyatomic molecules consist of only two atoms bound together. Such a structure can rotate end over end and, therefore, possesses an internal mode of motion called molecular rotation. In addition, the two atoms may vibrate as if connected by a spring, so that the molecule also possesses another internal mode of motion, called molecular vibration. More complicated molecules can possess more complicated rotations and vibrations.

The use of any laboratory container of gas involves many billions ( $10^9$ ) of particles; for example, one cubic metre of air at standard conditions contains more than  $10^{24}$  particles. Every one of these particles is moving throughout the container in random fashion, and this is called the external mode of motion, or the random thermal translational motion of the particle. It is called thermal because the intensity of this motion bears a direct relationship to the temperature: the greater the thermal energy of the particle the faster it moves through space. In addition, if the particle is polyatomic, it also possesses internal modes of motion, such as rotational and vibrational motion. In principle, all of these motions, both internal and external, are governed by the laws of quantum mechanics. In practice, however, the translational motion can often be accurately described by the

Inter-  
molecular  
forcesThe vast  
numbers  
of gas  
particles

much simpler laws of Newtonian mechanics. Such a simplification does not usually hold for the internal motions, but in some cases it is valid for the rotational motion. Consequently, a discussion of the quantum internal motions may be expected to be more involved than the Newtonian external motion of translation. For gases at densities near atmospheric density, all of the particles spend most of their time moving with a constant speed, called the thermal speed, just as if they alone occupied the container; *i.e.*, any particle behaves as if it were alone in its container, notwithstanding the enormous number of other particles also present. At any instant of time, however, about 1 particle in 100,000 will be colliding with another particle or the container walls, and, in a time interval of one second, each particle of the gas will experience about 1,000,000,000 collisions. A collision between two particles is called a binary collision, and in such a collision both particles may change their speeds and the directions in which they were moving.

**Distribution functions.** The microscopic picture of a gas, then, is one of billions of particles in incessant thermal motion (a manifestation of its thermal energy), each particle now and again suffering a collision as it wanders randomly throughout its container. Clearly, it would not be sensible to try to follow the behaviour of each particle, even if these could be seen, which they cannot. In fact, if the position in space and the speed of each of a million particles could be written down every second, it would still take the age of the universe to write down the same information for all of the particles in a normalized room, and this information would be true only for an instant of time. Actually, this is no loss, because the behaviour of individual particles is not interesting. All that is really of importance is their macroscopic behaviour; *i.e.*, their behaviour averaged out over the vast number of particles in the container. Mathematical statistics is able to handle large numbers, and the procedure for dealing with the problem is to examine the behaviour of groups of particles, where each group consists of a very large number of particles that all possess some common properties. The common properties used are the positions in space and the speeds of particles, and this leads to the concept of what is called a distribution function. The distribution function is a mathematical equation that indicates what fraction of all the vast number of particles in the container have spatial positions lying within some arbitrarily chosen, exceedingly small region of the container and whose thermal speeds lie within an exceedingly small spread of speeds about some arbitrarily chosen speed.

More precisely, the distribution function is the probable number of such particles, the word probable being a reminder that it is impossible to say exactly how many particles even an exceedingly small region of the container actually contains at a given instant; the reason is that the number continually varies about its most probable value as a result of the random arrival and departure of individual particles, so that there is a higher or lower particle density in the minute region than the average density, which can be calculated with great precision by dividing the total number of particles by the total volume of the container. These variations, or fluctuations, in density arise as an inevitable consequence of the particulate nature of a gas and lead to observable effects in the laboratory.

**Forces affecting distribution function.** A knowledge of the distribution function is essential for any microscopic theory of a gas; however, its determination involves postulating some mathematical description of a gas particle and how a gas-particle collision actually occurs. In any real gas, even a binary collision—one between two particles only—is a complicated process, because each particle is surrounded by a force field that varies in space. This force field is such that it attracts another particle when that other particle is relatively far away but repels it when the other particle comes relatively close. That these intermolecular forces exist is evident from the fact that gases do condense into liquids, a phenomenon that cannot be explained except as a consequence of attrac-

tive forces at work between the particles. In addition, liquids strongly resist being compressed, which must be evidence of the repulsive forces. The long-range attractive forces, called van der Waals forces, arise from electrostatic interactions between the whole particles. Short-range forces arise when the electron clouds that surround the nuclei of atoms in a molecule overlap. These short-range forces are called valence forces, and they become stronger than the van der Waals forces when the two particles come sufficiently close together in a binary collision.

**Multiparticle collisions.** So far, the discussion has been concerned with gases at pressures near atmospheric pressure and density near that of normal atmosphere, a condition in which binary collisions alone are significant. As the density of the gas is increased, there is the possibility of three particles coming together at the same place and colliding in what is called a ternary collision. Perhaps even four particles and, in dense gases, an even higher number of particles may come together in a collision. To include ternary and higher order collisions in the discussion, the nature of the intermolecular forces among the various colliding particles must be known. It is just this specification of the forces among collision partners that gives rise to the various mathematical theories of a gas. It has been shown that the most complete and satisfactory theory is the one designed for a dilute gas, in which ternary and higher order collisions can be completely ignored. The dilute gas is not the same as the thermally perfect gas, a distinction that will be discussed later. If ternary and higher order collisions must be allowed for, then a dense gas is under consideration, and the theories for it are still incomplete.

**Theory of binary collisions in dilute gas.** It has been stated that every particle spends most of its time moving freely with a constant speed between collisions throughout its container. Of course, any such collision may, and usually does, change the speed of each particle; each retains this new speed undiminished until the next collision. Consequently, only the single-particle distribution function is important, since the laboratory properties of the gas will not depend upon the relative spatial positions and speeds of clusters of two or more particles but only upon the spatial position and speed of particles taken one at a time. Although collisions between particles in a dilute gas are infrequent as far as any particle is concerned, they must be allowed for. If the gas consists of monatomic, structureless particles, then, in a binary collision, the mass, momentum, and thermal kinetic energy (energy due to random motion) of the collision partners remain constant. This is known as an elastic binary collision. If the particles are polyatomic molecules possessing internal structure and internal motions, then, in a binary collision, although mass and momentum remain constant, it is possible that some of the thermal kinetic energy of the collision pair may be transformed into internal energy of the molecules by increasing the amount of energy already involved in the internal motions of rotation and vibration. This is called an inelastic binary collision.

#### BOLTZMANN TRANSPORT EQUATION

It is not difficult to derive the mathematical equation, called the Boltzmann transport equation, that describes the way the single-particle distribution function changes with time due to both types of binary collision, but it is a difficult equation to solve. Although the Boltzmann equation lies at the very heart of transport theory, it cannot be solved in general terms but only under special conditions, which, fortunately, are not too restricted. This article is concerned with two solutions of the Boltzmann equation, the equilibrium solution and the near-equilibrium solution.

**Equilibrium solution for Boltzmann equation.** The equilibrium solution is considered first. Mathematical analysis shows that if no external forces act on the gas, then the distribution function tends toward a value that is independent of spatial position and time, a value called the Maxwellian translational distribution function of thermal speeds. The existence of this value means that

Van der  
Waals  
forces

Binary  
collisions

## Entropy

the gas reaches a uniform steady state known as a state of thermodynamic equilibrium. In this equilibrium state, all of the laboratory properties of the gas—pressure, density, temperature, energy, heat capacity, and entropy—are constant, and, in addition, the pressure, temperature, and density have the same values throughout the entire volume of the gas. Entropy is a measure of the disorganization of a gas. In any gas there is always some of the energy that can be converted into work (which is usually what an engineer wants); the amount that can be converted is determined by the entropy of the gas (see THERMODYNAMICS, PRINCIPLES OF). The equilibrium state is achieved because there is an overall balance in the collision processes suffered by the particles; *i.e.*, the number of particles with any particular spread, or range, of thermal speeds remains the same anywhere in the container because of a balance between the numbers of particles gaining and losing a given change of thermal speed due to binary collisions. In addition, further analysis (known as Boltzmann's H-theorem) shows that there is a detailed balance in the binary collisions, so that the number of particles in a particular thermal-speed spread, which are changed by binary collisions of a specified type, is exactly balanced by the same number of inverse collisions; if, for example, a collision is speed depleting for one of the particles, then the inverse collision is speed replenishing for the same particle. An inverse collision is distinguished from a reverse collision, in which the two particles merely reverse their original paths in space. The existence of the Maxwellian translational distribution function of speeds has been confirmed by direct measurement using a molecular beam. (Such a beam is produced by allowing gas particles to escape from a minuscule hole in the walls of a heated tube into a space kept at very low pressure by vacuum pumps; the individual particles fall in the earth's gravitational field and are separated out according to their thermal speeds.)

**Maxwellian speed distribution function.** The Maxwellian speed distribution for a dilute gas is, in fact, a general result and holds for dense gases as well. Once the translational distribution function (Maxwellian) of a gas has been obtained, it is a simple procedure to calculate the many equilibrium properties of the gas, such as the number of particles colliding with the container walls every second, by allowing for particles coming from all directions and with all thermal speeds. The result can be used to calculate the average force that the particles exert on the walls as they rebound from it, and that force is a measure of the pressure of the gas, since the collisions are sufficiently numerous to be thought of as a continuous force on the walls. Intermolecular forces affect the calculated pressure, because the attractive van der Waals forces exerted by the particles within the body of the gas restrain particles that are just about to collide with the wall. In addition, the mean free path of a particle can be calculated as the average distance travelled by a particle between binary collisions. A particle interpretation of the temperature of a gas can also be obtained in terms of the average kinetic energy of the particles as they move randomly throughout their container.

**Equilibrium distribution function for internal energies.** The Maxwellian distribution function refers to the external motions of the particles but does not refer to their internal motions of rotation and vibration. It might be expected that just as there is an equilibrium distribution function for the translational random kinetic energy, so there would be an equilibrium distribution function for the internal energies as well. In an evaluation of this equilibrium internal energy distribution function, a mathematical term arises that is called the internal partition function of the gas. The partition function, which is a mathematical series, has no immediate direct physical meaning but is intimately related to the manner in which the total energy of the gas particles, due to their structure together with the energy involved in the effects of intermolecular forces, is divided up (partitioned) among the particles. It is here that kinetic molecular theory merges into statistical thermodynamics, because the basic problem of the latter is to decide just how the total

energy of the gas in equilibrium is to be divided up among the various energy modes of the particles. The analysis of the partitioning of energy examines the infinite number of ways the energy can be distributed and seeks to find if there is a preferred, or most probable, partitioning that is overwhelmingly likely to occur. The results of the analysis are expressed in terms of the partition functions of the various energy modes of the gas particles, which, as has been said, are very closely related to the equilibrium distribution functions of kinetic theory. The evaluation of the internal partition functions for thermally perfect gases is relatively easy, and it is possible to calculate all of the thermodynamic properties (*e.g.*, energy, heat capacity, entropy, etc.) of a thermally perfect dilute gas of particles possessing internal structure. If, however, the gas is one of interacting particles, then the evaluation of the internal partition function can be difficult, especially if the gas is dense, requiring an evaluation of the effect of ternary and higher order collisions.

**The link between thermodynamic and microscopic properties.** The partition function provides a direct link between the microscopic properties of the particles—their quantum energy states, their moments of inertia, their intermolecular potentials, etc.—and the laboratory properties of the gas—the thermal equation of state, the thermodynamic energy, heat capacity, and entropy. If the thermal equation of state of a gas of interacting particles is evaluated from the partition functions, then it turns out to be the virial (average kinetic energy) equation of state already introduced above. Each virial coefficient involves a mathematical quantity called the cluster integral. The second virial coefficient involves that cluster integral relating to the binary collision, while the third virial coefficient involves the cluster integral relating to ternary collisions, etc. Consequently, to evaluate the cluster integral, the dynamics of the collision must be calculated for a known intermolecular potential. For a dilute gas, where binary collisions alone are involved, the second virial coefficient can be evaluated for a variety of intermolecular potentials (see below *Mathematical models: virial coefficients*). To calculate the higher order cluster integrals, it is customary, because of ignorance of the true behaviour of three or more mutually interacting particles (called the many-body problem), to make the assumption of pairwise additivity: this states that the intermolecular forces involved in a many-particle collision are made up of the sum of two particle forces; for example, if three or more particles are interacting, then their interaction energy is the sum of their energies obtained by taking them in pairs. Although the assumption must be made in order to evaluate the cluster integrals, it is only approximate. Consequently, the third virial coefficient can be evaluated only approximately, which is the case for higher virial coefficients as well.

The many-body problem

**The ideal gas versus real gas.** The relationship between the hypothetical thermally perfect gas, discussed earlier, and a real gas is that the former is a special type of the latter. The thermally perfect gas has particles that are not surrounded by attractive intermolecular force fields, so that its particles do not interact when separated. They can be thought of as rigid particles that interact with other particles only at the instant of collision, when, on touching, they repel each other with infinite force. Any gas of rigid particles will show thermally perfect behaviour provided its density is sufficiently low so that the second and higher virial coefficients are all extremely small; if the particles are "point" particles of vanishingly small volume, then all of the virial coefficients are zero, and the gas is thermally perfect at all densities. It is for this reason that the internal-partition functions for thermally perfect gases can readily be evaluated.

**Origins of particle theory of gases.** The particle description of gases grew from ideas in the 17th and 18th centuries concerning special aspects of the collective behaviour of structureless gas particles that were supposed to have no surrounding force fields. The pressure exerted by such a gas on the walls of its containers was calculated, and the idea developed that temperature was re-

lated to particle motion. In the 19th century, the heat capacity of a gas kept at constant volume was calculated and found not to agree with experimentally measured values. When the heat capacity at constant pressure was calculated for the same gas, agreement was obtained with experimental values. The ratio of the two heat capacities was also calculated, and the idea was introduced that gas particles that possessed internal structure also had internal energy modes, such as molecular rotation and vibration. The idea of mean free path and the concept of binary collision were introduced. The first formal mathematical attempt to calculate the single-particle distribution function of a dilute gas was made by Maxwell in 1859 and refined by Boltzmann in 1868. The work of Maxwell and Boltzmann led directly to the classical (Newtonian) statistical thermodynamic theory of dilute gases of structureless particles in thermodynamic equilibrium in terms of the external, or translational, partition function. The idea of imperfect gases, real gases whose particles are surrounded by force fields, goes back to Newton. The first attempt to analyze them correctly was made in the 18th century, but it was van der Waals (1873) who first deduced the thermal equation of state of a real gas. The German physicist Rudolf Clausius developed (1875) a general theorem that gives the relationship between the intermolecular forces and the thermal equation of state, but it was not until 1902 that the virial equation of state and the virial coefficients were introduced. The statistical thermodynamic theory of imperfect gases was formulated in general terms by the American physicist J. Willard Gibbs (1901) using classical Newtonian mechanics. The previous year, the German scientist Max Planck discovered energy quantization, but it was not until later that the quantum statistical thermodynamics of real gases was developed by Satyendra Nath Bose and, independently, by Albert Einstein in 1924 and Enrico Fermi and Paul A.M. Dirac in 1926.

*Mathematical models: virial coefficients.* Various mathematical models have been suggested for the intermolecular force between two particles. The commonest assumption is one that is made for the sake of mathematical simplicity, and it assumes that the particles are both essentially spherical, so that the force between them does not depend upon their orientation in space (the intermolecular force has no angular dependence and is spherically symmetrical) but only upon their distance apart. Intermolecular forces are more often discussed in terms of the intermolecular potential energy between the particles. The simplest spherically symmetrical intermolecular potential is the rigid-sphere potential, which states that the particle is a solid sphere of prescribed size but not surrounded by an attractive force field. Such an intermolecular potential belongs to the thermally perfect gas. Among the many spherically symmetrical intermolecular potentials that have been proposed, the commonest and most useful is called the Lennard-Jones potential, which accurately describes the attractive van der Waals forces and, in addition, includes a term that gives the repulsive valence force, chosen for mathematical convenience and also because it is in good agreement with experiment. Virial coefficients have been calculated for many such intermolecular potentials, and it is found that they are more sensitive to the attractive force than to the repulsive one, so that any comparison between measured and calculated virial coefficients should yield information on the attractive van der Waals forces. The results of all of these calculations show that all virial coefficients should be negative at low temperatures, becoming zero at some intermediate temperature and rising to a positive maximum value at high temperature. Consequently, a determination of the pressure, volume, and temperature behaviour of a gas over a wide range of values of these properties should yield experimental data that can be interpreted in terms of the values of the virial coefficients. Experimentally, only the second and third virial coefficients can be measured, since the others are too small. In addition, the intermolecular potential cannot be determined uniquely merely by making laboratory measurements on pressure, volume, and temperature. An in-

direct procedure must be used, by assuming a mathematical equation for the intermolecular potential that contains unspecified constants, then calculating the virial coefficients and their dependence on temperature and then comparing experimental and theoretical results in order to determine the unspecified constants. Thereafter, the intermolecular potential, now with known constants, can be used to calculate other measurable gas properties that also depend upon the virial coefficients, such as the Joule-Thomson coefficient, the heat of sublimation of crystals, and the transport coefficients (see below *Transport coefficients*). The ability of the intermolecular potential to predict the experimentally observed values of these properties is a good test of its accuracy. Unfortunately, the largest virial coefficient (the second) is not very sensitive to the precise form of the attractive intermolecular force, while the third virial coefficient suffers from uncertainties about the effects of assuming pairwise additivity and also the effects of experimental error, since it is so small. Because of these limitations, any comparison of theoretically calculated and experimentally observed virial coefficients seldom eliminates an assumed form of intermolecular potential; rather, it gives the best form from a group of assumed forms on the basis that the best form fits the widest range of properties.

*Virial equation of state and dense gas.* It had been hoped that the virial equation of state would be applicable to dense gases and even to condensing gases, provided that a sufficient number of virial coefficients were taken into consideration. Several difficulties have arisen, however. For example, for ternary and higher order collisions, the intermolecular potential must be guessed on the basis of pairwise additivity, and this means that the cluster integrals for many-particle collisions are only very approximately known and may be seriously in error. Also, during condensation, when an enormously large number of particles are mutually interacting, the cluster integrals become dependent on the volume of the gas as the clusters get bigger and bigger. This is a branch of statistical thermodynamics that is not well understood and is still under active investigation. It seems clear that a virial expansion up to the fifth virial coefficient is mathematically convergent for densities as high as the density of the saturated vapour, that portion of the gas still uncondensed; however, the virial expansion is mathematically divergent and, therefore, useless for the density of the liquid. Consequently, the virial expansion cannot give a theory that goes right through the condensation transition from entire gas to entire liquid. There is no complete theory of condensation available at the present time. Ultimately, the virial expansion must fail altogether at very high densities, when the concept of the existence of individual interacting particles loses its meaning. This has led to another approach to the thermal equation of state of extremely dense gases and of liquids where a structure is assumed and where the question of how this structure arose is ignored.

*Latent-heat theory.* Another phenomenon that a theory of condensation should predict is the latent heat; namely, the release of energy from a gas that is condensing as its temperature remains constant. There is no theory for the latent heat, because it is intimately related to the condensation process, and, at the present time, knowledge of latent heats is dependent on thermodynamics. An equation called the Clausius-Clapeyron equation enables the latent heat of condensation to be deduced from knowledge of the rate of change of vapour pressure with temperature, together with knowledge of the densities of the liquid and vapour in the mixture. The latent heat depends upon the pressure and temperature at which condensation occurs, and it becomes zero at the critical point. The Clausius-Clapeyron equation, being a thermodynamic equation, is independent of the particle theory of matter.

Historically, specific forms for the intermolecular potential were studied by Maxwell (1866) and others, but it was not until 1924 that the effects of both attractive and repulsive forces were considered. The physical ex-

Method of  
determina-  
tion

planation of why repulsive forces arise was given in 1927, and in 1930 the van der Waals attractive forces were explained. A virial-equation approach to the problem of the condensation of a gas into a liquid was pioneered in 1927 and considerably extended in 1937.

**Nonequilibrium solution for the equation.** Turning aside from the equilibrium solution of the Boltzmann transport equation, which describes the state of thermodynamic equilibrium of any gas, be it dilute or dense, the case can now be considered where the gas is in a nonuniform state. If there are variations (*i.e.*, gradients) of density, gas velocity, or temperature in the gas, then transport processes arise. This means that some physical property of the gas flows through the gas down the gradients. If the property transported is mass, then the transport process is called diffusion, and it arises because of a gradient in the density of particles between any two regions of the gas. If the property transported is momentum, then it is viscosity that arises from gradients of gas velocity in the gas, such as will occur if the gas is in motion along a wall. If the property transported is thermal energy, then the transport process is called thermal conduction, and it arises if there are regions of different temperature in the gas. The three transport processes are characterized by three transport coefficients.

For a dilute gas in which only binary collisions need be considered, the governing equation is the Boltzmann transport equation; it gives the space and time behaviour of the single-particle distribution function. The entire equation can be mathematically manipulated to give certain mathematical relationships called the flux vectors, which contain the transport coefficients. To evaluate the flux vectors and, therefore, the transport coefficients, two things must be known; namely, the single-particle distribution function of the nonuniform gas and, because the transport processes are related to binary collisions between particles, details of the dynamics of a binary collision, which, as has been pointed out, require a knowledge of the intermolecular potential.

**Transport coefficients.** It has been remarked that the Boltzmann transport equation for binary collisions can be solved only under special conditions: the effective diameters of the particles must be much less than their mean free path, and the changes in density, gas velocity, and temperature over a mean free path must be extremely small. Under these conditions, the Boltzmann equation can be solved (the Chapman-Enskog solution) by using the method of successive approximations; it yields a solution for the nonequilibrium distribution function in the form of a mathematical series. Each term in the series represents an increasing departure from the Maxwellian equilibrium distribution function, so that the nonequilibrium distribution function is expressed in terms of the localized density, gas velocity, and temperature values, all of which vary throughout the volume of the gas and also vary with time. The first approximation to the solution is one that is valid for small spatial gradients and gives a measure of the number of particles transferred, or the flux vectors, that depend on these gradients, so that the transport coefficients can be calculated after the intermolecular potential has been specified. In this respect, the calculation of the three transport coefficients is completely analogous to a calculation of the virial coefficients of the equilibrium gas; that is, the intermolecular potential is specified; the collision integral, a mathematical quantity relating the angle of deflection of one particle with respect to the other involved in the binary collision, is calculated; and, thereafter, the flux vectors are calculated, and the transport coefficients are obtained in terms of the assumed intermolecular potential.

Transport coefficients have been calculated for a variety of spherically symmetrical and other types of intermolecular potentials. Such calculations show that, although the transport coefficients are more sensitive to the repulsive than to the attractive part of the force between two particles (whereas the virial coefficient is just the converse), they depend essentially upon the fact that there is a repulsive force and not much on the precise form of the force. As with the virial coefficients, the form of the

intermolecular potential that agrees with laboratory measurements of the transport coefficients cannot be deduced.

**Transport coefficient for dilute, polyatomic gas.** The Chapman-Enskog solution of the Boltzmann equation was originally framed to deal with dilute, monatomic gases of structureless particles where all binary collisions are elastic. For the commoner case of polyatomic molecules, allowance must be made for inelastic collisions between nonspherical particles, when random kinetic energy is converted into internal energy of rotation and vibration. A Chapman-Enskog type of solution has been given to the Boltzmann equation for a dilute, polyatomic gas, but it involves details of the intermolecular potential in an inelastic binary collision that are still unknown. A simplified version of this theory, in which the inelastic collisions are dealt with in terms of rotational and vibrational relaxation times, (see below *Thermal relaxation stage*) has been given, and studies show that inelastic binary collisions do not appreciably affect the diffusion and viscosity coefficients but do significantly affect the thermal-conduction coefficient. Such a result would be expected, since the thermal-conduction coefficient deals with energy transfer through the gas, and inelastic collisions are concerned with energy-transfer processes between particles. The problem of calculating the transport coefficients of dilute, polyatomic gases is still under investigation, and much remains to be done.

**Transport coefficient for nonchaotic gas.** When the gas density is more than about 100 times atmospheric density, ternary and higher order collisions must be considered in addition to binary collisions, and this consideration affects the transport coefficients profoundly. The Boltzmann transport equation and its Chapman-Enskog solution are not applicable to the dense gas, because what may be called molecular chaos may not exist. Molecular chaos, which must hold if the Boltzmann equation is to be applicable, requires at all times that the spatial positions and speeds of the particles involved in collisions be in no way related to each other (they are not correlated), so that there is no effect of previous collisions on any collision occurring, which means that the results of a collision must depend upon the immediate state of the particles during the collision and not on their previous history. Molecular chaos is readily achieved in a dilute gas, because particle correlation is negligible, since a recollision between the same two particles is extremely unlikely. In a dense gas, a substantial proportion of all particles are suffering collisions at any instant, and such collisions may be recollisions, because the mean free path becomes comparable with the particle diameter (in a dilute gas, the mean free path is very large compared with the particle diameter, and most of the time particles in a dilute gas are travelling freely). In such a recollision, spatial positions and speeds may be correlated, and, thus, molecular chaos—and, therefore, the Boltzmann equation—no longer holds. What is required is a multiparticle distribution function that allows for particle correlation (*i.e.*, the relative spatial positions and speeds of clusters of two or more particles), recognizing the fact that any one particle can affect the spatial positions and speeds of all of the other particles in its vicinity.

**Distribution function for  $N$  particles.** It is possible to write down the equation (the Liouville equation) that gives the changes in space and time of the  $N$ -particle distribution function,  $N$  being the total number of gas particles in the container, a total that is, as has been discussed, an enormous number. From the equation it is possible to derive, by mathematical methods, a chain of equations in which each equation in the chain involves the changes in space and time of two consecutive lower order (*i.e.*, fewer particles) distribution functions.

At the end of the chain, there will be an equation that gives the single-particle distribution function used in the Boltzmann equation, in terms of the two-particle distribution function. The chain of equations is called the BBGKY hierarchy of equations. For purposes of calculation, the chain of equations must be broken, since it is

Recol-  
lisions

impossible to handle a vast number of equations at the same time, by making some assumption about the dependence of some higher-order distribution function on the lower-order distribution functions and then dealing with a finite, as opposed to an effectively infinite, set of chain equations.

**Time scales.** One method of doing this is based on a realization that if a gas achieves a state of thermodynamic equilibrium, or a nonequilibrium steady state with unchanging gradients of properties, solely by collisions between particles—be they collisions of second or of higher order, elastic or inelastic—then the process of achieving that state will require a finite time because such collisions do not occur infinitely fast. The problem of calculating the uniform state of thermodynamic equilibrium or nonuniform steady state of a gas is still unsolved and represents a great challenge to present-day research workers. Any progress that has been made has been based on the recognition that, during this approach to a final state, several quite different time scales are involved. The first time scale is that appropriate to the initial stage. This time scale is the duration of a collision; that is, the quotient of the effective range of the intermolecular force field between two colliding particles and their average random thermal relative speed; it has a value of about  $10^{-13}$  second. Analysis of the initial stage is a dynamic problem dealing with the detailed motions of individual particles, and the gas cannot be described in terms of its laboratory properties, such as density, gas velocity, and temperature. The next characteristic time interval is that between collisions, about  $10^{-11}$  second. In between the two times, the gas is being brought into a state where a statistical description is possible in terms of distribution functions but where a laboratory description is still not yet possible in terms of density, gas velocity, and temperature. This may be called the kinetic stage, and the gas must be described by its multiparticle distribution function. After a time equal to the duration of a collision—*i.e.*, after the initial stage—all the multiparticle distribution functions have changed so rapidly that they can all be described in terms of the single-particle distribution function, which effectively has not changed at all. Assuming such a simplification has enabled researchers to solve the BBGKY chain of equations that describe the kinetic stage and that allow, in principle, for multiparticle collisions before molecular chaos is established. Unfortunately, the solution is a mathematical series that diverges and, therefore, is useless when four-particle and higher-order collisions are considered. It would appear that the method (named Bogolyubov) is valid for gases having densities such that binary and ternary, but no higher-order, collisions occur.

This is as far as the kinetic theory of dense gases has been developed; a completely different approach may be required, one that does not treat a dense gas as a gas in which multiparticle collisions occur in terms of the binary, ternary, and higher-order collisions.

#### SPECIAL CONDITIONS

**Hydrodynamic properties of a gas.** The initial and kinetic stages in the process by which a gas approaches an equilibrium state or a steady nonuniform state take place so rapidly that they are, to all intents and purposes, beyond laboratory measurement. In view of the great difficulties involved in developing a theory of these stages, the discussion will revert to a consideration of the behaviour of a gas after they are complete. The next stage in the approach of the gas to its final state, one that does lie within the capabilities of laboratory techniques, is that describable by the Boltzmann equation, involving the single-particle distribution function and its solutions. This is called the hydrodynamic stage, because it can be described by mathematical equations that involve properties such as density, gas velocity, and temperature, rather than the statistical concept of a distribution function. The equations are called the Navier-Stokes and the Burnett equations of hydrodynamics. If the gas is polyatomic, there is another stage, which is the final approach to thermodynamic equilibrium or to a steady nonuniform

state; this is the thermal-relaxation stage and involves energy exchanges between the external (translational) energy mode and the internal energy modes of the polyatomic molecules.

**Hydrodynamic stage.** Rather than continue the discussion in general terms, it is easier to consider an important application of the hydrodynamic and thermal-relaxation stages: the passage of a plane sound wave through a gas. Such a sound wave causes any randomly chosen, small volume of gas to be alternately compressed and expanded, so that the density, gas velocity, and temperature of the small volume will vary cyclically with time as the sound wave continues to pass through the gas. The compressions heat the gas, and the expansions, called rarefactions, cool it. Transport processes, especially the transfer of heat and of momentum, occur between the regions of compression and rarefaction, and in each cycle some of the forward-directed energy of the sound wave is converted into random thermal energy of the gas. The energy of the sound wave suffers classical (*i.e.*, Newtonian) absorption and also classical dispersion, and the speed of passage of the wave through the gas depends upon the frequency of the alternations of compression and expansion. The frequencies for which significant sound-wave absorption and dispersion occur are usually higher than the frequencies of sound waves audible to the human ear, and the waves are called ultrasonic. Such waves disturb the state of thermodynamic equilibrium of the gas, and the rate of return to a state of thermodynamic equilibrium can be measured in the laboratory. This is the hydrodynamic stage governed by the macroscopic equations of Navier and Stokes and of Burnett.

Classical absorption and dispersion (the type just described) is the only type of energy-loss process occurring when a sound wave passes through a monatomic gas, whose particles possess no internal structure. If, however, the gas is composed of polyatomic molecules, much larger absorption and dispersion result from thermal-relaxation processes. Thermal relaxation is a consequence of the fact that the internal energy modes of polyatomic molecules cannot change their energies as quickly as the external (translational) energy mode.

The physical picture is one in which, before passage of the sound wave, the gas is in a state of thermodynamic equilibrium with the total energy partitioned out, in accordance with the partition functions already referred to, between the various energy modes. The sound wave comes along and disturbs this equilibrium, because the compressions increase the total energy of the gas, while the rarefactions decrease the total energy. The change in energy must be distributed between the various energy modes (external and internal) of the particles to allow a new state of equilibrium to be achieved. The redistribution (or repartitioning) requires inelastic collisions to transfer the energy from the external translational mode into the internal energy modes, and such inelastic collisions take a finite time to occur. Evidence obtained from experimental studies of the absorption and dispersion of ultrasonic waves by polyatomic gases suggests that the energy is transferred between the various energy modes by binary inelastic collisions, even for exceptionally dense gases having densities approaching those of liquids. It is found that the translational energy relaxation time (the time taken for the translational energy distribution function to change to its new equilibrium value) is about equal to the time between binary collisions. In addition, the rotational energy relaxation time for all polyatomic molecules (except such simple diatomic molecules as oxygen, nitrogen, and hydrogen) is only slightly longer. The vibrational energy relaxation time, however, may lie between  $10^{-8}$  and  $10^{-6}$  second, depending on the molecule concerned. Consequently, the vibrational energy changes in polyatomic molecules cannot keep in step, or in equilibrium, with the very rapid translational and rotational energy changes that occur as the sound wave passes through the gas. To calculate the amount of absorption and dispersion that occurs requires a calculation of the number of binary inelastic collisions occurring in the polyatomic gas every second and knowledge of how

Sound waves

Time scales

this number depends upon the density and temperature of the gas. It is a problem in quantum mechanics involving two polyatomic molecules, not necessarily possessing spherical symmetry, interacting with some complex intermolecular potential that depends upon the spatial orientation of the two molecules, as well as on their separation distance. Such a complicated collision problem can be solved only in rather approximate terms; it is a much more difficult calculation than that needed to evaluate the virial and transport coefficients of monatomic gases. The relative simplicity of the treatment of monatomic gases derives from the applicability of Newtonian mechanics to elastic collisions uncomplicated by the participation of internal energy modes and thermal-relaxation effects.

**Thermal relaxation stage.** Approximate calculations of inelastic collisions show that at any given temperature the relaxation time depends, roughly speaking, on the amount of energy to be exchanged between the translational energy mode and the internal energy mode under discussion. It does not take much energy to set molecular rotations into motion, and many of the binary collisions that occur in a room-temperature polyatomic gas are, in fact, sufficiently energetic to cause molecular rotation (they are inelastic collisions), and this is why rotational relaxation times are not much greater than the time between binary elastic collisions. It usually requires, however, a considerably larger amount of energy to start off molecular vibrations, and exceedingly few of the binary collisions in a room-temperature polyatomic gas are sufficiently energetic to pass translational energy into the vibrational energy modes of the molecules; hence, the vibrational relaxation time is long.

**High temperatures.** Since internal energy-relaxation-time measurements are capable of yielding valuable information on intermolecular forces, considerable effort is being given to studies of the temperature dependence of relaxation times. Ultrasonic absorption studies are limited to gases at room temperature and a few hundred degrees above it, so that another technique must be found to study high-temperature gas relaxation behaviour that is becoming so important in modern aerospace technology, as in the flow of a hot gas through a rocket nozzle. Such a technique is the shock-wave method, in which relaxation processes can be studied up to temperatures as high as 1,000,000°. The shock-wave method has been used for studying not only rotational and vibrational relaxation processes in polyatomic gases but also dissociation relaxation processes, in which the molecular vibrations have become so energetic that the atoms of the molecule fly apart and the molecule breaks up. In addition, at higher temperatures, the individual atoms, which previously had behaved as structureless particles, show that they are formed from electrons and nuclei, because electronic excitation of the electrons occurs, eventually resulting, perhaps, in ionization of the atoms, whereby they lose one or more of their electrons.

**Chemical reactions in gases.** Dissociation and ionization processes are more commonly thought of as chemical reactions. Polyatomic gases are capable of undergoing a vast number of different chemical reactions where the chemical bonds that bind atoms into molecules and electrons into atoms are broken and the molecules or atoms thereby change their chemical nature. Among the striking features of chemical reactions is the strong dependence of their velocities on density and temperature, indicating that reactions proceed because of inelastic collisions between molecules. Chemical-reaction-rate theory is a branch of kinetic theory, and a quantum kinetic theory of chemical reactions exists that is very similar in description to the kinetic theory of the transport processes in dilute, polyatomic gases and which suffers from all the limitations of that theory.

**Summary.** In conclusion, it can be stated that laboratory experiments on gases can provide a vast amount of data relating to the physical and chemical behaviour of gases as their pressure, density, temperature, and gas velocities are changed. It is the task of statistical thermodynamics and kinetic theory to provide procedures for calculating the various equilibrium and nonequilibrium

properties of gases. The equilibrium properties can be determined in terms of the virial coefficients and partition functions. The nonequilibrium properties must be determined in terms of the effective sizes of the particles (their collision cross sections) as they mutually interact because of the intermolecular forces that exist among them. Quantum mechanics is capable of solving these problems in principle but is far from doing so in practice. What has been achieved is a satisfactorily complete particle description of the thermodynamic equilibrium and transport properties of dilute, monatomic gases in terms of some assumed form of intermolecular potential. In addition, there is an equally satisfactory particle description of the thermodynamic equilibrium properties of dilute, polyatomic gases, but there is no comparable quantitative theory for their transport properties. The theory of the thermodynamic equilibrium and transport properties of dense gases is still incomplete and will remain so until a great deal more is known about both the many-body problem (the mutual interaction of three or more particles) and how to calculate exact inelastic collision cross sections.

**BIBLIOGRAPHY.** The full theory of the equilibrium properties of gases is given in J.O. HIRSCHFELDER, C.F. CURTISS, and R.B. BIRD, *The Molecular Theory of Gases and Liquids*, corrected printing (1965); the full theory of the transport processes of gases in S. CHAPMAN and T.G. COWLING, *The Mathematical Theory of Non-Uniform Gases*, 3rd ed. (1970); and the full theory of thermal-relaxation processes in gases in J.F. CLARKE and M. MCCLESNEY, *The Dynamics of Real Gases* (1964). A good but rather dated compilation of experimental values of equilibrium and transport properties of gases and liquids is R.C. REID and T.K. SHERWOOD, *The Properties of Liquids and Gases* (1958).

(M.McC.)

## Gases, Industrial and Domestic

Industrial and domestic gases include a variety of gases, some occurring naturally in the earth or atmosphere, some manufactured, which are used for heating or in certain manufacturing processes. The leading domestic gas throughout the world is natural gas, or methane, employed for space heating and cooling, for heating water, and for cooking. Gas manufactured from coal and oil is still burned in many countries but is being rapidly supplanted in industrialized areas by less expensive and more convenient natural gas, as reserves are discovered and long-distance pipelines constructed.

Industrial gases have a much broader range of chemical composition than domestic gas. This article includes not only manufactured gases consumed by industry for heat and power and as a chemical raw material but also other gases used extensively in industrial processing. Gases can be conveniently divided into two groups: those that are or can be recovered by the liquefaction of air, including oxygen, nitrogen, carbon dioxide, and the noble gases (helium, argon, krypton, xenon, and radon); and those that are manufactured and used in large quantities as intermediates in the production of another product, and in smaller quantities directly. They include hydrogen, carbon monoxide, acetylene, chlorine, ammonia, sulfur dioxide, and mixtures of hydrogen and carbon monoxide; other gases, such as fluorine, hydrogen chloride, hydrogen cyanide, and hydrogen sulfide, which are used commercially in relatively small quantities, are not covered. For each gas, its history, reserves, methods of production, transportation, prices, and uses are discussed.

### RESIDENTIAL AND INDUSTRIAL HEATING GASES

**Manufactured gas.** Manufactured gas, first produced in the late 18th century by heating coal in the absence of air, soon replaced the candle and oil lamp as a principal source of illumination. The charter for the first gas company was granted in London in 1812, with other cities of the world soon following. Gas was used first for street lighting and public buildings and later for private residences. When electricity, which provides a better, safer light, displaced gaslight in the late 19th century, the gas industry sought applications of its product in heating.

Coal gas, produced by the distillation of coal, has a

## Coal gas

heating value ranging from about 475 to 560 British thermal units per cubic foot (about 30 litres), depending on the temperature to which the coal is heated and the nature of the coal used. A British thermal unit (BTU) is the quantity of heat required to raise the temperature of one pound (454 grams) of water 1° F (0.56° C). Coke-oven gas, given off when coal is carbonized to make coke, the fuel for the blast-furnace production of pig iron, has a composition similar to coal gas and, in the past, was used extensively to supplement coal-gas supplies. Coke-oven gas, on leaving the oven, is treated to remove tar, ammonia, light oil, and other chemical substances before it is distributed to consumers. The coke ovens may be fueled by part of the coke-oven gas unless industry demand for it is high; if so, the ovens can be heated with a lower quality gas made in other ways from coal.

Another type of manufactured gas, called water gas, is made by a cyclic process in which steam is blown over a bed of burning coke. Water gas has a heating value of about 300 British thermal units per cubic foot, which can be increased to 500 or more, however, by carbureting it with petroleum fractions—a process in which the heat contained in the water gas raises the temperature of the oil high enough to convert it into hydrocarbon gases with high heating values. The heating value of water gas is increased to these levels to make it suitable for distribution to consumers.

Producer gas, which is easier and less costly to manufacture than either coal or water gas, has a much lower heating value (about 130 British thermal units per cubic foot) because it is produced in a continuous, air-using process that dilutes it with nitrogen. The largest use for producer gas is in industrial plants and for heating coke ovens when industry demand for coke-oven gas is high. When the gas is burned where it is produced, it is more valuable because it still contains the heat of its manufacturing process. When producer gas must be transported long distances, it cools and loses this heat.

Other manufactured gases are produced from various petroleum fractions or from natural gas. Originally, such gases were added to enrich gases of lower heating value made from coal to achieve a uniform-quality product. Production processes include (1) reforming of natural gas (and other higher molecular weight hydrocarbon gases) at high temperatures to break up the molecule; (2) cracking (breaking down into smaller molecules) of natural gas or other lightweight hydrocarbons over a catalyst; and (3) cracking oil into lightweight gases (oil gas) with a high heating value. A large number of processes, employing a wide variety of different types of equipment, have been developed for each of these raw materials. At any given location the particular manufacturing method depends on many engineering and economic factors.

Manufactured and natural gases have frequently been mixed to obtain the desired heating value and other physical and chemical properties. The amount of mixed gas supplied in any given area generally depends on the relative costs of manufactured and natural gas.

Generally speaking, the production and consumption of manufactured gas has declined steadily as new reserves of natural gas have been discovered and as long-distance pipelines have been built. The two largest sources of manufactured gas have been carbureted water gas and coke-oven gas. Bituminous coal has been the principal raw material, with lesser quantities of coke, anthracite, oil, and tar providing the balance.

**Natural gas.** Proved natural-gas reserves of the world, excluding the Soviet Union, are estimated at approximately 10<sup>15</sup> cubic feet. The United States has the largest share, about 25 percent, and Algeria the next largest. Important quantities are also found in Iran, The Netherlands, Saudi Arabia, Canada, Kuwait, and in the North Sea off the United Kingdom. The deposits found in The Netherlands and the North Sea have created a rapidly expanding market for natural gas in western Europe. Eastern Europe is supplied by the Soviet Union, which has recently increased its estimate of reserves; if the estimate proves accurate, the Soviet Union reserve will be the largest in the world.

Natural gas occurs in reservoirs beneath the surface of the earth; its existence must be proved by drilling. With the large discoveries under the North Sea and the Gulf of Mexico, drilling interest has shifted from onshore to offshore locations, resulting in development of new technology for drilling wells at ever-increasing depths (see also PETROLEUM AND GAS EXTRACTION). Though offshore drilling costs are much higher than those onshore, the potential for finding new gas reservoirs is thought to be much higher.

**Distribution and storage.** Natural gas usually undergoes processing of some kind before it is transported to the consumer, the amount and type of processing depending on the chemical characteristics of the gas as it comes from the well. If it is present, hydrogen sulfide must be removed (by-product sulfur is recovered and sold). Other nonhydrocarbon gases may also be removed to meet standards prescribed for pipeline gas. Valuable higher hydrocarbons (natural-gas liquids) are normally recovered before the natural gas is transported to markets.

Production and marketing arrangements vary in different parts of the world. In some nations, such as Mexico and the Soviet Union, the industry is completely nationalized. In Britain, Japan, Italy, and France exploration and development are carried out by either private firms or the government, but transportation and distribution are a government monopoly. In the United States, exploration, production, and transportation are handled by private firms, regulated by federal, state, and local commissions.

Storage facilities for natural gas have grown substantially. In the United States, for example, where demand is usually maximum during the winter months, it is not economically feasible to construct pipelines large enough to meet peak demands. Thus, natural-gas storage, mainly in depleted gas or oil reservoirs located near the large-volume consumers, has grown rapidly. Where natural storage facilities are not available, the product is stored in liquid form.

**Consumption.** Consumption patterns for natural gas vary. In western Europe, natural gas has not been available in most countries until very recently; therefore, it supplies only about 30 percent of gas demand, with liquefied petroleum gas supplying another 9 percent. In homes, it is used for cooking and water heating but is not as widely applied in space heating as it is in the United States. As natural gas becomes more widely available, however, its consumption is expected to increase. In western Europe, natural gas provides the same advantages to industrial users as it does in homes and thus is expected to continue making significant inroads into this market at the expense of coal and, to a lesser extent, oil. In the early 1970s, however, the cost of European natural gas was still much higher than U.S. gas.

By far the major use of natural gas is as fuel, though increasing amounts are being taken by the chemical industry for raw material. Among industries consuming large volumes are food, paper, chemicals, petroleum refining, and primary metals. In the United States, a large amount fuels household heating plants; in the Soviet Union, a considerable volume goes for electric-power generation.

In the chemical industry, natural gas supplies an ideal feedstock (raw-material source) for the manufacture of ammonia, methanol, acetylene, and hydrogen. Its advantages over other raw materials include longer life and lower capital requirements for plant facilities, generally lower operating costs, and less air pollution. Worldwide, natural gas supplies about 20 percent of total energy demand, with the United States consuming about 60 percent of the marketed production in 1970. Estimates made by the Economic Commission for Europe predict that the increases for natural-gas demand between 1967 and 1980 will be about 308 percent for western Europe, 286 percent for eastern Europe, 283 percent for the Soviet Union, but only 29 percent for the United States. Despite the rapid growth in natural-gas usage, there are still some countries where lack of marketing capabilities prevents utilization of all the gas produced.

Underground gas storage

Future world gas consumption

World reserves of natural gas

In South America, gas production exceeds  $3 \times 10^{12}$  cubic feet per year, of which about one-third is unsold and must be flared (burned at the well). Projections of future gas demand forecast large new world requirements, if the gas can be supplied. Incentives to increase exploration and drilling are expected to lead to additional supplies of natural gas, since large, yet-to-be-discovered deposits are believed to exist.

Ultimate recoverable (with present technology and economics) world reserves are estimated at  $13.3 \times 10^{15}$  cubic feet. The value of these reserves depends upon the ability of producers to transport the product to market. In this respect, an advantage of natural gas over oil is that a gas pipeline in a cold climate does not need to be kept heated as does an oil pipeline. In a region such as the North Slope of Alaska, this consideration raises ecological problems. Of course, possible damage done to land during construction of a pipeline is a concern with either gas or oil.

Some very large reserves of natural gas have been discovered but are uneconomic to tap. Gas and petroleum are held underground, as in a sponge, between grains of sand or in the spaces inside porous rocks, rather than in a simple pool. Sometimes the gas is so tightly held that it will not flow out easily, and extraction is uneconomic. Experiments using nuclear explosives to break up these tight formations and thus to increase gas flow to economic levels have been performed in the United States (see PETROLEUM AND GAS EXTRACTION).

Another potential method for augmenting natural gas supplies is by the gasification of coal. When coal reacts with oxygen and steam under controlled conditions, it is converted to a mixture containing hydrogen, methane, oxides of carbon, and impurities. After the impurities are removed, the gas can be upgraded to a product that is essentially methane, a gas with a much higher heating value than that previously manufactured from coal. A number of different upgrading processes have been studied on a pilot-plant scale, and many appear to be technically feasible, but the economics of producing a synthetic gas from coal had not yet been demonstrated in the early 1970s.

**Other petroleum-based gases.** These include liquefied petroleum gas and ethane.

**Liquefied petroleum gas (LPG).** Composed of propane, butane, or propane-butane mixtures, liquefied petroleum gas is part of the natural-gas liquid obtained at natural-gasoline plants, recycling plants, and petroleum fractionators after separating out the natural gas. Though founded early in the 20th century, the liquefied-petroleum-gas industry did not experience rapid growth until after World War II.

Reserves of liquefied petroleum gas and ethane (see below) are linked to natural gas and petroleum reserves. Estimates in 1968 put reserves of all natural-gas liquids (only part of which are liquefied petroleum gas) at 8,000,000,000 barrels. One barrel equals 42 U.S. gallons or 159 litres. At an average ratio of liquefied petroleum gas and ethane to total natural-gas liquids of about 3:5 this would represent ten years' supply at 1970 consumption rates. Strong demand and improved processing methods have encouraged production of maximum yields of liquefied petroleum gas and ethane from natural gas.

Transported and stored in liquid form under moderate pressure, either in steel cylinders for home use or in railroad tank cars, tanker trucks, barges, or pipelines, liquefied petroleum gas changes to gaseous form when the pressure is released and then can be used like natural gas. The product is stored in pressurized containers above ground and, more recently, in underground storage caverns.

About 40 percent of annual production goes for residential and commercial purposes, while another 40 percent is used as a raw material in the chemical industry. Important domestic users are farmers, who receive the product in steel cylinders and use it for cooking, water heating, powering trucks and tractors, burning weeds, drying crops, and curing tobacco. Liquefied petroleum gas also finds use in synthetic-rubber manufacture; in in-

ternal-combustion engines of taxis, trucks, and buses; in oil refineries; and in electrical utilities, where it has begun to supplant other fossil fuels, which cause objectionable amounts of pollution.

**Ethane.** Ethane is also recovered from natural-gas liquids or can be produced by cracking light petroleum fractions. Shipped as a liquid under moderate pressure, ethane is used both as a fuel and in a number of chemical processes. Relatively large amounts are consumed in the production of acetylene, the raw material for the manufacture of ethylene oxide, polyethylene plastics, styrene plastics, and ethyl alcohol.

#### GASES PRODUCED BY LIQUEFACTION OF AIR

**Oxygen.** The most abundant of the chemical elements, oxygen comprises about 21 percent by volume of the earth's atmosphere and is the most important of the industrial gases. Usually produced by cooling air until it liquefies (see illustration), then separating out its com-

Steps involved in the liquefaction of air.

ponent gases, oxygen may also be obtained as a by-product of the electrolysis of water in the production of hydrogen. Electrolysis involves passing an electric current through water, separating it into hydrogen and oxygen. Electrolysis, however, is economically feasible only if small quantities are required and low-cost electric power is available.

Of the total world production of oxygen in 1969, the United States produced about 30 percent, or about 12,800,000 tons. Japan produced 9,700,000 tons, or about 22 percent, while the Soviet Union and West Ger-

Transportation and storage of liquefied petroleum gas

many each accounted for about 11 percent of the total. During the 1960s world production increased more than fourfold.

Demands for large amounts of oxygen have resulted from the introduction of the basic oxygen process in the steel industry. Large oxygen plants sometimes serve a single consumer; frequently, however, a single plant provides for a number of consumers through a pipeline distribution system. Oxygen is marketed in eight different grades, according to the percentage of oxygen in the gas and to the type and quantity of impurities that are permitted.

Oxygen  
transport  
methods

Gaseous oxygen is transported at high pressures in steel cylinders, tank cars, and tube trailers. Liquid oxygen is shipped in insulated cylinders, tank trucks, and tank cars. In small quantities, liquid oxygen is shipped in insulated containers similar to those used for liquid nitrogen and liquid air. For large volumes, oxygen is often pipelined (the cheapest method of transportation). Oxygen prices have steadily declined, owing to improvements in production technology and economies of scale made possible by the large-volume demands of the steel industry. Plants with capacities as large as 1,400 tons per day have come into operation. The cost of power is the principal item of direct operating expense, so that site location generally is a compromise between nearness to markets and cost of electricity.

Most industrial oxygen is consumed in primary metal processing, with the steel industry taking the lion's share. The second-largest outlet for oxygen is in the manufacture of industrial chemicals, with acetylene manufacture comprising nearly half of this market. Ethylene oxide, methanol, and titanium dioxide production also require large amounts of oxygen. The gas is also used in a wide variety of other applications: in waste-water treatment; in liquid-oxygen explosives; in such aerospace applications as oxidizing liquid propellants and supplying life-support systems; in hospitals for the artificial atmosphere in oxygen tents and incubators and in the gaseous mixture in anesthetics; in torches for cutting and welding metals; and in a low-cost method of drilling certain types of hard rock formations in preparation for blasting.

**Nitrogen.** Because nitrogen—a colourless, odourless, tasteless gas—comprises about 78 percent of the earth's atmosphere, it is only natural that its large-volume preparation is by air liquefaction. The gas also occurs in a combined state in proteins, in other organic materials, in ammonium salts, and in large natural deposits as potassium and sodium nitrates. Reserves are virtually unlimited. During the 1960s, world nitrogen production increased sharply from about 2,700,000 tons in 1960 to 18,100,000 tons in 1969.

Producing  
nitrogen  
from the  
liquefac-  
tion of air

In the production of nitrogen by the liquefaction of air, the air is separated into its two major components, oxygen and nitrogen, by fractional distillation at extremely low temperatures. Nitrogen, with the higher boiling point, evaporates out, leaving oxygen in the liquid form. Costs of manufacturing elemental nitrogen depend mainly on the scale of operations, on the cost of electricity, and on purity requirements. Small volumes of nitrogen can be prepared on site by passing ammonia over a catalyst that causes it to dissociate into nitrogen and hydrogen. The hydrogen can be burned away, leaving only nitrogen. If purity is not important, a nitrogen-rich gas can be made simply by burning fuels in an inert-gas generator that consumes the oxygen and keeps the nitrogen.

Nitrogen is shipped in small quantities at high pressures in steel cylinders, in highway tube trailers, and in railroad tank cars that consist of several tubular containers mounted on a railcar. Liquid nitrogen is shipped in small, portable, heavily insulated containers holding up to 25 gallons (100 litres) and in special insulated tank cars.

The principal use of nitrogen in chemical processing is in the manufacture of ammonia, although the nitrogen is furnished as a mixture with hydrogen. About 35 percent of the relatively pure elemental nitrogen produced goes into a variety of other chemical processes that re-

quire an inert gas as a blanketing agent to prevent oxidation, fire, or explosion; or for drying or purging equipment of an undesired substance; for pressuring; or as a diluent. Metal processing provides another major market for elemental nitrogen (about 27 percent of the total). Nitrogen serves to control the atmosphere in annealing and heat-treating furnaces; to prepare metals such as rare earths; and, as a liquid, to harden steel and shrink metal. Other demands for nitrogen are divided among electronic products, aerospace applications, food processing, and miscellaneous uses. Nitrogen gas is used by the petroleum industry to regenerate spent reforming catalysts, to make petroleum wax, and to provide a blanket against the oxidation of gasoline while it is in storage.

In the electric and electronic industries, nitrogen competes with argon and helium, as it does in chemical processing. It purges and fills electronic devices and high-voltage compression cables (which it also tests); and, in liquid form, it acts as a coolant for electronic equipment. In aerospace applications, nitrogen is mostly used in liquid form. In the food industry, liquid nitrogen finds applications in processing, transportation, and storage of frozen food to prevent deterioration.

The miscellaneous category includes the use of nitrogen as a gas or liquid in the manufacture of float glass (plate glass formed on top of molten metal), for preservation of biologicals, for pulverizing plastics, and for refrigeration-shielding of hydrogen, helium, and neon.

**Carbon dioxide.** Exhaled by all animals and an important product in the decay of organic materials, carbon dioxide was one of the earliest gases to be identified and has been widely used for more than 70 years. Reserves can be considered limitless, since the gas can be extracted from the atmosphere and the earth and manufactured in several different ways.

Making  
carbon  
dioxide

Carbon dioxide can be produced in commercial quantities at any location by burning coke or other fuels that yield a gas low in dust and sulfur oxides. The carbon dioxide-nitrogen mixture produced by this process is bubbled through an absorbing solution; the nitrogen is discharged to the atmosphere, and the carbon dioxide is recovered from the absorbing solution, which is reused. Dry Ice, or frozen carbon dioxide, is produced by evaporating liquid carbon dioxide rapidly. When the vapours arising from the liquid are pumped away, the remaining liquid carbon dioxide cools until it freezes.

Carbon dioxide may be transported under high pressure in liquid form in steel cylinders; as a low-pressure liquid in insulated portable tanks, in tank trucks, and in railroad tank cars; or as a solid in large blocks wrapped in heavy paper or in insulated bags. The wrappings are used to minimize losses caused by the large temperature difference between the Dry Ice and the surrounding air. Demand for carbon dioxide in liquid form has rapidly increased, because it is more convenient to ship, store, and use than Dry Ice.

The largest quantities of gaseous carbon dioxide go into the carbonation of beverages, which require a gas of a high degree of purity so that their taste or odour will not be affected. Carbon dioxide also is important in gas welding, hardening molds in foundries, purging and filling industrial equipment with inert gas, preparing carbonates, and in a large number of other industrial chemical processes.

Liquid carbon dioxide finds employment as a blasting agent in coal mining, in fire extinguishers, and in fracturing of oil wells. Solid carbon dioxide is widely used as a refrigerant for ice cream, meat products, and frozen foods, especially during their transport, and, in smaller quantities, as a convenient, quick refrigerant.

**The noble gases.** The rare, or noble, gases, helium, neon, argon, krypton, xenon, and radon, are all found in the atmosphere. Argon is by far the most abundant, comprising nearly 1 percent of dry air by weight, against a total for the other gases of only 0.002 percent. All of the rare gases are colourless, odourless, and tasteless and are generally considered chemically inert, although some chemical compounds have been prepared from them.

Argon, krypton, neon, and xenon are produced as by-products of the liquefaction of air. Commercial quantities of helium are extracted from natural gas. The small quantities of radon used generally are prepared from the decay products of radioactive radium.

**Helium.** Lightest of the noble gases, helium was isolated in 1895 but was not produced in volume until after World War I. Between the two world wars, helium was used almost exclusively for lighter-than-air craft, with only small quantities for weather balloons and for creating synthetic atmospheres for diving operations and medical treatment.

Helium in  
World  
War II

In World War II large quantities were taken for submarine-searching blimps and as an inert gas in shielded-arc welding. After the war, consumption continued to increase steadily until 1966, when it began to decline. Leading world production in 1970 was the United States with 647,000,000 cubic feet (other than helium stored for conservation purposes); followed by the Soviet Union, with a reported 70,000,000 cubic feet; Canada, with 35,000,000 cubic feet; and France, which had a 1969 plant capacity of 7,000,000 cubic feet.

Although helium can be separated from the air, all commercial production is from natural gas, containing helium in relatively high percentages. Helium is extracted by cooling natural gas to the point at which it condenses to a liquid, leaving behind an uncondensed mixture of helium and nitrogen. Known as crude helium, this mixture is separated from the liquid natural gas and then further cooled until the nitrogen condenses. The liquid nitrogen is removed, and the helium gas remaining is purified to a concentration of 99.995 percent by passing it through a bed of activated charcoal at liquid-nitrogen temperatures.

Helium is transported as a gas, compressed to high pressure in gas cylinders. Larger volumes are shipped in specially designed railroad tank cars or in highway tube trailers. As larger volumes are marketed, an increasingly large share is transported as a liquid, to lower costs. Liquid helium is shipped in containers ranging in size from a few to more than 10,000 gallons.

Helium has the lowest boiling point of any element,  $-268.6^{\circ}\text{C}$  ( $-452^{\circ}\text{F}$ ), or only  $4.5^{\circ}\text{C}$  above absolute zero. Helium has a wide variety of applications in which its properties of inertness, low weight, and low temperature are of value. These include purging and pressurizing liquid rocket propellants (oxygen and hydrogen), creating the controlled atmospheres needed in growing germanium and silicon crystals, and shielded-arc welding of various metals and alloys. Other smaller volume uses are for leak detection on production lines for products that require a leakproof system; as a lifting gas for the chromatographic analysis of mixtures of gaseous compounds; and in synthetic breathing mixtures. Because of its unique low-temperature properties, it finds many diverse applications where the lowest possible temperatures are required.

**Argon.** Argon was discovered in 1894, but large-scale production did not begin until 1914, when 8,000 cubic feet was made, by chemical methods, to fill light bulbs. In 1915 argon was first produced commercially by the liquefaction of air, also for use in filling light bulbs.

Reserves  
of argon

Resources of argon can be considered unlimited, since the argon extracted from the atmosphere is returned unchanged. In 1970 the world productive capacity for argon extraction was greater than demand. If demand for argon should increase greatly, however, the simple addition of the necessary facilities at oxygen-producing plants could easily provide all foreseeable projected requirements.

Argon's boiling point is intermediate between those of oxygen and nitrogen; thus, an argon-rich mixture is extracted from the centre of the liquid-air-distillation column, as oxygen and nitrogen are being produced. This argon-rich mixture can be further redistilled to yield a high-purity product.

World argon production has been increasing rapidly since the end of World War II. In 1950 only 50,000,000 cubic feet of argon was used but, by 1969, this had in-

creased to 2,800,000,000 cubic feet, a nearly 60-fold increase in 20 years. The United States leads world production with about 40 percent of the total. With improved technology, argon prices have fallen steadily since 1950, and, because argon is less expensive than helium, it has been displacing helium in markets where the two gases are essentially interchangeable.

Argon is transported in steel cylinders at high pressures when used in small quantities. Large deliveries of liquid argon are made in railroad tank cars or tank trucks.

Argon is very stable and does not readily react chemically with other materials. This property accounts for most of its demand, as in shielded-arc welding of such metals as stainless steel, aluminum, magnesium, titanium, and copper and nickel alloys in which the welds must be protected from atmospheric oxygen while being formed. Argon also provides the inert atmosphere in which silicon and germanium crystals are grown for use in transistors. Except for a small number of specialty units, all modern incandescent and fluorescent electric-light sources contain argon, as do many electron tubes. Argon provides an inert atmosphere, preventing oxidation during the refining of metals. Other miscellaneous outlets include electric-arc cutting of nonferrous metal sheet and plate and in producing, melting, and rolling titanium. In 1968 the steel industry found that bubbling argon through molten steel drives unwanted oxides to the surface, where they then can be removed.

**Neon, krypton, and xenon.** The three gases neon, krypton, and xenon were all discovered in 1898. Neon was first produced commercially as a by-product of air liquefaction in 1907. Krypton and xenon were produced in commercial quantities at a later date, when it was discovered that, with careful treatment, these gases could be produced from impure liquid oxygen in which they concentrate when air is liquefied.

Virtually unlimited quantities of these gases can be produced, if needed, by liquefaction of air. Neon, the most abundant of the three, occurs in air in concentrations of 18.18 parts per million (ppm); krypton, in concentrations of 1.14 ppm; and xenon, .086 ppm.

In producing the three gases, air is first liquefied, leaving an uncondensed fraction containing neon and the other two gases. The neon is then separated by adsorption on activated charcoal, the krypton and xenon remaining with the crude oxygen after the separation of the air into oxygen and nitrogen streams. Distillation of the crude oxygen concentrates the krypton and xenon, after which they are absorbed on silica gel and further treated to increase their purity. When large quantities are needed, the gases are distributed in standard steel cylinders under pressure. Small amounts are shipped in glass containers at atmospheric pressure.

Neon provides the atmosphere in cloud chambers for the detection of subatomic particles, its largest use, followed by its application in liquid form as a coolant for electronic infrared and radar detection devices. The familiar neon signs still take small amounts of neon, which, under low pressure, emit a red light when an electric current passes through it. As it becomes less expensive, krypton is being more widely used in incandescent bulbs, since it imparts longer life and more light efficiency than argon or other gases. Xenon is used in high-intensity lights, in ultraviolet sources, and in flash lamps.

**Radon.** Discovered in 1900, radon is the only radioactive noble gas. It is one of the products of the radioactive decay of radium, its only useful source. It is prepared from aqueous solutions of radium salts by pumping off and purifying the gases that form when radium decays.

Because of its short half-life of less than four days, radon's applications are quite limited. In the past it was employed in medicine for studies of the biological effects of ionizing radiation, as a source of gamma radiation in clinical research, and in metallurgy for the detection of flaws in welds and gauging of metal thicknesses. Longer lived radioisotopes and high-voltage X-ray machines have largely supplanted radon, however, for those purposes.

Neon's  
role in  
subatomic  
research

## GASES DERIVED FROM OTHER SOURCES

**Hydrogen.** Colourless, odourless, and tasteless, hydrogen is the lightest element in nature and an industrial gas with one of the fastest growing demands in the world. Large-scale production of hydrogen to produce synthetic ammonia began between 1910 and 1920; in the following years large quantities went into the production of methanol and the hydrogenation of fats and oils and in high-temperature, hydrogen-oxygen flames for cutting and welding metals.

Supplies of hydrogen are virtually limitless, since it can be produced from water, natural gas, coal, crude oil, and many other substances. Thus, production cost determines the choice of raw material at any location. Electrolysis of water could produce hydrogen in any quantity required, but electric-power cost is relatively high.

Until natural gas became generally available, hydrogen was produced primarily by the reaction of coke with steam to yield water gas, a mixture of hydrogen and carbon monoxide. The carbon monoxide in water gas was reacted with steam over a catalyst to form more hydrogen and carbon dioxide. The carbon dioxide was removed by absorption along with other impurities, leaving hydrogen as the product. With the widespread introduction of natural gas into commercial markets, hydrogen manufacturers shifted from coke to natural gas, from which hydrogen can be made by two different methods. In the first, the steam-reforming process, natural gas is reacted with steam over a catalyst at high temperatures to produce a mixture of hydrogen and carbon oxides. In the second, the partial-oxidation process, the natural gas is reacted with oxygen under pressure, forming a mixture of hydrogen and carbon monoxide along with small quantities of other impurities. Other hydrocarbons, even heavy petroleum fractions, can be substituted for natural gas; a disadvantage is the high cost of oxygen.

Catalytic  
steam  
process

The catalytic steam process, which yields a very pure hydrogen at high pressures, requires a sulfur-free hydrocarbon feedstock with few or no unsaturated hydrocarbons. In the early 1960s a new process was developed that permitted steam reforming of naphtha, thus extending the scope of the process to higher molecular weight petroleum fractions. In all processes, some further purification of the primary gas produced is necessary for high-quality hydrogen.

The cost of making hydrogen in large volumes is generally lowest for steam reforming, followed by partial oxidation of hydrocarbons, production by reaction of steam and coke, and electrolysis, the latter two practical only in small-scale operations. Production from coke is declining rapidly worldwide as the availability of natural gas increases. As demand for natural gas grows, however, it is anticipated that supplies will be supplemented by synthesis gas produced from coal.

In small quantities, hydrogen is marketed at high pressures in steel cylinders. Large-volume consumers generally manufacture their own hydrogen on the site and thus require few extensive storage or distribution facilities. Hydrogen is generally stored at low pressure in gas-holders of either the dry or the wet type. Wet gas-holders use water as a sealant to contain the gas while dry gas-holders have flexible connectors that permit movement as gas is inserted or removed from the holder. Commercially available hydrogen is sold as a gas or highly purified liquid. As consumption of hydrogen for fuel and propellant in space flight has grown, large, insulated liquid-storage tanks have been constructed. Liquid hydrogen is transported in truck trailers and railroad cars with specially designed insulation.

As the scale of operations has grown, the price of hydrogen has declined steadily, resulting in a continual improvement in overall efficiency, better heat recovery, higher operating pressures, better use of raw materials, improved catalysts, and increased automation. World hydrogen production in 1969 was  $5.3 \times 10^{12}$  cubic feet, with the United States the largest producer ( $2.1 \times 10^{12}$  cubic feet).

The production of synthetic ammonia and petroleum refining take the greatest quantities of hydrogen. The two

major hydrogen-consuming refinery operations are hydrotreating and hydrocracking. Hydrotreating includes removing undesirable sulfur compounds from petroleum feedstocks, hydrogenation of olefin compounds, and treatment of lubricating oils and jet fuels. Hydrocracking involves simultaneous catalytic cracking (breaking apart long molecules) and hydrogenation (see PETROLEUM REFINING). The hydrocracking process has been growing faster than that of hydrotreating; the need to remove sulfur from fuel feedstocks to meet air-pollution standards, however, may reverse that trend. In the United States, refineries must produce supplemental hydrogen to supply the demands of the two processes. European refineries do not use hydrotreating or hydrocracking as extensively as in the U.S. Consequently the hydrogen produced in other refining steps is in excess of process requirements and is used as fuel. The remainder of the hydrogen goes into the manufacture of methanol, oxoalcohols, and other organic chemicals and into the hydrogenation of vegetable and animal fats and oils. Other smaller but important uses are for the production of pharmaceuticals, for cooling in the electronics and electrical-machinery industry, for welding, and as rocket fuel.

Hydro-  
cracking  
and  
hydro-  
treating

**Carbon monoxide.** Carbon monoxide, a colourless, odourless, and tasteless compound of carbon and oxygen, is a constituent of synthesis gas (a mixture of hydrogen and carbon monoxide; see below *Synthesis gas*) and is produced by a variety of methods. Large volumes of carbon monoxide are generated in blast furnaces during pig-iron manufacture, but it is so diluted with nitrogen that it is used almost exclusively for heating at steel mills.

Pure, or enriched, carbon monoxide can be obtained by its absorption in solutions of various copper compounds or by its low-temperature separation from other gases with which it is associated. The low-temperature separation method, with or without fractionation, is more common with gases produced from hydrocarbon feedstocks; and, since they are much more widely used than other feedstocks, most carbon monoxide is separated by low-temperature condensation.

Carbon monoxide is largely consumed in mixtures with hydrogen (synthesis gas) and, consequently, is not normally transported. When shipped, whether by rail, highway or boat, carbon monoxide is carried only in steel cylinders. The gas is sold in several different grades of purity.

Carbon monoxide is important in the production of phosgene gas, made by reacting carbon monoxide with chlorine over activated charcoal at elevated temperatures. Phosgene is used largely in the production of chemicals that serve as raw materials for plastics and adhesives. Carbon monoxide is also reacted with acetylene and water to form acrylic acid and with ethylene and ethyl alcohol to form ethyl acrylate. In a newly developed process, large volumes of carbon monoxide are reacted with methyl alcohol along with a rhodium catalyst to make acetic acid.

Products  
from  
carbon  
monoxide

**Synthesis gas.** Synthesis gas, a mixture of hydrogen and carbon monoxide, usually serves as an intermediate in the manufacture of some other chemical product. In a direct chemical reaction, it may be necessary first to adjust the ratio of hydrogen to carbon monoxide, either by additional processing of the original synthesis gas or, when it is made from petroleum fractions, by modifying the feed streams during the primary production of the gas. For example, if additional carbon dioxide is injected with the steam and methane, a synthesis gas with a higher percentage of carbon monoxide is produced.

Mixtures of hydrogen and carbon monoxide, when passed over different catalysts at various temperatures and pressures, produce a wide variety of hydrocarbons. In all the processes, mixtures of hydrocarbons are formed; in making methane and methanol, however, a nearly pure single product results. The largest commercial consumption of synthesis gas is in producing methanol, which is made by passing synthesis gas over a catalyst at very high pressure and elevated temperature.

Relatively large quantities of synthesis gas also go into the production of aldehydes from olefins (a type of un-

saturated hydrocarbon) under the oxo reaction process. Synthesis gas and olefins are brought together in the presence of a cobalt catalyst in the liquid phase at elevated temperatures and pressures. The resulting aldehydes are usually intermediate products and are subjected to further reactions with hydrogen to form alcohols.

Very large volumes of synthesis gas may be needed in the future, if synthetic liquid or gaseous fuels are produced from coal. The only commercial synthetic liquid-fuel plant in operation is in South Africa. A small plant by petroleum-industry standards, it produces only 5,000 to 6,000 barrels per day along with some petrochemicals. The synthesis gas is produced from coal at high pressure and temperature, using a mixture of oxygen and steam. The purified gas is then reacted over a catalyst under two different processes: one for synthetic liquid fuels, the other for petrochemicals. Even this single small plant requires an enormous quantity of purified synthesis gas per day. A large synthetic-fuels industry would bring a demand for synthesis gas dwarfing present requirements.

**Ammonia.** Ammonia gas was first produced from ammonium chloride late in the 18th century, but it was not until the 1870s that it became available in commercial quantities as a by-product of the carbonization of coal. Large volumes were not produced, however, until the development (1913) of the so-called Haber process, in which atmospheric nitrogen is combined with hydrogen to make ammonia. Because ammonia can be made by combining nitrogen from air with hydrogen, which can be produced from water, there is no limit to the amount that can be produced.

The Haber process and its modern modifications convert a mixture of three parts of hydrogen and one part of nitrogen into ammonia gas by reacting the mixture at high pressure and high temperatures over any of several catalysts. The two raw materials, hydrogen and nitrogen, are taken from the most economical source at any given location.

Anhydrous (dry) ammonia is transported as a liquefied gas in cylinders, in tanks, and in tank cars. Refrigerated barges are the least costly transportation method. Large volumes of ammonia are generally stored in insulated and refrigerated containers. Two long-distance pipelines have been constructed in the United States to carry anhydrous ammonia from large plants located near low-cost raw materials. The anhydrous ammonia is applied directly as a fertilizer and is transported in vehicles designed to carry it into the fields.

For many years ammonia plants were relatively small and located near markets to minimize high transportation costs. As improved transport methods were developed and as larger volumes supplanted solid salts such as ammonium nitrate as fertilizers, transportation costs were further reduced. As a result, ammonia plants could become larger and achieve further economies from large-scale production.

While there are more than 2,500 different uses for industrial ammonia, most is taken by agriculture, largely in the form of liquid ammonia or ammoniacal solutions. Ammonium nitrate, sulfate, phosphate, and urea provide the balance of ammonium compounds for agriculture. Another major market for ammonia is in the production of nitric acid, from which, in turn, ammonium nitrate, explosives, propellants, and urethane plastic foam are made. Other smaller quantities are taken for the production of hydrogen cyanide and amines.

World production of ammonia is growing rapidly to meet the greatly increased demand for fertilizer.

**Acetylene.** Commercial production of acetylene began in 1892 with the discovery of a method for manufacturing calcium carbide from coke and lime. Acetylene is formed when calcium carbide is brought in contact with water. The earliest use of acetylene was for illumination, since, on burning, it gives a pure white light similar to sunlight. Other early uses were in cutting and welding metals. In recent years it has been consumed in large volumes by the chemical industry.

Though acetylene can be manufactured under a variety of processes, a large portion is still made from calcium

carbide and water. Several variations of the original process have been developed to avoid the high temperatures and pressures that can result from the rapid generation of heat as the reaction proceeds. More recently, increasing amounts of acetylene have been produced from hydrocarbons. Energy to convert the hydrocarbons to acetylene can be supplied by an electrical discharge, in regenerative furnaces, and by combustion in either one or two stages. In all hydrocarbon processes, the primary product must be further treated to remove impurities from the crude acetylene gas, the degree of purification depending on the final use of the acetylene. For example, a very pure product is needed in catalytic chemical reactions to avoid damaging the catalyst. The relative economics of producing acetylene from calcium carbide and from hydrocarbons depends on the cost of the raw materials at any given location and on the value of the other products formed.

Acetylene can decompose explosively even in the absence of oxygen. The strength of the detonation depends on such factors as the initial pressure and the presence or absence of oxygen. Gaseous acetylene is not handled at pressures of more than 15 pounds per square inch (one kilogram per square centimetre) above atmospheric pressure (a total of two atmospheres) except in specialized equipment. Because of its explosive tendency, acetylene is stored and shipped in special steel tanks that contain porous filler whose minute cellular spaces are saturated with acetone. Under these conditions acetylene can be contained at moderate pressures without danger of explosion. Because of the special handling required for acetylene, the lowest cost form in which it can be transported is as calcium carbide, from which acetylene is easily made.

The chemical industry consumes most acetylene output to make such products as vinyl chloride, acetaldehyde, acrylonitrile, vinyl acetate, and vinyl ethers. These in turn go into the production of a diverse group of plastics, synthetic rubber, dyestuffs, and pharmaceuticals. The remainder is used for oxyacetylene welding and cutting; small amounts are still employed for special-purpose lighting.

**Sulfur dioxide.** Though a large number of different oxides of sulfur have been identified, sulfur dioxide is the one of major commercial importance. It occurs in nature and has served various purposes for thousands of years. The combustion of fuels containing sulfur produces sulfur oxides, a major source of air pollution. A large number of processes aimed at reducing sulfur oxide emissions into the atmosphere are under study. These processes either remove the sulfur from the fuel before combustion or scrub the sulfur oxides from the flue gases before they are emitted into the air.

Reserves of sulfur-bearing materials from which sulfur oxide could be produced are very large. Reserves of native sulfur and other sulfur compounds of commercial importance are also abundant. A large, new source of sulfur dioxide may develop as a by-product from one of the anti-air-pollution processes being studied. Should a synthetic-fuels industry develop to meet the increased demands for gaseous and liquid fuels, another large potential source of sulfur oxides could emerge, since at some point in the process some sulfur compounds must be removed from the gases resulting from the gasification of coal.

Sulfur dioxide is commercially produced by the combustion of native sulfur or pyrites (iron disulfide) in burners of a variety of designs. After cooling, the sulfur dioxide is separated from the nitrogen (left after the combustion of sulfur with air) by absorption, either with water or alkaline solutions or slurries (watery mixtures). Some sulfur oxides are removed from the waste gases at smelters and marketed commercially. Other, small-scale sources are from the combustion of hydrogen sulfide recovered at oil refineries and coke-oven plants.

Sulfur dioxide is stored and transported as a liquid under pressure. Smaller quantities are shipped in steel cylinders, large quantities in tank cars.

Sulfur dioxide is an intermediate product in the manu-

Explosion  
danger of  
acetylene

Haber  
process of  
making  
ammonia

facture of sulfuric acid but is not isolated for this purpose. Pulp and bleaching wood and paper manufacture take the greatest amounts of sulfur dioxide. Although it is normally manufactured at the pulp mill, large quantities of liquid sulfur dioxide must also be purchased. Soybean-protein preservation and oil and metal refining are among other markets for the gas.

**Chlorine.** Though first identified as a chemical element in 1774, chlorine was not used extensively until World War I. During the 1920s nearly one-half of the chlorine made went into the manufacture of paper and pulp, but, as new markets were found, the share going to the paper industry declined. Reserves of chlorine must be viewed as limitless, since it can be produced from the electrolysis of seawater and from salt solutions.

Elec-  
trolysis  
of salt  
solutions

Chlorine has been produced commercially for nearly 70 years by the electrolysis of salt solutions, which produces chlorine, sodium hydroxide, and hydrogen. As it is necessary to keep the sodium hydroxide and chlorine separate during production, two basically different methods have been developed: the mercury process and the diaphragm process. In the mercury process, the salt solution floats on a flowing stream of mercury, and, when the electric current is applied, the chlorine collects at the anode (positive electrode) and sodium amalgam at the cathode (negative electrode). Water is added to sodium amalgam to produce hydrogen, sodium hydroxide, and mercury, which can then be recycled.

In the diaphragm process, the chlorine is separated from the hydrogen and sodium hydroxide by an asbestos diaphragm when the electric current is applied to the salt solution. Because chlorine plants require large amounts of salt solution and electricity, most are located where these are abundant and low in cost.

Whenever possible, chlorine is shipped in either liquid or gaseous form by pipeline. The next preferred shipping method is in bulk quantities in barges. Railroad tank cars, however, are by far the most common method of shipping chlorine. Smaller quantities are shipped in cylinders and in tank trucks.

The largest share of chlorine output goes into the production of other chemicals, especially chlorinated hydrocarbons and vinyl plastics. Two of the most important chlorinated hydrocarbons are methyl chloride, used as a refrigerant, as a solvent, in plastics, and as a food additive; and fluorocarbon-12, a refrigerant. Polyvinyl chloride, another chlorine product, is an important plastic.

Chlorine is still used as a gas for bleaching paper and in water purification, both uses depending on the high level of chemical reactivity of chlorine. Smaller quantities of chlorine are taken for the production of insecticides and herbicides, for the manufacture of gasoline additives, and for the production of such metals as magnesium, titanium, and zirconium.

**BIBLIOGRAPHY.** AMERICAN GAS ASSOCIATION, *Historical Statistics of the Gas Industry* (1956), complete historical record of statistics relating to energy reserves, gas production, transmission and distribution, underground storage, customers, sales, revenues, utilization, finances, labour, and prices for U.S. and Canada; ORGANIZATION FOR ECONOMIC COOPERATION AND DEVELOPMENT, *Impact of Natural Gas on the Consumption of Energy in the OECD European Member Countries* (1969), describes natural gas in the energy economy of the Western European countries, its availability, the policies of the countries in the field of natural gas, competition of natural gas with other fuels, and the future role of natural gas in energy supply and its impact in practice; EMIL R. RIEGEL (ed.), *Industrial Chemistry*, (1962), an authoritative textbook on industrial processes covering the methods of manufacture of most industrial gases, the raw materials used, properties and uses of the products, and methods of storage and distribution; A.L. WADDAMS, *Chemicals from Petroleum*, 2nd ed. (1968), describes methods of producing synthesis gas from coke, petroleum, and natural gas by the numerous processes being commercially used and also the further utilization of these gases for the production of ammonia, methyl alcohol, oxo process, and phosgene; GERHARD A. COOK (ed.), *Argon, Helium, and the Rare Gases*, 2 vol. (1961), a very comprehensive and authoritative text on the rare gases covering their history, nuclear structure and reactions, atomic structure, chemical properties, gas-phase properties, thermodynamic properties,

liquid- and solid-state properties, phase equilibria, production, cryogenic and nuclear applications, inert atmospheres in metallurgy, inert gas shielded arc welding, and utilization in light sources and in medical applications; THE CHLORINE INSTITUTE, N.Y., *Chlorine Facts* (1968), a booklet that describes methods of chlorine manufacture, methods of shipping, safety precautions, the spectrum of uses, and gives statistical information on production.

(H.Pe.)

## Gasoline Engine

The gasoline engine is a specialized form of internal-combustion engine in which power is obtained by burning a mixture of gasoline vapour and air. The mixture is ignited electrically by a spark plug. Most gasoline engines are of the so-called reciprocating piston type, but recent developments suggest that superior performance in some respects may be obtained from either rotary piston (see below) or turbine types. Engines closely related to the gasoline engine include the diesel and the jet; for descriptions of these, see DIESEL ENGINE; JET ENGINE.

The gasoline engine is the most widely used of all internal-combustion engines. Size and power range from small engines of less than one horsepower, used in certain portable applications, to aircraft engines that may produce as much as 35,000 horsepower. Though more gasoline engines are used in automobiles than in any other single application, such engines represent less than half the total number in use throughout the world.

## History

While attempts to devise heat engines were made in ancient times, the steam engine of the 18th century was the first successful type. The internal-combustion engine, which followed in the 19th century as an improvement over the steam engine for many applications, cannot be attributed to any single inventor. The piston, thought to date as far back as 150 BC, was used by metal workers in pumps for blowing air. The piston and cylinder were basic to the steam engine, which brought the component to a high state of efficiency. But the steam engine suffered from low thermal efficiency, great weight and bulk, and inconvenience of operation, all of which were primarily traceable to the necessity of burning the fuel in a furnace separate from the engine. It became evident that a self-contained power unit was desirable.

As early as the 17th century several experimenters first tried to use hot gaseous products to operate pumps. By 1820 an engine was built in England in which hydrogen-air mixtures were exploded in a chamber. The chamber was then cooled to create a vacuum acting on a piston. The sale of such gas engines began in 1823. They were heavy and crude but contained many essential elements of later, more successful devices. In 1824, a French physicist, Sadi Carnot, published his now classic pamphlet, "Reflections on the Motive Power of Heat," which outlined fundamental internal-combustion theory. In the next several years engines using pressure resulting from combustion of fuels rather than vacuum and engines in which the fuel was compressed before burning were built, but none proved satisfactory, until in 1860 Étienne Lenoir of France marketed an engine that operated on illuminating gas and gave reasonably satisfactory service. The Lenoir engine was essentially a converted double-acting steam engine with slide valves to admit gas and air and to discharge exhaust products. Although it developed little power and utilized only about 4 percent of the energy in the gas, several hundred were sold over a period of years.

A major theoretical advance took place with the publication in Paris in 1862 of a description of the ideal operating cycle of an internal-combustion engine. The author, Alphonse Beau de Rochas, laid down the following conditions as necessary for optimum efficiency: (1) maximum cylinder volume with minimum cooling surface; (2) maximum rapidity of expansion; (3) maximum ratio of expansion; and (4) maximum pressure of the ignited charge. He described the sequence of operations necessary as (1) suction during an entire outstroke of the piston; (2) compression during the following instroke; (3)

The ideal  
operating  
cycle

ignition of the charge at dead centre and expansion during the next outstroke (the power stroke); and (4) forcing out the burned gases during the next instroke.

The engine Beau de Rochas described thus had a four-stroke cycle, in contrast to the two-stroke cycle (intake-ignition and power-exhaust) of the Lenoir engine. Beau de Rochas never built an engine, and no four-stroke engine appeared for 14 years. When it did it was the product of a German engineer, Nikolaus Otto, whose firm, Otto and Langen, of Deutz, earlier produced and marketed an improved two-stroke engine employing a vertical cylinder, open at the top and fitted with a heavy piston, below which was the combustion chamber. Gas and air were drawn into the cylinder during the first half of the upstroke, the charge was ignited electrically, and the piston lifted by the explosion. Although the piston tended to continue upward after the pressure on its underside had been reduced to a partial vacuum, atmospheric pressure acting on the top of the piston, together with the piston's weight, caused it to descend immediately. The motion was transmitted to a shaft and heavy flywheel by a toothed rack extending downward and meshing with a gear on the shaft. This gear turned freely on the shaft during the upward stroke, but a free-wheeling clutch engaged on the downward stroke and applied torque to the shaft. The engine was very noisy, of small power capacity, and the rack-and-pinion mechanism was mechanically unsound, but it consumed less than half as much fuel per unit of power as did the Lenoir engine and thus succeeded commercially.

In 1876 the firm applied the Beau de Rochas four-stroke cycle in the design of a new engine. It was an immediate success. In spite of its great weight and poor economy, nearly 50,000 engines with a combined capacity of about 200,000 horsepower were sold in 17 years, to be followed by the rapid development of a wide variety of engines of the same type. Manufacture of the Otto engine in the United States began in 1878, following the grant to Otto of a U.S. patent in 1877.

### Basic principles

In all internal-combustion engines the products of combustion act directly on piston or rotor surfaces, whereas the external-combustion engine employs a secondary working fluid that is interposed between the combustion chamber and the power-producing elements. Fundamentally, the steam engine operates with a high-pressure working medium produced by utilizing the expansion accompanying the vaporization of a liquid; by contrast, the internal-combustion engine utilizes the large volume of high-temperature combustion products that, when confined, become a high-pressure gaseous medium.

### GENERAL CONSIDERATIONS

**Classification.** The many types of internal-combustion engines can be grouped in a number of different ways on the basis of similarities among them. Important methods of classification include application, type of fuel and method of injection, ignition, reciprocating piston or rotary, cylinder arrangement, strokes per cycle, cooling system, and valve type and location. These various classifications will be discussed further as the various engine types are described.

**Valve type and arrangement.** Valves for controlling intake and exhaust may be located overhead, on one side, side and overhead, or on opposite sides of the cylinder. These are all the so-called poppet or mushroom valves consisting of a stem with one end enlarged to form a head that permits flow through a passage surrounding the stem when raised from its seat and prevents flow when the head is moved down to contact the valve seat formed in the cylinder block.

Another group of engines uses sliding valves that are usually of the sleeve type surrounding the cylinder bore.

**Pressure application.** Some power plants use the same combustion principle but apply the pressure resulting from combustion to different mechanical elements. There are, for example, gas turbines in which the products of combustion are directed through nozzles against

the blades of a turbine rotor to cause it to rotate. In the jet engine, the products of combustion simply flow through a nozzle and the reaction force tends to move the nozzle in the opposite direction.

The Wankel and Tri-Dyne engines (see below) burn the fuel within the engine; they are rotary and do not have conventional cylinders fitted with reciprocating pistons. Instead, the gas pressure acts upon surfaces formed by the configuration of a rotor. Both the gas-turbine and the jet engine have combustion furnaces separate from the power-producing units. The power is produced by the action of the products of combustion on the blades of the turbine or the interior wall of the jet nozzle.

**Comparison with other engines.** The so-called Stirling hot-air engine that was widely used early in the nineteenth century burned the fuel in an external chamber. A heat exchanger was employed to heat a secondary fluid (air) that was in contact with the piston faces in the cylinders. The products of combustion thus did not do the work of driving the pistons. This engine is not an internal-combustion engine, but because of the superior continuous combustion process used, it is of interest as a possible low-pollution engine.

The gasoline engine may now be defined as an engine designed to burn a volatile liquid fuel with ignition initiated by an electrical spark. When such an engine is compared with other types, certain similarities and differences are evident as well as some advantages and disadvantages. The diesel engine and the gas engine (an engine utilizing a gas such as propane as the fuel) have a good deal in common with the gasoline engine, since they are all cylinder-and-piston engines burning fuel-air mixtures in contact with moving components (piston, turbine blades). The important differences that distinguish the diesel engine are that it has a fuel-injection system (see below) and no spark-ignition system. The diesel is heavier and more expensive per horsepower of output, but it has a longer life and operates at less cost per horsepower-hour because it burns less fuel, and diesel fuel in general is less expensive than gasoline.

Because it does not have the quiet, smooth-running characteristic or the flexibility of the gasoline engine, the diesel engine has had little application in passenger automobiles. It has, however, taken over from the gasoline engine almost all of the heavy-duty vehicle field. Trucks, tractors, and buses, except for the smallest sizes, are diesel-powered.

The gas engine has much in common with the gasoline engine; in fact, in some instances their differences are very slight at best. Structurally, the difference lies primarily in the substitution of a gas-mixing valve for a carburetor. The cylinder and piston configurations are the same. In general, gases have better antiknock qualities than gasoline (see below), permitting slightly higher compression ratios without knock or other combustion difficulties.

From the standpoint of application, the gas engine burning natural gas, manufactured gas, or industrial by-product gas is limited primarily to stationary power plant use because it must remain connected to the gas pipe line. If, however, the fuel is liquefied petroleum gas, sometimes called bottled gas, the containers of gas can be carried in a vehicle, leading to much flexibility in applications. The present obstacle is that facilities are not readily available for replenishing the gas supply. Dual carburetors have been produced experimentally that make it possible to operate an engine on either liquefied petroleum gas or gasoline; thus dual gas-gasoline engines are a distinct possibility.

### ENGINE TYPES

Of the different techniques for recovering the power from the combustion process the most important so far has been the four-stroke cycle, a conception now over 100 years old.

**Four-stroke cycle.** The four-stroke cycle is illustrated in Figure 1. With the inlet valve open, the piston first descends on the intake stroke. An explosive mixture of gasoline vapour and air is drawn into the cylinder by the

Rotary engines

Combustion processes

The gas engine

Figure 1: Strokes of the four-stroke cycle.

partial vacuum thus created. The mixture is compressed as the piston ascends on the compression stroke with both valves closed. As the end of the stroke is approached, the charge is ignited by an electric spark. The power stroke follows, with both valves still closed and the gas pressure, due to the expansion of the burned gas, pressing on the piston crown. During the exhaust stroke, the ascending piston forces the spent products of combustion through the open exhaust valve. The cycle then repeats itself. Each cycle thus requires four strokes of the piston—intake, compression, power, and exhaust—and two revolutions of the crankshaft.

A disadvantage of the four-stroke cycle is that only half as many power strokes are completed as in the two-stroke cycle (see below) and only half as much power can be expected from an engine of a given size at a given operating speed. The four-stroke cycle, however, provides more positive clearing out of exhaust gases (scavenging) and reloading of the cylinders, reducing the amount of loss of fresh charge to the exhaust.

**Two-stroke cycle.** The two-stroke cycle was developed in 1878. In it the compression and power stroke of the four-stroke cycle are carried out without the inlet and exhaust strokes, thus requiring only one revolution of the crankshaft to complete the cycle.

Figure 2 illustrates the two-stroke-cycle engine of a so-

Figure 2: Blower-scavenged, two-stroke-cycle engine with uniflow scavenging.

called uniflow type in which the fresh fuel mixture is forced into the cylinder through circumferential ports by a rotary blower. The exhaust gases pass through poppet valves in the cylinder head that are opened and closed by a cam-follower mechanism. The valves are timed to start to open toward the end of the power stroke after the cylinder pressure has dropped appreciably. The inlet ports in the cylinder wall start to uncover after the exhaust opening has decreased the cylinder pressure to the inlet pressure produced by the blower. The exhaust valves are allowed to remain open for a few degrees of crank rotation after the inlet ports have been covered by the rising piston on the compression stroke, thus allowing the persistency of flow more thoroughly to scavenge the cylinder. The compression and power strokes are similar to those of the four-stroke engine.

In 1891 a simplified version of the two-stroke-cycle engine was introduced, using crankcase compression to pump the fresh charge into the cylinder. Instead of intake ports extending entirely around the lower cylinder wall, this engine has intake ports only half way around; a second set of ports starts a little higher in the cylinder wall in the other half of the cylinder bore. These larger ports lead to the exhaust system. The inlet ports connect to a transfer passage leading to the fully enclosed crank-

case. A spring-loaded inlet valve admits air into the crankcase on the upward or compression stroke of the piston. Air trapped in the crankcase is compressed by the descent of the piston on its power stroke. The piston thus uncovers the exhaust ports near the end of the power stroke and slightly later it uncovers the inlet or transfer port on the opposite side of the cylinder to admit the compressed fresh mixture from the crankcase. The top face of the piston is designed to provide a deflector or baffle that directs the fresh load upward on the inlet side of the cylinder and then downward on the exhaust side, thus pushing the spent gases of the previous cycle out through the exhaust port on that side. This outflow continues after the inlet ports are covered by the rising piston on the compression stroke until the exhaust ports are covered and compression of the fresh load begins. This loading process, called loop scavenging, is the simplest known method of replacing the exhaust products with a fresh mixture and completing the cycle with only compression and power strokes. The system is used in many small gasoline engines such as small outboard motors and for gasoline-powered appliances. A disadvantage is that the return flow of the gases causes a slight loss of fresh charge through the exhaust ports. Because of this loss, carburetor engines operating on the two-stroke cycle lack the fuel economy of four-stroke engines. The loss can be avoided by equipping them with fuel-injection systems (see below) instead of carburetors and injecting the fuel directly into the cylinders after scavenging. Such an arrangement is attractive as a means of attaining high power output from a relatively small engine, and development of the turbocharger (see below *Supercharger*) for this application may hold promise of further improvement.

**Opposed-piston engine.** The opposed-piston engine also provides uniflow scavenging. This engine (Figure 3A) has two pistons moving in opposite directions in the same cylinder. Two sets of ports extending entirely around the cylinder bore are so located that one set is covered and uncovered by one piston and the other set is controlled by the second piston. A second crankshaft, to which the upper pistons are attached, is located at the top of the engine and the two shafts are connected by gears.

The opposed-piston design has two major advantages: reciprocating masses move in opposite directions, providing excellent balance; and the poppet valves necessary in other uniflow-scavenged two-stroke-cycle engines are eliminated.

Figure 3: Internal-combustion engines.

**Wankel rotary engine.** A rotary-piston internal-combustion engine developed in Germany is radically different in structure from conventional reciprocating-piston engines. The engine was conceived by Felix Wankel, a specialist in the design of sealing devices, and experimental engines were built and tested by a German firm beginning in 1956. Instead of pistons that move up and down in cylinders, the Wankel engine has an equilateral triangular orbiting rotor (see Figure 3B). The rotor turns in a closed chamber and the three apexes of the rotor maintain a continuous sliding contact with the curved inner surface of the casing. The curve-sided rotor forms three crescent-shaped chambers between its sides and the curved wall of the casing. The volumes of the chambers vary with the rotor motion. Maximum volume is attained in each chamber when the side of the rotor forming it is parallel with the minor diameter of the casing, and the volume is reduced to a minimum when the rotor side is parallel with the major diameter. Shallow pockets recessed in the flank of the rotor control the shape of the combustion chambers and establish the compression ratio of the engine.

Action of  
the rotor

In turning about its central axis the rotor must follow a circular orbit about the geometric centre of the casing. The necessary orbiting rotation is attained by means of a central bore in the rotor in which an internal gear is fitted to mesh with a stationary pinion fixed immovably to the centre of the casing. The rotor is guided by fitting its central bore to an eccentric formed on the output shaft that passes through the centre of the stationary pinion. This eccentric also harnesses the rotor to the shaft so that torque is applied when gas pressure is exerted against the rotor flanks as the fuel and air charges burn. A 3-to-1 gear ratio causes the output shaft to turn three times as fast as the rotor turns about the eccentric. Each quarter turn of the rotor completes an expansion or a compression, permitting intake, compression, expansion, and exhaust to be accomplished during one turn of the rotor. The only moving parts are the rotor and the output shaft.

The fuel mixture is supplied by a carburetor and enters the combustion chambers through an intake port in one of the end plates of the casing. An exhaust port is formed in one of the flattened sides of the casing wall and a spark plug is located in a pocket communicating with the chambers through a small throat in the opposite side of the casing wall.

The rotor and its gears and bearings are lubricated and cooled by oil circulating through the hollow rotor. The apex vanes are lubricated by a small amount of oil added to the fuel in proportions as low as 1 to 200. Water is circulated through cooling jackets in the casing, the entrance to which is located adjacent to the spark plug where the temperature tends to be highest.

Maintaining pressure-tight joints by suitable seals at the apexes and on the end faces of the rotor is a major design problem. Radial sliding vanes are fitted in slots at the three apex edges and kept in contact with the casing by expander springs. The end faces of the rotor are sealed by arc-shaped segmental rings fitted in grooves close to the curved edges of the rotor and pressed against the casing by flat springs.

Advantages  
of the  
Wankel  
engine

The major advantages of the Wankel engine are its small space requirements and low weight per horsepower, smooth and vibrationless operation, quiet operation, and low manufacturing costs resulting from mechanical simplicity. The absence of inertial forces from reciprocating parts and the elimination of spring-closed poppet valves permit operation at much higher speed than is practical for reciprocating-piston engines, an advantage because shaft speed must be high for optimum performance. The induction of fresh fuel mixture and exhaust are more effective because the ports are opened and closed more rapidly than with poppet valves, and gas flow through them is almost continuous. Heat transfer and the resulting cooling requirement are low because the jacketed surface is small. Fuel economy is at least as good as that of conventional engines, providing knock-free combustion with a wider range of permissible fuels.

Lower weight and a lower centre of gravity make it much safer in an automobile in the event of a collision. There are approximately one third as many parts in a Wankel engine as in a typical six-cylinder automobile engine.

**Tri-Dyne rotary engine.** The Tri-Dyne engine, a British design (Figure 4), consists of three rotors. The large, triangular central rotor is called the power rotor. The other two are a combustion rotor and a barrier valve. The power rotor turns in the opposite direction from the combustion rotor and barrier valve. It has three curved lobes that fit into three semicircular cavities in the periphery of each of the two smaller rotors. The three are geared together by spur-shaped gears on the end of each rotor; all turn at the same speed. The motion is entirely rotary and there is no eccentricity. The three cavities in the combustion rotor form the combustion chambers and the profiles of all three rotors are such that, while not actually touching each other, they interact to connect these cavities alternately with the inlet and exhaust pipes

Figure 4: Simplified sketches showing operating principles of the Tri-Dyne engine.

and isolate them during the combustion process. It is not necessary that the cavities be positively sealed because of the high speed of operation. Clearance of 0.004 inch (0.01 millimetre) is provided between the interacting surfaces. Two spark plugs are installed in the casing at a point where they communicate with the combustion rotor cavities as they pass at the instant of firing. The advantage of this engine over the Wankel engine lies in the elimination of the seals that the latter requires at the apexes of its triangular rotor that limit the speed at which it can operate and are difficult to lubricate.

**The gas turbine.** Many of the imperfections of the reciprocating-piston engine are traceable to the noncontinuous motion and the cyclic interruption of combustion. The fundamental principle of the gas turbine was known before that of any other type of heat engine; historians have recorded that a toy turbine was built by Hero of Alexandria about the time of Christ. Nevertheless, practical development of the gas turbine did not take place until the 20th century.

The gas turbine is a simple power plant (Figure 3C). A compressor supplies air at about three to six times atmospheric pressure to a combustion chamber into which fuel (gasoline) is sprayed, thus maintaining continuous combustion. The resulting large volume of high-temperature gaseous products then expands through the turbine unit to atmospheric pressure. The compressor and turbine rotors may be on the same shaft. The excess of power developed in the turbine unit over that required to turn the compressor rotor is the power delivered by the engine (see also TURBINE; JET ENGINE).

**The free-piston engine.** In a free-piston engine (Figure 3D) the pistons are not connected to a crankshaft, as in a conventional engine; the exhaust gases transmit their power to a turbine instead. Originally built as an air compressor, the engine was first used extensively by the Germans for launching torpedoes in World War II. It is not strictly a gasoline engine in the true sense, because the fuel charge is ignited by the heat of compression rather than by a spark plug. Thus it falls into the diesel engine class (see DIESEL ENGINE).

### Engine construction and operation

A gasoline engine is made up of a large number of components that must be carefully engineered to work together. The major components are described below.

#### OVERALL STRUCTURE

The overall structure of a gasoline engine depends almost entirely upon the intended application. Many components require only slight modification. Apart from the type of cycle (two- or four-stroke) the provision for mounting is the main structural difference among automotive, marine, stationary, and aviation engines. When a clutch and transmission are used, as in automobiles, the engine is commonly of the so-called unit-power-plant type with a bell-shaped housing surrounding the flywheel and attached to the rear flange of the cylinder block integral with, or attached to, the transmission gear case. The clutch is incorporated in the flywheel of the engine. Three-point suspension is used in such engines; that is, projections on each side of the bell housing fit into the vehicle side frame members and a central tubular extension at the centre of the front end of the cylinder block attaches to the front cross member of the frame. This construction permits some flexing of the vehicle frame without stressing the basic structure of the engine.

The following description of general engine construction indicates the essential components of an engine and introduces the nomenclature of the various parts. The four-stroke cycle automobile engine is used as the basic type. Figure 5 shows a cross section of a typical automobile engine with the important parts indicated.

**Cylinder block.** The main structural member of all automotive engines is a cylinder block that usually extends upward from the centre line of the main support for the crankshaft to the junction with the cylinder head. The block serves as the structural framework of the engine and carries the mounting pad by which the engine

Figure 5: Cross section of an overhead valve V-8 engine.  
By courtesy of Cadillac Motor Car Division

is supported in the chassis. Large, stationary power-plant engines and marine engines are built up from a foundation or bedplate and have upper and lower crankcases that are separate from the cylinder assemblies. The cylinder block of an automobile engine is a casting with appropriate machined surfaces and threaded holes for attaching the cylinder head, main bearings, oil pan, and other units. The crankcase is formed by the portion of the cylinder block below the cylinder bores and the stamped metal oil pan that forms the lower enclosure of the engine and also serves as a lubricating oil reservoir or sump.

The cylinders are openings of circular cross section that extend through the upper portion of the block with interior walls bored and polished to form smooth, accurate bearing surfaces. The cylinders of heavy-duty engines are usually fitted with removable liners made of metal more wear-resistant than that used in the block casting.

There are two arrangements of cylinders in common automotive use—the vertical or in-line type (Figure 3E) and the V type (Figure 3F). The in-line engine has a single row of cylinders extending vertically upward from the crankcase and aligned with the crankshaft main bearings. The V type has two rows of cylinders, usually forming an angle of 60 degrees or 90 degrees between the two banks. V-8 engines (eight cylinders) are usually of the 90-degree type. Some small 6-cylinder aviation engines have horizontally opposed cylinders.

A passage bored lengthwise in the block houses the camshaft that operates the valves. A gear or chain compartment for the camshaft drive from the crankshaft is formed between the front or rear end of the block and a cover plate. The bell housing is formed at the rear of the cylinder block to enclose the flywheel and provide for attachment of a transmission housing. Water jackets are formed around the cylinders with suitable cored connecting passages for circulation of the coolant.

The design of the cylinder block is affected by the location of the valves of the four-stroke-cycle engine and by the provision of cylinder ports in the two-stroke type. An overhead-valve engine, which has largely replaced the L-head type, has its valves entirely in the cylinder head. The cylinder block of the L-head engine is extended to one side of the cylinder bores, with the valve seats and passages for inlet and exhaust, together with the valve guides, formed in this extension of the block. The cylinder head then becomes merely a water-jacketed cover, providing threaded locations for the spark plugs and with its underside so profiled that a combustion chamber of desired size and shape is formed above each cylinder bore. The shape of the space forming the combustion chamber when the piston is at its closest approach to the cylinder head and volume contained

Engine  
suspension

Block  
design

therein in relation to the piston displacement volume are extremely important in their effect upon performance. The cylinder head of the valve-in-head engine is narrower and deeper and carries the valve seats, valve guides, and valve ports.

**Combustion chamber.** The size of the combustion chamber relative to the volume displaced by the piston establishes the compression ratio of the engine. The piston displacement is the volume swept by the piston during one stroke and is equal to the cross-sectional area of the cylinder multiplied by the length of the stroke. The larger volume above the piston at the lowest point in its stroke, divided by the combustion-chamber volume when the piston is at its highest point, is the compression ratio of the engine. The larger volume is the sum of the piston-displacement volume and the combustion-chamber volume. The compression ratio may thus be expressed as the ratio of the sum of the piston displacement volume and the combustion-chamber volume to the combustion-chamber volume. Compression ratio is the most important factor affecting the theoretical efficiency of the engine cycle. Because increasing the compression ratio is the best way to improve efficiency, compression ratios on automobile engines have tended to increase. This requires stronger, more durable materials.

**Pistons.** The pistons are cup-shaped cylindrical castings of steel or aluminum alloy. The upper, closed end, called the crown, forms the lower surface of the combustion chamber and receives the force applied by the combustion gases. The outer surface is machined to fit the cylinder bore closely and is grooved to receive piston rings that seal the gap between the piston and the cylinder wall. In the upper piston grooves there are plain compression rings that prevent the combustion gases from blowing past the piston. The lower rings are vented to distribute and limit the amount of lubricant on the cylinder wall. Piston pin supports (bosses) are cast in opposite sides of the piston and hardened steel pins fitted into these bosses pass through the upper end of the connecting rod.

**Connecting rod and crankshaft.** A forged steel connecting rod connects the piston to a throw (offset portion) of the crankshaft and converts the reciprocating motion of the piston to the rotating motion of the crank. The lower, larger end of the rod is bored to take a precision bearing insert lined with Babbitt or other bearing metal and closely fitted to the crank pin. V-type engines usually have opposite cylinders staggered sufficiently to permit the two connecting rods that operate on each crank throw to be side by side. Some larger engines employ fork-and-blade rods with the rods in the same plane and cylinders exactly opposite each other.

Each connecting rod in an in-line engine or each pair of rods in a V-type engine is attached to a throw of the crankshaft. Each throw consists of a crankpin with a bearing surface, on which the connecting rod bearing insert is fitted, and two radial cheeks that connect it to the portions of the crankshaft that turn in the main bearings, supported by the cylinder block. Sufficient throws are provided to serve all the cylinders, and the angles between them equal the angular firing intervals between the cylinders. The throws of a six-cylinder, four-stroke-cycle crankshaft are spaced 120 degrees apart so that the six cylinders fire at equal intervals in two full rotations of the shaft. Those of an eight-cylinder engine are 90 degrees apart. The position of each throw along the shaft depends upon the firing order of the cylinders. Firing sequence is chosen to distribute the power impulses along the length of the engine to minimize vibration. Consideration is also given to the fluid flow pattern in the intake and exhaust manifolds. The standard firing order for a six-cylinder engine is 1-5-3-6-2-4, which illustrates the practice of alternating successive impulses between the front and rear valves of the engine whenever possible. Balance is further improved by adding counterweights to the crankshaft to offset the eccentric masses of metal in the crank throws.

The crankshaft design also establishes the length of the piston stroke because the radial offset of each throw is

equal to half the stroke imparted to the piston. The ratio of the piston stroke to the cylinder bore diameter is an important design consideration. In the early years of engine development no logical basis for the establishment of this ratio existed and a range from unity to one and one-half was used by different manufacturers. As engine speeds increased, however, and it became apparent that friction horsepower increased with piston speed rather than with crankshaft rotating speed, there began a trend toward short-stroke engines. Strokes were shortened to as much as 20 percent less than the bores.

From the requirement for the two-cylinder engine a general rule for the layout of the throws of four-stroke-cycle multicylinder crankshafts can be expressed. Regardless of the number of cylinders, two pistons must arrive at top dead centre in unison so that a second cylinder is ready to fire exactly 360 degrees after each cylinder fires. Half of the cylinders then will fire during each turn of the crankshaft. To follow this rule, there must be an even number of cylinders in order that there may be pairs of cylinders whose pistons move in unison.

An eight-cylinder engine fires each time its crankshaft makes a quarter turn if the intervals between impulses are equal. The crankshaft for an eight-cylinder, in-line engine is designed with each of its eight throws a quarter turn away from another throw.

For best lengthwise balance, the cylinders whose pistons are in phase are the first and last cylinders of an in-line engine, the second and next to the last, continuing in that order with crank throws that are in alignment equidistant from the centre of the engine.

**Valves, pushrods, and rocker arms.** The valve-in-head engine has push rods that extend upward from the cam followers to rocker arms mounted on the cylinder head that contact the valve stems and transmit the motion produced by the cam profile to the valves. Clearance (usually termed tappet clearance) must be maintained between the ends of the valve stems and the lifter mechanism to assure proper closing of the valves when the engine temperature changes. This is done by providing push-rod length adjustment or by the use of hydraulic lifters.

Noisy and erratic valve operation can be eliminated with entirely mechanical valve lifter linkage only if the tappet clearance between the rocker arms and the valve stems is closely maintained at the specified value for the engine as measured with a thickness gauge. Hydraulic valve lifters, now commonly used on automobile engines, eliminate the need for periodic adjustment of clearance.

The hydraulic lifter comprises a cam follower that is moved up and down by contact with the cam profile, and an inner bore into which the valve lifter is closely fitted and retained by a spring clip. The valve lifter, in turn, is a cup closed at the top by a freely moving cylindrical plug that has a socket at the top to fit the lower end of the push rod. This plug is pushed upward by a light spring that is merely capable of taking up the clearance between the valve stem and the rocker arm. A small hole is drilled in the bottom of the valve-lifter cup to admit lubricating oil that enters the cam follower from the engine lubricating system through a passage in the cylinder block. A small steel ball serves as a check valve to admit the oil into the valve-fitter cup but prevent its escape. When the clearance in the entire linkage between the cam profile and the valve stem is being taken up by the spring in the valve lifter, oil flows into the lifter chamber past the ball check and is trapped there to maintain this no-clearance condition as the engine operates. Expansion or contraction of the valve linkage is compensated by oil seepage from the lifter to correct for expansion of parts and oil flow into the chamber if clearance tends to be produced between the push rod and the lifter. Complete closure of valve is then assured at all times without tappet noise.

The intake valve must be open while the piston is descending on the intake stroke of the piston and the exhaust valve must be open while the piston is rising on the exhaust stroke. It would seem, therefore, that the opening and closing of the two valves would occur at the appropriate top and bottom dead centre points of the crank-

Crank  
throw  
layout

V-type  
engines

Valve  
timing

shaft. The time required for the valves to open and close, however, and the effects of high speed upon the starting and stopping of the flow of the gases requires that for optimum performance the opening events occur before the crankshaft dead centre positions and that the closing events be delayed until after dead centre.

All four valve events, inlet opening, inlet closing, exhaust opening, and exhaust closing are accordingly displaced appreciably from the top and bottom dead centres. Opening events are earlier and closing events are later to permit ramps to be incorporated in the cam profiles to allow gradual initial opening and final closing to avoid slamming of the valves. Ramps are provided to start the lift gradually and to slow the valve down before it contacts its seat. Early opening and late closure are also for the purpose of using the inertia or persistence of flow of the gases to assist in filling and emptying the cylinder.

**Camshaft.** The camshaft, which opens and closes the valves, is driven from the crankshaft by a chain drive or gears on the front end of the engine. Because one turn of the camshaft completes the valve operation for an entire cycle of the engine and the four-stroke cycle engine makes two crankshaft revolutions to complete one cycle, the camshaft turns half as fast as the crankshaft. It is located above and to one side of the crankshaft, which places it directly under the valves of the L-head engine or the push rods that extend down from the rocker arms of the valve-in-head engine. Because of the long push rods and the rocker arms, the speed of the valve-in-head engine is limited to that at which the cam followers can remain in contact with the cams when the valves are closing. Above that limiting speed the valves are said to float and their motion becomes erratic. For this reason, the overhead-camshaft engine is increasing in popularity. Located immediately above the valves, this type of camshaft is driven either by a vertical shaft and bevel gears or by a cog belt. Although new in automobiles, this arrangement was used as early as World War I in some aircraft engines.

**Flywheel.** The cycle of the internal-combustion engine is such that torque (turning force) is applied only intermittently as each cylinder fires. Between these power impulses the pistons rising on compression and the opposition to rotation caused by the load carried by the engine apply negative torque. The alternating acceleration caused by the power impulse and deceleration caused by compression results in nonuniform rotation. To counter this tendency to slow down and speed up is the function of the flywheel, attached to one end of the crankshaft. The flywheel consists of a heavy circular cast iron disc with a hub for attachment to the engine. Its heavy rotating mass has sufficient momentum to oppose all changes in its rotational speed, and to force the crankshaft to turn steadily at this speed. The engine thus runs smoothly with no evidence of rotational pulsations. The outer rim of the flywheel usually carries gear teeth cut on it to mesh with the starter motor. The driving component of a clutch or fluid coupling for the transmission may be incorporated in the flywheel.

**Bearings.** The crankshaft has bearing surfaces on each crank throw and three or more main bearings. These are heavily loaded because of the reciprocating forces at each cylinder applied to the crankshaft and the weight of the crankshaft and flywheel. All but the smallest engines use split shell bearings, usually made of bronze with Babbitt-metal linings. The surface material is sufficiently soft to minimize the possibility of scoring the crankshaft in the event of inadequate lubrication. The smallest engines usually have cast Babbitt bearings. A small amount of bearing clearance is necessary to permit an oil film to separate the surfaces (see also MACHINES AND MACHINE COMPONENTS).

**Ignition.** Electric ignition systems may be classified as magneto and battery-and-coil systems. Though these are similar in basic principle, the magneto is self-contained and requires only the spark plugs and connecting wires to complete the system, whereas the battery-and-coil system involves several separate components. The circuit consists of a battery, one terminal of which is grounded

while the other leads through a switch to the primary winding of the coil, and then to a circuit breaker where it is again grounded. Rotation of the circuit-breaker cam opens and closes the primary circuit. The secondary circuit, consisting of several thousand turns of fine wire, leads to the rotor of the distributor, which acts as a rotary switch, selecting the spark plug to be placed in the circuit. Each plug is connected to one of the outer terminals of the distributor to receive an electrical impulse in proper sequence. When the primary circuit is broken, a high potential (up to 20,000 volts) is developed in the secondary winding and conducted to the appropriate spark plug.

The spark plug is an important component of the ignition system and is the one that must operate under the most severe conditions. Because it is exposed to combustion-chamber temperatures and pressures and contaminating products of combustion, it requires more service attention and is usually the shortest-lived component of the gasoline engine. It consists of a steel shell threaded to fit a standard 14-millimetre hole in the cylinder head. A copper gasket insures a gas-tight fit between cylinder head and plug. A fused ceramic insulating element is molded into the plug body and the steel centre electrode passes through the insulator up to the connector to which the high-voltage lead from the distributor is attached. The other electrode is welded to the metal body of the plug, which is grounded to the cylinder head.

It is essential that the spark gap be as specified for the particular engine. Gauges are available to aid in making this adjustment by bending the ground electrode as required. Manufacturers specify gaps ranging from 0.020 inch to 0.040 inch (0.508 to 1.016 millimetre) between the centre electrode and the ground electrode. If the plug gap is too large, the possibility of misfiring increases. If the gap is too small, the spark will not be sufficiently intense. Gap growth from erosion of the electrodes may be corrected. The high voltage for the spark plug may also be produced by a capacitor discharge ignition system, which consists of a source of 250 to 300 volts direct-current power applied to a storage capacitor, a device for storing an electrical charge. A lead from the capacitor goes to one side of the spark coil primary through cam-actuated breaker points or an electronic switching device. At the instant this switching device establishes a contact, the capacitor discharges through the primary of the spark coil and an instantaneous high voltage is delivered to the distributor and thence to the spark plug.

The capacitor discharge system stem provides a more intense spark, thus improving starting a cold or flooded engine. It continues to fire the plugs when they are fouled by carbon or other deposits or when the spark gap has widened because of erosion of the points. Other advantages include increased spark plug life, improved firing over wider speed range, and better moisture tolerance.

The capacitor discharge ignition system is now being introduced for engines such as the Wankel; it has been used on research engines for many years.

A magneto is a fixed-magnet, alternating-current generator designed to generate sufficient voltage to fire the spark plugs. A high-tension magneto is entirely self-contained and requires only spark plugs, wires, and switches to do what is required in meeting ignition requirements. Everything else is built in.

**Carburetor.** The gasoline carburetor is a device that introduces fuel into the air stream as it flows into the engine. A simple carburetor is shown diagrammatically in Figure 6. Gasoline is maintained in the float chamber by the float-actuated valve at a level slightly below the outlet of the jet. Air flows downward through the throat, past the throttle valve, and into the intake manifold. A throat is formed by the reduced diameter and acceleration of the air through this smaller passage causes a decrease in pressure proportional to the amount of air flowing. This decrease in throat pressure results in fuel flow from the jet into the air stream. Any increase in air flow caused by change in engine speed or throttle position increases the pressure differential acting on the fuel and causes more fuel to flow.

Capacitor  
ignition  
system

Figure 6: A simple carburetor.

The volume ratio of air to fuel established by the throat and fuel jet sizes will be maintained with increased flow, but the weight of fuel per pound of air increases because the air expands to a lower density as the throat pressure decreases. This enriching tendency necessitates the inclusion of a compensating device in a practical carburetor. Carburetor design is further complicated by the need for an enriching device to provide a maximum-power ratio at full throttle, a choke to facilitate starting a cold engine, an idling system to provide the special needs of light-load operation and an accelerating device to supply additional fuel while the throttle is being opened.

**Fuel injection.** Gasoline-injection systems in which the fuel is forcefully injected into the cylinder by a pump were available for airplane engines before World War II and were extensively used then in aircraft. The performance of engines with this equipment was excellent, but the much greater cost of fuel injection systems compared with that of carburetors limited their application. Efforts to simplify and lower the cost of fuel-injection equipment without impairing performance yielded multicylinder pumps that could compete in cost with four-barrel carburetors. Gasoline injection equipment may consist of distributor systems employing a single pump for all of the cylinders, or multipumps.

The principal advantages of gasoline injection over the carburetor are: improved fuel economy because of more accurate fuel and air proportioning; greater power because of the elimination of fuel heating; elimination of inlet icing; and more uniform and direct delivery of fuel load to the cylinders.

**Supercharger.** The efficiency of the charging process in an automotive engine usually rises to a peak of slightly more than 80 percent at about half the rated speed of the engine and then decreases considerably at higher speed. This change in air charge per cycle with engine speed is reflected in proportionate changes in the torque or turning effort applied to the crankshaft and causes the power the engine can deliver at full throttle to reach a maximum as engine speed increases. At speeds above this peaking speed the air charge introduced per cycle falls off so rapidly that less power is developed than at lower speeds. The inability of the engine to draw in a full charge of fresh air at high speeds limits the power output of the engine.

Supercharging overcomes this disadvantage by the use of a pump or blower to raise the pressure of the air supplied to the cylinders, increasing the weight of charge. The loss in power suffered by unsupercharged engines at high altitudes can be largely restored; it is also possible to more than double the power of an engine by supercharging. Increased charge density and temperature, resulting from supercharging, increase the tendency for combustion knock or roughness in the spark-ignition engine and thus necessitates an undesirable decrease in compression ratio or the use of an antiknock fuel.

The supercharging blower may be geared to the crankshaft, in which case the power consumed in driving it is added to the friction loss of the engine. The turbocharger employs a gas turbine operated by the exhaust gases to drive a centrifugal blower. The turbocharged engine not only gains increased power capacity but also operates at

improved fuel economy. Airplane engines are usually supercharged both by geared blowers and by turbochargers to provide the large pumping capacity needed at high altitude.

**Cooling system.** The cylinders of all internal-combustion engines require cooling because of the inability of the engine to convert all of the energy released by combustion into useful work. Liquid cooling is employed in most gasoline engines, whether the engines are for use in automobiles or elsewhere. The liquid is circulated around the cylinders to pick up heat, and then through a radiator to dissipate the heat. Usually a thermostat is located in the circulating system to maintain the design jacket temperature, 160° to 180° F (71° to 82° C). The cooling system is usually pressurized to raise the boiling point of the coolant so that a higher outlet temperature can be maintained to improve thermal efficiency and increase the heat transfer capacity of the radiator. A pressure cap on the radiator maintains this pressure by valves that open outwardly at the design pressure and inwardly to prevent a vacuum as the system cools.

Some engines, particularly aviation engines and small units for mowers, chain saws, and other appliances, are air cooled. Air cooling is accomplished by forming thin metal fins on the exterior surfaces of the cylinders to increase the rate of heat transfer by exposing more metal surface to the cooling air. Air is forced to flow rapidly through the spaces between the fins by fans or blowers. Airplane engines are especially well adapted to air cooling because the propeller air stream provides ample cooling air without any power consumption.

**Lubrication system.** Lubrication is employed to reduce friction by interposing a film between rubbing parts. The lubrication system must continuously replace the films.

The lubricants commonly employed are refined from crude oil after the fuels have been removed. Their viscosities must be appropriate for each engine and the oil must be suitable for the severity of the operating conditions. Oils are improved with additives that reduce oxidation, inhibit corrosion, and act as detergents to disperse deposit-forming gums and solid contaminants. Various systems of numbers are used to designate oil viscosity; the lower the number, the lighter the body of the oil. Certain oils contain additives that oppose their change in viscosity between the winter and summer.

Oil filters, if regularly serviced, can remove solid contaminants from crankcase oil, but chemical reactions may form liquids that are corrosive and damaging. Depletion of the additives also limits the useful life of lubricating oils.

The lubrication system is fed by the oil sump that forms the lower enclosure of the engine. Oil is taken from the sump by a pump, usually of the gear type, and delivered under pressure to a system of passages or channels drilled through the engine. In some instances a so-called full-flow filter runs the length of the engine between the pump and the main oil passage. In other engines bypass filters continuously bleed off a small quantity of oil and return the filtered oil to the sump.

Oil is supplied under pressure to crankshaft and camshaft main bearings. Adjacent crank throws are drilled to enable the oil to flow from the supply at the main bearings to the crankpins. Leaking oil from all of the crankshaft bearings is sprayed on the cylinder walls, cams, and up into the pistons to lubricate the piston pins. Additional passages intersect the cam-follower openings and supply oil to hydraulic valve lifters when used. A spring-loaded pressure-relief valve maintains the pressure at the proper level.

**Exhaust system.** Exhaust gases from an internal-combustion engine are passed through a muffler to suppress audible vibrations. The pressure in the engine when the exhaust valve opens causes an initial gas outflow at explosive velocity. Successive discharges from the cylinders set up pressure pulsations that produce a sharp barking sound. The muffler damps out or absorbs these pulsations so that the gases leave the outlet as a relatively smooth, quiet stream.

Air cooling

Pumps  
versus  
carburetors

Mufflers of early design contained sets of baffles that reversed the flow of the gases or otherwise caused them to follow devious paths so that interference between the pressure waves reduced the pulsations. The mufflers most commonly used in modern motor vehicles employ resonating chambers communicating with the passages through which the gases flow. Gas vibrations are set up in each of these chambers at the fundamental frequency determined by its dimensions. These vibrations cancel or absorb those present in the exhaust stream of about the same frequency. Several such chambers, each tuned to one of the predominant frequencies present in the exhaust stream, effectively reduce noise.

#### Emission control

Emission control devices to reduce air pollution are frequently added to the exhaust system. Beds of a suitable catalyst (a material for promoting desirable reactions) are placed in the muffler to reduce unburned hydrocarbons and carbon monoxide in the exhaust output. These catalysts are adversely affected by tetraethyl lead in gasoline.

The reactor system for controlling emission is composed of a belt-driven air compressor connected to small nozzles installed in the exhaust manifold facing the outlet from each exhaust valve. A small jet of air is thus directed toward the red-hot outflowing combustion products to provide oxygen to consume the hydrocarbons and carbon-monoxide.

#### FUELS

Gasoline was originally considered dangerous and was discarded and destroyed at the early refineries, which were manufacturing kerosene for lamps. As the gasoline engine developed, gasoline and the engine were harmonized to attain the best possible matching of characteristics. The most important properties of gasoline are its volatility and antiknock quality. Volatility is a measure of the ease of vaporization of gasoline in the carburetor. The volatility is made higher for winter use to make engines start more readily and lower in summer to avoid vapour lock (blockage of gasoline feedline by excessive gasoline vapour) and excessive evaporation loss.

To suit the needs of a modern engine a gasoline must have the volatility for which the fuel system of the engine was designed, and antiknock quality sufficient to avoid knock under normal operation. Though other specifications must also be met, volatility and knock rating are the most important. The size and structural arrangement of the molecules principally determine the knocking tendency of a gasoline as well as its volatility. (For a detailed description of antiknock gasoline blending techniques, see PETROLEUM REFINING.)

Tetraethyl lead, added to gasolines for many years to improve antiknock fuelling, has been found to contaminate the exhaust gases with poisonous lead oxides, and the practice is ending. Lower compression ratios and improved combustion-chamber designs are eliminating the need for extremely high antiknock gasolines.

Lubricating oil is added to gasoline used in crankcase-compression two-stroke cycle engines.

#### PERFORMANCE

The performance of an engine is expressed in terms of power, speed, and fuel economy. The three quantities are evaluated with a dynamometer, a laboratory device that applies a controllable load in the form of resistance to the turning of the crankshaft and also measures the torque exerted at the shaft coupling. The resistance imposed by a dynamometer may be so adjusted that the desired engine speed is established at any throttle position. It is thus possible to run the engine at various speeds throughout its operating range, to maintain these operating conditions continuously, and to measure the precise load and speed at which each run is made. Additional test equipment permits measurement of the exact quantity of fuel consumed as well as the duration of the runs. From these data the power-speed-economy relationships can be calculated, and performance plotted.

The power produced by an engine is expressed in horsepower, a unit established by James Watt, who tested sev-

eral horses to determine the rate at which they could work and decided that 33,000 foot-pounds per minute was a liberal unit. A foot-pound is equivalent to lifting a weight of one pound a distance of one foot.

When the power developed is measured by means of a dynamometer or similar braking device, it is called brake horsepower. This is the power actually delivered by the engine and is therefore the capacity of the engine. The power developed in the combustion chambers of the engine is greater than the delivered power because of friction and other mechanical losses. This power loss, called the friction horsepower, can be evaluated by "motoring" the engine (driving it in a forward direction) with a suitable dynamometer when no fuel is being burned. The power developed in the cylinder can then be found by adding the friction horsepower to the brake horsepower. This quantity is the indicated horsepower of the engine, so called from an instrument known as the engine indicator, which is used to measure the pressure on the piston and thus calculate the power developed in the cylinder.

Mechanical efficiency is defined as brake horsepower in percent of indicated horsepower and is usually between 70 percent and 90 percent within the normal operating speed range.

A quantity called brake mean effective pressure is obtained by multiplying the mean effective pressure of an engine by its mechanical efficiency. This is a commonly used index expressing the ability of the engine, per unit of cylinder bore, to develop useful pressure in the cylinders and delivery power. If the power delivered is increased by any change other than an increase in speed or cylinder dimensions, its brake mean effective pressure increases proportionately.

#### APPLICATIONS

Gasoline engines can be built to meet the requirements of practically any conceivable power-plant application. In some instances, however; other kinds of engines or electric motors have certain advantages. The important applications for which the gasoline engine is most likely to be chosen in preference to other types are in the areas of passenger automobiles, small trucks and buses, aircraft, outboard and small inboard marine units, moderate-sized stationary pumping, lighting plant, machine tool and similar installations, and power tools.

Automobile engines range from small four-cylinder engines of less than 100 horsepower to 500 cubic inch piston displacement engines developing well over 400 horsepower. These engines meet the needs of motor-car propulsion so well that in the early 1970s they had practically no competition in that field.

## Gasterosteiformes

Gasterosteiformes is an order of fishes characterized generally by soft fin rays, pelvic fins located on the abdomen, an air bladder without a duct to the gut, and a primitive kidney. Gill structures are somewhat degenerate. Most species have bony rings around the body or ganoid (*i.e.*, thick, bony, enamelled, and diamond-shaped) plates rather than scales. Families within the order are Gasterosteidae (sticklebacks), Aulorhynchidae (tube snout), Indostomidae (indostomid), Aulostomidae (trumpet fishes), Fistulariidae (cornetfishes), Centriscidae (shrimpfishes), Macrorhamphosidae (snipefishes), Solenostomidae (ghost pipefishes), and Syngnathidae (pipefishes and sea horses).

Power measurements

Representative gasterosteiform fishes.

Drawing by J. Helmer based on (G,F) G. Whitley and J. Allan, *The Sea-Horse and Its Relatives*; (D,E,H) A.H. Leim and W.B. Scott, *Fishes of the Atlantic Coast of Canada* (1966), Fisheries Research Board of Canada, reproduced by permission of Information Canada

**Natural history. Distribution, size, and importance.** Gasterosteiform fishes occur in both salt water and fresh-water and are widely distributed. The smallest species are about three centimetres (1.2 inches) long, the largest about 200 centimetres (about 80 inches). They are of limited economic importance, but many forms are popular aquarium fishes. Two families, Indostomidae and Aulorhynchidae, are represented by only one species each.

**Reproduction and life cycle.** Except for sticklebacks, pipefishes, and sea horses, little is known of the life cycles of Gasterosteiformes. The male stickleback builds nests of plant materials cemented together with mucus secretions. The usually drab body hues of the male change, reflecting red, which is sexually attractive to the female. Male pipefishes and sea horses brood the eggs, deposited by the female within the male's brooding pouch. The brooding organ of the male sea dragon is a specialized area of soft skin beneath the tail. In some ghost pipefishes, eggs are fastened to the female on filaments of skin in pouches formed by specialized fins on the ventral, or lower, side. The dwarf sea horse, *Hippocampus zosterae*, breeds nine months of the year; eggs hatch after ten days into miniatures of the adult. They mature in two or three months and live less than a year. Tube snouts deposit eggs in cavities of ascidia (primitive colonial chordates) or in masses of algae bound with threads secreted in a manner similar to that of sticklebacks. Egg clusters, often multiple, are cared for by the

male. Snipefish eggs are enveloped in a mucilaginous substance from which the larvae are freed as development proceeds. Cornetfishes lay free pelagic (*i.e.*, drifting) eggs; thus, they do not receive parental care. The reproductive habits of shrimpfishes and trumpet fishes are unknown.

**Ecology and behaviour.** For defense, most gasterosteiforms assume a vertical position among grasses, gorgonians (*i.e.*, sea fans, a type of coral), and sea urchins. Such a posture serves to camouflage them; it also tends to present body spines or shields to predators normally oriented to the horizontal plane.

In most families, locomotion is by means of the caudal, or tail, fin. Snipefishes swim forward or backward with equal ease on the vertical plane and do not seek shelter among marine growths. The caudal fin is absent in sea horses. The coiled tail of the sea horse is used for gripping seaweed and other plants or objects. Propulsion is by means of the dorsal fin (*i.e.*, the large fin arising from the midline of the back). Tiny pectoral fins are used for steering. Vertical movement is by swimming. All fishes with an air bladder use it to some degree for vertical motion. With little effort the sea horse rises or settles to another depth by changing the air volume within the bladder.

With the exception of the snipefishes, most gasterosteiforms live among a wide variety of aquatic growths where they find food and safety and reproduce. Certain pipefishes and sticklebacks, in particular, are able to tolerate a wide range of salinity.

**Form and function.** Sticklebacks are the most varied in form. The number of spines and bony plates is greatest in individuals living in the ocean. Each heavily armoured marine species is represented by half-mailed or naked (plateless) varieties in brackish or fresh waters. They are small scaleless fishes that grow to about 15 centimetres (six inches) in length. The short jaws are well armed with sharp teeth. The body is more nearly fusiform (*i.e.*, tapered at both ends) than are those of other members of the order. Body plates may be absent or may vary in number. The soft dorsal fin is preceded by from two to 11 free spines, each connected to the dorsal surface by its own triangular membrane. Pelvic fins are thoracic (*i.e.*, near the midsection) in position, each with a well-developed spine and one or two soft rays. The anal fin is preceded by a spine. The caudal fin is truncate (*i.e.*, abbreviated).

The body of the tube snout is elongated, slender, and cylindrical. It is tipped by a prolonged snout, the small, toothed mouth of which has a hinged upper jaw. The scaleless body is armoured with series of embedded bony plates. The first dorsal fin is represented by about 25 free spines; the rayed dorsal fin is far back on the body above the anal fin. Pectoral fins are broad and the caudal fin furcate (forked).

In the indostomids the elongated body is covered with bony rings as in pipefishes and sea horses. The small mouth is at the tip of the snout. The teeth are minute, the gills rather lobe shaped, and the eyes large. The anterior (*i.e.*, forward) dorsal fin consists of five isolated spines. Ventral fins (*i.e.*, paired fins arising from the sides of the belly) bear no spine, have four rays each, and are located not far behind the pectorals. The anal fin is below the soft dorsal fin, and the rounded caudal fin has a short peduncle, or stem.

Trumpet fishes, which seldom grow to more than 30 centimetres (one foot) in length, have an elongated, compressed, scaled body; the snout is prolonged into a rigid tubelike beak. The short, weak jaws have minute teeth. There are numerous dorsal spines. The ventral fins are abdominal; the caudal fin is truncate.

Cornetfishes, which grow to more than 180 centimetres (six feet) in length, are similar in structure to trumpet fishes; however, there are no scales. Instead, bony plates are embedded in the skin. Dorsal spines are absent, and the ventral fins are located in the abdominal region; each has a spine and four rays. Four anterior vertebrae are elongated. The backbone extends through the forked caudal fin as a long central filament.

Sticklebacks

Brooding organ of the male

Shrimpfishes, also known as razor fishes, are small, with toothless jaws at the end of a long snout. Scales are absent; the back is covered by transparent plates, forming the cuirass. Anteriorly the cuirass is affixed to the ribs; posteriorly it extends beyond the displaced dorsal, caudal, and anal fins. The body is compressed to a sharp edge ventrally; hence the name razor fish.

In snipefishes the tubular snout has short jaws. The body form is variable, but all snipefishes tend to be short and deep and partly covered with the bony-plated cuirass, which is strengthened by its union with parts of the vertebrae. Areas lacking plates sometimes have scales. In addition to having several shorter spines, the dorsal fin has a very long, strong, serrated spine reaching nearly to the tip of the caudal fin. Each ventral fin has one spine and five rays. A long snout, and two posterior "handles" of spine and tail lends an appearance that is the basis for another common name, bellows fish.

Ghost pipefishes have a tubular snout tipped with a small mouth; the short body has spinous dorsal and ventral fins. Gills are reduced to lobe-shaped tufts attached to rudimentary gill arches. Bony plates unite to form rings. This supporting external framework has reduced the need for well-developed musculature. Ventral fins and a pointed caudal fin are large in proportion to the body size.

## Pipefishes

Pipefishes are long and slender. The axis of the head is in line with that of the body, and the long snout is tipped with a small mouth. Bony rings replace scales. The dorsal and pectoral fins are spineless, and ventral fins are absent. Generally, the caudal fin is rounded and reduced, but it is effective in moving the fish rapidly through the water. The slender posterior body portion, though not truly prehensile (*i.e.*, capable of coiling and grasping), can be somewhat used in that manner. Sea horses are similar to pipefishes but differ in several important respects. The head is at an angle to the body proper. This, in addition to the shape of the head, creates a somewhat horselike appearance. The tail is prehensile and lacks a caudal fin.

**Evolution and classification.** *Paleontology.* Gasterosteiformes appears to represent an early but highly specialized branch of the Acanthopterygii. Its evolution has been traced through limited paleontological data. Fossil sticklebacks occur in Miocene (7,000,000 to 26,000,000 years ago) strata and are moderately abundant in Tertiary (2,500,000 to 65,000,000 years ago) strata. Most of the order occurs in fossil remains in Eocene (38,000,000 to 54,000,000 years ago) and Oligocene (26,000,000 to 38,000,000 years ago) strata in the area of Monte Bolca near Verona, Italy. Deposits there (and in Sumatra) include an extinct family, Protosynbranchiidae, related to the tube snouts. Trumpet-fish species, a closely related extinct scaleless family, Urosphenidae, and a small species of cornetfish have also been found there. Shrimpfishes, too, are within these strata, as well as in Oligocene deposits in various parts of Europe. Snipefishes are represented by an extinct genus, as are ghost pipefishes. Pipefishes are in Miocene deposits in Sicily. Tertiary rocks contain *Syngnathus* and *Calamostoma*, pipefish forms with a close relationship to true sea horses. Fossil sea horses are unknown.

**Distinguishing taxonomic features.** The Gasterosteiformes are classified mainly on the basis of general body form, the structure and distribution of scales or body plates, fin form and position, and the structure of the skeleton and its individual parts.

**Annotated classification.** The classification here is essentially that of P.H. Greenwood *et al.* (Bulletin of the American Museum of Natural History, no. 131, 1966).

### ORDER GASTEROSTEIFORMES

Eocene to Recent. Frequently with strong spines in dorsal and pelvic fins, spines absent in some; snout often elongated; body often with dermal plates; 9 families, marine and freshwater, widely distributed. Length about 3–200 cm.

#### Suborder Gasterosteoidae

##### Family Gasterosteidae (sticklebacks)

Jaws short, armed with sharp teeth; body quite fusiform (tapered at both ends); body plates may be absent or may

vary in number; body length to about 15 cm; 11 species, fresh, brackish, and marine waters of Northern Hemisphere.

##### Family Aulorhynchidae (tube snout)

Body elongated, slender, and cylindrical; snout long, upper jaw hinged. One species, occurs in northeastern Pacific Ocean.

##### Family Indostomidae (indostomid)

Body elongated, covered with bony rings; teeth minute, gills lobe-shaped, eyes large. One species, *Indostomus paradoxus*, found in Lake Indawgyi in northern Burma.

#### Suborder Aulostomoidei

##### Family Aulostomidae (trumpet fishes)

Body elongated and compressed sideways; jaws short and weak, teeth minute; dorsal spines numerous; length to about 30 cm; about 4 species, tropical seas.

##### Family Fistulariidae (cornetfishes)

Similar in appearance to Aulostomidae; no scales, bony plates imbedded in skin; dorsal spines absent; backbone extends through caudal fin as a central filament. Grow to more than 180 cm; about 4 species, tropical seas.

##### Family Centriscidae (shrimpfishes)

Body small, jaws toothless, scales absent, back covered by transparent plates; 4 species, shallow waters of Indian and Pacific Oceans.

#### Suborder Syngnathoidae

##### Family Macrorhamphosidae (snipefishes)

Snout tubular, jaws short, body rather short and deep; in profile shaped like bellows; 11 species, temperate and tropical seas.

##### Family Solenostomidae (ghost pipefishes)

Snout tubular, mouth small; body short, with spiny dorsal and ventral fins; bony plates united to form body rings; about 5 species, tropical Indo-Pacific waters.

##### Family Syngnathidae (pipefishes and sea horses)

Pipefishes long and slender, snout tipped with small mouth; dorsal and pectoral fins spineless, ventral fins absent. Sea horses with head bent downward in horselike relation to body; tail prehensile; bony rings instead of scales; about 24 species of sea horses, widely distributed, marine; about 150 species of pipefishes widely distributed in shallow tropical seas.

**Critical appraisal.** The American Fisheries Society (Special Publication No. 6, 1970) arranges the Gasterosteiformes as in Greenwood *et al.*, above, with the following exceptions: suborders are not used; family Gasterosteidae is expanded to include Aulorhynchidae; family Centriscidae is expanded to include Macrorhamphosidae.

Of the several families considered in this article, the Indostomidae are the least known. They appear to be intermediate between Gasterosteidae and Aulostomidae.

A tenth family, Pegasidae, is tentatively placed between Gasterosteidae and Syngnathidae. Some authorities list them separately as Pegasiformes. These small fishes are the so-called sea moths, found in Asiatic seas. The toothless mouth is not terminal but lies under the head and is overhung by a snout, or rostrum, often adorned with spines. The body is protected by knobby armoured plates, with the posterior portion rather elongated, square to rectangular in cross section and bearing a small dorsal fin. Spines along either side of this region may be absent or developed to varying degrees. Pectoral fins form expansive fans on either side. Ventral fins are reduced to a few fingerlike rays used for crawling on the bottom. The pegasids have no air bladder. Swimming ability for more than short distances is poor. Fossils of Pegasidae are unknown.

## Gastronomy

Gastronomy is the art of selecting, preparing, serving, and enjoying fine food. Brillat-Savarin, the celebrated French aphorist and gastronomic authority of the 18th century, called gastronomy "the intelligent knowledge of whatever concerns man's nourishment."

Through the ages gastronomy has proved to be a stronger cultural force among the peoples of the world than linguistic or other influences. Today, the world may be divided into definite gastronomic regions, areas where distinctive cuisines prevail and common culinary methods are practiced. Most of Asia, for example, is in the region of the rice and coconut cuisine. Rice is the staple there, enjoyed by millions who speak a broad variety of languages and have little in common except their dietary habits. India and Indonesia are the lands of the spices, the distinctive feature of the cooking of those lands being the generous and imaginative use of spices to lend an added zest to foods. Olive oil is the common denominator of the Mediterranean cuisines. In Spain, south Italy, Portugal, Greece, and the Middle Eastern lands rimming the Mediterranean, it is the basic cooking fat. Northern Europe and North America use a variety of cooking fats: butter, cream, lard, goose and chicken fats, but the common gastronomic denominator throughout most of these lands is wheat, the basic crop. Latin America is the land of corn (maize) in every form.

This article covers the history of gastronomy from ancient civilizations through Greece and Rome, the Middle Ages, and the Italian Renaissance; the development of the great cuisines of France and of China; and the leading regional and national cuisines of the world.

### HISTORY

The first significant step toward the development of gastronomy was the use of fire by primitive man to cook his food, which gave rise to the first meals as families gathered around the fire to share the foods they had cooked. Prehistoric cave paintings such as those in Les Trois-Frères in Ariège, in southern France, depict these early gastronomic events.

In the ancient civilizations of Assyria, Babylonia, Persia, and Egypt, the selection, preparation, service, and enjoyment of food was practiced on an elaborate scale. In the Book of Daniel the Bible tells how Belshazzar, the king of the Chaldeans, "made a great feast to a thousand of his lords, and drank wine before the thousand." He then commanded gold and silver vessels to be brought, and he and his wives, princes, and concubines drank wine and praised gods of gold, silver, brass, iron, wood, and stone.

**Greece and Rome.** In ancient Greece, the Athenians believed that mealtime afforded an opportunity to nourish the spirit as well as the body. They reclined on couches while eating and accompanied their repasts with music, poetry, and dancing. The Greeks provided a philosophical basis for good living, Epicureanism. It held that pleasure was the main purpose of life; but pleasure was not intended to imply the self-indulgence that it connotes today. The Epicureans believed that pleasure could best be achieved by practicing self-restraint and indulging as few desires as possible. Today the epicure is defined as one who is "endowed with sensitive and discriminating tastes in food and wine."

The ancient Greeks practiced moderation in all things, but the Romans were known for their excesses. Ordinary citizens subsisted on barley or wheat porridge, fish, and ground pine nuts (edible pine seeds), but the Roman emperors and wealthy aristocrats gorged themselves on a staggering variety of foods. They staged lavish banquets where as many as 100 different kinds of fish were served, as well as mountainous quantities of beef, pork, veal, lamb, wild boar, venison, ostrich, duck, and peacock. They ordered ice and snow hauled down from the Alps

to refrigerate their perishable foods, and they dispatched emissaries to the outposts of the Roman Empire in search of exotic delicacies. Mushrooms were gathered in France, and Juvenal describes a dinner at his patron's house where mullet from Corsica and lampreys from Sicily were served.

Yet whereas the Romans placed great value on exotic delicacies, they were not gastronomes in the true sense of the word. The term implies a sensitivity and discrimination that they lacked. The unbridled appetites of the Roman emperors and nobles often carried them to wild extremes. The emperor Caligula drank pearls dissolved in vinegar. Maximus reportedly consumed 60 pounds of meat in a day, and Albinus was alleged to have eaten 300 figs, 100 peaches, ten melons, and vast quantities of other foods at a single sitting. Lucullus was an immensely wealthy man who entertained so lavishly that his name became a symbol for extravagance and culinary excellence.

The vulgarity and ostentation of Roman banquets were satirized by Petronius in the *Satyricon*. A former slave named Trimalchio entertains at a gargantuan feast at which the guests are treated to one outlandish spectacle after the other. A donkey is brought in on a tray, encircled with silver dishes bearing dormice that have been dipped in honey. A huge sow is carved and live thrushes fly up from the platter. A chef cuts open the belly of a roast pig, and out pour blood sausages and blood puddings.

**The Middle Ages.** Through most of the Middle Ages banquets and feasts were characterized by their crudity and extravagance. In more affluent households in Gaul, for example, huge quarters of beef, mutton, and pork were served. Wild game was frequently served, including wild boar, hedgehog, roebuck, crane, heron, and peacock. Meats and other foods were cooked on spits and in caldrons positioned close by the tables. Diners seated themselves on bundles of straw and gobbled huge quantities of food, sometimes drawing knives from sheaths in their sword scabbards to saw off huge chunks of meat.

The Frankish emperor Charlemagne introduced a touch of refinement. He decorated the walls of his banquet halls with ivy. Floors were strewn with flowers. Tables were laid with silver and gold utensils, but food was coarse, and menus offered little variety. The subtle seasonings and sauces that later were to characterize French cooking were still unknown. An insight into the relative crudeness of the French culinary art during the Middle Ages is provided by *Le Viander* (c. 1375), the first French cookbook of importance. It was written by Guillaume Tirel, more familiarly known as Taillevent, who served as chef to King Charles VI. Like the Romans, he used bread as the thickener for his sauces, instead of flour (which has been used for the past two centuries). He relied heavily on spices—such as ginger, cinnamon, cloves, and nutmeg (a Moorish influence via Spain and Italy). His menus consisted mostly of soups, meats, and poultry, which were so heavily seasoned that the taste of the food was largely obscured. French cooking ultimately would be distinguished by the subtlety of its seasonings and sauces and by the imaginative blend of textures and flavours. But in Taillevent's day the principal object of cooking was to disguise the flavour of the unrefrigerated food rather than to complement it.

**The Italian Renaissance.** The turning point in the development of gastronomic excellence was the Italian Renaissance. By the beginning of the 15th century wealthy merchants in Italy were dining in elegant style. In place of the crude slabs of meat served elsewhere, they savoured such delicacies as mushrooms, garlic, truffles, tournedos (thick slices of beef fillets), lasagne, or ravioli. In wealthier households such delicacies were served in sumptuous style. When Vincenzo I, the duke of Mantua, celebrated his wedding feast in 1581, a guest reported that there were

100 ladies beautiful beyond measure and most richly garbed . . . on a handsome sideboard, was visible a perspective of divers cups, carafes and goblets, and such beautiful vessels of Venetian glass as I think would defy description . . .

The gastronomic regions of the world

Epicurean restraint and Roman excesses

The first French cookbook of importance

The duke's wedding feast lasted three hours. Tables were laid with delicately embroidered cloths. The guest reported that

the first service from the sideboard was large salads decked out with various fantasies such as animals made of citron, castles of turnips, high walls of lemons; and variegated with slices of ham, mullet roes, herrings, tunny, anchovies, capers, olives, caviar, together with candied flowers and other preserves.

The duke's guest also reported that the tables were tastefully and imaginatively decorated.

There were three large statues in marzipan. One was the horse of Campidoglio come to life, the second Hercules with the lion, and the third a unicorn with its horn in the dragon's mouth.

The bounty of these tables was almost beyond belief.

The table was filled with many other things—jellies, blanc-manges in half relief, spiced hard-bake, royal wafers, Milanese biscuits, pine kernels, minced meat, salami, cakes of pistachio nuts, sweet almond twists, flaky pastries . . . Indian turkey hens stuffed and roasted on the spit, marinated pullets, fresh grapes, strawberries strewn with sugar, wild cherries, and asparagus cooked in butter in various ways.

#### DEVELOPMENT OF FRENCH GRANDE CUISINE

**The Italian influence on France.** Italy has been called the mother of the Western cuisines, and perhaps its greatest contribution was its influence on France. The crucial event was the arrival of Catherine de Médicis in France in the 16th century. The great granddaughter of Lorenzo the Magnificent, Catherine married the young man who later was to become Henry II of France. She brought with her a retinue of Florentine cooks who were schooled in the subtleties of Renaissance cooking—in preparing such elegant dishes as aspics, sweetbreads, artichoke hearts, truffles, liver *crêpinettes*, quenelles of poultry, macaroons, iced cream, and zabagliones. Catherine also introduced a new elegance and refinement to the French table. Although during Charlemagne's reign, ladies were admitted to the royal table on special occasions it was during her regime that this became the rule and not the exception. Tables were decorated with silver objects fashioned by Benvenuto Cellini. Guests sipped wine from fine Venetian crystal and ate off beautiful glazed dishes. An observer reported that

the Court of Catherine de' Médici was a veritable earthly paradise and a school for all the chivalry and flower of France. Ladies shone there like stars in the sky on a fine night.

Catherine's cousin, Marie de Médicis, who married Henry IV of France, also advanced the culinary arts. An important new cookbook appeared in her time. It was called *Le Cuisinier françois* (1652) and was written by La Varenne, an outstanding chef, who is believed to have learned to cook in Marie de Médicis' kitchens. La Varenne's cookbook reflected the great progress since the time of Taillevent. He was the first to present recipes in alphabetical order, and his book included the first instructions for vegetable cooking. By now spices were no longer used to disguise the taste of food. Truffles and mushrooms provided subtle accents for meats, and roasts were served in their own juices to retain their essential flavours. A basic point of French gastronomy was established; the purpose of cooking and of seasoning and spices was to bring out the natural flavours of foods—to enhance rather than disguise their flavour. In keeping with this principle, La Varenne cooked fish in a fumet, or stock made with the cooked fish trimmings (head, tail, and bones). The heavy sauces using bread as a thickener were discarded in favour of the roux, which is made of flour and butter or another animal fat.

**Contributions of the Sun King.** La Varenne's cookbook was a gastronomic landmark, but a long time was to pass before the French cuisine would achieve its modern forms. In pre-Revolutionary France extravagance and ostentation were the hallmarks of gastronomy. Perhaps the most extravagant Frenchman of the time was the Sun King, Louis XIV, who wine and dined in unparalleled splendour at his palace at Versailles. There the

kitchens were some distance from the king's quarters; the food was prepared by a staff of more than 300 people, and was carried to the royal quarters by a procession headed by two archers, the lord steward, and other notables. As the cry "the King's meat," proclaimed their progress, an assemblage laden with baskets of knives, forks, spoons, toothpicks, seasonings, and spices, solemnly made their way to the king's quarters. Before the king dined tasters sampled the food to make certain it had not been poisoned. The king himself was such a prodigious eater that members of the court and other dignitaries considered it a privilege merely to stand by and watch him devour his food. His sister-in-law reported that at one meal he ate

four plates of different soups, an entire pheasant, a partridge, a large plateful of salad, mutton cut up in its juice with garlic, two good pieces of ham, a plateful of cakes, and fruits and jams.

Louis XIV is remembered principally for his extravagance, but he was genuinely interested in the culinary arts. He established a new protocol for the table; dishes were served in a definite order instead of being piled there in a jumble. The fork came to be widely used in France during his reign, and the manufacture of fine porcelain (Sèvres) was begun. The king himself hired a lawyer-agronomist, La Quintinie, to supervise the gardens at Versailles, and was intensely interested in the fruits and vegetables—strawberries, asparagus, peas, and melons—that were grown there. He paid special honour to members of his kitchen staff, conferring the title of officer on his cooks.

**New order and logic.** During the reigns of Louis XV and Louis XVI, culinary methods were refined and a new order and logic were introduced into the French cuisine. Brillat-Savarin noted that in the reign of Louis XV

there was generally established more orderliness of meals, more cleanliness and elegance, and those refinements of service, which having increased steadily to our own time . . .

By the time of the Revolution the interest in the culinary arts had intensified to the point where Brillat-Savarin could report:

The ranks of every profession concerned with the sale or preparation of food, including cooks, caterers, confectioners, pastry cooks, provision merchants and the like, have multiplied in ever-increasing proportions . . . New Professions have arisen; that, for example, of the pastry cook—in his domain are biscuits, macaroons, fancy cakes, meringues . . . The art of preserving has also become a profession in itself, whereby we are enabled to enjoy, at all times of the year, things naturally peculiar to one or other season . . . French cookery has annexed dishes of foreign extraction . . . A wide variety of vessels, utensils and accessories of every sort has been invented, so that foreigners coming to Paris find many objects on the table the very names of which they know not, nor dare to ask their use.

The Revolution changed almost every aspect of French life: political, economic, social, and gastronomic as well. In pre-Revolutionary days the country's leading chefs performed their art in wealthy aristocratic households. When the Revolution was over those who had survived the guillotine and remained in the country found employment in restaurants. The restaurant became the principal arena for the development of the French cuisine, and henceforth French gastronomy was to be carried forward by a succession of talented chefs, men whose culinary genius has not been matched in any other land. From the long roll of great French chefs, a select company have made a lasting contribution to gastronomy.

**The great French chefs.** The first, and in many ways the most important of all French chefs, was Marie-Antoine Carême, who has been called the Architect of the French Cuisine. As the French novelist and gastronome Alexandre Dumas *père* related the story, when Carême, born shortly before the Revolution, the 16th child of an impoverished stonemason, was only 11, his father took him to the gates of Paris one evening, fed him supper at a tavern, and abandoned him in the street. Fortunately for gastronomy, Carême found his way to

Carême,  
the  
"Architect  
of the  
French  
Cuisine"

an eating house, where he was put to work in the kitchen. Later he moved to a fine pastry shop where he learned to cook, read, and draw.

Carême was an architect at heart. He liked to stroll about Paris, admiring the great classic buildings, and he fell into the habit of visiting the Bibliothèque Royale, where he spent long hours studying prints and engravings of the great architectural masterpieces of Greece, Rome, and Egypt. He designed massive, elaborate table decorations called *pièces montées* (mounted pieces) as an outlet for his passionate interest in architecture. In an age of Neoclassicism his tables were embellished with replicas of classic temples, rotundas, and bridges constructed with spun sugar, glue, wax, and pastry dough. Each of these objects was fashioned with an architect's precision, for Carême considered confectionery to be "architecture's main branch," and he spent many months executing these designs, rendering every detail with great exactness.

Carême was employed by the French foreign minister, Charles-Maurice de Talleyrand, who was not only a clever diplomat but a gastronome of distinction. Talleyrand believed that a fine table was the best setting for diplomatic manoeuvring. Following his service with Talleyrand, Carême practiced his art for a succession of kings and nobles. He catered a series of feasts for Czar Alexander of Russia, was *chef de cuisine* to England's Prince Regent (who later became George IV), and finally was employed by the Baroness Rothschild in Paris.

Today Carême's monumental table displays seem ostentatious almost beyond belief, but he lived in an opulent age that was obsessed with classical architecture and literature. To appreciate him fully, it is necessary to put him in the context of his time. Before Carême, the French cuisine was largely a jumble of dishes; little concern was given to textures and flavours. Carême brought a new logic to the cuisine. "I want order and taste," he said. "A well displayed meal is enhanced one hundred per cent in my eyes." Every detail of his meals was planned and executed with the greatest of care. Colours were carefully matched, and textures and flavours carefully balanced. Even the table displays, mammoth as they were, were designed and carried out with an architect's precision.

Carême's voluminous cookbooks, *L'Art de la cuisine au dix-neuvième siècle* (1833) and *Le Pâtissier royal Parisien* (1815), included hundreds of recipes, menus for every day in the year, a history of French cooking, sketches for Carême's monumental *pièces montées*, instructions for garnishes, decorations, and tips on marketing and organizing the kitchen.

Montagné  
and  
Escoffier

After Carême, the two men who probably had the greatest impact on French gastronomy and that of the world at large were Prosper Montagné and Georges-Auguste Escoffier. Montagné was one of the great French chefs of all time, and he achieved a secure place in gastronomic history by creating *Larousse Gastronomique* (1938), the basic encyclopaedia of French gastronomy. As a young man, while serving as an assistant chef at the Grand Hotel in Monte Carlo, he came to the conclusion that all *pièces montées*, superfluous garnitures and decorations, should be discarded. This was a drastic step, and Montagné's call might have gone unheeded had it not been brought to the attention of Escoffier. Escoffier was unimpressed at first. But his friend and literary collaborator Philéas Gilbert (also an outstanding chef) persuaded him that Montagné was right. Escoffier became a zealot for culinary reform, insisting on refining and modifying nearly every aspect of the cuisine. He simplified food decorations, greatly shortened the menus, accelerated the service, and organized teams of cooks to prepare the food more expertly and efficiently.

All of this progress was greatly facilitated by the introduction of the Russian table service around 1860. Before then, the service *à la française* was used. Under that method the meal was divided into three sections or services. All of the dishes of each service were brought in from the kitchen and arrayed on the table at once. Then, when this service was finished, all of the dishes of the

next service were brought in. The first service consisted of everything from soups to roasts. The second service comprised cold roasts and vegetables, and the third was the desserts. Under the Russian table service, which was popularized by the great chef Félix Urbain-Dubois, each guest was served each course individually, while the food was still hot.

Escoffier invented scores of new dishes. One was *poularde Derby*, roast chicken with rice, truffles, and foie gras stuffing, garnished with truffles and foie gras. Other better known Escoffier inventions were *pêche Melba* and Melba toast, tributes to the Australian soprano Nellie Melba.

In naming some of his culinary creations after friends and celebrities Escoffier was following a well-established tradition. *Tournedos Rossini*, the tender slices of the heart of the fillet of beef, topped by foie gras and truffles, was named after the celebrated Italian composer. The composer Giuseppe Verdi and the actress Sarah Bernhardt were among those who were similarly honoured. Many famous dishes have taken their names from the chefs who invented them—*Sole Dugléré*, for example, was named after the chef Adolphe Dugléré, who presided at the Café Anglais in Paris in the middle of the 19th century. French dishes have also been named after their dominant colours, such as *carmen* or *cardinale*, which refers to a pinkish-reddish hue. Great events have also given dishes their names: chicken Marengo, for example, was named after the battle in 1800 in which Napoleon defeated the Austrians.

Escoffier created a cold dish called chicken Jeannette. It was named after a ship that was crushed by icebergs. Escoffier's creation was stuffed breast of chicken, and, in honour of the ill-fated ship, he served it on top of a ship carved out of ice.

The Grande Cuisine of France is the only structured and organized system of gastronomy in the world. Many dishes are interrelated, and their names contain clues as to their ingredients. For example, soups are broken down into "consommés" (clear soups), "potages" (thick soups), "crèmes" (cream soups), and "veloutés" (made with a white sauce). Within each of these categories there are sub-categories, depending upon the base used, the thickening agent, the garniture, the flavouring spice, herb, or alcohol, and other considerations.

Escoffier's fame today rests mostly on the cookbooks he wrote—*Le Livre des menus* (1924), *Ma Cuisine* (1934), and *Le Guide culinaire* (1921), written in collaboration with Gilbert—in which he codified the French cuisine in its modern form, setting down thousands of menus and clarifying the principles of French gastronomy. With the great hotel entrepreneur, César Ritz, he established a string of the world's most luxurious hostels in Paris, Rome, Madrid, New York, Budapest (Hungary), Montreal, Philadelphia, and Pittsburgh (Pennsylvania).

Since Escoffier's day, French gastronomy has continued to evolve toward greater simplicity and order. The difference between the French cuisine of today and that of Escoffier probably is as great as that between Escoffier and Carême. Nowadays, people spend less time eating. Packaged and frozen foods have made great inroads—to the despair of the more fastidious gastronomes. Judging by the progress made in the so-called convenience foods, however, it is apparent that soon food technology will raise the eating standards of the general public in highly industrialized countries.

**Use of wines and sauces.** French gastronomy is distinguished not only by the genius of its chefs, but by well-established culinary practices as well. One of these practices is the use of fine wines, such as those produced in Bordeaux and Burgundy, as accompaniments to good food. The proper choice of wines—according to vintages, vineyards, shippers—is an indispensable part of French gastronomy.

In the preparation of food, the hallmark of French gastronomy is the delicate sauces that are used to enhance the flavours and textures. Sauces are prepared with stocks, or *fonds de cuisine*, "the foundations of cooking." These stocks are made by simmering meats, bones, poul-

Impact of  
convenience foods

The  
basic  
sauces

try or fish trimmings, vegetables, and herbs in water to distill the essence of their flavours.

There are literally hundreds of French sauces, but among the more familiar ones are the families of white sauces, brown sauces, and tomato sauces, the mayonnaise family, and the hollandaise family. White sauces, which are served with poultry, fish, veal, or vegetables, are prepared by making a white roux, a mixture of butter and flour, which is cooked and stirred to smoothness. Béchamel sauce is prepared by adding milk and seasoning to this thickening agent. Sauce velouté is made by mixing a fish, poultry, or veal stock with the roux. A broad variety of sauces is derived from these basic white sauces. Sauce mornay, the famous cheese sauce, for example, is simply sauce béchamel with grated cheese and seasonings. Sauce suprême is béchamel with cream. Sauce normande is prepared by mixing a fish velouté with tarragon and white wine or vermouth.

Brown sauces, which are served with red meats, chicken, turkey, veal, or game, are prepared by simmering a meat stock for many hours and then thickening it with a brown roux, a mixture of butter and flour cooked until it turns brown. Among the better known brown sauces are sauce ragout, which is flavoured with bone trimmings or giblets; sauce diable, which is seasoned with lots of pepper; sauce piquant, a brown sauce with pickles and capers, and sauce Robert, which is seasoned with mustard.

The hollandaise family is another important branch of French sauces. Hollandaise is closely related to mayonnaise. It is prepared by delicately flavouring warmed egg yolks with lemon juice and then carefully stirring in melted butter until the mixture achieves a creamy, yellow thickness. Sauce mousseline is made by adding whipped cream to hollandaise, while sauce bernaïse also has an egg and butter base with tarragon, shallots, wine, vinegar, and pepper. Sauce vin blanc also belongs to the hollandaise family with the addition of a white-wine fish stock.

## GASTRONOMY IN CHINA

Apart from the French cuisine, the highest expression of the gastronomic art is generally regarded to have been that of the Chinese. It is no accident that China and France should have had produced the world's most distinctive and respected cuisines. Both countries were naturally blessed with an abundance and rich variety of raw ingredients. In each of these countries gastronomy traditionally commanded great interest and respect. The intellectual, artistic, political, and financial leaders of China and France traditionally attached great importance to good eating. It has already been noted how this worked in the case of the Bourbon kings of France and with statesmen of such eminence as Talleyrand. In ancient China the preparation and service of food played an important part in court rituals. The first act of many emperors was to appoint a court chef, and once they were on the job these chefs strove mightily to outdo each other.

In ancient China, hunting and foraging supplied much of the food. Wild game, such as deer, elk, boar, muntjak (a small deer), wolf, quail, and pheasant, was eaten, along with beef, mutton, and pork. Vegetables such as royal fern, smartweed, and the leafy thistle (*Sonchus*), were picked off the land. Meats were preserved by salt-curing, pounding with spices, or fermenting in wine. To provide a contrast in flavours the meat was fried in the fat of a different animal.

As Chinese agriculture developed, a more varied fare began to emerge and tastes grew more refined. By the time of Confucius (551–479 BC) gastronomes of considerable sophistication had appeared on the scene. Confucius wrote of one of these fastidious eaters,

For him the rice could never be white enough. When it was not cooked right, he would not eat. When the food was not in season, he would not eat. When the meat was not cut correctly, he would not eat. When the food was not served with the proper sauce, he would not eat.

**Emergence of a cuisine.** Like all other forms of *haute cuisine*, classic Chinese cooking is the product of an af-

fluent society. By the 2nd century AD the Chinese court had achieved great splendour, and the complaint was heard that idle noblemen were lounging about all day, feasting on smoked meats and roasts.

By the 10th or 11th century a distinctive cuisine had begun to emerge, one that was to reach its zenith in the Ch'ing dynasty (1644–1912). This cuisine was a unique blend of simplicity and elegance. The object of cooking and the preparation of food was to extract from each ingredient its unique and most enjoyable quality.

As in the case of the French cuisine, the *hors d'oeuvre* set the tone of the meal. "The *hors d'oeuvre* must look neat," say the Chinese gastronomic authorities Tsuifeng Lin and her daughter Hsiang Ju Lin.

They are best served in matched dishes, each containing one item. Many people like to garnish the dishes with parsley and vegetables cut in the shape of birds, fish, bats, etc., or even to make baskets of flowers from food. These are all acceptable if kept under control, and if the rest of the meal is served in the same florid style. The worst offense would be to start with a florid display of food and then suddenly change style midway. . .

**Common foods and traditions.** Certain foods and culinary traditions are prevalent throughout most of the country. Rice is the staple except in the north, where wheat flour takes its place. Fish is extremely important in all regions. Pork, chicken, and duck are widely consumed, as well as large quantities of such vegetables as mushrooms, bamboo shoots, water chestnuts, and bean sprouts. The Chinese season their dishes with monosodium glutamate and soybean sauce, which takes the place of salt. Another distinctive feature of Chinese cooking is the varied and highly imaginative use of fat, which is prepared in many different ways and achieves the quality of a true delicacy in the hands of a talented Chinese cook. The Chinese take tea with their meals, whether green or fermented. Jasmine tea is served with flowers and leaves in small-handled cups.

**The great Chinese schools.** Traditionally, China is divided into five gastronomic regions, three of which are characterized by the great schools of Chinese cooking, Peking, Szechwan, and Chekiang-Kiangsu. The other two regions, Fukien and Kwangtung, are of lesser importance from a gastronomic point of view.

**Peking.** Peking is the land of fried bean curd and water chestnuts. In pre-Communist days vendors sold steamed bread and watermelon seeds in the streets. They dispensed buns called *paotse* that were stuffed with pork and pork fat, and *chiaotse*, or crescents, cylindrical rolls filled with garlic, cabbage, pork, scallions, and monosodium glutamate. Wheatcakes wrapped around a filling of scallions and garlic, and noodles with minced pork sauce are also traditional Peking specialties. But the greatest of all delicacies of this region is of course the Peking duck. This elaborate, world-renowned dish requires lengthy preparation and is served in three separate courses. In preparing it, the skin is first puffed out from the duck by introducing air between the skin and the flesh. The duck is then hung out to dry for at least 24 hours, preferably in a stiff, cold breeze. This pulls the skin away from the meat. Then the duck is roasted until the skin is crisp and brown. The skin is removed, painted with Hoisin sauce (a sweet, spicy sauce made of soybeans) and served inside the folds of a bun as the first course. The duck meat is carved from the bones and cut into slivers. Sautéed onions, ginger, and peppers are added to the duck meat and cooked with bean sprouts or bamboo slivers. This forms the second course. The third course is a soup. The duck bones are crushed and then water, ginger, and onion are added. The mixture is boiled, then drained, and the residue is cooked with cabbage and sugar until the cabbage is tender.

**Szechwan.** The cooking of Szechwan in central China is distinguished by the use of hot peppers, which are indigenous to the region. The peppers lend an immediate sensation of fiery hotness to the food, but once this initial reaction passes, a mingled flavour of sweet, sour, salty, fragrant, and bitter flavour asserts itself. Fried pork slices, for example, are cooked with onions, ginger,

The gas-  
tronomic  
traditionThe prep-  
aration of  
Peking  
duck

red pepper, and soy sauce to achieve this aromatic hotness.

**Chekiang and Kiangsu.** The provinces of Chekiang and Kiangsu feature a broad variety of fish—shad, mullet, perch, and prawns. Minced chicken and bean-curd slivers are also specialties of these provinces. Foods are often arranged in pretty floral patterns before serving.

**Fukien.** Fukien, which lies farther south, features shredded fish, shredded pork, and *popia*, or thin bean-curd crepes filled with pork, scallions, bamboo shoots, prawns, and snow peas.

**Kwangtung.** To Americans perhaps, the most familiar form of Chinese cooking is that of Kwangtung, for Canton lies within this coastal province. Mushrooms, sparrows, wild ducks, snails, snakes, eels, oysters, frogs, turtles, and winkles are among the many exotic ingredients of the province. More familiar to Westerners are such Cantonese specialties as egg roll, egg foo yung, and roast pork.

specialties

#### CUISINES OF THE WORLD

**Japanese.** Nowhere has greater care and imagination been given to the presentation of food than in Japan. The delicacy and exquisiteness of Japanese table arrangements are matched only by the fragile beauty of Japanese painting.

The Japanese bride receives as many as 50 different kinds of dishes as wedding gifts and she may use a dozen at one meal. She will devote the most painstaking attention to the angle at which a sprig of green vegetable is propped against a lump of crabmeat, or the way a fish is garnished. Meals are served in many small dishes, but the total amounts offered each diner are large.

The waters around Japan abound with fish and shellfish, and Japanese seafood is regarded by many gourmets as the finest in the world. Fish is eaten raw (*sashimi*), broiled, or fried in deep fat (*tempura*), or salted and broiled (*shioyaki*). The popular *tempura* method of deep frying food was learned from Portuguese traders who came to Japan in the 16th century. Rice is the staple; it accompanies every meal. *Sushi*, or vinegared rice, is served with a variety of toppings and fillings, including mushrooms, squid, fish, shrimp, and caviar.

The Japanese like clear soups, garnished with eggs, vegetables, or seafood. The thicker "miso" soups are flavoured with fermented soybean paste. Japanese vegetables include bamboo shoots, snow peas, eggplant, mushrooms, and potatoes. The popular *sukiyaki* consists of beef and vegetables simmered in soy sauce. Pork or chicken may be substituted for the beef. *Saké* or fermented rice wine is the national drink, and tea is taken with all meals and at virtually all hours of the day.

The Japanese tea ceremony or *chanoyu* is a highly formalized ritual dating back to the 13th century. The tea is meticulously prepared and is accompanied by a variety of delicate seasonal dishes. Every aspect of the ceremony—the setting, the flavours and textures of foods, the colours and shapes of the containers, even the conversation—is carefully calculated to achieve the most harmonious and satisfying effect.

**Indian.** Spices are a distinctive feature of the cooking of India and Indonesia. In India, every good cook prepares a curry—a mixture of such fragrant powdered spices as cardamom, cinnamon, cloves, cumin, nutmeg, and turmeric. The spice blend is kept in a jar in the kitchen and is used to season all sorts of foods.

India is, of course, predominantly Hindu, and the Hindus have developed what is perhaps the world's greatest vegetarian cuisine. They use cereals, pulses (lentils, peas, and beans), and rice with great imagination to produce a widely varied but meatless cuisine. Indian cooks prepare delicious chutneys, highly seasoned vegetables and fruits used as side dishes that must be fresh to be fully appreciated. They also make such little delicacies as *idlis*, cakes of rice and lentils that are cooked by steaming; *pakorras*, vegetables fried in chickpea batter; and *jalebis*, pretzel-like tidbits made by deep-frying a batter of wheat and chickpea flour and soaked in a sweet syrup. *Raytas*, yogurt with fruits or vegetables, are another favourite.

Other specialties include *biryānī*, a family of complicated rice dishes cooked with meats or shrimp; *samosa*, a flaky, stuffed, deep-fried pastry; *korma*, lamb curry made with a thick sauce using crushed nuts and yogurt; *masala*, the dry or wet base for curry; and a great variety of breads and hot wafers, including *naan*, *pappadam*, *parāthas*, and *chapātīs*.

In southern India and especially in Andhra, the food is seasoned with fresh chili peppers and can be fiery hot. Lamb is the most important dish in northern India. It is prepared in hundreds of different ways as kabobs, curries, roasts, and in lamb and rice dishes. In pre-independence days the Mughal cuisine there ranked among the most lavish in the world. The Mughal cuisine developed during the Muslim empire of the great Mughal kingdom. It is based, mostly because of religious and geographic limitations, on lamb. The preparations are mostly roasted, barbecued dishes, also kabobs and the so-called dry curries, versus the stew-type cooking of the south.

In India festivals and holidays are marked by feasting and revelry. Among the more prominent festivals are Onam, a rice harvest celebration; *Dīwālī* which marks the beginning of the Hindu New Year; *Dashera*, which marks the triumph of the good Prince Rama over evil; and *Holī*, the festival of lights, which honours Lord Krishna, an incarnation of the god Vishnu. Feasting and the offering of food to gods and friends are a highlight of these festivals.

**The Pacific and Southeast Asia.** The cuisine of the Pacific and Southeast Asia is a fascinating melange of raw ingredients, methods, and dishes with a strong influence of the Chinese cuisine. The most important ingredients to tie together this vast area are the coconut, which is used in every one of these countries; rice, which is the basic food everywhere except in the Philippines; native spices and herbs, especially the omnipresent ginger and chili. The skillful use of condiments and relishes makes these countries gastronomically individual entities.

A Hawaiian staple is the taro bulb, which is the main ingredient for many dishes of the famous luau feasts, chopped and steamed alone, or mixed with other ingredients, often wrapped in ti leaves. Poi is also made out of the taro root, after being peeled, cooked, and mashed into a paste.

Another famous delicacy is *lomi lomi*, a fresh salmon that is hand massaged to break down its tissues and remove the salt, and then the chunks are mixed with onion and tomatoes. Besides the stone-baked pig, which is always a part of the luau, and several other local specialties, the Hawaiians adapted a number of Chinese, Japanese, Korean, and Indian dishes, together with a great many standard U.S. dishes.

Indonesia consists of several thousand islands, yet its cuisine is almost unified by the use of coconut. It is employed as a vegetable, main course, ingredient, cooking fat, relish, fruit, and even beverage in the popular *tjendol* throughout the islands. Although 300 years of Dutch occupation, a sizable Chinese population, and Portuguese merchants had a very strong influence on the islands' cooking style, Indonesia still can boast of a unique cuisine. Because rice (*nasi*) is the most important part of their meals, all other preparations are actually served to surround and enhance the rice itself. The Dutch themselves created *rijsttafel*, which formalized into an almost endless procession of beautifully arranged, carefully organized dishes, ranging from sweet to sour, from mild to very spicy, from cold to hot.

Each guest was given two plates and was served a long succession of excellent dishes. On one plate a meat or fish preparation would be served, and the other would be filled with rice. The entire meal, with all its courses, took from two to three hours. Since Indonesia gained independence, the *rijsttafel* has been replaced by the *prasmanan*, a lengthy, buffet-style meal also featuring scores of dishes.

One of the nationally popular preparations is *nasi goreng* that originates in China's fried-rice concept. In the Indonesian version, however, most of the meats,

vegetables, and garnishes surround the pile of fried rice and only the diner mixes them while eating it, allowing many fascinating taste and texture combinations.

Although there are many dishes common to all areas, each region has its own specialties and style of cooking. The West Javanese cooking is rather mild and tends to be much simpler than that of Central Java, which favours very hot, rich, and sweet flavours. East Java, on the other hand, is the place where the spicing becomes very complex and subtle, and the Balinese enjoy many of the dishes forbidden to the Muslim population. For instance, the Bali Hindu religion allows the eating of pork, and *sate babi*, the little skewers of charcoal-grilled pork bits, is one of the more interesting of their preparations.

One of the most essential elements of an Indonesian meal is the *sambals*. These are spicy-hot condiments that are served separately to be mixed with the various foods to make it as "fiery" as the individual desires. *Krupuk*, the deep-fried shrimp wafers, also originated in Indonesia before turning up in other nations' cuisines. Few Indonesian meals exist without *gado-gado*, an interesting mélange of cooked and raw vegetables and bean cake with a sauce made of peanuts, coconut, and spices. Sumatra and Malaysia absorbed much of the Arab and Indian culinary influences. *Rendang*, for instance, is a beef stew that absorbs a large amount of coconut milk, using the same technique as some of the so-called dry curries of India. *Gulai* is this area's favourite version of liquid-type curry so common in India.

The Philippine food is much simpler than many of the other Pacific and Southeast Asian cuisines. Although the four centuries of Spanish domination brought considerable influence to this part of the world, it does have some specialties that can be called its own. Perhaps most typical of these is the fish paste called *bagoong* and the liquid flavouring sauce *patis*. Both are based on fermented seafood and, depending on the area or the household, their variety is almost limitless. Generally speaking, a sour-salty taste is the single most characteristic taste of the Philippines.

Perhaps the strongest Chinese influence can be detected in Vietnam, which was dominated or ruled by China throughout the 2nd millennium. The degree of influence is discernible even in the manner of eating. For instance, this is the only country in the entire area of the Pacific and Southeast Asia where the food is eaten with chopsticks. *Nuoc mam*, a flavouring sauce, is used in many dishes and, although it is related to the Philippine *patis*, it really is a specifically Vietnamese flavour, based again on fermented salted fish and spices. Almost every nation's southern inhabitants prefer their food spicier than those in the northern region and Vietnam is no exception. The tie-in perhaps between the two is the use of fish, which is the most important part of the daily diet. The recent French occupation in Vietnam mostly contributed to the level of the gastronomy of the upper classes, without influencing much of the average housewife's cooking.

One of the most complex and structured cuisines of the entire area is the one of Thailand. The fact that the Thais lived in comparative peace and political independence had beneficial influence on their gastronomy, together with the fact that, just as in China and France, the ruling classes were actively interested in gastronomy. Having basically the same ingredients to work with as Indonesia, Malaysia, or India, the categories of the Thai repertoire are not unlike those countries, but the subtleties and complexities of flavour and texture are often superior. For instance, *nam prik*, the spicy Thai condiment, has even more varieties than the *sambals* do with many more ideas employed in their combinations. *Kaeng* is a liquid stew (or perhaps soup-stew) to be mixed with rice. It is very strongly related to the liquid curries, but again the repertoire of *kaengs* is infinitely larger than almost any other food family in Southeast Asia. Within the formalized gastronomy, the Chinese and Indian influences blend in with such artistry that the emerging cuisine of Thailand is truly its own.

**Middle Eastern.** Eggplant, olives, and yogurt are widely eaten in all Middle Eastern countries. Chickpeas

are toasted or ground up. Lamb is the staple meat throughout the region.

The Turkish influence is still dominant in the countries of the old Ottoman Empire: Turkey, Greece, Bulgaria, and part of Yugoslavia. Vine leaves stuffed with rice and meat are popular. They are called *dolma* in Turkey. *Börek*, a turnover filled with meat or cheese, is another favourite. *Şişkebabı* (shishkebab), skewered mutton or lamb, is enjoyed in all these countries, as is *kofte*, a lamb patty. Yogurt dishes and a sweet known as *balvah* are commonly found. A favourite dessert is baklava, a rich pastry filled with nuts and dipped in honey or syrup. (Baklava was brought by Turkish invaders to Hungary in the 16th century where it became strudel.)

The Arab states of the Middle East and North Africa share many fine dishes. Among these is the hotly seasoned eggplant dip called *bābā qhanūj*. Other dishes common to the Arab countries include *hummus bi tahinah*, chickpeas with a sesame paste; *tabbūlah*, a salad of onions, chopped tomatoes, radishes, parsley, and mint; and *kibbi*, a ground mixture of wheat and lamb.

**African.** The great indigenous dish of North Africa is couscous—steamed wheat or semolina grains—served with meats, poultry, and vegetables piled on top of and around the grain. Another is *brik*, a deep-fried pastry turnover stuffed with fish or meat and a whole egg. A sampler from this continent would include, in East Africa, peanut (groundnut) soup and beef and cassava stew, cooked with coconut, chilies, and coriander; in West Africa, fish *imojo*, a fish and seafood salad; in Ethiopia, *yetemola cheguara*, steamed stuffed whole tripe. South Africans prepare a cinnamon- and clove-flavoured stew called lamb and pumpkin *bredi*, and date and onion salad. Angola has a yellow coconut pudding in which the colour comes from the predominance of eggs among the ingredients.

**Spanish and Portuguese.** Spain and Portugal have much in common from a culinary point of view. Olive oil is the cooking oil of both countries. Cod is widely used. The *cocido*, a heavy stew of boiled chicken, meats, and vegetables, is Spain's national dish. In Portugal it is called the *cozido*.

But the two countries also have their own distinctive dishes, which vary greatly from one region to the next. The paella is perhaps Spain's best-known dish. It is a colourful combination of rice, chicken, pork, clams, mussels, shrimp, peppers, sausages, and peas. The home of the paella is Valencia, but the dish varies from one province to the next. Another regional specialty is the *zarzuela*, a Catalan seafood medley, a stew of fish, lobster, shrimp, scallops, clams, ham, almonds, white wine, and saffron. Fish is popular throughout Spain, especially cod, hake, and red snapper. Many people consider the Basque-style cooking (*à la Vasca*) the best in Spain. It is a surprisingly sophisticated cuisine for one based on ancient shepherds' cooking. *Tapas* are appetizers served in Spanish bars, and often there are several dozen varieties from which to choose. *Jamón serrano*, a mountain-cured ham; chorizo sausages; gazpacho, a cold puree of vegetable soup; and empanada meat pies are some of the highlights of the quite remarkable cuisine of Spain.

The Portuguese kitchen produces somewhat spicier and richer foods, favouring hearty soups, marinated seafoods, braised meats, and such spices as cumin and coriander. The entire Iberian Peninsula is strongly influenced by the honey-almond paste, figs, and dates of the Moors.

**Italian.** The Italians are especially fond of pasta *asciutta* (an unending variety of dried noodles), the huge assortment of hot and cold appetizers known as *antipasti*; sausage and salami; *gelati e granite*, ice creams and ices; and *caffè espresso*, coffee made by forcing steam through the coffee grounds.

Italy, like France or China, has many culinary regions, but basically the north's staple is rice and butter and the south lives on pasta and cooks with olive oil. Cooking techniques are less important than the quality of the raw ingredients.

Bologna's rich cooking is perhaps the best of the

Culinary  
influence  
of the old  
Ottoman  
Empire

northern cuisine with its famed *tagliatelle*, *tortellini*, and other freshly made noodle preparations, egg pastas, sausages, and complex main courses. Piedmont supplies many of the finest chefs to the luxury restaurants around the world. Its local white truffles and Fontina cheese are the base for their *fonduta*, the famous hot melted cheese casserole eaten with bread bits.

Lombardy cooks exclusively with butter, replacing the pasta with rice and corn-flour polenta, and blends successfully the cooking style of several of the northern provinces. Genoese cooking's most characteristic flavour comes from the use of basil leaves pounded into a sauce called *pesto* together with cheese, garlic, pine nuts, and olive oil. Florence is famous for its *Chianina* beef cattle that provide the meat for its *bistecca alla Fiorentina*.

Alla Romana-type cooking produces the best gnocchis, *calamaretti* (baby squid), *abbacchio* (young lamb, usually roasted with rosemary), and vegetable preparations. Naples represents the best gastronomy of southern Italy with the use of pasta, crusty white bread, robust tomato sauces, mozzarella, and other types of cheese. Generally speaking, the array of fresh herbs and some of the finest vegetables and fruits of Europe, fine seafood, and the liberal use of fresh herbs create the best moments of the Italian gastronomy.

**Austro-Hungarian.** The gastronomic regions of the world existing today do not conform to geographic or political divisions. A good example is the Austro-Hungarian cuisine, a culinary entity the boundaries of which have not been discernible on maps since the end of World War I. This gastronomic region comprises the old Austro-Hungarian Empire. It includes Austria and Hungary, as well as parts of Romania, Yugoslavia, and Czechoslovakia. The people of these countries live in different political, economic, and social systems and speak different languages, but their culinary heritage remains as a link between them. *Gulyás*, or goulash, occurs in varying forms in all of these countries. Wiener schnitzel (breaded veal cutlets) is eaten throughout the area. Coffeehouses are popular throughout this part of the world. In Austria a traveller will encounter *nockerl*; in Hungary, he may eat *nokedli*; in Czechoslovakia he will find a similar food under the name *noky*, in Serbia under the name *nokla*. In Hungary the *nokedli* would accompany *pörkölt*, a stew made by browning onion in lard and adding paprika, or a *paprikás*, similar to the above, but with the addition of sweet or sour cream. As dessert he would order *Rigó Jancsi*, a chocolate square glazed with chocolate and filled with chocolate mousse. Cakes, tortes, and desserts are the glory of this cuisine. Prune dumplings, strudels, the coffee ring called *gugelhupf*, and the Dobos torte, a caramel-topped cake filled with chocolate-cocoa cream, are enjoyed. And one of the greatest glories of Vienna's old empire is Sacher torte, a chocolate sponge cake with a touch of apricot jam, iced with a bittersweet chocolate.

Each section developed its own specialties. Czechoslovakia, for instance, cooks *játernice* (a sausage made with innards), bakes *kolačič* (coffee cake), and makes *povidla* (prune jam). Austria offers *Backhendl* (breaded-fried spring chicken), *Tafelspitz* (the boiled beef considered the finest, a cut near the tail of the steer), Linzer torte (a ground almond and jam lattice cake), *buchteln* (jelly buns), and *Palatschinken* (thin pancakes with various fillings). In Yugoslavia there are the *čevapčići* (charcoal-grilled meatballs), *gibanica* (cheesecake), *lonac* (a Bosnian meat and vegetable stew), and *šumadija* (a tea made with plum brandy and caramelized sugar).

**Slavic.** Russia is the mother country of the Slavic cuisine, another culinary entity that does not exist on the map. This cuisine comprises the Soviet Union, Armenia, Poland, Albania, and parts of Yugoslavia and Bulgaria. A Russian-speaking traveller through this region might find it difficult to make himself understood, but he could order the familiar borsch, a beet or cabbage soup, wherever he went. He might dine on blintzes (stuffed pancakes) or *zrazy* (stuffed fried fish or seafood). He could enjoy beef stroganoff, beef cooked with onions in sour cream, or sample a seafood pie called *rakov*. Wherever he went, vodka would be the most popular drink.

The Russians developed *zakusky*, their equivalent of the French hors d'oeuvres. *Potage Bagation* (cream of veal with asparagus tips) is also part of the French Grande Cuisine together with many other dishes the French chefs learned in the Russian court kitchens. Interesting specialties are the *botvinya* (green vegetable soup with a fish base), *solyanka* (cucumber soup), *pelemeni* (Siberian meat dumplings, boiled, fried, and served with sour cream), *kasha* (buckwheat porridge), *holubtsi* (Ukrainian stuffed cabbage), *bitki* (meat- or fish balls with strong spices), *packha* (cottage-cream cheesecake with candied fruits made in a pyramid shape for Easter), and *babka* (a round coffee cake).

**German.** The emphasis of the cuisine of Germany and its neighbours is on "hearty" foods—roast meats, dumplings, fish dishes, cream sauces, puddings, and rich desserts. The Germans eat sauerbraten, a marinated pot roast with a sweet-and-sour sauce, the earthy hasenpfeffer (rabbit stew), *Königsberger klopse* (a fancy meatball), *badischer Hecht* (a sour cream baked pike), and *Schweinebraten mit pflaumen und apfeln* (roast pork with prune and apple stuffing). They like sausages; sauerkraut (fermented cabbage); dumplings; thick soups made from potatoes, peas, or lentils; herring; and roast meats, or braten. They wash these foods down with great quantities of beer, and for dessert they prefer puddings, fruit pancakes, or dumplings, egg custards, jellies topped with whipped cream, the medieval invention marzipan (an almond paste confection), lebkuchen (a kind of gingerbread), and *Baumkuchen* (the tree-cake baked on a special horizontal spit).

**Scandinavian.** Fish is a mainstay of the Scandinavian diet. It is prepared in many different ways; a favourite appetizer is *gravlax*, salmon marinated in salt and dill and accompanied by a mustard sauce. Swedish pancakes are popular and are served with lingonberries or fruit preserves.

Sweden's great contribution to international eating is the smorgasbord, literally a "bread-and-butter table," but actually a sumptuous feast of three courses. The first course is herring—filleted, pickled, baked, jellied, stewed, or prepared in many other different ways. Cold meats comprise the second course, whereas the third course is made up of Swedish meatballs and other hot dishes.

Danish open sandwiches, called *smørrebrød*, became popular all over the world. There are many fine dishes in these north European countries, such as the following: *nyponsuppe* (Swedish rose-hip, almond, and whipped-cream soup), *vorshmack* (ground meat, herring, and onion cooked Finnish style), "Jansson's Temptation" (a Swedish potato and anchovy casserole), *frikadeller* (a Danish mixed ground meat hamburger, sautéed in butter), *kalakukko* (a Finnish bird-shaped pie stuffed with fish), *sandkage* (Danish sand cake), and *krumkage* (a Norwegian Christmas cookie). Aquavit, the favourite grain or potato spirit of Scandinavia, is an ideal beverage for the cold seasons.

**British.** The English like roast beef with the muffin or pie known as Yorkshire pudding; steak and kidney pie, and veal and ham pie are other English favourites. They eat fish—haddock, mackerel, and smoked kipper—especially fish-and-chips, or deep-fried potatoes. They are also fond of jellies, jams, marmalade, hot cross buns, crumpets, and scones.

Traditional fare in the British Isles would include beef tea (a beef extract), whitebait (miniature fish, fried and eaten as snacks), boxty (Irish potato pancakes), brawn (aspic made with pork bits), cockaleekie (Scottish hen and leek soup), bubble and squeak (chopped, fried leftover meat and vegetables), angels on horseback (grilled oysters wrapped in bacon), kedgerie (a casserole of smoked fish, rice, and eggs), shepherd's pie (ground lamb and beef with onion and topped with mashed potatoes), crumpets (hot muffins), banbury cake (a spiced flat cake made with dried fruits), fool (a fruit custard), and sylabub (a dessert made with whipped cream, lemon, wine, and sugar). The savoury, a nonsweet course served instead of or after the dessert, is an interesting custom in the British Isles. Bitter is the most popular English beer

The sumptuous bread-and-butter table

in pubs. In the winter, hard cider, a fermented apple juice in varying strengths, is often preferred.

**Latin American.** Corn (maize) is the culinary common denominator of Latin America. Ground into meal, it is used in Mexico to prepare the corn pancakes known as tortillas. Tortillas provide a variety of other Mexican specialties. Enchiladas are tortillas dipped in sauce, then fried and rolled up with a filling of pork or chicken. *Tostados* are tortillas fried crisp and sprinkled with onion, chili peppers, grated cheese, or meat. *Quesadillas* are tortillas folded over a filling of meat, beans, cheese, or vegetables. Another, different use of corn is for tamales, which are steamed, filled corn husks.

Chili peppers are widely used to season Latin-American dishes. Beans are another distinctive food. Brazil's national dish, the *feijoada completa*, consists of a bed of rice with black beans, sausages, beef tongue, spareribs, and dried beef, sprinkled with toasted manioc meal, and garnished with orange slices. Argentina is famous for its beef. Empanadas served there are beef-filled turnovers. A favourite dessert in all of these lands is flan, or caramel custard.

**North American.** The United States is a culinary, as well as racial, melting pot. European, Middle Eastern, African, and Oriental influences are evident. In New York, for example, can be found almost any kind of food on earth. Outside New York, Greek food and Cuban food are common in Florida, German food in the cities of the Middle West, Chinese food in California, Huguenot food in Charleston, South Carolina, African food in the South and most other parts of the country, Mexican and Spanish food in the Southwest, and Portuguese dishes in New England—all of it adapted and modified to suit the local tastes.

Outside the great metropolitan areas, American food used to have a distinctive regional character. New England was famous for its clam and lobster dishes, its New England boiled dinner, and its red flannel hash. The South, with its fried chicken and many forms of cornbread, was one of the country's most distinctive culinary regions. The Far West prided itself on its Dungeness crab, abalone, fish, and shellfish.

But as communications and transportation have improved, and packaged and frozen foods have come into being, people all over the country read the same recipes in newspapers or magazines. They go to cooking schools where the same principles are taught, and they watch the same cooking lessons on television. As a result, regional distinctions have tended to fade and cooking has become more uniform all the time.

North America has contributed many fine gastronomic institutions. North American cities such as New York, New Orleans, San Francisco, and Montreal have produced many excellent restaurants and hotels. The Mississippi riverboats of the 19th century were floating gourmet palaces. But the unique American contribution to gastronomy has been quick-service and convenience foods. The first cafeteria came into being in San Francisco during the Gold Rush of 1849. The first automated cafeterias were introduced in New York and Philadelphia. Coffee shops, sandwich counters, and drive-in restaurants are uniquely American institutions. Vegetables, fruits, and meats are quick-frozen, packaged, and shipped to stores thousands of miles away. Perhaps the ultimate in packaged, convenience foods is the capsuled meals provided for United States astronauts for their journeys to the moon.

**BIBLIOGRAPHY.** PROSPER MONTAGNE, *Larousse Gastronomique* (1938), the most authoritative contemporary encyclopaedia of food, wine, and cookery, from prehistoric stages to the modern day; J.A. BRILLAT-SAVARIN, *Physiologie du goût* (1826), classic that set the stage for thinking about dining as an experience and a form of art, and its philosophy and aphorisms became the foundation of modern gastronomy; ANDRÉ L. SIMON, *A Concise Encyclopaedia of Gastronomy* (1952), a most complete history relating to its subject, written by the dean of food and beverage writing; J.J. WEBER, *Universal-Lexicon der Kochkunst*, 3 vol. (1913), the German viewpoint expressed in a concise encyclopaedia; U. DUBOIS and E. BERNARD, *La Cuisine classique*, 2 vol. (1856), perhaps the only

work that perhaps no one questions as the finest expression of the Golden Age of the French Grande Cuisine; ALEXIS SOYER, *The Pantaropheon* (1853), a world history of food and its preparation from the early ages with many arbitrary but important observations on gastronomy; ABRAHAM HAYWARD, *The Art of Dining* (1889), a small book containing much of the material on the 18th- and 19th-century gastronomy, chefs, and related subjects that has since been used in countless books; GEORGE H. ELLWANGER, *The Pleasures of the Table* (1902), a popular book with considerable original material on eating and drinking habits and gastronomic influences of the past; P. NORTON SHAND, *A Book of Food* (1928), a highly personal approach to gastronomy, manners, and foods throughout the world.

(G.L.)

## Gastropoda

The class Gastropoda, a subgroup of the phylum Mollusca, comprises the snails. Gastropod, which means "belly-footed," refers to the broad tapered foot on which these animals glide.

The gastropods include land, freshwater, and marine forms. Land gastropods lacking shells are commonly called slugs; marine forms lacking shells are known as nudibranchs or sea slugs.

Because they occupy such a wide range of habitats and show such different ways of living, gastropods are a difficult group to describe succinctly. A few are used as food, a very few transmit animal diseases (only a fraction of these carry human diseases), and some have shells used as ornaments or in making jewelry; most, however, act as scavengers, removing dead animal and plant matter.

### GENERAL FEATURES

**Abundance and distribution.** The gastropods constitute the largest group of mollusks in terms of species and are one of the few animal groups to inhabit successfully all three environmental systems—ocean, freshwater, and land. Of the perhaps 50,000 species, 23,000 are marine, 22,000 are terrestrial, and 5,000 are freshwater. Gastropods have been dredged from the deepest ocean trenches and from glacial lakes in the Himalayas. A few land-snail species, such as *Vitrina*, can be found crawling on snowbanks in Alpine meadows; others inhabit the driest deserts. In these hostile regions a snail survives by retreating into its shell and waiting for the short, infrequent wet conditions during which it can feed and reproduce. Often the wait is long: specimens of the Egyptian desert snail (*Eremina desertorum*) have survived four years, and some Mexican desert snails have lived for six years without food or water in museum collections. Their period of survival under natural conditions is probably even longer.

Snails and slugs are sometimes especially abundant. Millions of some brackish-water species occur on mud flats. An acre of British farmland may have 250,000 slugs; one region in Panama averaged 7,500,000 land snails per acre. Despite this, gastropods often pass unobserved. Snails are marginally terrestrial, being active in areas or periods of high humidity. They are conspicuous and abundant only on the seashore and in shallow ocean waters. Even in these habitats their shells, often covered with algae and debris, look like bits of encrusted rock.

**Size and appearance.** The size range of gastropods is considerable. Some marine snails (*Homalogyra*) and forest-litter snails (*Punctum*) are less than 0.04 of an inch (one millimetre) long as adults. The largest land snail, the African *Achatina achatina*, is almost eight inches long; the largest marine species, the Australian *Megalatractus aruanus*, may exceed two feet in shell length. The longest snail, however, is *Parenteroxenos doglieli*, which lives as a parasite in the body cavity of a sea cucumber: it is almost 52 inches (132 centimetres) long, though only 0.2 inch (0.5 centimetre) in diameter. Probably 90 percent of all gastropods are less than one inch long.

The basic groups of gastropods are the prosobranchs, marine and land dwellers with a protective covering (operculum) to plug the opening in the shell and with a rather simple body structure; the opisthobranchs, marine

foods

Snails as food

species many of which show a reduction in both the shell and visceral mass; and the pulmonates, land, freshwater, and marine dwellers with a "lung," or pulmonary, cavity and more complex body structures. These groups, which separated over 350,000,000 years ago, have undergone considerable evolution. Gastropods show a great variety of structure (Figure 1) and habits and are thus an excellent group to demonstrate evolutionary principles. The snails display a wide variety of shells, from those of the colourfully decorated tree snails of the tropics to the plain drab shells of pond snails of temperate zones.

**Importance to man.** From earliest times, man has utilized many snails as food. Periwinkles (*Littorina*) from Europe and South Africa, queen conchs (*Strombus gigas*) in the West Indies, abalones (*Haliotis*) in California and Japan, and turban shells (*Turbo*) in the Pacific are the most frequently eaten snails. Occasionally limpets are used, and many species of whelks are caught for fish bait. Land snails of the family Helicidae have been eaten in the Middle East and Europe since prehistoric times. Today, many tons of the European edible snails *Helix aspersa* and *H. pomatia*, in addition to several species of *Otala* and *Eobania* from Morocco and Algeria, are exported to the United States as food. During World War II, the Japanese introduced the giant African snail (*Achatina fulica*) onto various Pacific Islands to serve as food for their troops.

In some places, introductions of *Achatina* and *Helix* have resulted in damage to crops and gardens by these rapidly multiplying snails. California orange groves are plagued by *Helix aspersa*, and in the eastern United States many slugs accidentally introduced from Europe are a great nuisance in gardens. Freshwater snails of the family Bythinidae sometimes become so numerous that they clog the filter systems of big city pumping stations.

Shells of certain snails are highly prized by collectors, and a few rare species may be very highly valued. The operculum of some *Turbo* species is used in making earrings; cameos are cut from the shell of the Red Sea snail *Cassis rufa*. Abalone shells are used in many cultures for decorative purposes; the shell of the golden cowrie served at one time as a badge of a chief in Fiji. Shells have been used as money: at one time the price of a bride in West Africa was 100,000 cowries.

More serious matters concern the few freshwater snails (*Pomatiopsis*, *Bulinus*, *Biomphalaria*) that serve as intermediate hosts for parasitic worms of man. More than half the deaths in Egypt, for example, are at least in part caused by the ravages of schistosomiasis, a disease caused by minute blood flukes (schistosomes) with a complicated life cycle. Both snails and flukes are most common in areas where fields are irrigated. The building of dams for paddy irrigation can increase the disease percentage from 5 percent to over 90 percent in less than four years.

Snails as intermediate hosts of disease organisms

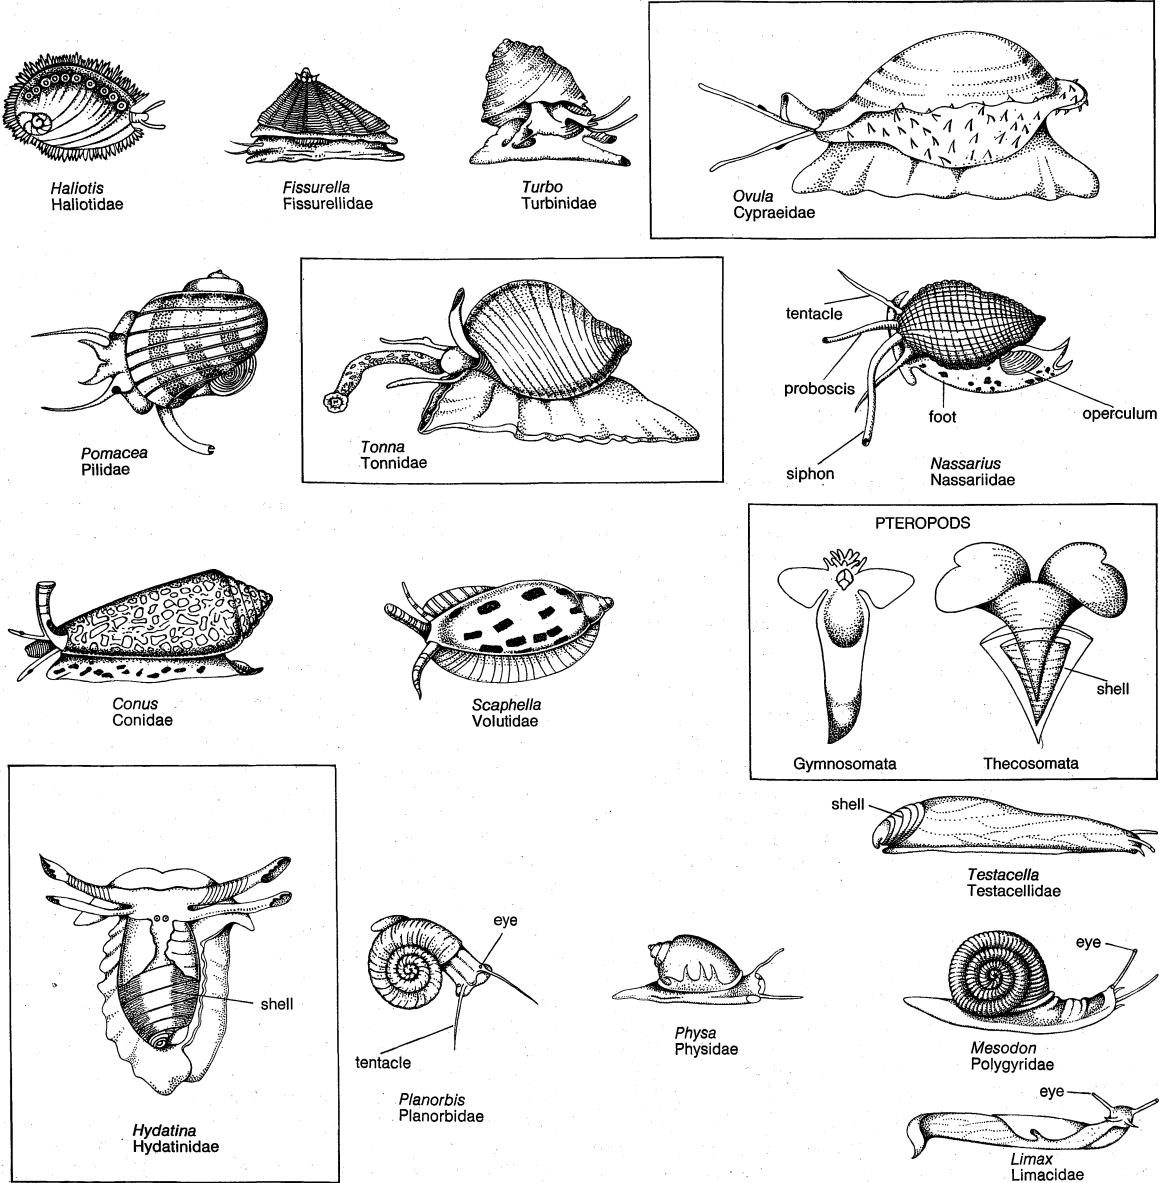

Figure 1: Diversity among gastropods.

Schistosomes also parasitize birds and mammals. Occasionally, swimmers in the United States develop a skin rash called swimmer's itch, resulting from bird schistosomes trying, only partly successfully, to penetrate human skin. They die in the upper skin layers, and their decomposition causes the local infection. Other health problems are caused by several snails and slugs (e.g., *Bradybaena*, *Angustipes*, *Veronicella*) that serve as intermediate hosts for the rat lungworm. If an infected land snail or slug is accidentally chopped up in a salad and eaten, the worm can migrate to the brain and encyst, causing moderate to severe damage. Poisonous cone shells, from tropical oceans, have caused human deaths through collectors' careless handling of the living snail.

Most gastropods, however, are useful to man in that they help break down the dead bodies of plants and animals into substances that can be used by plants to manufacture new organic compounds. In both field and forest, as in ponds, rivers, and oceans, gastropods are an important part of this decomposer group.

#### NATURAL HISTORY

Because the gastropods occupy such a bewildering array of habitats and exist under such a wide range of environments, it is virtually impossible to present a generalized living pattern. Instead, emphasis is given in this section to the evolutionary shifts with respect to feeding mechanisms, life cycle and reproduction, and ecology.

**Feeding mechanisms.** As in all molluscan groups except the bivalves, gastropods have a peculiar organ called an odontophore at the anterior end of the digestive tract. Generally, this organ forms a broad ribbon (radula) covered with a few to many thousand "teeth" (denticles). The radula is used in feeding: muscles extrude the radula from the mouth, spread it out, and then pull it back into the mouth carrying particles or pieces of food and debris into the esophagus. Although attached at both ends, the radula grows continuously during the gastropod's life, with new rows of denticles being formed posteriorly to replace the worn denticles cast off at the anterior end. Both form and number of denticles vary greatly among species—the differences correlating with food and habitat changes. Radular denticles are shown in Figure 2.

Evidently, the most primitive type of gastropod feeding involved browsing and grazing of algae from rocks. Some species (archaeogastropods) still retain the basic rhipidoglossan radula, with its many slender marginal teeth in each transverse row. During use the outer, or marginal, denticles swing outward, and the radula is curled under the anterior end of the odontophore. The latter is pressed against the feeding surface, and, one row at a time, the denticles are erected and scrape across the surface, removing fine particles as the odontophore is withdrawn into the mouth. As the marginals swing inward, food particles are carried toward the midline of the radula and collected into a mucous mass. By folding the teeth inward, damage to the mouth lining is avoided and food particles are concentrated. Mucus-bound food particles are then passed through the esophagus and into the gut for sorting and digestion.

From this basic pattern, numerous specializations have developed, including docoglossan, taenioglossate, rachiglossate, and toxoglossate radulae. Many limpets, which scrape algae directly from rock surfaces, have what is called a docoglossan radula, with the marginals greatly reduced in number. *Patella*, for example, has five pairs of cartilages and greatly increased musculature. When the radula is extruded, several rows of denticles on the lower odontophoral margin are pressed against the surface. There is no elevation of single rows and no lateral movement of the few marginals. Consequently, wear against the rock surface is great, and, although the denticles are heavily impregnated with mineral salts, tooth damage and loss is extensive. In rock-grazing species, replacement and growth are relatively rapid, and the radula is very long in relation to shell size. In some European limpets, the radula is three times as long as the shell, whereas, in the Indo-Pacific gastropod *Tectarius pagoda*, it is more than seven times the shell length.

The odontophore: a rasping organ

Wear and replacement of "teeth"

Figure 2: Gastropod radula and types of teeth.

Members of the suborder Mesogastropoda (or Taenioglossa) have a taenioglossate radula, in which a central tooth is flanked on either side by three laterals, for a total of seven denticles. This is a highly flexible pattern, which has allowed great diversity in feeding by alteration of cusp and tooth size. Many periwinkles (family Littorinidae) scrape algae from rock surfaces, as do the limpets; the small snail *Omalogyra* scrapes surface cells of algae and sucks out the cytoplasm. Larger mesogastropods, such as *Strombus*, graze upon standing algae in sand or mud flats. Often members of a genus may show striking differences. The limpet-like *Hipponyx antiquatus* attaches permanently in rock crevices or on clamshells, where organic debris can accumulate, and feeds on the accumulations, whereas *H. australis* attaches to the shell of the archaeogastropod *Turbo*, near its exhalant water current, to capture and consume fecal pellets. Other limpet-like, or burrowing, mesogastropods collect food particles off the gill and pass them into the mouth by action of hairlike projections (cilia). *Hipponyx* and *Aporrhais* grasp the trapped particles with the radular teeth, whereas in *Crepidula* a food-laden mucous cord is formed, bits of which are torn off by the radula.

Gastropods that feed on sessile (inactive) animals have evolved an extensible proboscis capable of reaching into narrow openings. Such minute sponge feeders as *Tri-*

*phora* extend the slender proboscis into the openings of a sponge to reach delicate fleshy cells. Similarly, many cowries feed on sea squirts, or ascidians. Numerous mesogastropods and prosobranch-opisthobranch transition groups are external parasites (ectoparasites) on larger animals. A few are internal parasites (endoparasites) of echinoderms.

Floating  
snails

Floating snails such as *Janthina* drift along until they contact prey to feed upon. Certain mesogastropods are active swimmers; one, *Pterotrachea*, has the foot modified into a small sucker for holding prey. Mesogastropods of the families Naticidae and Doliidae feed upon bivalves and echinoderms. The naticids use their large foot to hold the prey while they drill through the bivalve shell. A combination of mechanical rasping by the radula and chemical loosening of the calcium by secretions produces a hole in the bivalve shell through which the proboscis is inserted to enable the naticid to feed upon the soft tissues. Doliids tend to be surface hunters, drilling through the tests (hard outer covering) of echinoderms and other invertebrates. Several species are known to secrete sulfuric acid from the proboscis gland.

In gastropods of the suborder Stenoglossa, the basic radular type is rachiglossate, with only three denticles—a central and two laterals. Families such as the Buccinidae and Nassariidae include carnivores and scavengers, the latter feeding on dead and decaying organisms. Members of the family Olividae are active predators and burrow through sandy flats in search of prey; those of the family Muricidae are predators that may either use a secretion to bore holes into shells or the physical force of their proboscis to pry into shelled prey. Many genera (e.g., *Busycon*, *Fasciolaria*, some *Murex*) use part of their shell to wedge open a clam for feeding. The North American *Melongena* simply inserts its very long muscular proboscis between the shells of an open clam and then seems to ignore the pinch of the closing shells on its own flesh.

Finally, the toxoglossate radula has only two teeth, which are formed and used alternately. Most toxoglossate gastropods inject a poison via the functional tooth. Varying degrees of poison usage are known, being especially notable in the cone family (Conidae). Prey selection usually is highly specific, and the presence of many cone species (*Conus*) in one area is linked to restriction of feeding to only one species of prey. Although many cones hunt polychaete worms, others prey on gastropods or fishes, using the radular tooth as a harpoon, with poison being injected into the prey through the hollow shaft of the tooth. Several of the large fish-eating cones, which produce a potent nerve poison, have been known to kill humans.

Opisthobranch gastropods show less clearly defined types of radular structure. Anaspideans such as *Dolabella* may have up to 460 teeth per row with a total of 25,000 denticles; sacoglossans have only one longitudinal row of teeth. In terms of feeding, opisthobranchs are extremely varied. Besides the algae-sucking sacoglossans, *Aplysia* cuts up strips of seaweed several centimetres long (about an inch) for swallowing, and a number of the more primitive species feed on algae encrusted on rocks. Perhaps the majority of opisthobranchs, including the sea slugs, are predators on sessile animals, ascidians and coelenterates being especially favoured. Pyramidellids are ectoparasites on a variety of organisms. *Calma* feeds on fish eggs. *Scaphander* and *Haminea* swallow whole mollusks, which then are crushed in the gizzard by a series of calcareous plates. Some of the pteropods are ciliary feeders on micro-organisms, whereas others, such as *Clione*, are fast-swimming predators of the pteropods.

Pulmonate  
modifica-  
tions  
for feeding

Pulmonate gastropods are predominantly herbivores, with only a few scavenging and predatory species. Basically, on the radula there is a central tooth flanked by a few to many denticles, which may be differentiated into laterals and marginals. The central tooth may be reduced in size or lost, whereas the other teeth show modifications correlated with diet. Primitively, the pulmonate radular tooth has three raised points, or cusps (i.e., is tricuspid), but modifications involving splitting of cusps

or reductions to one cusp are numerous. With each successive appearance of a carnivorous type during evolution, however, the teeth have been reduced in number, each tooth usually having one long, sickle-shaped cusp. The New Caledonian *Ptychorhytida*, for example, has 11 teeth: three large laterals on either side of a middle row of five tiny sickle-shaped teeth. The American *Euglandina* has about 30 teeth in a row, with the posterior margins modified into a supporting buttress. Tree-climbing algal and lichen feeders, such as the East African *Rhachidina* and neotropical *Orthalicus*, have broad, gougelike median cusps for scraping, whereas feeders on decaying vegetation have narrow, sharp-edged cusps for slicing. Many of the latter species have extremely large numbers of denticles. A Thailand species, *Durgella libas*, has 148,000 denticles, even though the size of its shell is less than 0.5 inch (1.25 centimetres).

Unquestionably, much of the diversity achieved by the gastropods relates to the evolutionary shifts in radular structure, which have led to exploitation of a variety of food sources. Predators capable of swimming, surface crawling, and burrowing to capture prey have evolved among the prosobranchs and opisthobranchs; predators that produce chemical substances for entering the shells of their prey have evolved among the mesogastropods (Naticidae, Tonnacea), stenoglossans (Muricidae), and a nudibranch opisthobranch (*Okadaia*); and, in the pulmonates, predation and thus a carnivorous diet have evolved at least 12 times.

**Life cycle and reproduction.** Equally important to the success of the gastropods has been a life-history pattern capable of wide variation. Only in the most primitive prosobranchs are the sex products released into the water for fertilization to take place outside the female. The fertilized egg hatches into a free-swimming form (trochophore larva), which undergoes torsion, a 180° rotation of the fleshy organs from a posterior to an anterior position behind the head. Upon the expansion of the ciliary girdle of the trochophore larva into large, heavily ciliated swimming lobes (vela), the larva is called a veliger. Torsion is an embryological distinction of the gastropods (a diagram of its stages is shown in the article MOLLUSCA). One possible advantage of torsion to the larva is provision of a place to withdraw the vulnerable head and velar lobes. Torsion has resulted in both advantages and disadvantages that channelled the patterns of further evolution of the gastropods.

The  
rotation  
of larval  
structure

In some species the veliger stage may persist for a long period of larval life, during which dispersal of the species occurs. The veliger has a small shell into which the velar lobes and head can be withdrawn and a larval heart that seems to exist solely to provide circulation in the velar lobes. Food consists of certain organisms called diatoms and other small plankton collected by ciliary currents of the velum and channelled by the currents into the mouth. Special excretory cells located on either side of the mouth and the larval heart disappear when the veliger settles to the bottom and changes into a crawling snail. Upon settling, the snail starts a typical pattern of rapid growth until sexual maturity, at which point growth either ceases or is greatly slowed, because energy is being diverted to the production of the next generation. In opisthobranchs and many pulmonates, the life-span is about one year, although there are notable exceptions. Prosobranchs in general seem to have a much longer life-span, with some species of the freshwater *Vivipara* having lived 20 years in captivity. Desert and arid-area snails form a conspicuous exception to the generally short life-span of pulmonates. Some southwestern U.S. species have a life-span of more than 15 years. This, of course, includes the semidormant stages assumed during unfavourably dry periods. Whether the total length of active life substantially exceeds that of related pulmonates living in moist areas is unknown.

Several trends are evident in gastropod evolution from this basic pattern. First, there is a tendency toward development of internal fertilization, with pallial reproductive tubes of male and female becoming closed tubes and a male copulatory organ developing on the

The trend  
toward  
internal  
fertiliza-  
tion

right side of the head for transmission of sperm to the female. Second, the trochophore and veliger stages tend to be passed within an egg capsule provided with a food supply, rather than as free-swimming periods during which the immature organisms must find their own food. At first, provision of nutriment for the young probably involved laying eggs in a mucous mass. As evolution progressed, capsules containing yolk and with a protective cover might have been laid singly or in masses. Still later forms may have provided parental care of the eggs or egg mass. Finally the egg was retained inside a brood pouch or the uterus until the young were ready to hatch (ovoviviparity). Third, there are tendencies toward sex reversal and the development of hermaphroditism—the presence of both male and female sex organs in one animal; hermaphroditism occurs in most opisthobranchs and pulmonates.

Such changes occurred more than once during gastropod evolution, and there is no clear pattern of changes that would suggest relationships. The differences correlate with habitat and frequently are seen within species of one genus. *Littorina*, on the English coasts, is a classic example: *Littorina neritoides* lives in crevices of exposed rocks above normal high water but releases floating (pelagic) egg capsules during fortnightly high tides or storms; *L. littorea*, on the lower half of the shore, also has pelagic egg capsules, which hatch six days later into veligers; *L. littoralis*, which lives on seaweeds that are rarely exposed by the tides, deposits gelatinous egg masses on the seaweeds, and the larvae pass through the veliger stage in the egg mass, emerging in two to three weeks as crawling young; and *L. saxatilis*, which extends from midtide level to several feet above the high-water mark, retains the eggs inside the female until they hatch as crawling young.

In the most primitive prosobranchs, the duct carrying eggs or sperm (gonoduct) opens into the kidney or renopericardial duct; in higher archaeogastropods it opens into the ureter. Separation of the excretory and reproductive ducts occurred later in evolution and is evident in the mesogastropods and stenoglossans. The female individuals of these latter forms have the upper portion of the oviduct specialized for secreting nutritive material around the fertilized eggs and the lower portion for encapsulating the egg and nutritive material.

Storing  
sperm in  
the female

Various ways have been developed for storing sperm received from another individual and for transferring sperm. Prosobranchs such as *Cerithiopsis*, *Janthina*, and *Turritella* have extremely large sperm that carry thousands of smaller sperm from the male into the oviduct of the female; the large sperm swim the comparatively great distance between individuals. More frequently a penis is used to insert a stream of sperm into a special storage organ or the oviduct. In the opisthobranch *Limapontia*, the penis stylet injects sperms through the body wall into a storage organ (bursa) of the mate.

Internal fertilization is a necessity for land gastropods, which, accordingly, have appropriate specializations for sperm transfer. The more primitive species directly transfer a stream or gelatinous mass of sperm by insertion of the penis. One individual can act as a male and the other as a female, or copulation can be reciprocal. During evolution, loosely adherent masses of sperm gave rise to enclosed packets of sperm and then to horny or calcareous sperm bundles (spermatophores) with elaborately ornamented exteriors. In some Southeast Asian land snails (helicarionids), the long, curved, horny spermatophore has rows of three- to five-pronged spikes on either side of a shaft. Frequently, as many as 12 such spermatophores are found inside the bursa of a female. Closely related species show clear differences in the number and spacing of these spikes. Undoubtedly, this difference provides a method of species recognition among these snails. Other pulmonates depend on explicit courtship patterns (limacid slugs) or structural differences in the penis (endodontid land snails) to distinguish close relatives. The European dart-bearing helices, particularly *Cepaea* species, have elaborate rituals of courtship, in which a calcareous dart is jabbed into the flesh of the

potential partner as a prelude to mating. Two closely related species, *C. hortensis* and *C. nemoralis*, which overlap in distribution, have different forms of darts, thus helping each species recognize its own kind.

Of general interest is the pattern of sex reversal seen in some prosobranchs. Most members of the family Calyptraeidae begin life as functional males but, after a transitional phase, spend their remaining span as females. *Crepidula* species attach to one spot when young and rarely move again. Other members of the species frequently attach to the shell surface of a settled individual, forming piles of up to 19 specimens. The younger ones on top are male, the old ones on the bottom female, and those in the middle are intermediate in sex. Isolated young function as males for only a week or two, but young males in a pile remain male for a longer period, through some unidentified influence of the larger females underneath. Some limpets also undergo sex reversal, but the circumstances are much less striking than those in *Crepidula*.

Sex  
reversal

Egg production is correlated with the degree of care given the eggs or young. The extremes are the production of enormous numbers of eggs, which receive no care and hence suffer mass mortality (a fraction of 1 percent surviving), and the production of only one or two eggs, which receive intensive care. Of course, there are many gradations between the extremes. Many mesogastropods and all stenoglossans produce egg capsules that may contain from one to more than 1,000 eggs. In *Busycan*, for example, each capsule may contain up to 1,000 eggs, but extensive cannibalization occurs among the early hatched young and upon unhatched eggs in the capsule. *Strombus* can lay a tubular string of eggs 23 metres (75 feet) long, with up to 460,000 eggs. Many *Conus* cement up to 1,500,000 eggs in capsules on the undersides of rocks. Opisthobranchs weave delicate ribbons of eggs in colourful sheets—sometimes up to 50 millimetres (two inches) of ribbon per hour—that contain many millions of eggs. In these cases, the eggs hatch into swimming veligers. Freshwater snails frequently deposit eggs in capsules on plant leaves or rocks, but the number of eggs is much less than in the marine gastropods.

Direct care of the eggs is given in different ways. A small trochid, *Clanculus bertheloti*, deposits its eggs in grooves on the shell surface and covers them with a sheet of mucus to hold them in place; many *Neptunea* simply cement the egg capsules to their shell surface. Many *Crepidula* deposit a mass of 5,000 to 20,000 eggs under the shell edge just in front of the female's foot, brooding them until they hatch as veligers. Freshwater viviparids and thiarids have either uterine or neck brood pouches, in which the fertilized eggs develop to a crawling stage. The vermetid *Stephopoma* and the acmaeid *Acmaea rubella* brood their young in the mantle cavity between the fleshy body and the shell. A number of endodontid land snails on the Pacific Islands deposit their eggs in the umbilicus, an opening in the shell base. In one species, *Libera fratercula*, the young gnaw their way out through the apex of the maternal shell. One pteropod, *Hydromeles*, has an internal brood chamber that apparently ruptures, freeing the young into the body cavity of the parent; it is suspected that the escape of the young results in the parent's death.

Parental  
care of  
eggs

Even without direct care of the eggs, land snails generally lay fewer than 200 eggs at a time, compared with the millions produced by many marine species. This reflects the different problems encountered on land and the lower mortality of larvae that are protected within the egg coverings. Many slugs and some snails bury egg masses in soil or under moist pieces of bark. Others, such as *Discus*, scatter their eggs singly over bark and decaying wood. One tropical genus (*Amphidromus*) rolls a leaf into a tube, seals one end with mucus, and lays its eggs in the cylinder thus formed. The South American *Strophochelilus* lays one large egg about four centimetres long (1.5 inch). Among the many ways in which land snails minimize losses from drying is the adoption of ovoviviparity, or the hatching of eggs within the parent body.

As in the case of feeding mechanisms, the basically sim-

ple pattern of reproduction shows considerable diversity in the different habitats occupied by gastropods. Both prosobranchs and pulmonates have colonized land and freshwaters and show similar alterations in reproduction.

**Ecological relationships.** Although all levels of the ocean are inhabited by snails, they are in greatest abundance in and just below the tidal zones, where food is most abundant. On rocky shores they are arranged in bands determined by physical factors of the environment and, to some degree, by predation. The extent of their effect on a coastline is indicated by the estimate that an average population of 860,000,000 *Littorina* on one square mile of rocky shore ingests 2,200 tons of material each year, only about 55 tons of which is organic matter. Limpets of all types are even more influential in such habitats, browsing and grazing on the algae and sessile animals. One interesting characteristic of limpets is that of homing. Numerous species have the tendency to settle on one spot and to feed on regular pathways from this home base.

Some larger prosobranchs are selective herbivores, cutting off one- to two-centimetre (0.4- to 0.8-inch) strips of seaweed for swallowing. More characteristic of the sand and mud flats are scavengers that indiscriminately take in surface debris; scavengers are found in various of the groups, including limpets, strombids, and nassariids. Carnivores include both surface hunters and burrowing forms such as the naticids. As an adaptation to sedentary life, several families have adopted a form of mucociliary feeding by collecting food particles from water currents. Sensory reception is highly developed in many carnivores, some of which employ a peculiar organ in the palial cavity (the osphradium) to detect prey.

During the evolution of prosobranchs and opisthobranchs, floating and swimming forms have evolved several times. *Janthina* builds a float of air bubbles in mucus; the float is attached to the middle part of the foot. Heteropods swim either by undulations of the foot or by the action of fleshy fins. Pelagic opisthobranchs show almost every conceivable type of swimming mechanism and are at times extremely abundant on the ocean surface. Many opisthobranchs and most small freshwater pulmonates can glide on the underside of the surface film of the water but are not able to swim.

Diversity of mollusks in the ocean has resulted from specialization in food resources within habitats and tidal zonation. Temperature and salinity are the prime physical factors limiting range extensions, usually by preventing successful breeding rather than by preventing settlement and growth of young.

Migration of the snails into freshwater and onto land required new adaptations. Physiological and biochemical adjustments are the same in all taxonomic groups, but the snails had extra problems to solve, relating to their basic feeding and reproductive patterns. In the ocean, dispersal can take place via a veliger stage transported passively by currents and waves. In streams and rivers such a means of dispersal would result in downstream spread only. Hence, the veliger stage was suppressed; instead, many freshwater prosobranchs brood the young inside the female, and pulmonates attach egg capsules to rocks, to vegetation, or to other snail shells. This essentially restricts snail dispersal to individual movement. In prosobranchs with separate sexes, the freshwater distributions closely follow drainage systems, because, in order to colonize a new body of water, either a pregnant female or both a male and a female must be transported at about the same time. Most pulmonates in freshwater are hermaphrodites and are capable of self-fertilization as well as cross-fertilization with other individuals. As a result, any pulmonate entering a new body of water can establish a considerable population of that species in a short time. For this reason, isolated ponds often have several species of pulmonates but only rarely prosobranch gastropods. In crawling over waterweeds, the pulmonates frequently come in contact with the feet or feathers of wading birds to which they adhere accidentally by mucus secretion and are carried to a new pond.

Land snails avoid drying out in several ways. Proso-

branches retreat into their shells, and the operculum effectively seals the opening against the exterior. In the tropics, land operculates have developed elaborate breathing tubes to allow gas exchange during dry periods and yet minimize water loss. Pulmonates lack an operculum, but many forms secrete either simple mucous coverings (epiphragms) across the shell aperture or, in some arid areas, a calcium-impregnated seal that is almost as thick as the shell itself. Most land snails, however, have adjusted to life on land primarily through behaviour patterns. They stay in areas of high moisture or retreat into damp niches during short dry spells. A few burrow into soil. *Sonorella* species survive by remaining dormant during the years between rains; many genital structures are reduced or lost to minimize use of energy in reproductive activities.

Only in the wet and warm tropics have tree snails developed. These species have brightly coloured shells that usually are much thinner than those of their terrestrial counterparts. In the humid mountain regions of the world, where a constant supply of moisture is available throughout the year, there has been a marked tendency toward reduction of the shell and the evolution of slugs. This probably results from two different selective pressures that reinforce each other. The shell, useful primarily in providing protection against drying out, is no longer needed when moisture is plentiful. Secondly, construction of the shell requires large quantities of calcium, which generally is in short supply on volcanic-mountain slopes. With the need for the shell lessened and the primary constituent in short supply, any mutation favouring shell reduction is advantageous. Although most slugs seem to have evolved in mountain areas, their spread into lowlands is greatly aided by irrigation and garden watering.

By far the majority of land snails occupy the surface litter and upper soil zone. This microhabitat is generally moist, and food is plentiful in the form of decaying animals and plants as well as fungi. Most land snails have shells that are drab in colour and inconspicuous. Frequently, the shell surface is highly sculpted. The minute species (less than three millimetres [0.1 inch] in diameter) face a problem of predation by small arthropods. The normal instinct of a snail to withdraw into its shell is of no help, since the predator simply follows the snail into its shell. Elaborate barriers that narrow the shell opening and tiny spines along the opening must provide some protection, since this construction occurs in more than 12 pulmonate families.

Most land snails feed directly on decaying plant matter, which is a simple shift in feeding behaviour from the primitive browsing of their marine ancestors. About 30 percent of land snails scrape algae from tree trunks or limbs or consume fungae hyphae (threadlike structures). The carnivorous habit probably evolved through a transitional period of carrion eaters. Many slugs feed on dead animal matter as well as plants. Pursuit and capture of other snails or earthworms demand increased sensory equipment and more rapid motion. Most carnivores, such as *Euglandina*, have greatly elongated bodies for reaching further into the shells of their victims. The New Zealand *Paryphanta* smothers its earthworm prey in its broad foot before it eats the worm.

**Locomotion.** The foot is the organ of locomotion in land gastropods. In swimming and sessile forms, however, the foot is greatly reduced and in many groups greatly modified. The normal progression of a snail is by muscular action, with a series of contraction waves proceeding from the posterior to the anterior end of the gliding portion of the foot. This type of progression is called monotaxic locomotion. A few groups have the foot divided into right and left halves, with separate waves moving on each side, a condition termed ditaxic locomotion. Certain species move by the action of cilia of the foot on the mucous sheet secreted by the anterior part of the foot. When the foot is narrow, as in *Strombus* and *Aporrhais*, the animal moves in fits and starts, tumbling along by a digging action of the foot and the pointed operculum. Most prosobranchs are relatively slow moving, with

and land  
habitats

Movement  
by  
contraction  
of the foot

a speed of less than eight centimetres (about three inches) per minute, although *Haliotis* has been reported to move at almost ten times that rate.

Many opisthobranchs employ monotaxic locomotion; some can glide on the underside of water-surface films through ciliary action. Swimming has been achieved in a number of ways. Body undulations propel such large snails as *Dendronotus* and *Melibe*. Pteropods, *Gastrop-teron*, *Akera*, and others move foot flaps (parapodia) to provide motion. The sea hare, *Aplysia*, uses an inch-worm-like progression, and some nudibranchs swim by beating accessory breathing organs (cerata).

Freshwater pulmonates use ciliary action on a bed of mucus secreted by the snail. Many snails, especially *Physa*, can form a cord of mucus from the water surface to the bottom.

Land pulmonates depend on a combination of muscular action and cilia. In many of these species, the foot is divided longitudinally into three parts, with locomotor activity confined to the central section, which glides on a mucous track. An additional use of slime by slugs is in mating. A slime rope is secreted from which the mating pair suspend themselves. If irritated, slugs can secrete copious quantities of slime. This reaction is the basis for one method of controlling slugs: spreading enough ashes in slug-infested areas causes exhaustion and death of the animals through overproduction of slime.

Rate of movement in the land pulmonates varies greatly. Some small, tropical, brightly coloured sluglike species will, when disturbed, travel very rapidly with the anterior half of the foot lifted off the ground. This can continue for a distance of two or three feet at a rate of almost four feet (122 centimetres) a minute in snails less than two to three centimetres (or about one inch) in body length. Large species, such as *Achatina* or *Strophochelilus*, are much slower, and carnivores are usually relatively fast moving.

#### FORM AND FUNCTION

**The shell.** The typical snail has a calcareous shell coiled in a spiral pattern around a central axis, or colu-

mella. Generally, the later coils, or whorls, are larger than the earlier ones. At the end of the last whorl is the aperture, or opening, on the outer lip of which shell growth occurs. The shell is secreted by the fleshy part of the animal called the mantle, first by outward additions to the shell lip and then by secretion of inner thickening layers. The outer layer, or periostracum, is a mixture of proteins known as conchin. Inner layers of calcium carbonate interlace with a network of conchin and are impregnated with a variety of mineral salts. The calcium usually is in the form of calcite crystals in marine species and aragonite crystals in terrestrial species, but mixtures of crystal types do occur.

Modifications and ornamentations of the basic shell are widely variable. Frequently, the shell is altered into a nonspiral cap or a cup-shaped limpet form as an adaptation to life in swift currents (freshwater Ancyliidae) or amid pounding waves on rocks (marine Acmaeidae, Patellidae, Fissurellidae, and Calyptraeidae). In many groups, such as the abalones (Haliotidae), only traces of spiral coiling are evident, because the rate of successive whorl widths is so large that the last, or body whorl, occupies more than 90 percent of the shell volume. Elaborate surface sculpture, including knobs and spines, develop as protection against predation. In a few species of the genera *Leucozonia* and *Acanthina*, a spine on the lip edge is used to wedge open clam valves so that the snail can feed. As implied earlier, land gastropods in dry regions tend to have very thick shells; on the other hand, those in very humid mountain situations have thin shells or none at all. Many carnivorous snails have the calcareous part of the shell greatly reduced. The New Zealand *Paryphanta* is perhaps the most extreme example: the calcareous layer is only a thin sheet, and the outer, organic periostracum accounts for 90 percent of the shell thickness.

**The body.** The gastropod body consists of four main parts: visceral hump, mantle, head, and foot. The body is attached to the shell either by one columellar muscle or by a series of muscles. Typical snails can withdraw the head and foot into the shell, but numerous species have

Shell ornamentation

**Slug life cycle.** Stages in the life cycle of the black slug (*Limax*), a hermaphroditic pulmonate. (Left) Pair of slugs, having lowered themselves from a branch by means of a mutually produced mucous string, intertwine and mate while suspended. (Top) Shiny, gelatinous eggs are laid in clusters in sheltered places. (Right) Eggs hatching and recently emerged slugs.

Lynwood M. Chase

shells so reduced in size as to be unable to contain the body; slugs, of course have either an internal shell vestige or no shell at all.

**The visceral hump.** The visceral hump is always contained within the shell; it generally holds the bulk of the digestive, reproductive, excretory, and respiratory systems (Figure 3). A significant part of the visceral hump consists of the pallial cavity. In both prosobranchs and shelled opisthobranchs, this is a cavity completely open anteriorly; in pulmonates it is closed except for a narrow pore. The upper surface of the pallial cavity serves a respiratory function. In marine species, the ciliated lining of the cavity produces a water current that passes pos-

The  
pallial  
cavity

Figure 3: Adult gastropod structure. (A) Primitive; (B) advanced.

teriorly across the gill, or ctenidium, and the osphradium, which is thought to be a sensory receptor of chemical changes in the environment. Both organs lie on the left anterior side of the cavity. The water current sweeps across the posterior part of the pallial cavity, where the nephridiopore, or kidney opening, lies, and then passes anteriorly along the right margin past the anus, through which undigested particles of food are eliminated, and usually past the gonopore, through which sexual products are released.

An often overlooked function of the pallial cavity is as a space for containment of the head and foot, when these organs are retracted in an attempt to avoid a predator or to avoid drying out (in land snails) during dry periods. Many land pulmonates apparently also use the pallial cavity to retain water. Prosobranchs use the operculum, the horny or calcareous disk located on the back of the foot at the posterior end, to seal the shell opening.

**The mantle.** The mantle is the fleshy lining of the outer wall of the shell; it roofs the pallial cavity. At its anterior end lie glandular tissues that deposit the various shell layers. In terrestrial forms with reduced shells, various lobes and laps extend anteriorly over the neck and head or are reflected back over the shell surface. These are highly vascularized and probably serve both in respiration and in water balance of the body. Many marine forms have the mantle collar extended forward and rolled into a siphon, which functions in both food location and chemoreception.

**The head.** Generally, the head is bilaterally symmetrical, bearing one or two pairs of tentacles, often with accessory palps, and the mouth in the middle of the ventral margin. Eyespots or, rarely, eyes capable of image formation are present near or on the larger pair of tentacles. In stylommatophoran land snails the upper tentacles, or ommatophores, are invaginable (capable of being rolled in), and the eyes are borne at the tips. In freshwater basommatophorans and most prosobranchs, the eyes are located at the base of the tentacles, although in such forms as *Strombus* the eyes are elevated onto an accessory stalk. Prosobranchs have contractile (not invaginable) tentacles. In carnivorous snails, the lateral lips of the mouth form lobes called labial palps, which help to locate prey. The mouth itself frequently is prolonged into a proboscis that extends well in front of the tentacles. Carnivorous species often have a proboscis capable of great extension, either invaginable or contractile.

**The foot.** Although the basic form of the foot is a flat, broadly tapered, muscular organ, which is highly glandularized and usually ciliated, numerous modifications occur in various groups. Frequently, there is an anterior-posterior division into a propodium and a metapodium, with the former capable of being reflexed over the shell. In *Strombus*, the foot is greatly narrowed; in limpets and abalones, it is broadly expanded and serves as an adhesive disk. In pelagic gastropods, the foot is a swimming organ. Many prosobranchs and some opisthobranchs have lateral projections of the foot called parapodia; they are used in swimming or else are reflexed over the shell surface. An unusual feature found in several kinds of land slugs, some nudibranchs, and the stenoglossan marine family Harpidae, is the ability to self-amputate the posterior portion of the foot, which remains wriggling violently to distract a predator, while the anterior foot and visceral mass creep slowly away to safety.

Modifica-  
tions of  
the foot

#### EVOLUTION AND PALEONTOLOGY

The basic trends in snail evolution involve changing from a herbivorous to a carnivorous diet, shifting from the ocean to freshwater and terrestrial life, and adopting a sluglike form through reduction or loss of the shell and visceral hump. Each change has occurred independently several times in the course of gastropod evolution.

Prosobranch gastropods are the most primitive. One group, the Diotocardia, which retains two sets of pallial organs, is nearest to the generalized gastropod in structure. Gradual loss of the right set of pallial organs occurs in the Trochacea and Neritacea, thus providing a transition to the more highly developed Monotocardia, with only one set of pallial organs. Among the numerous changes in the Monotocardia are a reduction in numbers of radular teeth and a shift from grazing on algae and fungi to consumption of larger sessile organisms and predation. The two main divisions of the Monotocardia show different evolutionary patterns. Although most Taenioglossa have remained coastal marine, several families moved into freshwater. Others crossed to land directly from the tidal zone, rather than passing through a freshwater transitional period. At the peak of prosobranch evolution are the predatory Stenoglossa, all marine inhabitants, with highly modified radular teeth and often well-developed poison glands to aid in capturing prey. Reduction and loss of the right pallial organs are correlated with more efficient respiration and sensory apparatuses, in which a water current crosses over the sensory organs and gills on the left side, then out on the right side, together with excretory and fecal deposits.

Opisthobranchs probably arose from an unknown group of primitive prosobranchs and have evolved extensively into different lines showing a reduction of the visceral hump and shell. In certain forms the foot is shortened, and external cerata develop to provide a respiratory surface to replace the lost mantle-cavity surface. Such groups as the Pyramidellacea contain a mixture of prosobranch and opisthobranch characteristics.

Pulmonates show varying degrees of adjustment to freshwater and land life, with increasing union of the male and female gonoducts characterizing the more advanced groups. Similarly, the highly advanced Holopoda and Limacacea show complex accessory organs on the genitalia and a more sophisticated means of water conservation through development of a closed secondary ureter and resorption of water from the excretory products. More than a dozen different groups of pulmonates have become predators, usually upon other snails or earthworms.

Fossil gastropods are known from Cambrian deposits (more than 500,000,000 years old). Since the shell is often very similar in unrelated families, fossil gastropods more than 350,000,000 years old are not usually placed in the classification outlined below but instead are treated separately. Most stenoglossan prosobranchs appeared near the end of the Mesozoic (about 65,000,000 years ago), and many groups of land snails are known from Eocene formations (38,000,000 to 54,000,000 years old). Snails had their adaptive radiation early in geologic history. Living genera of marine, freshwater, and land-snail families are known from Miocene to Oligocene deposits (26,000,000 to 38,000,000 years old). Unlike mammals, who have undergone great evolutionary change in the last 50,000,000 years, gastropods have shown little progressive evolution during that time.

#### CLASSIFICATION

**Distinguishing taxonomic features.** Higher category groupings of the gastropods depend on the relative importance assigned to the nervous system or to the pattern of respiration. The groupings date back to observations made in the mid-1800s. The following provide the basic data from which a classification can be derived: patterns of change in the reduction of torsion from a streptoneurous (twisted) to a euthyneurous (straight) nerve loop; progressive loss of the right part of the primitively paired pallial organs; increasing sophistication of hermaphroditism (both sexes in one animal); tendency toward reduction of the visceral hump and shell; multiple changes from a herbivorous to a carnivorous diet; habitat shifts to freshwater and land from the marine environment and, occasionally, return from the land to the ocean; and shifts in locomotor mechanics.

Euthyneury has evolved separately in the opisthobranchs and pulmonates; a few opisthobranchs, such as the Acteonidae, retain a streptoneurous nervous system.

The division into Prosobranchia, Opisthobranchia, and Pulmonata recognizes basic adaptive patterns and is utilized here, although with the recognition that, in particular, the Pulmonata probably have arisen from several discrete lineages (*i.e.*, are polyphyletic in origin).

**Annotated classification.** The classification given here borrows from many sources; the general follows V. Fretter and A. Graham (1962), as does the internal classification of the Prosobranchia. Internal classification of the Opisthobranchia is basically that of C.F. Boettger (1954) except that the Onchidiacea are considered to be pulmonates. The Pulmonata is classified according to A. Solem (1974).

#### CLASS GASTROPODA (snails and slugs)

About 50,000 species widely distributed in marine, freshwater, and land regions; snails typically with a calcareous shell; slugs with greatly reduced shell; length ranges from about 0.04 inch to 52 inches.

##### Subclass Prosobranchia

Streptoneurous (twisted) gastropods with an anteriorly located mantle cavity (space lined with epidermis); operculum (protective cover) generally present; sexes separate; shell can usually hold entire animal; primarily marine, several freshwater and terrestrial groups. About 26,000 species.

##### Order Diotocardia (Archaeogastropoda)

Heart usually with 2 auricles; 1 or 2 internal gills; no penis, siphon (organ used in food location), or proboscis (feeding organ); nervous system not concentrated; sex cells discharged by way of the right nephridium (kidney). About 3,000 species.

**Superfamily Zeugobranchia (Pleurotomariacea).** Slit shells (Pleurotomariidae) in deep ocean waters; abalones (Haliotidae) in shallow waters along rocky shores of western North America, Japan, Australia, and South Africa; keyhole limpets (Fissurellidae) in intertidal rocky areas.

**Superfamily Patellacea (Docoglossa).** Conical-shelled limpets, without slits or holes, found in rocky shallow waters (Acmaeidae and Patellidae).

**Superfamily Trochacea.** Small to large spiral shells in shallow to deep ocean waters, often brightly coloured, with or without heavy shell ornamentation; Trochidae (top shells), Turbinidae (turban shells), and Phasianellidae (pheasant shells).

**Superfamily Neritacea.** Small, generally intertidal marine shells (Neritidae), with some freshwater dwellers, particularly in Indonesia and the Philippines (Neritidae), and 2 groups of land dwellers: one sparsely distributed in the Old World (Hydrocenidae) and one widely distributed in both Old and New World tropics (Helicinidae).

##### Order Monotocardia

Heart with 1 auricle; 1 gill, often modified; siphon and chemoreception osphradium (sensory receptor) progressively more complex; penis present; head frequently modified into a proboscis; nervous system progressively more concentrated. About 23,000 species.

**Suborder Taenioglossa (Mesogastropoda).** Radula (broad ribbonlike structure covered with teeth) taenioglossate (with 7 denticles, or teeth) or reduced; most taxa herbivorous; a few families parasites or predators.

**Superfamily Cyclophoracea.** Land snails, particularly abundant in the West Indies and southern Asia to the Melanesian islands.

**Superfamily Viviparacea.** Large, 1 to 2 inch, globular pond and river snails of the Northern Hemisphere (Vivipariidae) and tropical regions (Ampullariidae); frequently used in freshwater aquariums with tropical fish.

**Superfamily Littorinacea.** Periwinkles, on rocky shores (Littorinidae) of all oceans; land snails of the West Indies, part of Africa, and Europe (Pomatiasidae).

**Superfamily Rissoacea.** About 17 families of small to minute, generally cylindrical, marine, freshwater and land snails found in most tropical and warm-temperate regions of the world.

**Superfamily Cerithiacea.** Minute to large, generally elaborately sculptured shells, common in mud flats and mangroves, many species sand dwellers, with 1 group of families (Thiariidae, Pleuroceridae, Melanopsidae) especially abundant and varied in the Tennessee and Alabama River systems; 13 marine families, including worm shells (Vermetidae), horn shells (Potamididae), and button shells (Modiolidae).

**Superfamily Strombacea.** Conchs (Strombidae) of tropical oceans and the pelican's foot shells (Aporrhaidae) of near Arctic waters, have foot and operculum greatly modified and move with a lurching motion; feed on algae and plants; some species used for human food.

**Superfamily Calyptraeacea.** Cap shells (Capulidae) and slipper shells (Calyptraeidae) are limpets with irregularly shaped shells with a small internal cup or shelf; many species show sex reversal, becoming males early in life, then changing into females during old age; common on rocks, clamshells, and in dead large snail shells in most oceans.

**Superfamily Cypraeacea.** Cowrie shells (Cypraeidae) and egg shells (Ovulidae) have highly polished and brilliantly coloured shells; mantle, which may cover the shell, is a totally different colour pattern; if touched, members of group suddenly withdraw, the change in colour serving to confuse predators; common in shallow tropical oceans, some species in cooler waters.

**Superfamily Naticacea.** Moon shells (Naticidae) medium-sized, globular predators on burrowing bivalves, bore a hole in the clamshell using acid secretions, then insert the radula to feed; common in most oceans.

**Superfamily Ptenoglossa (or Scalacea).** Wentletraps (Epitonidae) live in shallow to deep ocean waters; purple snails (Janthinidae) float on the ocean surface after building a raft of bubbles; large numbers of bubble shells occasionally blow ashore.

**Superfamily Aglossa.** Parasitic or predatory snails either with a reduced radula or with none, jaws often modified into a stylet-shaped structure; many occur on echinoderms; consists of several poorly known families.

**Superfamily Doliacea (Tonnacea).** Generally tropical predators on echinoderms; often burrow in sand; includes

The earliest gastropods

helmet shells (Cassidae), tun shells (Doliidae), frog shells (Bursidae), triton shells (Cymatiidae), and fig shells (Ficidae); frog and triton shells often live in rocky areas; most species large in size.

**Suborder Stenoglossa (Neogastropoda).** Carnivorous or scavengers with rachiglossate (with 3 denticles) or taxoglossate (with 2 denticles) radula; shell often with long siphonal canal; proboscis well developed and often extensible; shells generally large; all marine.

**Superfamily Muriceae.** Murex shells (Muricidae), rock shells (Purpuridae), and coral shells (Coralliophilidae) are common predators, often boring into shells of their prey; rock shells common in cooler waters; others mostly tropical.

**Superfamily Buccineae.** Scavengers that have lost the mechanisms for boring; dove shells (Columbellidae), mud snails (Nassaridae), tulip shells (Fasciolaridae), whelks (Buccinidae), and crown conchs (Galeodidae) mainly cool-water species; but dove and tulip shells have many tropical representatives.

**Superfamily Volutacea.** Harp shells (Harpidae), olive shells (Olividae), mitre shells (Mitridae), volute shells (Volutidae), nutmeg shells (Cancellariidae), and marginellas (Marginellidae) generally have operculum reduced or lacking; most are tropical ocean dwellers, active predators or scavengers; many olive, volute, and marginella shells are highly polished and colourful.

**Superfamily Toxoglossa.** Auger shells (Terebridae), cone shells (Conidae) and turrid shells (Turridae) are carnivorous marine snails with poison glands attached to highly modified radular teeth; several cone shells have caused human deaths through poisoning and can catch and kill fish.

#### Subclass Opisthobranchia

Shell reduced or lacking, usually too small for withdrawal of animal; mantle cavity often lost, rotated to right side and facing anteriorly; hermaphroditic; marine except for 4 species; operculum generally lost; nerve ganglia (clusters) very concentrated. About 2,000 species.

#### Order Cephalaspidea

Shell present, often capable of containing whole body; head shield developed; Acteonidae with operculum; 14 families.

#### Order Pyramidellacea

Spiral shell; operculum present; gill and radula absent; long proboscis with stylet; ectoparasitic; generally minute; in warm oceanic areas.

#### Order Acochlidacea

Three families with visceral mass longer than foot; 4 species in freshwater; a few with sexes in separate animals; size minute.

#### Order Philinoglossacea

No head appendages; gill lacking; no external shell; 2 families.

#### Order Anaspidea

Sea hares (Aplysiidae); 1 other small family; shell reduced to flat plate; feed on large seaweed rather than microscopic algae.

#### Order Notaspidea

Shell and gill usually present; no parapodia (extensions of foot); sperm groove open; shell prominent, reduced, or hidden by mantle; 2 families.

#### Order Sacoglossa

One file of radular teeth; sperm duct a closed tube; shell reduced to bivalved (Juliidae); many feed by sucking juices out of algae; several families with uncertain limits.

#### Order Thecosomata

Shell present; pelagic (open-sea dwelling) ciliary feeders; no gill; 6 families.

#### Order Gymnosomata

Shell absent; no mantle cavity; complicated feeding mechanisms; pelagic carnivores; 7 families.

#### Order Nudibranchia

Sea slugs without shell, mantle cavity, osphradium, or internal gill; many, as carnivores, feed on sessile animals; few swimmers (family Tethyidae); highly colourful, often conspicuous.

#### Subclass Pulmonata

Mantle cavity altered into a pulmonary sac; no gills or operculum; 1 auricle of heart anterior to ventricle; hermaphroditic; shell spiral to limpet-like, often reduced to a fragment hidden by mantle; mainly terrestrial or freshwater, few marine. About 21,200 species.

#### Superorder Systellommatophora

Mantle cavity absent; anal and usually nephridial opening at posterior; male gonopore behind right tentacle; female gonopore middle of right side; sole of foot narrow; no shell; 2

pairs of retractile, or invaginable, tentacles. Marine (Onchidiidae), terrestrial and herbivorous (Veronicellidae), or terrestrial and carnivorous (Rathouisiidae). About 200 species.

#### Superorder Basommatophora

Mantle cavity present; eyes at base of 1 pair of tentacles; male and female gonopore separate, usually on right side of body; shell conical to patelliform; mostly freshwater, but a few land and marine taxa. (No agreement exists concerning suprafamilial classification of the Basommatophora. The following superfamilies, though not grouped into formal orders and suborders, are listed in order of increasing specialization.) About 1,000 species.

**Superfamily Patelliformia.** Brackish water or marine limpets with (Siphonariidae) gill-like structures or with a lung (Gadinidae).

**Superfamily Amphibolacea.** Operculum present; shell conical; with pulmonary cavity; brackish water; burrow in sand; 1 family.

**Superfamily Ellobiacea.** Conical shells; pulmonary chamber; tidal zone, salt flats, under rocks in spray zone, to completely terrestrial; 2 families.

**Superfamily Lymnaeacea.** Small to large, spiral-shelled snails of ponds, lakes, and rivers. One limpet group (Lancidae) and larger typical group (Lymnaeidae).

**Superfamily Ancyloceae.** Limpets (Ancylidae), ramshorns (Planorbidae), and pond snails (Physidae); all restricted to freshwater habitats.

#### Superorder Stylommatophora

Mantle cavity a pulmonary sac; gonopores with common opening on right side or at most narrowly separated; shell conical to vestigial, heavily to weakly calcified; eyes at tips of upper (usually) tentacles; terrestrial. About 20,000 species.

#### Order Orthurethra

Pore of ureter opening into pallial cavity (part of the viscera) near anterior margin of lung after ureter passes forward from anterior kidney margin. About 6,000 species.

**Superfamily Achatinellacea.** Minute to medium-sized Pacific Island land snails with multicuspid radular denticles; many Hawaiian species highly coloured and variable.

**Superfamilies Cionellacea and Pupillacea.** Minute leaf-litter to arboreal snails, occasionally (Enidae) large; shells often with denticles in the aperture; 10 families.

**Superfamily Partulacea.** Small generally arboreal snails found on high volcanic islands of Polynesia and Micronesia, a few in Melanesia.

#### Order Mesurethra

Ureter represented by lateral opening of very short kidney, pore of ureter opening near or behind middle of pallial cavity. About 1,500 species.

**Superfamily Clausiliacea.** Elongated shells of West Indian shore salt-spray zone (Cerionidae) or Andean mountains of South America and Eurasia (Clausiliidae).

**Superfamily Strophocheilacea.** Large helicoidal to elongated shells of South America (Strophocheilidae) or southwest Africa (Dorcasiidae).

#### Order Sigmurethra

Ureter originates near anterior margin of kidney, follows backward to posterior end, then reflexes forward along hindgut to open alongside anus; position greatly altered in slug-like forms. About 12,500 species.

**Suborder Holopodops.** A group of 4 superfamilies.

**Superfamily Achatinacea.** Besides the giant African snail, 4 families, including many species spread by commerce throughout the world.

**Superfamilies Streptaxacea and Rhytidacea.** Carnivorous snails and slugs (4 families) in most tropical areas, plus the herbivorous Acavidae of Australia, Ceylon, and Madagascar.

**Superfamily Bulimulacea.** Large, often arboreal snails of Melanesia and Neotropica (Bulimulidae); long, cylindrical snails of West Indies and Central America (Urocoptidae).

**Suborder Aulacopoda.** A group of 3 superfamilies.

**Superfamily Succineacea.** A problematic group including amber snails (Succineidae), which inhabit swamps and damp areas, and peculiar slugs from the South Pacific (Athoracophoridae).

**Superfamily Arionacea.** Marginal teeth of radula with squarish basal plates and 1 to several cusps; small litter or tree snails mainly in Southern Hemisphere (Endodontidae), and slugs (Arionidae and Philomycidae) of the Northern Hemisphere.

**Superfamily Limacacea.** Marginal teeth of radula with narrow, lengthened basal plates, usually unicuspid; zonitid snails with smooth shells and many sluglike species, common in wet, tropical areas and in temperate regions; about 12 families, including limacid and milacid slugs.

**Suborder Holopoda.** A group of 3 superfamilies.

**Superfamily Polygyracea.** Common woodland snails of eastern North America (Polygyridae), plus a Neotropical group (Thysanophoridae) and a relict group of Asia (Corilidae).

**Superfamily Oleacinacea.** Carnivorous (Oleaciniidae) and herbivorous (Sagdiidae) snails of the Neotropical region.

**Superfamily Helicacea.** Land snails without (Oreoheliciidae and Camaenidae) or with (Bradybaenidae, Helminthoglyptidae, and Helicidae) accessory glands on the genitalia; dominant land snails in most regions, including the edible snails of Europe (Helicidae).

## Gaudí, Antonio

The work of the architect Antonio Gaudí is remarkable for its range of forms, textures, and polychromy and for the free, expressive way in which these elements of his art seem to be composed. The complex geometries of a Gaudí building so coincide with its architectural structure that the whole, including its surface, gives the appearance of being a natural object in complete conformity with nature's laws. Such a sense of total unity also informed the life of Gaudí; his personal and professional lives were one, and his collected comments about the art of building are essentially aphorisms about the art of living. He was totally dedicated to architecture, which for him was a totality of many arts.

The Colonia Güell church by Antonio Gaudí, 1898–c. 1915. In Santa Coloma de Cervelló, Spain.

Antonio Gaudí y Cornet was born on June 25, 1852, in or near the provincial Catalan city of Reus, on the Mediterranean coast, in Spain. Of humble origins, he was the son of a coppersmith who was to live with him in later life, together with a niece; Gaudí never married.

Showing an early interest in architecture, he went in 1869/70 to Barcelona, which was then the political and intellectual centre of Catalonia as well as Spain's most modern city. He did not graduate until eight years later, his studies having been interrupted by military service and other intermittent activities.

Gaudí's style of architecture went through several phases. On emergence from the Escuela Provincial de Arquitectura in Barcelona in 1878, he practiced a rather florid Victorianism that had been evident in his school projects, but he quickly developed a manner of composing by means of unprecedented juxtapositions of geometric masses the surfaces of which were highly animated with patterned brick or stone, gay ceramic tiles, and floral or reptilian metalwork. The general effect, although not the details, is Moorish—or Mudéjar, as Spain's special mixture of Muslim and Christian design is called. Examples of his Mudéjar style are the Casa Vicens and "El Capricho" of 1883–85, and the Güell Estate (Finca Güell) and Palacio Güell of the later 1880s, all but "El Capricho" located in Barcelona. Next, Gaudí experimented with the dynamic possibilities of historic styles: the Gothic (at the Palacio Episcopal, Astorga, 1887–94, and Casa de los Botines, León, 1891–94) and the Baroque (Casa Calvet at Barcelona, 1898–1901). But after 1902 his designs elude conventional stylistic nomenclature.

Except for certain overt symbols of nature or religion, Gaudí's buildings became essentially representations of their structure and materials. In his Torre (villa) Bell Esguard and the Güell Park, in Barcelona, and in the Colonia Güell church, south of that city, he arrived at a type of structure that has come to be called equilibrated—that is, a structure designed to stand on its own without internal bracing, external buttressing, and the like—or, as Gaudí observed, as a tree stands. Among the primary elements of his system were piers and columns that tilt to transmit diagonal thrusts, and thin-shell, laminated tile vaults that exert very little thrust. Gaudí applied his equilibrated system to two multi-storied Barcelona apartment buildings: the Casa Batlló, a renovation that incorporated new equilibrated elements, notably the facade; and the Casa Milá, the several floors of which are structured like clusters of tile lily pads with steel beam veins. As was so often his practice, he designed the two buildings, in their shapes and surfaces, as metaphors of the mountainous and maritime character of Catalonia.

As an admired, if eccentric, architect, Gaudí was an important participant in the Catalan *Renaixença*, an artistic revival, especially of the arts and crafts, combined with a political revival in the form of fervent anti-Castilian "Catalanism"; both movements sought to reinvigorate the way of life in Catalonia that had long been suppressed by the Castilian-dominated and Madrid-centred government in Spain. The religious symbol of the *Renaixença* in Barcelona was the church of the Sagrada Família, a project that was to occupy Gaudí throughout his entire career. He was commissioned to build this church as early as 1883, but he did not live to see it finished. Working on it, he became increasingly pious; after 1910 he abandoned virtually all other work and even secluded himself on its site and resided in its workshop. In his 75th year, while on his way to vespers, he was struck down by a trolley car, and he died from the injuries on June 10, 1926.

In his drawings and models for the uncompleted church of the Sagrada Família (only one transept with one of its four towers was finished at his death), he equilibrated the cathedral-Gothic style beyond recognition into a complexly symbolic forest of helicoidal piers, hyperboloid vaults and sidewalls, and hyperbolic paraboloid roof that boggles the mind and outdoes the bizarre concrete shells built throughout the world in the 1960s by engineers and architects inspired by Gaudí. Apart from this and a similar, often uncritical, admiration for Gaudí by Surrealist and Abstract Expressionist painters and sculptors, Gaudí's influence was quite local, represented mainly by a few devotees of his equilibrated structure. He was ignored during the 1920s and '30s, when the International Style was the dominant architectural mode. By the 1960s, however, he came to be revered by professionals and laymen alike for the boundless and tenacious imagination that he used to attack each design challenge with which he was presented.

### MAJOR WORKS

Most of the major works of Gaudí are in or near Barcelona.

Gaudí's  
styles  
and  
historic  
phases

His equi-  
brated  
system

Influence  
on his  
followers

Casa Vicens (1883–85); church of the Sagrada Família (begun 1882, Gaudí in charge 1883–1926); Villa “El Capricho,” Comillas, Santander (1883–85); Finca Güell (Güell Estate; c. 1884–87); Palacio Güell (1886–89); Palacio Episcopal, Astorga (1887–94); Colegio (school) de Sta. Teresa de Jesús (1888–91); Casa de los Botines, León (1891–94); Casa Calvet (1898–1901; some furnishings to 1904); Colonia Güell church, Santa Coloma de Cervelló (1898–c. 1915); Villa Bell Esguard (1900–02); Park Güell (1900–14); liturgical renovation of the cathedral of Palma, Majorca (1901–15); Casa Batlló (1904–06); Casa Milá (1906–10).

Gaudí's surviving drawings and modern measured drawings of his works are also in Barcelona, mainly at the Escuela Técnica Superior de Arquitectura, the Amigos de Gaudí, and the Sagrada Família workshop. Small museums of Gaudí's work exist at the Park Güell and at the church of the Sagrada Família in Barcelona.

**BIBLIOGRAPHY.** The most complete bibliography to date is in Ráfols' books, supplemented by Collins 1960 and Pane (all cited below). The Amigos de Gaudí of Barcelona and the Catalan Archive of Art and Architecture in New York are the primary research archives.

**Biography and criticism:** JUAN BERGOS, *Gaudí, l'home i l'obra* (1954); ENRIQUE CASANELLES, *Nueva vision de Gaudí* (1965; Eng. trans., *Antonio Gaudí: A Reappraisal*, 1967), critical essays; ALEJANDRO CIRICI PELLICER, *El arte modernista catalán* (1951 and 1960), comprehensive on background, with more than 500 illustrations; GEORGE R. COLLINS, *Antonio Gaudí* (1960), chronology and annotated bibliography; “Antonio Gaudí: Structure and Form,” *Perspecta*, 8:63–90 (1963), a summary of Gaudí's structural procedures; “Transfer of Thin Masonry Vaulting from Spain to America,” *J. Soc. Archit. Hist.*, 27:176–201 (1968), includes complete bibliography on the Catalan vaulting tradition that Gaudí inherited; “Gaudí and the Catalan Movement,” *Pap. Am. Assn. Archit. Bibliographers* (in press), a listing of some 1,800 publications, based on the Catalan archive at Columbia University; and with JUAN BASSEGODA NONELL, *Portfolio of Gaudí Drawings* (in press), large size reproductions of drawings by Gaudí and architectural drawings of his buildings; and (ed.), *La Vision artistique et religieuse de Gaudí* (1969; Eng. trans., *Gaudí, the Visionary*, 1971), essays by Salvador Dalí, R. Descharnes, J. Alevedra, F. Pujols, and photos by C. Prevost—strong on anecdote and Gaudí as sculptor; CESAR MARTINELL, *Gaudí; su vida, su teoría, su obra* (1967), an encyclopaedic work summarizing the author's many publications; and *Conversaciones con Gaudí* (1969), the most complete collection of Gaudí's sayings; ROBERTO PANE, *Antoni Gaudí* (1964), the most detailed work to its date of publication (in Italian); ISIDRO PUIG BOADA, *El Templo de la Sagrada Família* (1952), the most useful monograph on a single project; JOSE F. RAFOLS and FRANCISCO FOLGUERA, *Gaudí* (1929), the first and most basic monograph (in Spanish), with complete bibliography and chronology—originally 1928 in Catalan, later, and briefer, by Ráfols in Catalan, 1952 and 1960; JOSE L. SERT and JAMES J. SWEENEY, *Antoni Gaudí*, rev. ed. (1970), contains Sert's earlier valuable essays. The Barcelona periodicals *El Propagador de la Devoción a San Jose* (1867–1936, 1943–48), and its successor *Templo* (1948– ), are dedicated to the church of the Sagrada Família and, inevitably, to Gaudí.

(G.R.Co.)

## Gauguin, Paul

Paul Gauguin, the leading French painter of the Postimpressionist period, in the late 19th century, was unique in his ability to hold a mysterious balance between idea, perception, and visual image. His pictures make their effect visually, not as a result of literary overtones. He was a great stylistic innovator, and, when he rejected the conception of a picture as a mirror image of an actual scene and turned from an empirical to a conceptual method of pictorial representation, his step was decisive for the developments in art during the first half of the 20th century.

Eugène-Henri-Paul Gauguin was born in Paris on June 7, 1848, the son of a journalist from Orléans and of a mother who was half French and half Peruvian Creole. After Napoleon III's coup d'état, the Gauguin family moved in 1851 to Lima, and four years later Paul and his mother returned to Orléans. At the age of 17 he went to sea and for six years sailed about the world in freighters or men-of-war. In 1871 he joined the stockbroking firm of Bertin in Paris and in 1873 married a Danish girl, Mette Sophie Gad. His artistic leanings were first aroused by his guardian, Gustave Arosa, whose collection included pictures by Corot, Delacroix, and Millet,

“Self-Portrait,” panel painting by Paul Gauguin, 1889. In the National Gallery of Art, Washington, D.C. 0.792 m × 0.513 m.

By courtesy of the National Gallery of Art, Washington, D.C., the Chester Dale Collection

and by a fellow stockbroker, Émile Schuffenecker, with whom he started painting. Gauguin soon started going to a studio to draw from a model and receive instruction. In 1876 his “Landscape at Viroflay” was accepted for the official annual exhibition, the Salon. He developed a taste for Impressionist painting and between 1876 and 1881 assembled an impressive group of paintings by Manet, Cézanne, Pissarro, Monet, and Jongkind.

Gauguin met Camille Pissarro in 1875–76 and began to work with him, struggling to master the techniques of drawing and painting. In 1880 he was invited to contribute to the fifth Impressionist exhibition, and this invitation was repeated in 1881 and 1882. He spent holidays painting with Pissarro and Paul Cézanne and made visible progress, though his early works are often marred by clumsiness and have drab colouring. Gauguin thus became more and more absorbed by painting and in 1883, when the Paris stock exchange crashed and he lost his job, he decided “to paint every day.” This was a decision that changed the course of his whole life. He had a wife and four children, but he had no income and no one would buy his paintings. In 1884 Gauguin and his family moved to Copenhagen, where his wife's parents proved unsympathetic, and his marriage broke up. He returned to Paris in 1885, determined to sacrifice everything for his artistic vocation. From then on he lived in penury and discomfort, his health was undermined by hardship, he became an outcast from the society to which he had belonged and could never establish himself in any other, and he came to despise Europe and civilization.

In 1886 the expressive possibilities of colour were revealed to him in the pictures of Georges Seurat and Paul Signac, and he began to occupy himself with this aspect of painting at Pont-Aven, Brittany. Gauguin then had two decisive experiences: a meeting with Vincent van Gogh in Paris (1886) and a journey to Martinique (1887). The one brought him into contact with a passionate personality who had similar pictorial ideas and tried to involve him in working them out communally; this attempt came to a disastrous end after a few weeks at Arles in 1888. The other enabled Gauguin to discover for himself the brilliant colouring and sensuous delights of a tropical landscape and to experience the charm of a primitive

Early years

## Break with Impressionism

community living the "natural" life. Gauguin decided to seek through painting an emotional release, in consequence of which he reacted against Impressionism. The key to his artistic attitude from 1888 on is to be found in these significant phrases:

Primitive art proceeds from the spirit and makes use of nature. The so-called refined art proceeds from sensuality and serves nature. Nature is the servant of the former and the mistress of the latter. She demeans man's spirit by allowing him to adore her. That is the way by which we have tumbled into the abominable error of naturalism.

Gauguin therefore set out to redeem this error by "a reasoned and frank return to the beginning, that is to say to primitive art." A possible method for arriving at a new form of pictorial representation was suggested to him by Émile Bernard, a young artist well acquainted with stained glass, manuscripts, and folk art. He pointed out that in these arts reality was generally depicted in non-imitative terms and that the pictorial image was made up of areas of pure colour separated by heavy black outlines. Such was the origin of the style known as *cloisonnisme* or *synthétisme*, which attained its most expressive possibilities in such paintings by Gauguin as "The Vision After the Sermon" (1888), "Bonjour Monsieur Gauguin!" and "The Yellow Christ" (1889).

When Gauguin broke with his Impressionistic past he gave up using lines and colours to fool the eye into accepting the flat painted image as a re-creation of an actual scene and explored instead the capacity of these pictorial means to induce in a spectator a particular feeling. His forms became ideated and his colours suggestive abstractions. Maurice Denis, in *Théories* (1920), described a small painting executed by Paul Sérusier under Gauguin's direction in 1888; this landscape seemed to

have no form as a result of being synthetically represented in violet, vermillion, Veronese green and other pure colours. . . . "How does that tree appear to you?" Gauguin had asked. "It's green isn't it? All right, do it in green, the finest green on your palette. And that shadow? Isn't it blue? Well then, don't be frightened of making it as blue as possible." Thus [writes Denis] was presented to us for the first time, in a paradoxical but unforgettable manner, the fertile conception of a painting as "a flat surface covered with colours arranged in a certain order."

## Gauguin's primitivism

Gauguin indulged in "primitivism" because he could make a more easily intelligible image; his simple colour harmonies intensified this image; and, because he wanted his pictures to be pleasing to the eye, he aimed at a decorative effect. His purpose in all this was to express pictorially an "idea." It was as a result of this that he was acclaimed as a leading painter of the Symbolist movement. Gauguin's whole work is a protest against the soul-destroying materialism of bourgeois civilization. "Civilization that makes you suffer. Barbarism which is to me rejuvenation," he wrote (1891) to the Swedish playwright August Strindberg. So Gauguin installed himself in Brittany (Pont-Aven and Le Pouldu, 1889-90, 1894), Tahiti (1891-93, 1895-1901), and the Marquesas Islands (1901-03), where he could paint scenes of "natural" men and women.

Before 1891, Gauguin tended to flatten things deliberately, and his effect was often strained, but throughout the 1890s his primitivism became less aggressive as the influences of J.-A.-D. Ingres and Puvis de Chavannes led to increasingly rounded and modelled forms and a more sinuous line. This process can be followed in works such as "Nafea Faa Ipoipo" ("When Shall We be Married?"), "Nave Nave Mahana" ("Holiday"), and "Golden Bodies." Simultaneously, Gauguin's images became more luxuriant and more naturally poetic as he developed his marvellously orchestrated tonal harmonies. His chief Tahitian work—"Where Do We Come From? What Are We? Where Are We Going?"—is an immense canvas painted in 1897-98. This is the consummate expression of much that he had painted in the previous six years, and the aura of dreamlike, poetic inconsequence which surrounds this semi-philosophical allegory of primitive life is most powerful.

From 1899 on, Gauguin became increasingly ill and was

continually in pain; he was also involved in frequent rows with the governing authorities for siding with the natives against them. Yet despite melancholy, his last pictures still have serenity and hope. He died at Atuana (Marquesas) on May 8, 1903.

In 1889-90 a group of young followers had gathered round him at Pont-Aven, including Sérusier, Charles Filiger, and Denis, who transmitted Gauguin's ideas to Édouard Vuillard and Pierre Bonnard. The Norwegian painter Edvard Munch owed much to Gauguin, as did the painters of the Fauve group—Henri Matisse in particular—who profited from his use of colour. Gauguin's primitivism and stylistic simplifications greatly affected the young Picasso and led to the aesthetic appreciation of Negro art and hence to the evolution of Cubism. In Germany, too, Gauguin's influence was very strong.

## MAJOR WORKS

FRANCE: "La Seine au Pont d'Iéna" (1875; Louvre, Paris); "Seamstress" (1880; Ny Carlsberg Glyptotek, Copenhagen); "Still Life in an Interior" (1885; private collection, U.S.); "Dance of Four Breton Women" (1886; Neue Pinakothek, Munich); "Martinique Landscape" (1887; National Gallery of Scotland, Edinburgh); "The Vision After the Sermon" (1888; National Gallery of Scotland); "The Swineherd" (1888; N. Simon Collection, Los Angeles); "Old Women of Arles" (1888; Art Institute of Chicago); "La Belle Angèle" (1889; Louvre); "Bonjour Monsieur Gauguin!" (1889; Národní Galerie, Prague); "Self-Portrait" (1889; National Gallery of Art, Washington, D.C.); "The Yellow Christ" (1889; Albright-Knox Art Gallery, Buffalo, N.Y.); "Marie Derrien" (1890; Art Institute of Chicago); "La Perte du pucelage" (1890-91; Chrysler Art Museum, Provincetown, Mass.).

TAHITI: "Femmes de Tahiti ou sur la plage" (1891; Louvre); "Street in Tahiti" (1891; Toledo Museum of Art, Ohio); "Suzanne Bambridge" (1891; Musées Royaux des Beaux-Arts, Brussels); "Reverie" (1891; William Rockhill Nelson and Atkins Museum of Fine Arts, Kansas City, Mo.); "Ja Orana Maria" (1891; Metropolitan Museum of Art, New York); "Nafea Faa Ipoipo" ("When Shall We Be Married?"; 1892; Kunstmuseum, Basel); "The Market" (1892; Kunstmuseum); "Manao Tupapau" (1892; private collection, U.S.); "Hina Tefatou" (1893; Museum of Modern Art, New York); "Poèmes Barbares" (1896; Fogg Art Museum, Cambridge, Mass.); "The Moulin David" (1896; Louvre); "Women with Mangoes" ("The King's Wife"; 1896; Pushkin Museum, Moscow); "Nave Nave Mahana" ("Holiday"; 1896; Musée des Beaux-Arts, Lyon); "Te Rerioa" (1897; Courtauld Institute Galleries, London); "Nevermore" (1897; Courtauld Institute Galleries); "Where Do We Come From? What Are We? Where Are We Going?" (1897-98; Museum of Fine Arts, Boston); "The White Horse" (1898; Louvre); "Two Tahitian Women" (1899; Metropolitan Museum of Art, New York); "Sunflowers and Pears" (1901; private collection, Paris); "Golden Bodies" (1901, Louvre); "L'Appel" (1902; Cleveland Museum of Art, Ohio); "Contes barbares" (1902; Museum Folkwang, Essen, West Germany).

**BIBLIOGRAPHY.** Only in recent years has an effort been made to get at the true facts of Gauguin's unhappy life and to divorce them from the legends that have grown up around his personality. Gauguin was the first to romanticize his own existence, by way of consoling himself and deceiving the world, while for reasons of their own many of his friends carried on the process. The most reliable source documents for information about Gauguin are his own letters, but unfortunately many of those to his wife and friends have still only been published in French in an incomplete and, textually as well as chronologically, inaccurate version. His personal writings are more significant for the light they throw on his character, imaginative processes, ideals, and imagery than for their factual accuracy. There is no definitive biography of Gauguin.

*Biographies by friends:* CHARLES MORICE, *Paul Gauguin*, new ed. (1920), in French; JEAN DE ROTONCHAMP, *Paul Gauguin, 1848-1903*, 2nd ed. (1925), in French; memoirs by his son, POLA GAUGUIN, *My Father, Paul Gauguin* (Eng. trans. 1937).

## Gaul

Gaul (Latin Gallia) was the name given by the ancient Romans to the country inhabited by the Gauls—the Celtic peoples of present France, Belgium, western Germany, and northern Italy. These peoples began to move south and west from the Rhine Valley before 1500 bc; they reached the Mediterranean coast by the 5th century bc and by the 4th had moved into the Po Valley and down the Adriatic shore of Italy. There they were influenced by their more civilized Etruscan neighbours. Before the 7th century bc they had come into contact with the Greeks, and had frequent commercial relations with them after c. 600.

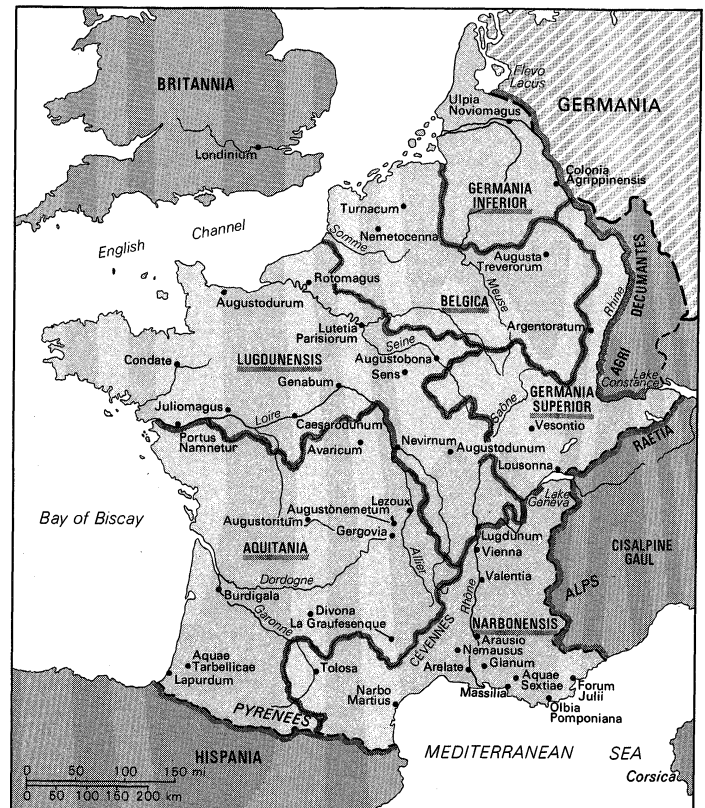

**Cisalpine Gaul.** In 350 bc the Gauls took possession of Bononia (Bologna), completing their occupation of what the Romans called Gallia Cisalpina (Gaul this side of the Alps). The Cisalpine Gauls were composed of several peoples: the Insubres (around Milan), the Cenomani (around Brescia and Verona), the Boii (between the Po and Apennine Mountains), and the Senones (between the Apennines and the Adriatic Sea), whose country was called the Ager Gallicus (the Gallic domain) by the Romans. The Gauls' capture and sack of Rome in 390 bc was a bitter experience for the Romans and was an important motive for their later conquest of Gaul.

Between 350 and 300 there are no recorded Gallic expeditions into central Italy. A new wave of expansion, probably caused by fresh Celtic migrations from the north, began after 300, and in the 3rd century bc friction between the Romans and Gauls in Italy reached its highest point. The Gauls won victories at Clusium (Chiusi) in 295 and Arretium (Arezzo) in 284. They were stopped by the Romans at Sentinum (near present Sassoferrato) in 295 and at Lake Vadimon in 283. In the same period Rome began to found colonies in the borderland between its territory and that of the Gauls, seeking to prevent further Gallic expansion. After a period of peace (282–250) the Gauls began to push south once more. They suffered a major defeat at Cape Telamon (Talamone). The Cenomani were thereafter subjects and allies of Rome. In a series of offensives between 225 and 218 bc, the Romans inflicted defeat on the Insubres; they occupied Mediolanum (Milan) and founded colonies at Cremona and Placentia (Piacenza). The Carthaginian general Hannibal invaded the area in 218. After some initial conflicts with the Gauls he was able to make use of their help against the Romans. With the defeat of the Carthaginians, the Cisalpine Gallic peoples one by one submitted to Rome: the Cenomani in 197, the Insubres in 196, and the Boii in 191. Bononia became a Roman colony in 189 and Aquileia in 181. From this time on Cisalpine Gaul was subject to Roman rule.

Possession of this Gallic territory gave the Romans an advantage in extending their power into the rest of Gaul. It provided them with a base and a source for recruiting soldiers who knew the Gallic language and customs.

**The Roman conquest of Gallia Narbonensis.** Underwater explorations off the coast of southern France have shown that as early as the 2nd century bc Italian merchants controlled the greater part of sea traffic between Transalpine Gaul and the rest of the Mediterranean area. This commercial hegemony prepared the way for territorial conquest.

In 154 the Romans, at the request of the town of Massilia (Marseilles), conducted operations against the Ligurians in the area around Nicaea (Nice). Two expedi-

Roman Gaul from the 1st to the 3rd centuries AD.

tions, one in 125 and another in 124, led to the subjugation of the Vocontii, and to the defeat of the Salluvii. The Romans then made an alliance with the Aedui that gave them control over the routes between the Rhône, Saône, and Loire rivers and allowed them to intervene in the Rhône valley against the Arverni and Allobroges, enemies of the Aedui.

In 122 the Roman consul Domitius Ahenobarbus led an army through the Alps and defeated the Allobroges near the confluence of the Rhône and Sorgue rivers. Bituitus, king of the Arverni, intervened but was defeated in 121. Domitius established Roman control over the Rhône valley between 120 and 117. Narbo Martius (Narbonne) was founded as a colony in 118.

The invasion of the Rhône valley by the Germanic Cimbri and Teutones between 120 and 103 impressed on the Romans the strategic importance of their new acquisition. They were unsuccessful against the invaders until Marius defeated them at Aquae Sextiae (Aix) and Vercellae (Vercelli) in 102.

In the 1st century bc exploitation of the province of Narbonensis by governors, tax collectors, and bankers caused great discontent among the population. In 63 the Allobroges sent a delegation to Rome to protest to the Senate against these injustices, but were given only promises in reply. The result was a rebellion in 62 that had to be put down by Roman armies.

**Roman expansion northward.** Julius Caesar led the Roman forces that conquered the remainder of Gaul between 58 and 50 bc. The entire country was under Roman rule from then until the second half of the 5th century AD. The final phase of Roman conquest was triggered by the migration of the Helvetii into Gaul from what is now Switzerland, and the movement of Germanic peoples, notably the Suevi under Ariovistus, into northeastern Gaul. The Helvetii were halted at Bibracte (near present Autun) in 58. The Romans then turned to the Germans, who had occupied Alsace, defeating them near present Mulhouse in the same year.

Caesar extended Roman authority over most of Gaul with relatively little difficulty between 57 and 54, but the

The Gauls' sack of Rome

Caesar's campaigns

outbreak of a general revolt in 53 necessitated a second, and far more arduous, conquest.

The revolt, led by the Gallic chieftain Vercingetorix, brought Caesar back to Gaul. A siege war followed, centred in the area between the Loire and Allier rivers. The Romans took Avaricum (modern Bourges) and prevented the southern rebels from joining forces with the Belgae in the north, finally defeating and capturing Vercingetorix at his stronghold in Alesia (near modern Alise-Sainte-Reine). This campaign demonstrated Caesar's military genius and the Gauls' fatal lack of organization. Some resistance continued after Vercingetorix's defeat, particularly by the Belgae and the peoples of the Massif Central, but by 50 Roman supremacy was re-established.

Caesar destroyed Gaul's capacity for resistance but left its cities with a large degree of autonomy. Gallic soldiers served him faithfully during his civil wars with Pompey (49–45). During those wars, in 49, Caesar's forces captured the pro-Pompeian city of Massilia after a long and difficult siege.

The colonies of Lugdunum (Lyon) and Augusta Raurica were founded in 43. Lugdunum became the administrative capital and economic centre of Roman Gaul. It was also a centre for Gallic religious assemblies surviving from pre-Roman times. In 27 BC, after the pacification of the more remote areas in the Alps and Pyrenees, the emperor Augustus divided Transalpine Gaul into four provinces: Narbonensis (present southeastern France), Aquitania (western France south of the Loire River), Celtica or Lugdunensis (between the Loire and the Seine), and Belgica (between the Seine and the Rhine, extending into present Switzerland). Germania Inferior and Germania Superior were created from parts of eastern Belgica late in the 1st century AD. Aquitania, Celtica, and Belgica were collectively known as the "Three Gauls" or Gallia Comata (long-haired Gaul). Augustus founded colonies for Roman veterans in Narbonensis, and encouraged the establishment of towns in other parts of the country. He also promoted the construction of a road system, conducted a census for taxation purposes, and established an ordinance survey. The extension of Roman control east to the Elbe River was prevented by a rising of the German tribes (AD 6) and the subsequent defeat of the Romans under Varus in AD 9.

Initially, the Gauls resisted romanization, but the suppression of a Gallic rebellion by the emperor Tiberius in AD 21 proved to be a turning point. It broke the power of the old Gallic land-owning class, which was the mainstay of Celtic civilization. This class had suffered from Roman taxation and was unable to adapt to the new regime which favoured the development of an urban class of merchants and craftsmen loyal to the emperor. Roman colonization also encouraged small-scale agriculture and raised the standard of living in rural areas.

The emperor Claudius (reigned 41–54) paved the way for the political integration of the Gallic nobles by making them eligible for membership in the Roman Senate. They were then given posts in the Roman administration. This policy furthered the assimilation of Gaul.

The Roman conquest of Britain in the last part of the 1st century opened up a new market for Gallic exports, which, with the completion of Gaul's road system and increased commerce with other parts of northern Europe, led to expansion of the Gallo-Roman economy and furthered the prosperity of the urban middle class.

**Roman Gaul.** By the time of Nero (reigned 54–68), Gaul had become sufficiently integrated into the Roman system to play a major role in imperial politics. The rebellion of Gaius Julius Vindex, governor of Lugdunensis (68), began the movement that ended in Nero's overthrow. In 70 a rebellion of the Batavi in the north, and the Treveri of the Moselle region, was suppressed by Vespasian.

In the political situation of the later 1st century, a division developed between the civilian and military classes in Roman Gaul. One was representative of the senatorial aristocracy and the interior provinces (Gallia Comata), and favoured permissive government, including the independence of the cities and the prerogatives of the no-

bility. The other represented the frontier army districts and the cities dependent on them; this group favoured more authoritarian control. The opposition between these factions dominated the political life of Gaul until the end of the Roman period.

In the period of the Flavian emperors (AD 69–96), the conquest and colonization of the Agri Decumates or tithe land (present southwestern Germany) and the construction of a line of fortifications—the *limes*—connecting the middle Rhine with the upper Danube, extended the frontiers of Gaul and increased the influence of the frontier-military faction. The authoritarian government of the Flavians was popular with the army and the inhabitants of the newly annexed territories, but disliked by the civilian aristocracy. Economic expansion continued. An active industrial sector developed in northeastern Gaul, and agricultural production was stimulated by the colonization of the Agri Decumates. Under Vespasian (69–79) increasing amounts of government land came into the possession of small private owners.

In 96, when Nerva was made emperor by the Senate, his policies aroused the army, and there were disturbances along the Rhine frontier. Order was restored by Trajan in 97, and under him began a period of peace and stability that lasted until the time of Marcus Aurelius (reigned 161–80), when there was an uprising of the Sequani (in the Jura region) and the *limes* was crossed by German invaders. Under Commodus (reigned 180–92) an army of deserters and brigands laid waste to the southwest. The civil wars that followed Commodus' death had part of their origin in Gaul, where there was a rebellion among Rhine legions. An economic recession also began under Marcus Aurelius.

Christianity was introduced probably early in the 2nd century; over the next 200 years Gaul became an important Christian centre in the Western Empire.

*The period of decline.* In the 3rd century the country shared in the general decline of the Roman system in the West. Its towns, which often lacked a secure economic base, were hardest hit. The aristocracy was also hard pressed by increasing tax burdens, but was less hurt by the falling value of currency because its wealth was primarily in the land. The aristocracy were also given favoured treatment by some of the 3rd-century emperors. Many small farmers were ruined, though, and agricultural land tended to become concentrated in large estates. The army largely dominated politics, and the administration began to exercise increasing control over the economy in an attempt to arrest the growing inflation, mounting prices, and impoverishment of the wage-earning population. The Severan emperors (193–235) attempted to take corrective measures. The *limes* was restored and the Rhine frontier reoccupied; new industries—glassmaking at Colonia (Cologne) and Vienne (Vienna), weaving at Lugdunum—were introduced in an attempt to diversify the economy.

In the period 235–75, Gaul experienced a series of civil wars and invasions. The unity of the Western Empire disappeared for a time; after 260, an independent empire including Gaul, Spain, and Britain was established as a measure of self-defense in the wake of an invasion by the Germanic Franks. It was governed from Augusta Treverorum (Trier) by three successive rulers: Postumus, Victorinus, and Tetricus. In 273 the Roman emperor Aurelian reunited Gaul to the empire after defeating Tetricus near modern Chalons. The survival of locally minted coins and other artifacts from the period of the Gallic empire indicate a revival of the old Celtic tradition. The *limes* had been abandoned in 260, and in 275 the Agri Decumates was permanently evacuated. In 276, the country down to the borders of Spain was devastated by a new Germanic invasion. In the chaos that followed, bands of peasants and townsmen (*Bagaudae*) turned to brigandage. Order was restored once again by the emperors Aurelian and Probus, who fortified the principal towns to guard against future invasions.

Under Diocletian (reigned 284–305), Trier became the capital of one of the four new divisions of the empire, established to facilitate defense and administration. Gaul

The spread of Christianity

Diocletian's reforms

Political and economic integration

was governed by two "sub-emperors," Maximian (reigned 286–93) and Constantius Chlorus (reigned 293–306). Maximian established effective defenses against the Germans and suppressed the Bagaudae. Constantius put down the revolt of Marcus Aurelius Carausius in Britain and Gaul. The restoration of Gaul took 15 years, and the efforts of a numerous corps of officers and administrators. The old senatorial aristocracy was favoured once more. One of Constantius' projects was the revival of the school of rhetoric at Augustodunum (Autun).

In 306, on the death of Constantius, his son Constantine came to power. Seeking to make Trier the rival of Rome, Constantine beautified it with a circus, an amphitheatre, a forum, basilicas, and baths. In 312 he became emperor, and returned to Gaul only on short visits.

In 350 a usurper, Magnentius, tried to seize power, provoking a civil war in the course of which the Franks and Alemanni invaded northeastern Gaul. Julian (later, as emperor, called Julian the Apostate) defeated the Alemanni at Argentoratum (Strasbourg) in 357, and in the next few years expelled the Germans and reformed the administration of Gaul. The frontiers were precariously held until the great invasions of Vandals and other tribes at the end of 406. Even then Gaul remained a bastion of Roman civilization. A Roman general, Aetius, led his Gothic and Frankish allies to victory over the invading Huns in 451, and the classical literary tradition was kept alive in this last period of the empire by Ausonius, Symmachus, Sidonius Apollinaris, and other Gallic writers.

In the 5th century the Visigoths established themselves in Aquitania, the Franks occupied all of Belgica, and the Burgundians settled along the Rhine. Long before the Frankish Merovingians established control over the country in the early 6th century, Roman authority in Gaul had ceased to be a reality. (For the later history of the area, see MEROVINGIAN AND CAROLINGIAN AGE.)

HAMERTON, *The Mount: Narrative of a Visit to the Site of a Gaulish City on Mount Beuvray* (1897).

(J.-J.H.)

### Gaulle, Charles de

Charles de Gaulle twice saved his country from disaster and restored it to political and constitutional normality and twice retired voluntarily into private life when it became clear that he no longer had the support of the ma-

jority of his fellow citizens. A rare, if not unique, figure in political life, he combined these achievements with distinction both as a writer and as a military theoretician. Indeed, he did not emerge as a political figure until he was nearly 50 years old, though his previous career, both as soldier and writer, had already revealed some of the moral, intellectual, political, and temperamental qualities that characterized his subsequent career: first, as leader of a vanquished France and head of its first provisional postwar governments; second, as president of the Republic; and third, as autobiographer and historian of the events in which he had taken part.

Bruno Barbey—Magnum

De Gaulle, 1967.

Charles-André-Marie-Joseph de Gaulle was born on Nov. 22, 1890, in Lille. The second son of a Catholic, patriotic and nationalist, upper middle class family, he was brought up in a scholarly atmosphere. The family had produced historians and writers, and his father taught philosophy and literature. But as a boy, Charles de Gaulle already showed a passionate interest in military matters. He was trained at the Military Academy of Saint-Cyr and, in 1913, as a young second lieutenant, joined an infantry regiment commanded by Col. Philippe Pétain.

His military career showed him to be an intelligent, hard working, and zealous young soldier, a man of original mind, great self-assurance, and outstanding courage. In World War I, he fought at Verdun, was three times wounded, spent two years and eight months as a prisoner of war (during which time he made five unsuccessful attempts to escape), and was three times mentioned in dispatches. After a brief visit to Poland as member of a military mission, a year's teaching at Saint-Cyr, and a two-year course of special training in strategy and tactics at the École Supérieure de Guerre (War College), he was promoted by Marshal Pétain in 1925 to the Staff of the Conseil Supérieur de la Guerre (Supreme War Council). During 1927–29, and again during 1936–38, he served as major in the army occupying the Rhineland and was able to see for himself both the potential danger of German aggression and the inadequacy of the French defense effort. He also spent two years in the Middle East and then, having been promoted to lieutenant colonel, spent four years as a member of the secretariat of the Conseil supérieur de la Défense Nationale (National Defense Council).

His writing career began with a study of his reflections on the relation of the civil and military powers in Germany (*La Discorde chez l'ennemi*, 1924), followed by lectures on his conception of leadership, published in 1932, *Le Fil de l'épée* (English translation, *The Edge of the Sword*, 1960). A study on military theory, *Vers l'armée de métier*, in 1934 (English translation, *The Army of the Future*, 1940), defended the idea of a small professional army, highly mechanized and mobile, in

His early military career

preference to the static theories of the time, exemplified in reliance on the Maginot Line, which, running along the German and part of the Belgian frontier, was intended to protect France against German attack. He also wrote a memorandum in which he tried, even as late as January 1940, to convert politicians to his way of thinking. His views made him unpopular with his military superiors, and, in 1938, the question of his right to publish under his own signature a historical study of the French Army, *La France et son armée* (France and Her Army, 1945) led to a dispute with Marshal Pétain.

**World War II.** At the outbreak of World War II he was in command of a brigade of tanks attached to the French 5th Army. In May 1940, having been made a temporary brigadier general in the 4th Armoured Division—the rank that he retained for the rest of his life—he was twice given the opportunity to apply his theories on tank warfare, as far as that was possible with the inadequate material available at the time. As a result, he was mentioned by Gen. Maxime Weygand, the commander-in-chief, in a dispatch of June 2, as “an admirable, energetic, and courageous leader.” On June 6, he entered the government of Paul Reynaud as undersecretary of state for defense and war, and undertook several missions to England to explore the possibilities of continuing the war. When the Reynaud government was replaced by that of Marshal Pétain, who intended to seek an armistice with the Germans, de Gaulle left for England. On June 18, he broadcast from London his first appeal to his compatriots to continue the war under his leadership.

Contrary to popular legend, this appeal did not include the famous phrase: “France has lost a battle; she has not lost the war.” That phrase appeared on posters in England. But the emphasis was the same: the war could be won, France was not alone, General de Gaulle would lead French resistance from London. On August 2, 1940, a French military court tried him and sentenced him in absentia to death, deprivation of military rank, and confiscation of property.

De Gaulle entered on his wartime career as a political leader with tremendous liabilities. He had only a handful of haphazardly recruited political supporters and volunteers for what were to become the Free French Forces. He had no political status and was virtually unknown both in England and in France. What assets he had were wholly personal: his absolute belief in his own mission, his conviction that he possessed the qualities of leadership he had described in his writings, his total devotion to France, and the strength of character (or obstinacy, as it often appeared to the British) to fight for French interests as he saw them with all the resources at his disposal, however puny they might be. His impact on his hosts was unforgettablely described by Sir Winston Churchill in *Their Finest Hour*:

He had to be rude to the British to prove to French eyes that he was not a British puppet. He certainly carried out this policy with perseverance. He even one day explained this technique to me, and I fully comprehended the extraordinary difficulties of his problem. I have always admired his massive strength.

His liabilities in the eyes of his own countrymen were increased by the fact that, to the politicians of the left, a career officer who was a practicing Catholic was not an immediately acceptable political leader, while to those on the right he was a rebel against Philippe Pétain, a national hero and then France's only field marshal. Gradually, however, the course of the war, the broadcasts from London, the action of the Free French Forces, and the contacts of resistance groups in France either with his own organization or with those of the British secret services brought national recognition of his leadership. But full recognition by his allies came only after the liberation of Paris and the demonstration beyond all doubt of the French nation's acceptance of him.

Meanwhile, in London, de Gaulle's relations with the British government were never easy and de Gaulle often added to the strain, at times through his own misjudgment or touchiness. In 1943 he moved his headquarters to Algiers, where he became president of the French

Committee of National Liberation—the central organization guiding the Free French war effort—at first jointly with Gen. Henri Giraud. De Gaulle's successful campaign to edge Giraud out gave the world proof of his skill in political manoeuvre. On Sept 9, 1944, he and his shadow government—the Committee of National Liberation—returned from Algiers to Paris. He headed two successive provisional governments but, on January 20, 1946, abruptly resigned apparently owing to irritation with the political parties forming the left-wing tripartite coalition government.

From then until 1958 he remained an opponent of what became, in November 1946, the Fourth French Republic. He campaigned against the new constitution, which he disapproved of as being likely to lead to a repetition of the political and governmental inadequacies of the Third Republic, which in part had led to France's capitulation to Germany in 1940. In April 1947, he formed the *Rassemblement du Peuple Français* (RPF), a mass movement that grew rapidly in strength and that to all intents and purposes became a political party in 1951, when it obtained 120 seats in the National Assembly in the elections of that year. The movement expressed de Gaulle's hostility to the constitution, to the party system, and, in particular, to the French Communists, whom he described as *les séparatistes* because of their unswerving loyalty to Moscow directives. He became dissatisfied with the parliamentary group, however, and in 1953 severed his connection with the parliamentary organization. In 1955 the RPF organization in the country was disbanded.

From 1955 to 1958, the General himself made no public appearances but retired to his home in Colombey-les-deux-Églises, where he continued to write his memoirs. Between 1954 and 1969, three volumes were published, dealing with the years from 1940 to 1946 (*L'Appel*, 1940–42; *L'Unité*, 1942–44; and *Le Salut*, 1944–46; English translations: *The Call to Honour*, 1955; *Unity*, 1959; *Salvation*, 1960). The last was completed only after his return to power in 1958, and it is possible, therefore, that the reasons there given for his retirement in 1946 owe something to hindsight. “In the prevailing state of affairs, I decided to go, because the disease was too advanced to be cured before the inevitable upheaval.” At what precise point of time he began to feel that he might be called on to take up his mission again is a question on which accounts differ. The concluding words of the third volume of the memoirs describe his feelings during this period in the political wilderness but give no hint:

An old man, worn out by all that he has gone through, remote from events, feeling the cold approach of eternity, but never tired of looking for the gleam of hope among the shadows.

**Postwar return to public life.** His compatriots were deeply divided on the question of his return. The reasons for their hesitations belong to the political history of the period. But, to those who know them, these reasons help to justify the view that the opportunity that presented itself in May 1958 (when the insurrection that had broken out in Algiers threatened to bring civil war to France) must have entailed for de Gaulle the most carefully balanced calculation of a life that had had its share of political gambles. He was cautious, for it was by no means certain that the French Parliament would accept his return on any conditions that he could accept. He affirmed his determination not to come to power by other than legal means, and there was never any evidence of his association with insurgent plans to bring him back. It was in any case inconsistent with his conception of leadership either to risk becoming an instrument of sedition or to risk political failure. On the other hand, his carefully worded statements (on May 15, 19, and 27) certainly helped the insurgents. On June 1, three days after President René Coty threatened to resign unless de Gaulle's return to power was accepted, he presented himself before the National Assembly as a prime minister designate and on the following day attended the session (having been duly “invested” as prime minister) and was authorized to reform the constitution and accorded the special powers that he demanded.

President  
of the  
Republic

The man who then became head of government and, on Dec. 21, 1958, was elected president of the Republic had learned a great deal from his wartime exile and his postwar experiences, both in government and in opposition. The powers given to the president in the new constitution, which had been approved by referendum on Sept. 28, 1958, and especially those providing for the use of the referendum and for presidential rule during a state of emergency, reflected his firm conviction that a strong state required a leader with power to make decisions. His belief in his own "legitimacy"—by which he understood the essential rightness of his claim to be the leader and the incarnation of France—was now accompanied by the realization that his fellow citizens would share this view only in a crisis and that he must, therefore, take steps to retain the support of the general public and to disarm the power of "the system of parties" in Parliament, always potentially hostile to him. Since he believed firmly that power must rest on popular consent, his tactics were first to obtain consent to the personal control of government policy by the president and then to ensure its renewal in regular consultations through elections or referendums. He, therefore, undertook throughout his presidency what was virtually a continuous election campaign, in the form of provincial tours, in which he visited every *département* and during which he was able to meet ordinary citizens as well as local notabilities. He appeared on television several times a year. In order to be able to control government policy effectively, he relied as far as possible on ministers who were *compagnons*—that is, whose Gaullist loyalties went back to the wartime days—and he relied on their use of the constitutional provisions to curb the powers of the deputies to obstruct parliamentary business or harass governments. He retained the essential parliamentary function in a democracy; namely, the right to criticize governments and to withdraw confidence in them. The right of the National Assembly to dismiss governments was exercised on only one occasion, on October 5, 1962, in circumstances described below. There were frequent complaints of progovernmental bias on the radio, but these had been regularly made under pre-Gaullist regimes. Under a law of 1881, insults to the president of the Republic constitute an offense, and, though there was certainly more recourse to this law under the presidency of de Gaulle than under previous regimes, it presented no obstacle at all to political criticisms of Gaullist policies and Gaullist ministers in the press and in political parties, where criticism of the president's political actions and statements was continuous and widespread.

Accom-  
plishments

For the first four years of his presidency, de Gaulle's indispensability, as providing the only remaining hope of ending the Algerian war without civil disorder, protected him from serious challenge by his opponents. But the demands of the Algerian war prevented him from doing more than prepare the way for future positive policies. He used these years to strengthen the country's economic situation, to plan the future reorganization of the army, to develop an independent nuclear deterrent, and to prevent fresh "Algerias" in the future, by providing for the constitutional transformation of the African overseas territories into 12 politically independent states, still effectively bound to France by ties of language and culture, as well as by their need of French technical, financial, and administrative aid to ensure their political survival. But from the middle of 1962 onward, with the recognition of an independent Algerian state, it became necessary to consolidate his own position by obtaining a fresh vote of confidence from the electorate, for he was no longer politically indispensable.

One lesson that he had learned from his experience as wartime leader and from the failure of the RPF was that his personal position was stronger if he remained, at least in theory, above the political and party battle, as he had tried to do during the wartime and early postwar years. In his press conference of Oct. 23, 1958, before the elections of 1958, he had therefore forbidden his supporters to use his name, "even in the form of an adjective," in the title of any group or candidate. In 1962

the issue on which he asked for the renewal of confidence in his leadership was the constitutional provision governing the election of the president. He offered the electors the choice between his resignation and acceptance of a constitutional amendment substituting election by universal suffrage for election by an electoral college consisting of some 80,000 members, mainly mayors and local notabilities. On October 28, the electors' reply was 13,150,516 votes in favour of the amendment and 7,974,538 against. The government's defeat in the National Assembly, on a censure motion condemning the use of the referendum in order to amend the constitution, entailed a general election in November, in which the Gaullist party gained an additional 64 seats, thus obtaining, with the support of a group of some 30 conservative deputies, a majority in the National Assembly. The first real challenge to the continuance of his mission had been successfully met. From November 1962 onward, he was in a position of strength that allowed him to carry out, with public consent, the plans that he regarded as essential in order to restore France to the status in the world that he had always regarded as its permanent right—that of a great power, in no way inferior to those whom he liked to call "the Anglo-Saxons." His methods belonged essentially to the man. As a soldier, he had always seen military problems as inseparable from politics. As a statesman, he fought his political battles like a military campaign, using all the devices that he had learned to use so effectively in his dependent situation in London, in order to transform France's postwar international position of weakness into one of strength and to overcome opposition to his plans at home. These devices have been often described by his fellow citizens: "egoism, pride, aloofness, guile," according to Raymond Aron; "empiricism, intuition, flexibility of mind if not of soul . . ." according to one of the most perceptive of his biographers (Jean Lacouture, *De Gaulle*).

During the first phase of his subsequent career, from 1962 until his re-election as president in 1965, he used the European Economic Community (EEC) as an instrument in the service of French interests and especially of agricultural interests. He attempted to use it to establish a European political community, of which France would be the leader, but fell back on German cooperation under the Franco-German Treaty of January 1963, when it was clear that agreement on political cooperation was not obtainable from France's five partners. The rejection, in January 1963, of Great Britain's application to join the EEC was also a personal decision. France's participation in the supranational defense organizations of the North Atlantic Treaty Organization (NATO) was progressively withdrawn, because de Gaulle's policy for France was one of "national independence" and of international cooperation based, not on any supranational organization but only on agreements between nation-states. This was the main theme of his presidential campaign in 1965. On Dec. 21, 1965, he was re-elected, though only on the second ballot, and on March 7, 1966, he announced France's complete withdrawal from NATO, though not from the Atlantic Alliance.

During the three years and four months of the second term of his presidency, he turned his attention increasingly to wider fields. He had already begun the policy, described by him as that of "*détente* and cooperation" with countries behind the Iron Curtain, by encouraging trade and cultural relations with the Soviet Union and the countries of eastern Europe, and by recognizing Communist China in January 1964. For the solution of the conflict in Indochina he advocated a policy of neutrality for all nations concerned. This was to be based on a negotiated peace, of which a necessary preliminary was to be the withdrawal of all U.S. troops from Vietnam, though he never indicated at what date he thought this might become possible. These activities, together with visits to Mexico, all the countries of Latin America, Canada, and the Far East, formed part of a consistent policy aiming first at increasing the influence of France in French-speaking countries or countries in which there existed some bond derived from a common attachment

Second  
term

to Latin culture; then in Europe, which he saw as going, sooner or later, beyond the boundaries created by membership in the European Economic Community or the division into western and eastern blocs; and finally in a world, in which he foresaw the gradual dissolution of the two great blocs. In his scheme, France could hope to play an important role, both by virtue of its independence of, and its good relations with, the Soviet Union as well as the United States and by virtue of the confidence in France that this independence could create in the uncommitted nations of sub-Saharan Africa and more especially in the countries of the Middle East and North Africa, which belonged, as he saw it, to France's natural sphere of influence.

Circumstances were against his success. First, while remaining within the Atlantic Alliance and dependent in practice on U.S. nuclear defense, he felt obliged to take up attitudes that were generally interpreted as anti-American. Anti-Americanism was popular with many of the uncommitted countries that he hoped to influence, and wartime experiences had made it popular with many of his own countrymen. But it was not popular with his partners in Europe. Second, the theory of what he called "desatellization," the progressive loosening of the Soviet hold on the countries of eastern Europe, was brutally invalidated by the Soviet invasion of Czechoslovakia in 1968. Nor was there any evidence that France carried any real weight with the countries that it hoped to influence. The Latin American tour did nothing to weaken the dominant influence of the United States. De Gaulle's policies of neutrality, whether in the Vietnamese War or in the Arab-Israeli War of 1967, did not influence the combatants nor were his *bona fides* as an "honest broker" recognized by them. In any event, as the political and economic crisis of May 1968 revealed, France had neither the internal cohesion nor the financial resources to play the role of leader in what, in his frequently repeated but never defined phrase, de Gaulle called "Europe from the Atlantic to the Urals."

It was the impact of cold facts such as these that led many of his opponents to conclude with Jean Lacouture that:

Of all contemporary statesmen, Charles de Gaulle is the one whose political destiny will be seen to have depended most constantly on words. The soldier—brought out of obscurity by writing a book; the rebel—made into the leader of a nation by a speech; the man in opposition—who survived politically owing to a few interviews with the press; the President ruling by radio and television; and finally the lone wolf—in touch by words alone with the fickle mob. . . .

The truth is far more complex, though the last year of his presidency certainly justified the view that he could no longer count on his "words"—what it was then fashionable to call charisma but what he preferred to call "the personal equation." For this, circumstances were mainly responsible. His strength had been in his appeal for unity against a common enemy—in 1940, Germany; in 1958, subversion and civil disorder. In 1968 there was no common enemy. Once order had been restored, the students' and workers' revolt was seen for what it was, a temporary outburst of hysteria by sections of the community with real grievances but mutually incompatible aims. The solution of their problems required the patient negotiation of a government rather than leadership by a man of destiny. Moreover, the first of his broadcasts during the disturbances (on May 24), with its call for yet another referendum and its promises of "participation," proved ineffectual. The second, on May 30, was authoritative and brought a massive demonstration of support and a landslide Gaullist victory in the subsequent election, but the victory was for peace and normality rather than for the President and his policies.

There is no doubt that in the long run de Gaulle's position was weakened by the revolt of May 1968. When, in April 1969, he called once again for a referendum, it was not clear whether or not he really wanted to remain in power. If he did, he made three major errors of judgment. First, the referendum, calling for the acceptance of regional reorganization and a reform of the Senate, was

presented to the electors, as other referenda had been, as a choice between acceptance of both (though the second measure was generally unpopular) or of his own resignation. Second, the diplomatic methods that had been welcomed during his first term, as assertions of France's claim to equality with, and influence among, the great powers had been creating increasing unease for the past few years. In September 1966, his advocacy in Phnom Penh of Vietnamese neutrality had been widely interpreted as an expression of personal anti-Americanism. In 1967, on his visit to Canada, he had seemed to be actively encouraging French-Canadian separatism. His declarations of neutrality in the Arab-Israeli War had seemed, to a population that was in the main pro-Israel, to show pro-Arab bias. France was not actively involved in, but had not formally withdrawn from, the Atlantic Alliance, and the so-called independent nuclear deterrent was neither independent nor within France's means, as the cost in terms of neglect of the needs of conventional forces and of basic social and economic reforms was by then revealing. And, third, the question: "After de Gaulle, who?" had been answered by the president himself, when he dismissed Georges Pompidou in 1968 after a record six years as prime minister, thus leaving him free to present himself in his own way as a credible and acceptable successor to the presidency.

On April 28, 1969, following his defeat in the referendum, de Gaulle resigned and returned to Colombey-les-Deux-Églises, to permanent retirement and a resumption of the writing of his memoirs. He died there on November 9, 1970, of a heart attack. Throughout the decade of his presidency, his aims and actions had been the subject of more exegesis and speculation than those of any other French statesman.

**Assessment.** To some, de Gaulle was a 19th-century traditionalist or a nationalist—perhaps influenced by the ideas of Charles Maurras—who sought to recover for France a status that was no more than an outdated dream, while his picture of France was a nostalgic abstraction. To others, he was a farsighted statesman, subtle, and intelligent, who merely used popular "myths" as a means of persuading his fellow countrymen to accept his leadership, while he sought to compel them to make the economic and political adjustments required by the conditions of the 20th century. And there were some to whom de Gaulle's ideas themselves were also, in part at least, popular myths used by him as political instruments to enable him to take the maximum advantage of circumstances. These saw him as a pragmatist, an opportunist, even a gambler, doing what he could in incredibly difficult circumstances but with a fundamental fatalism, even pessimism, regarding the extent to which any political leader can change the "nature of things" or any French leader the nature of French politics. To some, he offered the only hope of obtaining the political stability that had eluded all regimes since the Revolution. But to others, he was inescapably an anachronism, because they saw him only as a man to turn to in a crisis, a man "at his best in the storm" and, as such, a passing phenomenon.

History will certainly recognize his undeniable qualities. As president, he maintained a regime of republican legality demonstrably based on popular consent and, when that ceased to be forthcoming, left the scene with dignity. He settled the problem of Algeria when no one else could, and though the cost in internal dissension and violence was high, the patience and political astuteness that he brought to what had seemed an insoluble task prevented the cost from being much higher. He achieved the peaceful "decolonization" of France's African territories in the shortest possible time, with a minimum of friction and a maximum of cooperation. These were personal achievements in the sense that he alone combined the sureness of purpose, authority, and courage to take the necessary decisions with all the political and personal risks that they often entailed—and these included several attempts to assassinate him. He also had the courage both to undertake unpalatable policies and to confront his compatriots with uncomfortable facts.

The qualities were accompanied by political and per-

Retirement  
and death

Crisis of  
May 1968

sonal liabilities, the consequences of which were bound to create problems for post-Gaullist statesmen. He was neither a team man nor a conciliator but a man alone, who disliked sharing either power or credit with ministers, Parliament, or parties, apparently refusing to recognize that these, imperfect as they may be, make up the permanent machinery of all stable democratic government. He served eternal France while distrusting Frenchmen and sometimes combined farsighted political strategy with nearsighted and even petty personal tactics. As an internationalist he understood the need for the strong to help the weak better than the need, at times, to make concessions that might be to France's short-term disadvantage in the interests of its long-term international relations.

As revealed in the memoirs, the personality of the man is deliberately submerged in that of the statesman and the leader. He appears as an artifact, the embodiment of "the leader" he describes in *Le Fil de l'épée*, and is often, indeed, referred to in the third person. That is how his contemporaries saw him. His personality is in sharp contrast with that other national hero in the same "darkest hour." While Winston Churchill was a career politician with a profound faith in Parliament and a passionate interest in defense, an expansive, warm-hearted man, with capricious, and even puckish, streaks, Charles de Gaulle was a career soldier with a passionate, indeed all-consuming, interest in politics and a profound contempt for career politicians. He was an aloof and remote man, because, in his own words, "authority requires prestige, and prestige requires remoteness." Future biographers may find, as their predecessors have done, that the "private face" of de Gaulle remains unknown and is perhaps unknowable.

**BIBLIOGRAPHY.** JEAN LACOUTURE, *De Gaulle* (1969; Eng. trans., 1970), the most penetrating study to date; AIDAN CRAWLEY, *De Gaulle* (1969), a critical but fair-minded study from a British point of view; EDWARD ASHCROFT, *De Gaulle* (1962), a straightforward account of his life up to 1962, sympathetic to Gaullism; DAVID THOMSON, *Two Frenchmen: Pierre Laval and Charles de Gaulle* (1951), the best short study of the pre-war military career and the war years; FRANÇOIS MAURIAC, *De Gaulle* (1964; Eng. trans., 1966), an adulatory biography including copious quotations from de Gaulle's speeches and press conferences; ALEXANDER WERTH, *De Gaulle* (1965), a journalistic, readable account; F.R. WILLIS (ed.), *De Gaulle: Anachronism, Realist, or Prophet?* (1966), a symposium on different aspects of de Gaulle that is somewhat superficial, but provides a useful introduction.

(D.M.P.)

## Gauss, Carl Friedrich

Carl Friedrich Gauss, who, with Archimedes and Newton, ranks as one of the greatest mathematicians of all time, at an early age overturned the theories and methods of 18th-century mathematics and, following his own revolutionary theory of numbers, opened the way to a mid-19th-century rigorization of analysis. Although he contributed significantly to pure mathematics, he also made practical applications of importance for 20th-century astronomy, geodesy, and electromagnetism. His own dictum, "Mathematics, the queen of the sciences, and arithmetic, the queen of mathematics," aptly conveys his perception of the pivotal role of mathematics in science.

Born on April 30, 1777, in Brunswick, now in West Germany, Gauss was the only son of poor parents. Impressed by his ability in mathematics and languages, his teachers and his devoted mother recommended him to the Duke of Brunswick, who granted him financial assistance to continue his education in secondary school and from 1795 to 1798 to study mathematics at the University of Göttingen. In 1799 he obtained his doctorate in absentia from the university at Helmstedt. The subject of his dissertation was a proof of the fundamental theorem of algebra—which was proven only partially before Gauss—which states that every algebraic equation with complex coefficients has complex solutions; moreover, Gauss skillfully formulated and proved this theorem without the use of complex numbers.

At age 24 he published the *Disquisitiones Arithmeticae*,

Gauss, oil painting by C.A. Jensen (1792–1870). In the Archiv der Georg-August-Universität, Göttingen, West Germany.

By courtesy of the Archiv der Georg-August-Universität, Göttingen, West Germany

one of the most brilliant achievements in the history of mathematics, in which he formulated systematic and widely influential concepts and methods of number theory—dealing with relationships and properties of integers ( $-2, -1, 0, +1, +2, \dots$ )—which, for him, was of paramount importance in mathematics. He dealt extensively with the theory of congruent numbers—(i.e., those numbers that have the same remainder when they are divided by another number (for example, 7 and 9 are congruent modulo the number 2 since there is a remainder of 1 when each is divided by 2); he gave the first proof of the law of quadratic reciprocity, which has to do with the quadratic residues ( $a$  is called quadratic residue with respect to  $b$ , if there is an integer  $x$  such that when  $a$  is divided by  $b$ , the remainder is the same as  $x^2$  divided by  $b$ ); and he applied this law to special cases of equations in which he was able to bring together algebraic, arithmetic, and geometric ideas. Using number theory, for example, Gauss proposed an algebraic solution to the geometric problem of constructing a regular polygon that has  $n$  sides. Euclid had shown that regular polygons, with 3, 4, 5, and 15 sides and those the sides of which result from doubling the above could be constructed geometrically with compass and ruler. No progress had been made in this subject since then. Gauss developed a criterion based on number theory by which it can be decided whether a regular polygon with any given number of corners can be geometrically constructed: these include, for example, the regular polygon with 17 sides, which he inscribed within a circle using only compass and ruler, the first such discovery since the time of Euclid.

This work on number theory contributed to the modern arithmetical theory of algebraic numbers—that is, to the solution of algebraic equations—in which Gauss introduced the first step—that is, the arithmetic of all complex numbers  $a + b\sqrt{-1}$ , in which  $a$  and  $b$  are integers. The complex numbers  $a + b\sqrt{-1}$  had been introduced only intuitively before Gauss. In the *Disquisitiones Arithmeticae* Gauss did not hesitate to use complex numbers  $a + b\sqrt{-1}$ , in which  $a$  and  $b$  are real numbers. In 1831 (published 1832) he gave a detailed explanation of how an exact theory of complex numbers can be developed with the aid of representation in the  $x, y$  plane.

In 1801 Gauss had the opportunity to apply his superior computational skills in a dramatic way and, by so doing, to express gratitude to the Duke for assisting him in obtaining an education. On the first day of the year, a body, subsequently identified as an asteroid and named Ceres, was discovered as it seemed to approach the Sun. Astronomers had been unable to calculate its orbit, although they could observe it for 40 days until lost from view.

Contributions to number theory

Astronomical and geodetic research

After only three observations Gauss developed a technique for calculating its orbital components with such accuracy that several astronomers late in 1801 and early in 1802 were able to locate Ceres again without difficulty. As part of his technique, Gauss used his method of least squares, developed about 1794, a method by which the best estimated value is derived from the minimum sums of squared differences in a particular computation. This achievement in astronomy won Gauss prompt recognition. His methods, which he described in his book, in 1809, *Theoria Motus Corporum Coelestium*, are still in use today, and only a few modifications have been required to adapt his methods for modern computers. He had similar success with the asteroid Pallas, for which he refined his calculations to take into account the perturbations of its orbit by planets.

The Duke continued to finance Gauss's research so generously that in 1803 he was able to decline an offer of a professorship in St. Petersburg, where he was by then a corresponding member of the Academy of Sciences. In 1807 he became professor of astronomy and director of the new observatory at the University of Göttingen, where he remained for the rest of his life. His first wife died in 1809, after a marriage of four years and soon after the birth of their third child. From his second marriage (1810–31) were born two sons and a daughter.

About 1820 Gauss turned his attention to geodesy—the mathematical determination of the shape and size of the Earth's surface—to which he devoted much time in theoretical studies and field work. To increase the accuracy of surveying he invented the heliotrope, an instrument by which sunlight could be utilized to secure more accurate measurements. By introducing what is now known as the Gaussian error curve, he showed how probability could be represented by a bell-shaped curve, commonly called the normal curve of variation, which is basic to descriptions of statistically distributed data. He also was interested in determining the shape of the Earth by actual geodetic measurements, which led him back to pure theory. Using data from these measurements, he developed a theory of curved surfaces by which characteristics of a surface could be found solely by measuring the lengths of the curves that lie on the surface. This "intrinsic-surface theory" inspired one of his students, Bernhard Riemann, to develop a general intrinsic geometry of spaces with three or more dimensions. It was the subject of Riemann's inaugural lecture at Göttingen in 1854, and is said to have agitated Gauss. About 60 years later Riemann's ideas formed the mathematical basis for Einstein's general theory of relativity.

Gauss was one of the first to doubt that Euclidean geometry was inherent in nature and thought. Euclid was the first to build a systematic geometry. Certain basic ideas in his model are called axioms; they were the points of departure from which his entire system was constructed through pure logic. Of these, the parallel axiom played a prominent role from the beginning. According to this axiom, only one line can be drawn parallel to a given line through any point not on the given line. From this axiom soon arose the supposition that it can be deduced out of the other axioms and thus can be omitted from the system of axioms. All proofs of it however contained errors, and Gauss was one of the first to realize how there might be a geometry in which the parallel axiom does not apply. Gradually he came to the revolutionary conclusion that there is indeed such a geometry that is internally consistent and free of contradiction. Because it ran counter to contemporary views, he feared publication (see GEOMETRY, NON-EUCLIDEAN).

When a Hungarian, János Bolyai, and a Russian, Nikolay Lobachevsky, independently published a non-Euclidean geometry around 1830, Gauss announced that he had made the same conclusions approximately 30 years before. Neither did he publish his work on special complex functions, perhaps because he was unable to derive them from more general principles. Thus, this theory had to be reconstructed by other mathematicians from his calculations in work extending over several decades after his death.

Closely related to his interest in gravitation and magnetism was his published paper in 1840 on real analysis. This paper became the starting point for the modern theory of potential. It is probably the only work he did that failed to meet his own high standards. Only at the beginning of the 20th century was it possible for mathematicians to develop potential theory anew, on the basis of different principles or by finding the conditions under which Gauss's conclusions are completely correct.

Around 1830, principles of extremals (maximum and minimum quantities) began to assume a substantial role in his mathematical investigations of physical problems, such as the conditions in which a fluid remains at rest. In his treatment of capillary action, he devised mathematical formulations that took into account the mutual actions of all the particles in a fluid system, the force of gravity, and the interaction of its fluid particles and the particles of solid or fluid with which it is in contact. This work contributed to the development of the principle of the conservation of energy. Beginning in 1830, Gauss worked closely with the physicist Wilhelm Weber. As a result of their intense interest in terrestrial magnetism, they organized a worldwide system of stations for systematic observations. The most important practical result of their work in electromagnetism was the development, by other workers, of electric telegraphy. Because their finances were limited, their experiments were conducted on only a small scale; Gauss was rather frightened at the thought of worldwide communication.

Gauss was deeply religious, aristocratic in bearing, and conservative. He remained aloof from the progressive political currents of his time, asking only that his country enable him to do his creative work undisturbed. In Gauss, apparent contrasts were combined in an effective harmony. A brilliant arithmetician with a phenomenal memory for numbers, he was at once a profound theoretician and an outstanding practical mathematician. Theory and practice were mutually stimulating to him. Teaching was his only aversion, and, thus, he had only a few students. Instead, he effected the development of mathematics through his publications, about 155 titles, to which he devoted the greatest care. Three principles guided his work: "Pauca, sed matura" ("Few, but ripe"), his favourite saying; the motto "Ut nihil amplius desiderandum relictum sit" ("That nothing further remains to be done."); and his requirement of utmost rigour. It is evident from his posthumous works that there are extensive and important papers that he never published because, in his opinion, they did not satisfy one of these principles. He pursued a research topic in mathematics only when he might anticipate meaningful relationships of ideas and results that were commendable because of their elegance or generality. He was not inspired by the prospect of practical applications, for he sought truth for its own sake, finding his reward and pleasure in the success of his efforts alone.

The golden anniversary of the granting of the doctorate to Gauss was celebrated in 1849. For this event, he prepared a new edition of his earlier proofs of the fundamental theorem of algebra, which, because of his declining health, was his last publication. The honour that gave him the greatest joy, however, was the bestowal of honorary citizenship on him by the city of Göttingen. On the basis of his outstanding research in mathematics, astronomy, geodesy, and physics, he was elected as a fellow in many academies and learned societies. He declined numerous invitations of other universities to become a professor, and remained on the faculty of the University of Göttingen until his death on February 23, 1855. Soon after his death, coins were struck in his honour. The title of *mathematicorum princeps* is a fitting tribute.

## Gay-Lussac, Joseph-Louis

The French chemist and physicist Joseph-Louis Gay-Lussac was a pioneer in the study of gases, recognizing the simplicity of the laws describing the physical properties and chemical reactions of matter in the gaseous state. He also made a variety of significant contributions to all branches of chemistry and excelled in careful quantitative experimentation.

Gay-Lussac, engraving by Ambroise Tardieu (1788–1841).  
By courtesy of the Bibliothèque Nationale, Paris

Gay-Lussac was born on December 6, 1778, at Saint Léonard in the *département* of Haute-Vienne. His father, a public official and judge under Louis XVI, was imprisoned for aristocratic sympathies during the Revolution. Young Gay-Lussac entered the new École Polytechnique in Paris in 1797 and was graduated in 1800. He started further engineering studies at the École des Ponts et Chaussées but withdrew in 1801 when invited to become assistant to the distinguished chemist Claude-Louis Berthollet. Much of Gay-Lussac's early research was done in the laboratory at Berthollet's country house at Arcueil, near Paris. This village was the centre of an active group of young scientists known as the Arcueil circle and guided by Berthollet and Pierre-Simon Laplace, both of whom enjoyed the patronage of Napoleon.

Gay-Lussac's first major investigation was a study of the thermal expansion of gases. In 1802 he showed that all gases expand by the same fraction of their volume for the same increase in temperature. The existence of this common thermal-expansion coefficient made it possible to define a new temperature scale, the profound thermodynamic significance of which was established by Sir William Thomson (later Lord Kelvin) almost half a century later.

On August 24, 1804, Gay-Lussac and Jean-Baptiste Biot ascended in a hydrogen-filled balloon to a height of some 13,000 feet (about 4,000 metres) in order to study the variation of the Earth's magnetic intensity with altitude. Gay-Lussac made a second ascent alone on September 16 of the same year, reaching a height of 23,018 feet (7,016 metres), an altitude record that was unbroken for half a century. On his second flight Gay-Lussac repeated the magnetic measurements, studied the variation of pressure and temperature, and collected samples of air at an altitude of more than 20,000 feet (6,000 metres). He concluded from his observations and subsequent analyses that both the Earth's magnetic intensity and the chemical composition of the atmosphere were constant up to the altitude he had reached.

Shortly after the balloon flights, Gay-Lussac began to

collaborate with Alexander von Humboldt, a Prussian nobleman, world traveller, self-taught scientist, and (later) scientific popularizer, who was then a new member of the Arcueil circle. Their experiments led in 1805 to a precise determination of the relative proportions with which hydrogen and oxygen combine to form water. Gay-Lussac emphasized that the proportion by volume rather than by weight should be studied, and the results justified his position: one volume of oxygen combines with two volumes of hydrogen in forming water.

On December 31, 1808, the year in which he was married, Gay-Lussac announced the law that now bears his name and constitutes his greatest contribution to science. By this time he had been elected a member of the Institut de France and appointed to a professorship in Paris. His chemical researches in collaboration with another French chemist, Louis-Jacques Thenard, had brought him back to the problem of the proportions in which chemical reagents combine. His own experiments, in conjunction with results already reported by others, led Gay-Lussac to the conclusion that "gases combine in very simple proportions" and that "the apparent contraction in volume which they experience on combination has also a simple relation to the volume of the gases, or at least to one of them." This relationship is known as the law of combining volumes and as Gay-Lussac's law. Among the simple proportions he cited as examples were the equal combining volumes of hydrogen chloride and ammonia and the 2:1 ratio of the combining volumes of carbon monoxide and oxygen.

Gay-Lussac pointed out that the simple regularities of his law were realized only for gases, for which matter behaves in the simplest and most universal manner. It is worth noting that the English chemist John Dalton's laws of definite and multiple proportions in chemical composition (formulated in the same period) referred to combining weights and not to volumes. This basic difference in approach led each scientist to be skeptical of the other's results, and they did not reach mutual understanding. (The Italian physicist Amedeo Avogadro showed how the results of Dalton and Gay-Lussac could be reconciled.)

The collaborative work Gay-Lussac did with Thenard was prompted by Sir Humphry Davy's successful electrochemical research, and they used methods similar to Davy's to study the chemical effects of the electric current. After Davy isolated potassium and sodium, Gay-Lussac and Thenard prepared much larger quantities of the two newly discovered elements by purely chemical methods and were able to establish the properties of potassium. They anticipated Davy in discovering the element boron, which they named. Gay-Lussac and Davy independently and virtually simultaneously studied the properties of iodine (named by Gay-Lussac) in 1813.

Gay-Lussac's studies of hydrogen chloride, hydrogen iodide, and hydrogen fluoride prepared the way for a new theory of the nature of acids, although Gay-Lussac himself did not formulate it. (It had been held several years earlier by Antoine Lavoisier that oxygen is a common constituent of all acids.) In further work along this line, Gay-Lussac showed prussic acid (hydrocyanic acid, or hydrogen cyanide) to be composed only of hydrogen, carbon, and nitrogen. In 1815 he identified the gas cyanogen, (CN)<sub>2</sub>, and pointed out that the combination of one carbon atom (C) and one nitrogen atom (N) acted as a compound radical—i.e., a group of atoms acting as a single unit in chemical reactions.

Among Gay-Lussac's many other investigations were his early analyses of vegetable and animal substances, his studies of the solubility of salts as a function of temperature, and his important contributions to volumetric analysis. In 1832 he gave up his professorship of physics to accept the chair of chemistry at the Muséum National d'Histoire Naturelle in Paris. He also held a number of advisory positions, in which he used his technical knowledge to suggest improvements in industrial chemical processes.

He was elected to the Chamber of Deputies in 1831, 1834, and 1837 and in 1839 accepted a peerage from Louis-Philippe, after having refused one that had been

Gay-Lussac's law

Early investigations

offered years earlier by Charles X. Gay-Lussac died in Paris on May 9, 1850, and was buried in Père Lachaise Cemetery.

**BIBLIOGRAPHY.** A more detailed discussion of Gay-Lussac's work may be found in the article by MAURICE P. CROSLAND in *Dictionary of Scientific Biography*, vol. 5, pp. 317-327 (1972), that contains a bibliography of Gay-Lussac's major works and works about him. See also CROSLAND's *The Society of Arcueil: A View of French Science at the Time of Napoleon I* (1967); and EDMOND BLANC and LEON DELHOUME, *La vie émouvante et noble de Gay-Lussac* (1950).

## Gemstones

The word gem derives from the Latin *gemma*, "a bud," which was once used for engraved stones such as cameo or intaglio. Subsequently it came to embrace those minerals, except the metals, that man uses for personal adornment. The term has been extended to include pearl and a few other materials of organic origin. It is still true that diamond, ruby, emerald, and sapphire come first to most minds, but less popular gems may surpass some of the above in beauty and indeed in value. In his desire for more of these beautiful objects than nature has provided, man has striven to synthesize them, and in recent time he has met with considerable success. It is still possible, however, to distinguish the synthetic from the natural, and each occupies its own role in the modern world. Some of the synthetic gems have important applications in industry and have supplanted the natural material. In the field of gems, however, the natural still holds prime place and value. By the middle of the 20th century, the terms precious and semiprecious, once applied to gems, largely had been discarded.

The use of gemstones dates to prehistory; evidence of their use turns up in graves wherever man dwelt. They were used for decoration and as amulets, and because of their value, they could be used as currency; the treasuries of many countries, particularly in the East, bulked large with gemstones. They still offer a means of condensing great value into minimum bulk for easy and hidden transportation.

For much relevant information on the mineralogy and crystallography of the gemstones, see also MINERALS; the separate articles on pertinent mineral groups (e.g., OLIVINES; SILICA MINERALS); and for individual gem and mineral entries, see RELATED ENTRIES under GEMSTONES in the *Ready Reference and Index*.

### GEM MINERALS

Although there are approximately 2,000 mineral species, less than 100 of these provide material usable for gems. The number is very much less if only those commonly for sale in the average jewelry store are considered. Some of these minerals supply more than one gem (e.g., corundum: ruby and sapphire), and in the following discussions, the gems will be discussed under the appropriate mineral name.

Qualities  
required in  
a gem

Why is a gem so designated? What makes it one? The prime requisite for a gem is that it must be beautiful: if it does not attract, then it is worthless. The beauty may lie in colour or in lack of colour. In the latter case, extreme limpidity or "fire" or both may provide the attraction. Iridescence, opalescence, asterism, chatoyance, pattern, and lustre are other features that may make a material beautiful. It must also be rare and durable. The latter is necessary if the gem is to retain the polish applied to it and to withstand the wear and tear of constant handling. These features make a gemstone, but fashion also plays a part. Not all gems have these requisites in the same degree, which is, of course, the reason for variation in value of different minerals and of different gems of the same mineral.

**Beryl.** Beryl is a mineral that provides four specifically named gems of different colours: emerald, green; aquamarine, blue; morganite, pink; and heliodor, golden. In addition, some gems may be known as beryl but with the appropriate colour prefixed. The mineral is a beryllium

aluminum silicate, and the several named varieties differ from each other in many small ways.

**Emerald.** Emerald, the green beryl, is, after ruby, the most valuable gem. It owes its colour to the presence of a trace of chromic oxide; variations in the colour of emeralds may be due to additional traces of iron and possibly vanadium. The earliest known mines for emerald were in Egypt in the Sikait-Zubara region near the Red Sea. Operated as early as 2000 BC, then lost for centuries, their locations were rediscovered only in the 19th century. It is probable that the emeralds of virtually all ancient jewelry came from these so-called Cleopatra's Mines.

Figure 1: Emerald box from the crown jewels of Iran. Size c. 6 × 5 × 3 cm.

The world's finest emeralds come from Colombia. Those from the Chivor Mine are blue-green and occur in pockets of crystals with albite and pyrite in fissure veins in clayey sediments of (probably) Cretaceous age. These Chivor emeralds have tiny, well-formed crystals of pyrite, which identify their locality. The emeralds found at the Muzo Mine are a rich, velvety green. They occur with quartz in calcite veins in limestones and shale. Colombian emeralds appear distinctly red when viewed through a Chelsea filter; Siberian emeralds appear pink, but most other emeralds appear green.

When the Spaniards invaded South America, they found the Incas in possession of vast quantities of fine emeralds, which they seized and transported to Europe, where they were avidly received. The French traveller and jewel trader Jean-Baptiste Tavernier, in his *Travels in India* of Jean Baptiste Tavernier, states that the Spaniards carried emeralds across the Pacific Ocean to Southeast Asia. These fine emeralds were purchased in tremendous quantity by the Moghuls and in due course fell into the hands of the Persian Nadir Shah in the sack of Delhi in 1739. Thousands of these emeralds, five over 300 carats in weight, still grace the collection of the crown jewels of Iran.

The Russians, who had long shown a liking for emeralds, in 1830 located a deposit of emeralds in mica, talc, and chlorite schists in the Ural Mountains near Ekaterinburg, now known as Sverdlovsk. These gems are lighter in colour than the Colombian stones and in general more flawed.

Emeralds have been found also in New South Wales, Western Australia, the State of Rājasthān in India, Brazil, Austria, Transvaal, and Rhodesia. Those from Rhodesia are small but of superb quality.

Because of their high value, few large, fine emeralds are included in Western museum collections, but there is a fine 48-carat, hexagonal cut emerald in the Palace da Ajuda, Lisbon. Many fine emeralds, including a step cut of 136.25 carats, are exhibited in the Armoury and Diamond Fund in the Kremlin in Moscow and in the

Topkapi Museum in Istanbul, but without doubt the largest and finest collection of this beautiful gem is in the crown jewels of Iran.

**Aquamarine.** Aquamarine is the sky-blue to greenish-blue variety of beryl, the most prized colour being the former. The colour is due to a trace of iron and usually is original, but it often is produced by heat treatment of greenish or even brownish crystals. Crystals usually show more complex terminations than do emeralds and may occur in large size and flawless condition, usually in pegmatite (coarse granite) dikes. Along with beryl of other colours it is found in Minas Gerais, Brazil, near Sverdlovsk in the Urals, and in some other localities in the U.S.S.R. It is found also in the Malagasy Republic and several places in the New England states of the U.S. The Smithsonian Institution and the Geological Museum, London, have large, fine aquamarines on display.

**Morganite.** The pink beryl is known as morganite after the American financier John Pierpont Morgan, who was a lover of gems. Its colour is due to the presence of a trace of lithium. Like other beryls, with the exception of emerald, crystals of this gem occur in pegmatite dikes. Fine gem material comes from Minas Gerais, Brazil, the Malagasy Republic, and San Diego County, California. A fine 236-carat morganite and several other large stones are displayed in the Smithsonian Institution, Washington, D.C.

**Yellow beryls and heliodor.** Yellow beryls in fine quality and colour are found usually wherever aquamarines occur. Many shades of colour, from greenish yellow through pure yellow to fine golden yellow (heliodor), may be procured. The yellow colour is probably due to iron, but that of heliodor is attributed to the presence of a trace of uranium oxide. A tremendous, 2,054-carat, greenish-yellow Brazilian beryl and a 133-carat, yellow Malagasy stone are displayed in the Smithsonian Institution.

**Other beryls.** When the green colour of beryl is caused by iron rather than chromium, the gem is referred to as green beryl. Colourless beryl is known sometimes as goshenite, but it is seldom cut as a gem. A bright orange coloured beryl, some of which has been cut into gems, has been mined in the Governador Valadares region of Minas Gerais, along with aquamarine. A nearly clean, 1,625-carat, step-cut orange stone is displayed by the Royal Ontario Museum. No special name has been given to this colour.

The various coloured beryls are simulated by other gems, synthetic corundum and spinel, and by glass. Emerald has been synthesized hydrothermally.

**Chrysoberyl.** The mineral chrysoberyl provides greenish-yellow, yellow, green, and brownish gems of the same name and, in addition, two other gems, alexandrite and cat's-eye (sometimes called cymophane). Chrysoberyl is an oxide of beryllium and aluminum. Chromic oxide in small amount replacing alumina gives the green colour to alexandrite. There are no synthetic chrysoberyls, but simulations of alexandrite are common. These are either synthetic corundum or synthetic spinel, with the former more common. It appears grayish green in daylight and rather purple in incandescent tungsten light. Quartz cat's eyes may appear similar to chrysoberyl cat's eyes, but the low specific gravity and hardness are positive identification.

Chrysoberyl is a pleasingly lively gem, which is usually faceted in mixed cut; however, alexandrite and cat's-eye are the more interesting. Alexandrite has the peculiar property of appearing green in daylight and red in incandescent tungsten artificial light. The change is so startling and these gems are so rare that they command a very high price. In cat's-eye, very narrow parallel hollow tubes cause a sharp cat's-eye or chatoyant effect when the stone is cabochon cut with the base parallel to the tubes. The fineness of the tubes also produces an opalescent appearance that distinguishes it from the quartz variety of cat's-eye. These gems also are held in very high esteem, the value increasing with the richness of colour and sharpness of line. The finest alexandrites

were found in mica schist with emerald, northeast of Sverdlovsk (Ekaterinburg) in the Ural Mountains of the U.S.S.R. The gem was named after Tsar Alexander II on whose 21st birthday the discovery was made. Alexandrites also are found as pebbles in the Ceylon gem gravels, but these are less prized than the Russian gems. Their colour is less green, in artificial light there is considerable brown in the red, and the colour change is often not so marked. The Ceylonese gem gravels are the most important source of cat's-eye, and the state of Minas Gerais, Brazil, produces the best chrysoberyls. Other localities for chrysoberyl are the Malagasy Republic; Mogok, Burma; and Rhodesia.

The Hope chrysoberyl, once in the Hope collection with the more famous Hope diamond, is a flawless, yellowish-green, oval brilliant that weighs 45 carats. It is displayed in the British Museum of Natural History along with two fine Ceylon alexandrites, a 43-carat, square brilliant and a somewhat smaller one of 27.5 carats. The Smithsonian Institution has a 66-carat Ceylon alexandrite, a 121-carat chrysoberyl, and two great cat's-eyes of 172 carats and 58 carats, the latter cat's-eye known as the Maharani.

**Corundum.** Corundum, the oxide of aluminum ( $Al_2O_3$ ), provides two gems, ruby and sapphire, which differ only in colour. The red gems are designated ruby and all other colours are sapphire. In the trade, however, sapphires other than blue in colour are called fancy sapphires. The name *padparadschah* (Sinhalese "lotus colour") is sometimes used for those sapphires of orange colour. The fine red colour of ruby is due to a trace of chromium oxide, that of blue sapphire to iron and titanium. Ruby is the most valued of gemstones, and its hardness of 9 exceeds that of any natural material save diamond.

Rubies and blue sapphires show marked dichroism (the property of presenting different colours in two different directions), and the darkest colour is presented when the stone is viewed along the hexagonal axis of the crystal. Faceted stones must be cut with the table facet at right angles to this direction in order to obtain the greatest depth of colour.

Mogok, 75 miles (120 kilometres) north of Mandalay, Burma, has produced the finest rubies from prehistoric times. Fine rubies, but of a slightly brownish hue, are produced in southeast Thailand and western Cambodia near the Thailand border. These rubies show little if any fluorescence. The red corundum of Ceylon is more correctly called pink sapphire. Ruby is also found in Tanzania, India, and a few other countries. Sapphires occur in and around Ratnapura, Sri Lanka (formerly Ceylon); Mogok, Burma; Kashmir; Thailand; Cambodia; Queensland and New South Wales, Australia; and Montana. Fine star rubies come from Mogok, whereas fine star sapphires have been found in both Mogok and Ceylonese deposits.

Rubies of large size have always been rare. Historically, any ruby found in the mines of Burma that exceeded ten carats was reserved to the ruler. It seems likely that many such stones were broken to reduce their weight and so save them from appropriation. Nevertheless, some did survive and many are displayed among the crown jewels of Iran. The finest and largest star ruby is the de Long (100 carats) in the American Museum of Natural History. The Smithsonian Institution displays 50- and 34-carat star rubies. The red gems known as the Timur ruby, Black Prince's ruby, and Catherine the Great's ruby, are all red spinels. Sapphires occur in larger size, and fine blue-faceted stones may be seen in such collections as the British and Iranian crown jewels. Large star sapphires also are known. The largest, the Star of India—a gray-blue, 563-carat stone from Ceylon—is in the American Museum of Natural History, as is the 116-carat, deep-purple Midnight Star. In the Smithsonian Institution are the blue, 330-carat Star of Asia; the blue, 316-carat Star of Artaban; and the blue, 98.6-carat Countess of Bismarck. The 194-carat, blue Star of Lanka and an unnamed blue, 174.76-carat star sapphire are in

the Royal Ontario Museum, along with a faceted, golden-yellow, 179.41-carat sapphire.

**Diamond.** Diamond is the most popular of gemstones and is supposed to be the symbol of true love. It is the hardest substance known and is ranked 10 on the Mohs Scale. Sometimes there are so many natural faces on a diamond crystal that it appears almost spherical. It has excellent cleavage parallel to the four planes of the octahedron and therefore may be easily damaged by a blow. Strong dispersion of light is the cause of the "fire" in this gem. The best diamond is considered to be completely colourless, without tinge of yellow. On rare occasions, diamonds are found that display pure yellow, red, blue, or green, and such stones are highly prized. The lustre of the diamond is adamantine, a hard brilliant lustre, which is the result of the high refractive index and the strong dispersion (prismatic effect) of the mineral. The term is derived from the Greek name *adamas* ("invincible") for diamond. Composition of the stone is pure carbon, although inclusions may be small crystals of the minerals diamond, diopside, enstatite, pyrope garnet, graphite, iron hydroxide, magnetite, olivine, rutile, serpentine, and chrome spinel. Diamonds with inclusions obvious to the eye are usually used commercially for grinding and cutting. Some diamonds fluoresce in ultraviolet light, but the colours are unpredictable, blue-white being most common but green, peach, and apricot not infrequent.

Since the beauty of the colourless, relatively small diamond is dependent on the fire that it displays, great care must be taken in cutting. It was for this gem that the brilliant cut was designed, and the angle between the crown and pavilion facets is calculated so that the maximum of white light entering the crown will be reflected back from the pavilion facets and be as widely separated into its spectral colours as possible. If the diamond is large enough, such cutting is not required, because the white light travels far enough in traversing the stone so that its spectrum is well developed. Such is the case with large Indian diamonds that still retain their rather crude pre-18th century cutting.

The world's diamonds came almost entirely from India until the discovery of diamond in Brazil about 1725. It is not known when they were discovered in India, but they were reportedly known to Alexander the Great nearly 2,000 years before Tavernier gave a written account of the diamond mines as they were at the time of his visit in 1642. It was from the Golconda area, near Hyderabad in south-central India, that most of the

famous historical diamonds came: the *Küh-e Nūr*, *Daryā-i Nūr*, Orlov, *Taf-e-Māh*, the Hope, and others. Production in India waned as Brazilian production increased, and in time Brazil became the bigger producer until in 1867 diamonds were discovered in South Africa. In due course that country and its neighbours took over first place, a position still held. Not until some time after the discovery of diamonds in Africa was it known in what rocks diamonds originated. In India and Brazil the diamonds are found in gravel deposits or in somewhat consolidated sedimentary rocks, which are obviously not the original deposit. In South Africa they were eventually traced to cylindrical bodies of igneous rock, called pipes, that come from great depths in the earth. This rock, a brecciated, ultrabasic material, is known as kimberlite, after the original diamond mining town of Kimberley. Because of its rather bluish-gray colour, the miners dubbed it "blue ground." On the surface, this material weathers to a yellowish colour. In the more than a century since the initial discovery, diamonds have been found also in Rhodesia, South West Africa, Congo, Angola, Ghana, Sierra Leone, Guinea, and Tanzania. It was in the latter country that a Canadian geologist, John Thoburn Williamson, found, by scientific search, the source of the alluvial diamonds in the largest diamond pipe yet known.

Figure 3: (Left) The Hope diamond; 44.5 carats. (Right) The Star of Asia; 330-carat sapphire. Both in the Smithsonian Institution, Washington, D.C.

The need for diamonds in the U.S.S.R. initiated a scientific search, and in 1955 diamonds were discovered in pipes in far eastern Siberia, in the valley of the Vilyuysk River, a tributary of the Lena. Diamonds are still produced in Brazil, and there is a small production from India. Diamonds are found also in British Guiana and Venezuela. Borneo, an early producer in a very small way, still provides limited production of small stones. Small diamonds, mainly of industrial grade, are found occasionally in New South Wales and Queensland in Australia. In North America, diamonds occur in a pipe of peridotite (a rock similar in composition and origin to kimberlite) at Murfreesboro, Arkansas. The largest diamond found there was a 40.23-carat crystal. The deposit is now worked as a tourist attraction. Some fifty diamonds have been found in the glacial gravels that lie south of the Great Lakes. It seems likely that the source of these stones lie in or north of the Great Lakes in Canada, but they have not been discovered.

**Feldspar.** The feldspars (*q.v.*) are a group of sodium, calcium, and potassium aluminum silicate minerals that provide some gem and ornamental materials. Those of interest as gems fall into two subgroups; one contains the potash feldspars, orthoclase and microcline, and the other consists of the plagioclase feldspars. All feldspars have vitreous lustre and hardness of about 6, with two

excellent cleavages at about right angles. Gem material occurs in pegmatite dikes.

**Potash feldspars.** Orthoclase is the monoclinic potash feldspar and is found occasionally in transparent yellow crystals and lumps that are faceted into an attractive yellow stone, albeit without fire. This material comes from Itongay, Malagasy Republic.

Moonstone is colourless orthoclase that exhibits a blue opalescence or schiller from within the stone. The material is not pure orthoclase but an interlayering of very thin individuals (discrete plates) of orthoclase and the corresponding sodium feldspar, albite. The material from the gem gravels of Ceylon and Mogok, Burma, is the best. Indian moonstone is somewhat opaque and displays a variety of colours, from white through yellowish and reddish to bluish gray.

Amazon-  
stone,  
sunstone,  
and  
labradorite

Amazonite (also called amazonstone) is the green variety of microcline, the triclinic potash feldspar. It is usually opaque, but a transparent variety has been reported recently from Baffin Island. It is not uncommon in small amounts in pegmatite dikes. The principal localities are: Virginia, Colorado, and other states in the U.S.; Ontario and Quebec, Canada; Minas Gerais, Brazil; Ural Mountains, U.S.S.R.; Malagasy Republic; and Tanzania. Because of its opacity it is cut *en cabochon*, as beads, and for ornaments. The colour varies from yellow green to blue green and from quite pale to very deep colour.

**Plagioclase feldspars.** All members of the plagioclase series exhibit fine, repeated, lamellar twinning (essentially plates that are side by side), which gives rise to fine parallel striae on the surface parallel to the base. Three varieties serve as gem materials.

Peristerite, a soda-rich variety, occurs in white and pastel shades of pink to gray. It shows a fine iridescence in flashes of pink and blue. Fine peristerite comes from the Canadian provinces of Ontario and Quebec, particularly the areas bordering the Ottawa River.

Sunstone, sometimes called aventurine feldspar, is an oligoclase (intermediate plagioclase) that has inclusions of tiny platelike crystals of iron oxide (goethite or hematite) arranged in parallel orientation through the host material. The reflections from the flakes give the otherwise colourless material a pleasing reddish glow. Sunstones occur on the south coast of Norway, Lake Baikal in the U.S.S.R., and in minor amounts in pegmatite dikes in many areas.

Labradorite is usually gray-coloured with brilliant iridescence, which, as in peristerite, may spread across large areas. Solid colours, as red, yellow, green, blue, and purple, or a mixture of two or more colours, may be displayed. The material may be cut *en cabochon* or slabbed. It was named for the fine deposit near Nain on the coast of Labrador, Canada. Gem quality labradorite occurs also in minor amounts in other countries.

**Garnet.** Garnet is a group of silicate minerals (*q.v.*), all of which are similar in crystal habit and correspond to the same general chemical formula even though the elements differ. Although spoken of as individuals, the members of the garnet group are probably only the relatively pure end members in several series of intermingled solid solutions (literally solids dissolved in other solids). Some of the physical and optical properties therefore vary considerably.

**Pyrope and almandine.** Pyrope always contains some iron and chromium, which are responsible for its blood-red colour. There seems to be a continuous solution series (no break or discontinuity in composition) with almandine, an iron aluminum silicate, which is a dark-red stone, often with a trace of purple. The colour of these gems is frequently quite dark, and to bring out the beauty they are often cut as hollow cabochons. Almandine occurs wherever there are metamorphic schists and gneisses. Two of the best localities of gem material are in Rājasthān, India, and in Brazil. Pyrope is found in the gem gravels of Ceylon and in Arizona. Asteriated (star-bearing) almandine has been found in India and Idaho.

**Spessartine (spessartite).** Spessartine is a manganese aluminum silicate in which some manganese commonly

is replaced by ferrous iron, and the alumina by ferric iron. The colour is usually yellowish orange but may range through brownish to orange-red. It can be confused with the similarly coloured hessonite. Spessartine is rare and is not often found in the cut form. It occurs in the Ceylon and Burmese gem gravels; Malagasy Republic; and Virginia.

**Grossularite.** Grossularite is a calcium aluminum silicate with a colour range from brownish yellow through brownish orange to orange, red, and green. Chrome green grossularite comes from Tanzania. Transparent material in the other colours, more usually called hessonite, comes mostly from the Ceylon gem gravels.

**Andradite.** Andradite is a calcium iron silicate; a variety containing a trace of chromium is termed demantoid, the most desired garnet and one of the rarest of gems. Demantoid is emerald green, has an adamantine lustre similar to that of diamond, a lower hardness, and a higher dispersion. Its "fire," however, may not be so apparent due to the deep colour of the gem. The main occurrence is in serpentine in the Ural Mountains of the U.S.S.R. in the Sisserts district.

**Uvarovite.** Uvarovite is a garnet that occurs in lovely green crystals; their size, unfortunately, is too small for use as gems.

**Jade.** The term jade includes two massive mineral species, jadeite and nephrite, which have a certain similarity in appearance. Nephrite has been carved and revered by the Chinese for 3,000 years and is called by them *yu* (Jewel of Heaven). Jadeite was not introduced into China until the middle of the 18th century. As a result, much of the material thought of by Westerners as Chinese jade is nephrite. In addition to its use by the Chinese for beautiful carvings, jade has been used for tools, ornaments, and burial objects by Maori of New Zealand, the Indians of North and Central America, and by the Japanese in the vicinity of their small deposits at Omi and Kotaki on Honshu Island. Apparently the Spaniards who invaded Mexico saw a resemblance in the flat pebbles of jade to kidneys and called them kidney stones. Hence from *piedra de ijada* (stone of the loins) came "jade," and from *piedra de los riñones* (kidney stones) came the Latin *lapis nephriticus* and the English word nephrite.

**Nephrite.** Nephrite varies in colour as a function of iron content, ranging from a deep spinach green to a near white known as mutton-fat, a jade much loved by the Chinese. It is a member of the amphiboles (*q.v.*) but is cryptocrystalline in form.

For centuries, nephrite was carried by camel train from Khotan in Sinkiang Province in far western China. There nephrite occurs as a thick layer in metamorphic schists and gneisses and as large boulders in the nearby streams. It is also found as very dark green boulders in the vicinity of Lake Baikal in southern Siberia. New Zealand jade is a dark green nephrite found *in situ* in talc and serpentine rocks at several places on the west side of South Island, where it is known as New Zealand greenstone, Maori jade, or axestone. Nephrite is found in northwestern Alaska; British Columbia; Lander, Wyoming; and in Placer County, California. Boulders from California and the Fraser River were shipped to China by Chinese gold miners and railroad labourers, respectively, and carved pieces undoubtedly have been returned as "Chinese jade." Small pieces of alluvial nephrite have been found in Mexico and Brazil. The occurrence of the stone in what is now part of Poland may be the source of the material found in the Swiss Lake dwellings.

**Jadeite.** Jadeite is one of the pyroxenes (*q.v.*) and always contains some calcium and magnesium. It is both harder and heavier than nephrite, not so fibrous, and is cryptocrystalline. Jadeite ranges in colour from pure white to black; it may occur in shades of red and brown, yellow, blue, mauve, and various shades of green, with which colour the name is wrongly considered synonymous. It is seldom that any of the colours occurs alone in a block of any size, and mottling is common. The most prized jadeite is the very translucent rich emerald green called "Imperial jade."

Uses and  
occurrence  
of jadeite  
and  
nephrite

The only important source of jadeite is in Burma, about 60 miles by jungle track northwest of Mogaung, the jade shipping point on the railroad to Rangoon. The jadeite occurs in bands in metamorphic rocks, from which it is mined. It is also obtained as alluvial boulders from the bed of the Uru River and other nearby streams. Jadeite has been found in minor amounts in a number of localities in California, and it occurs with nephrite in relatively small amounts in Japan, near Omi and Kotaki on the north side of Honshu Island. Some jadeite occurs in Central America, possibly near Costa Rica.

Jade is highly prized and there are a number of simulations. White jadeite has been dyed a fine bright green colour, but the colour is concentrated in fractures and on grain boundaries, and it is said to fade. A hard serpentine called bowenite, in light and dark green shades, is used in quantity to simulate nephrite. Much of this material comes from China, but is of worldwide occurrence. Bowenite is softer than jade, however, and a scratch test with a knife point on the base is usually sufficient to make the distinction. This material is sold as "New Jade"; it is attractive in its own right, but not as a fraud.

**Lapis lazuli.** The beautiful, blue, ornamental material lapis lazuli is a rock in which the principal components are the blue minerals haiynite and sodalite. Small crystals of pyrite, small amounts of white calcite, and other minor accessories commonly are included. The material is fine-grained and opaque and is usually cut as beads and plates or is carved. The darker the blue and the smaller the amount of pyrite and calcite present, the more highly it is prized. The physical properties of the material approximate those of haiynite but are modified by the presence of the pyrite and calcite.

Antiquity  
of lapis  
extraction

Lapis, as it is called in the trade, occurs in thermally metamorphosed limestones. The best material comes from north of the Hindu Kush Mountains of Badakhshan in northern Afghanistan, where for 6,000 years it has been extracted by primitive methods in relatively small blocks (about ten pounds). Lapis lazuli of a lighter blue is found also in Chile, and it has been reported from a number of other localities, including Colorado and Baffin Island. During the tsarist regime of Russia, great quantities of lapis lazuli were used in the form of small plates about one inch square to veneer ornamental objects. Many of these may be seen in museums, in particular the Hermitage and St. Isaac's Cathedral in Leningrad. Because of the beauty and rarity of lapis, simulations are attempted, with particles of brass or gold sometimes included to imitate the pyrite. Such materials as glass, sintered synthetic blue spinel, plaster of Paris dyed blue, and dyed jasper have been encountered in the guise of lapis. A natural simulation, massive sodalite, has been found in mineable quantity in Ontario; in Bahia, Brazil; and in South West Africa. It is more crystalline in appearance, usually lacks pyrite and calcite inclusions, and has a lower specific gravity.

**Olivine (peridot).** The olivines (*q.v.*) are magnesium iron silicate minerals, and the magnesium-rich member chrysolite provides the gem peridot. The finest material is dark bottle green, but light yellowish green and brownish shades are known. Peridot is relatively soft and must be treated with care. There is little fire and so it is usually step cut, depending on its somewhat oily vitreous lustre and colour for its beauty.

The two sources of the best material are the Island of Zebirget (also known as Saint John's Island) in the Red Sea and near Mogok in Burma. The Zebirget gems often contain inclusions of brown biotite flakes, whereas those of Burma may contain crystals of magnetite. Large stones are not uncommon; there are peridots of 310 and 287 carats in the U.S. National Museum in Washington; a 146.17-carat in the Geological Museum, London; and a 193-carat in the U.S.S.R. Diamond Fund. The two gems with which peridot has been most commonly confused are emerald and chrysoberyl. The greater specific gravity and strong birefringence (transmission of light in different crystallographic directions) of peridot easily distinguish it.

**Opal.** Opal provides a gem that is highly prized for its iridescence. When this play of colour is not present the material is usually of little consequence. Chemically it is a hydrate of silica ( $\text{SiO}_2$ ) and traditionally has been considered as an amorphous silica gel. Refinements in research techniques indicate that there is some form of crystallized silica present and that, in the case of iridescent material, the silica is present as minute spherical particles arranged in a three-dimensional lattice from which the spectral colours are produced by diffraction.

The quantity of water in opal ranges from 6 to 10 percent. It is deposited in openings of various shapes in sedimentary and igneous rocks through the action of hot water. It may replace mollusk shells, vegetable material, and even mineral crystals (see also SILICA MINERALS).

(Top) John H. Gerard—EB Inc., (bottom) John H. Gerard

Figure 4: Opals from Australia. (Top) Black opal from the collection of the Department of Earth Sciences, Washington University, St. Louis, Mo. (Bottom) Cabochon-cut black opals, jelly opal (centre, right), and fire opal (upper left) from the collection of Joseph and Helen Guetterman, Belleville, Ill.

A number of gem varieties are recognized: white opal, black opal, water opal, and fire opal. In white opal, the body colour is in light pastel shades, whereas in black opal, it is dark-gray to black or blue. In both, the iridescence springs from the surface since the material is nearly opaque. Water opal has a transparent colourless body from the interior of which a spangled pattern emanates when the stone is viewed in incident light. In a rare variety of water opal, known as *contra luz* opal, the iridescence is seen only by transmitted light. Fire opal is transparent to translucent, orange-red to red in colour, with or without iridescence or fire, which of course may be masked by the depth of the body colour.

Opals are usually cut *en cabochon* or in slabs; faceting is reserved for fire opal. In the latter case, the table of the stone is usually buff topped, that is slightly convex. Since opal often occurs in thin seams and is opaque, it may be cut *en cabochon* but with the back often including considerable material that may be the country rock or non-iridescent opal, usually referred to as *potch*.

All opal until modern times came from mines near Czerwenitz, Czechoslovakia. White opal occurs in volcanic rocks in this area and has been mined there since

(Left) John H. Gerard—EB Inc., (right) Lee Boltin

Roman times. Australia, however, is the big modern producer. The deposit at Lightning Ridge in northwestern New South Wales, discovered in the early 1900s, produces magnificent black opal from sandstones. More recent discoveries are at Coober Pedy (1915) and Andamooka (1930), both in South Australia. Opal has been found in numerous places in Mexico, but at the present time most production is centred on Queretaro, about 140 miles northwest of Mexico City. In that area, white opal, water opal, and fire opal occur as amygdulites in rhyolite (fillings in cavities of volcanic rocks). In the United States the most important occurrence is in Virgin Valley, Humboldt County, Nevada, where black opal replaces wood.

**Quartz.** Quartz is a silica mineral species that, through variation of crystallization and colour, gives rise to a considerable number of varieties. Depending on colour, the gems are: colourless—rock crystal; lilac to purple—amethyst; shades of brown—carnelian (with smoky tinge, smoky quartz; and when nearly black, morion); yellow—citrine.

**Macrocrystalline quartz.** Rock crystal is sometimes faceted. In the past, large crystals were carved into art objects and spheres, particularly by the Japanese and Chinese. Many museums display fine carved rock crystal objects dating even from Grecian times. Probably the largest sphere is the one in the U.S. National Museum, 12 $\frac{5}{8}$  inches in diameter, weighing 106 $\frac{3}{4}$  pounds, and flawless. Large transparent crystals have come from the Malagasy Republic; Kai Province, Japan; Sakangyi, Burma; the states of Goyaz, Bahia, and Minas Gerais, Brazil. The latter is the principal source today. Rock crystal exhibiting inclusions of rutile needles is called rutiled quartz and may be used for carved objects.

The original carnelian was found in the Cairngorm Mountains of Scotland. Faceted stones are still popular in Scotland, but most faceting carnelian now comes from Brazil and is probably heat-treated amethyst. Fine crystals of brown quartz have come from Switzerland, from Colorado and Maine, among other localities in the U.S., and from Japan and other countries.

Citrine occurs naturally in shades from light yellow to reddish yellow. Most of the material on the market, however, is heat-treated amethyst from Brazil.

Amethyst occurs usually in stubby crystals lining the interior walls of rock cavities. Only occasionally, as in Mexico, are the prism faces much developed. The colour, which may vary in intensity, may also vary in shade from bluish to reddish purple. Colour may be concentrated in the crystal tips, but care in cutting can cause the finished stone to appear uniformly coloured. By heating to temperatures up to 500° C, amethyst from various sources may provide a variety of colours in yellow, red, and even

green. The yellow shades are most popular and are frequently, though wrongly, marketed as topaz.

Rose quartz seldom occurs as crystals but rather as coarse semitranslucent crystalline masses in pegmatite. These masses are used principally for carving.

Quartz containing closely packed fibres of asbestos in parallel orientation will provide quartz cat's-eye, some examples of which are rather similar to chrysoberyl cat's-eye. The quartz variety, however, lacks the translucency, sharpness of line, and slight opalescence of chrysoberyl. Quartz cat's-eyes may be yellow to gray-green and occur chiefly in the Ceylon gem gravels.

Quartz, pseudomorphous (false form) after blue asbestos called crocidolite, provides a massive chatoyant material which is used in carved objects and jewelry. If the material retains its blue colour, it is referred to as hawk's-eye. Usually, however, the iron content of the original material has become oxidized and the resulting golden-coloured material is known as tiger's-eye. Tiger's-eye turns red if heat treated and may be chemically bleached and then dyed. The best tiger's-eye comes from South West Africa.

Aventurine is a granular quartzite, a metamorphic rock, in which flakes of mica or other minerals may be included. A green variety used in jewelry comes mainly from Mysore, India.

**Cryptocrystalline quartz.** In this material, submicroscopic fibres of quartz are embedded in common opal in a mixture too fine grained to resolve except under magnification in polarized light. Some of it occurs in nature in gem quality.

Massive forms of the material are known as chalcedony, banded forms as agate. Both are produced by deposition from solution in openings, joints, or other cavities in older rocks, often basic volcanics such as basalt. The colour of chalcedony may be white, gray to blue gray, yellow to red, or green. The reddish-coloured variety is called carnelian. A "nephrite green" chalcedony, found in Rhodesia, owes its colour to the presence of chromium but the colour of most green chalcedony results from the presence of nickel. Such material, of which the apple green is most prized, is called chrysoprase. It is translucent and is usually cut as cabochons or slightly buff-topped stones with many facets around the girdle. As chrysoprase has always been scarce, simulations in glass and dyed gray chalcedony have been common.

Most agate is banded and usually occurs in shades of gray although it may be coloured naturally. The present colour of most chalcedony and agate has been produced by dyeing in Idar-Oberstein, West Germany. Some agate contains inclusions of other minerals, in a branching or dendritic pattern. Black inclusions are manganese diox-

Colours of  
amethyst

Agate  
and its  
varieties

ide, green are chlorite, and red are iron oxide. Numerous varieties of agate have been given special names based on some feature such as pattern. One such material, known as moss agate, may be cut to exhibit interesting patterns that resemble trees, scenes, etc. Agates are of common occurrence, but their most important commercial source is in the Rio Grande do Sul area of Brazil and Uruguay. Thousands of tons of agates have been collected in North America in recent years.

Agate in which the bands are straight and parallel is known as onyx, and the bands are usually alternately black and white or gray. If the bands are alternately red or brown with white, the material is known as sardonyx. Much of the material marketed today is dyed, the coloured bands being separated by white bands impervious to the dyeing agent.

Jasper is an opaque form of cryptocrystalline quartz that is often strongly coloured: yellow, green, brown, red, and gray varieties are known. Dark-green jasper is also called plasma. When the latter contains red spots of iron oxide it is called bloodstone (heliotrope).

Buried organic material may be replaced by silica while retaining the cell structure. Petrified wood is a common pseudomorph of this type and is used for ornamental purposes.

**Spinel.** The gem spinel is an oxide of magnesium and aluminum that may contain iron, manganese, and chromium. These possibilities give rise to a wide variety of colour; carmine red, orange red, amethyst, and blue spinels are known. In the past, the red variety was thought to be ruby and was called balas ruby, probably for the source that was reported by Marco Polo to be in Badakhshan in Afghanistan on the Oxus River (Amu Darya). Although the red spinel resembles ruby, it may be distinguished by its single and lower index of refraction and its lower specific gravity. All the spinels take a fine polish but only the red one provides a gem in much demand. The two principal sources of gem spinel today are in the ruby and sapphire deposits of Mogok, Upper Burma, and in the gem gravels near Ratnapura, Sri Lanka. The deposits of Marco Polo's time in Afghanistan seem to have been worked out long ago.

Three world famous gems—the Timur ruby (361 carats) and the Black Prince's ruby (170 carats), both in the British crown jewels, and Catherine the Great's ruby (414 carats)—in the Russian Imperial crown gems are actually polished lumps of red spinel. All are matched in quality and surpassed in size by a 500-carat, polished but uncut red spinel in the crown jewels of Iran.

**Topaz.** Topaz is a gem of many colours, despite the common belief that all topaz is yellow and all yellow stones are topaz. Crystals may be colourless, blue, yellow, or brown. The most prized colour is the sherry brown. Although natural pink topaz is known, most is obtained through heat treatment of yellow material. Topaz may occur as crystals in cavities in fine-grained volcanic rocks but the origin of most gem material is as crystals in pegmatite dikes. In Minas Gerais, Brazil, where much gem topaz is found, the crystals are embedded in clays. The best localities for gem topaz are Ouro Preto, Brazil; in the Ural Mountains near Sverdlovsk, U.S.S.R.; and at Sakangyi, about 20 miles west of Mogok in Upper Burma.

Because of its transparency, topaz is usually faceted in brilliant or mixed cut, but the large gems are usually step cut. Crystals are often large and large cut stones are not rare. The 1,680-carat Braganza "diamond" of the Portuguese crown jewels is thought to be a colourless topaz. The Smithsonian Institution and the Royal Ontario Museum display large blue topazes of 3,273 and 3,000 carats, respectively. In addition, the Smithsonian displays a 7,725-carat yellow, a 1,469-carat yellow-green, and a 129-carat sherry topaz. The Royal Ontario Museum displays also a peach-coloured 364.79-carat stone from Burma and a magnificent 159.14-carat sherry-brown topaz from Brazil. The British Museum of Natural History possesses a 614-carat blue topaz and a colourless stone of 1,300 carats, while in the Geological Museum,

John H. Gerard—EB Inc.

London, there are an emerald-cut blue topaz of 385.26 carats and an oval mixed-cut pink topaz of 33.46 carats.

**Tourmaline.** Tourmaline is a borosilicate mineral of variable composition that supplies gem material in almost kaleidoscopic colour variety: red, yellow, green, blue, brown, and variations of these. In the past some of these colours have been recognized by special names: red and pink—rubellite, blue—indicolite, colourless—achroite, and brown—dravite. Other colours were called tourmaline with the appropriate colour prefixed. This latter nomenclature is now being broadened, and the special names are being less used. Some material is chatoyant and some provide bicoloured stones, red at one end, green at the other, with possibly a colourless zone between. Tourmaline usually occurs in prismatic crystals with small dispersion and, therefore, with little fire. Its beauty depends on its colour and fine vitreous lustre.

John H. Gerard—EB Inc.

Figure 7: Tourmaline crystals from the United States (horizontal crystals in foreground) and from Brazil (other examples). In the collection of Joseph and Helen Guetterman, Belleville, Ill.

A most important feature of tourmaline is its marked dichroism, and this feature must be considered in cutting the gem. If a crystal has pleasing colour when viewed at right angles to its length it will be almost opaque when viewed along its length. It should therefore be cut with its table parallel to the long axis of the crystal. By contrast, some tourmalines may appear too light in colour if cut in this orientation and should be cut so that the table is at right angles to the long axis, thus appreciably deepening the preferred colour. The mixed cut seems to be most favoured in the faceting of tourmaline. Crystals containing large flawless areas are rare, and faceted tourmalines in excess of 100 carats are quite scarce. The Smithsonian Institution displays five tourmalines above this figure, the largest being a 173-carat champagne-coloured mixed cut from Mozambique. Fine stones below 100 carats are displayed in many museum collections.

Large cut stones

Colours  
and  
fracturing

Tourmaline commonly occurs in pegmatite dikes but also is found as rounded pebbles in gem gravels such as those of Ceylon. Fine gem tourmalines occur near Mursinka in the Ural Mountains, U.S.S.R.; Mogok in Upper Burma; northeastern Minas Gerais, Brazil; the Malagasy Republic (Island of Madagascar); South West Africa; Tanzania; and in Pala, California, and Paris, Maine.

**Turquoise.** Turquoise is an opaque mineral prized as a gem since antiquity. Except in parts of the Far East, the most prized colour is sky-blue (robin's-egg blue), the desirability decreasing with increase of green colour. Turquoise is one of the complex phosphate minerals (*q.v.*) and is found in veinlets, with the iron oxide limonite, in weathered volcanic rocks. Although tiny crystals have been found in Virginia, the actual gem material is massive. Sometimes the turquoise has been fractured and recemented by limonite. Such material is called turquoise matrix. Pure pieces larger than a walnut have always been rare. Turquoise fades on exposure to sunlight and its colour may be damaged by absorption of grease, perspiration, and coloured liquids. It is almost always cut *en cabochon* or is carved or engraved.

The finest material has always been obtained from Nishāpūr, near Meshed in northeastern Iran. Exports from this source reached Europe through Turkey, and it is likely that the name turquoise, which is French for *Turkish*, originated in this way. The Iranian output now appears to be small and most is exported to the U.S.S.R. and India. Turquoise is found in the U.S. in New Mexico, Arizona, Nevada, and California. It was mined by the ancient Egyptians in the Sinai Peninsula.

**Zircon.** Zircon is a zirconium silicate with traces of iron, hafnium, uranium, and thorium. The mineral may be brown, leaf green, blue, golden, or colourless, and heat treatment can cause colour changes.

Colourless zircon, because its dispersion rivals that of diamond, has been used as a substitute for that gem. It may be distinguished readily, however, by its double refraction, much greater specific gravity, and by its relative softness. The brilliant cut brings out the maximum beauty in zircons of all colours. Most gem zircons come from Pailin, Cambodia, and near Chantaburi, Thailand, but they are also found in the gem gravels around Ratnapura, Sri Lanka.

**Other gems.** At the present time there are countless numbers of amateur lapidaries, many of whom rival or surpass professionals in skill. Since any mineral specimen that is beautiful, rare, and relatively durable may be cut as a gemstone, many minerals not mentioned above may appear in gem collections as collectors' items. Occasionally there may be enough of the material available and enough public demand so that the gem enters the normal retail market.

**Spodumene.** Spodumene is a lithium aluminum silicate whose beauty lies in its colour. It may be colourless or greenish yellow, but the two best colours are rose pink to purplish red, and emerald green. Those in the reddish shades provide the gem variety kunzite, named after the gemmologist George Frederick Kunz. Large crystals, originating in pegmatite dikes, have been found in the Malagasy Republic, in Connecticut and the Pala district of California, and in Governador Valadares, Minas Gerais, Brazil. A chrome-bearing emerald-green variety called hiddenite occurs in North Carolina, but in very small amounts.

**Scapolite.** Scapolite is a sodium aluminum silicate that may be colourless, pink, yellow, gray, or white. The major producers are Mogok, Upper Burma; Malagasy Republic; and the state of Espirito Santo, Brazil. Only the yellow variety is found outside Burma. The Smithsonian Institution displays a 288-carat colourless, a 30-carat colourless cat's-eye, and others. There is a yellow 76.11-carat Brazilian in the Geological Museum, London. The best scapolites in the Royal Ontario Museum are a 65.63-carat colourless mixed cut and an 18.30-carat pink cat's-eye.

**Zoisite.** In 1967, near Arusha in the Gerevi Hills in Tanzania, gemmy pebbles and pleochroic (differently

coloured in different directions) crystals of a blue- to amethyst-coloured mineral were discovered. Eventually identified as zoisite, but never before seen in such discrete and large crystals, it is being offered by some gem dealers under the name "Tanzanite." Stones cut to exhibit the deep sapphire blue usually show flashes of purple in the outer crown facets due to the amazing pleochroism. Although most gem zoisite is amazingly free of inclusions, a cat's-eye of 18.2 carats has been obtained by the Smithsonian Institution, which also displays a very dark blue 122.7-carat faceted stone. The largest zoisite in the Royal Ontario Museum collection is a fine sapphire blue of 26.90 carats.

**Sinhalite.** A pale-yellow-brown to dark-brown borate mineral identified in 1952 but considered previously to be peridot is found in the Ceylon gem gravels. The name is derived from the Sanskrit name for Ceylon. Sinhalite is still a collector's item.

## ORNAMENTAL MATERIALS

Although not gems in the strict sense, a number of minerals find use as ornamental materials because of their rich colour or pattern or both. Amazonite, chalcedony and agate, jade, jasper, labradorite, and lapis lazuli have been described above. Others that merit mention are: alabaster, blue-john (a massive fluorite from Derbyshire, England), malachite, rhodonite, serpentine, and sodalite (see the *Ready Reference and Index* for descriptions.)

**Pearls.** Pearls are organic in origin, and they have been prized since early times for the beauty of their form, colour, and lustre. They are formed in mollusks by the natural secretion of nacre, a mixture of organic conchiolin and tiny platy crystals of aragonite, around an irritant, such as a parasite or grain of sand, within the body of the animal. The pearls used in the gem trade are produced in the mollusk genus *Pinctada*. Beds of such mollusks were avidly harvested in the past in the Persian Gulf and across the Indian Ocean to northern Australia. Pearls also have been obtained off the shores of Venezuela and along the Pacific coast of Mexico.

John H. Gerard—EB Inc.

Figure 8: Natural pearls from the Persian Gulf. In the collections of Walter C. Blatt, St. Louis, Mo., and William V. Schmidt, New York.

Few new natural pearls enter today's market due to depletion of oyster beds, increase in costs of harvesting, and the high development of the Japanese cultured pearl industry. In this process, baby oysters, called spat, are collected in submerged cages and carefully tended until they are three years old. Then small beads of mother-of-pearl are inserted carefully into the mantle of each oyster and they are returned to their submerged cages for periods ranging from three to six years. During this time, the oyster secretes nacre in the usual manner around the artificially induced irritant. After harvesting, the pearls are graded for colour, size, and thickness of nacre.

It is said that the natural life of pearls, unlike the inorganic gems, is probably less than 300 years. This period may be drastically shortened by exposing the pearl to hot and arid conditions, which will dry out the conchiolin, or, conversely, to very moist conditions, which may cause the conchiolin to swell and the pearl to peel. They must therefore be handled with care in order to preserve the beauty of their orient, the natural pearly lustre. Most

from  
Africa

Production  
of cultured  
pearls

pearls are white or silvery white but they may be pinkish, yellowish, dark gray, or black. Other colours—yellow, blue, purple, green, and bronze—occasionally are found. Pearls may be treated by bleaching or dyeing to improve colour.

**Other organic gems.** In addition to pearl, a number of other organic materials are considered as gems.

**Amber.** Amber is a fossil resin, usually yellowish brown, but on occasion deep brown to red, green, or blue. It is an amorphous hydrocarbon and may contain particles of various foreign materials, trapped insects, and air bubbles. Its lustre is greasy to resinous. The most noted occurrence of amber is along the shores of the Baltic Sea, where pieces have been washed up by wave action. Other important occurrences are along the coast of Sicily, in Romania, and in Burma near Myitkina.

**Coral.** Coral is the skeletal material of calcium carbonate built up by small animals that live in colonies in the sea. This material is usually branchlike and occurs in a variety of colours, of which the most sought after are rose red to red. The best coral comes from the Mediterranean Sea, particularly off the coasts of Algeria and Tunisia. A black horny coral growth, probably conchionin, which hardens on exposure to air, has been obtained off the islands of Hawaii. Coral is carved into art objects and cut as beads, cameos, and other ornaments.

Figure 9: (Top) Red coral from Italy. (Centre row, left to right) Serpentine from Burma, bloodstone or helliotrope from India, malachite from Rhodesia. (Bottom row) Tiger's-eye from Republic of South Africa, carnelian from Brazil, turquoise from Iran. In the collections of Walter C. Blatt, St. Louis, Mo., and William V. Schmidt, New York.

**Ivory.** The use of ivory for ornamental purposes dates to prehistory. The term should be restricted to the material derived from the tusks of certain animals, namely, the elephant, hippopotamus, warthog, walrus, sperm whale, narwhal, and the extinct mammoth (fossil ivory). The pale cream colour of new ivory darkens with age to yellow. All types are brittle and will not peel as do the plastics used to simulate them.

**Jet.** Jet is a dense variety of lignite formed by the submersion of driftwood in the mud of the sea floor. It has been recovered since Roman times from the shales near Whitby in northeast England. It takes a high polish and was once popular as mourning and ecclesiastical jewelry but has been superseded by black onyx, black tourmaline, and plastics. Because it is actually a variety of coal it will burn.

**Birthstones.** One of the earliest uses of gemstones was as talismans to bring good fortune or to ward off evil. About the middle of the 16th century, gems were assigned to each month, and a person looked on the gem of his birth month as his birthstone, hoping that its possession would bring him safety and fortune. The stones originally chosen were related to those of the Breastplate of the High Priest (biblical), but the list has varied from time to time. Although modern buyers probably seldom

credit the gems with supernatural powers, the "birthstone of the month" is still a popular feature of the jewelry trade. The current representatives are:

Birthstones of the Months	
month	stone
January	garnet
February	amethyst
March	bloodstone or aquamarine
April	diamond
May	emerald
June	pearl or moonstone
July	ruby
August	sardonyx or peridot
September	sapphire
October	opal or tourmaline
November	topaz or citrine
December	turquoise or lapis lazuli

#### IDENTIFICATION OF GEMSTONES

Because of the high intrinsic value of gems, testing for identification must be of a nondestructive nature. For example, under suitable conditions diamond will burn completely to carbon dioxide, leaving little or no residue. It is exceedingly good proof that the material *was* diamond. The tests carried out by gemmologists usually consist of determination of optical properties and specific gravity. Only when other tests to establish identity are unavailable is recourse made to the hardness test with its attendant risk.

**Index of refraction.** When light enters a mineral there is a change in its velocity and a concomitant change of direction. These changes are characteristic for a given substance or material and are measured in terms of a parameter called the index of refraction (see MINERALS). In gemmological testing, refractive indices are determined on a small instrument known as a refractometer. The stone is placed face down on the prism or hemisphere of the instrument and the index is read directly on an internal scale. By using a polarizing eyepiece or by changing the orientation of the gem or both, it may be determined whether the gem has more than one index of refraction. These simple steps go far toward identification of the gem.

**Pleochroism.** The gem may be placed between the crossed polarizers of a polariscope to provide further evidence of its optical character. This instrument may be used also to determine the nature of pleochroism in a coloured gem but pleochroism usually is determined with a dichroscope, in which the pleochroic colours are observed, two at a time, side by side in the eyepiece. Quite delicate differences of colour may be noted, and, by turning the gem, it may be determined if there are three colours, two, or only one.

**Specific gravity.** Specific gravity, or density of a gem, is a characteristic property but, like the index of refraction, it may show limited variations depending on slight changes in chemical composition and the presence or absence of inclusions. In the latter instance, the specific gravity of an emerald ( $G = 2.70$ ) might be increased slightly by the presence of small crystals of pyrite ( $G = 5.0$ ), or decreased by the presence of cavities containing fluid or gas. Two similar-appearing gemstones may have similar indices of refraction or similar specific gravity, but it is unlikely that they will show similarity in both respects. The combination of tests is therefore diagnostic.

**Fluorescence.** Further diagnostic information may be obtained by examination of the absorption lines of gemstones as observed in a spectroscope. Ultraviolet light is useful in some tests. For example, ruby and red spinel fluoresce red, but red garnet and red tourmaline do not; natural emerald does not fluoresce but most synthetic emerald fluoresces red.

The Chelsea filter is a simple device that transmits only red light and yellow green. Emerald, despite its green colour, absorbs yellow-green light and yet transmits deep red, which is masked in normal vision by the dark-green

Physical  
and optical  
tests

colour. Because the filter will not transmit the dark-green colour, the dark red is transmitted and most emeralds viewed through such a filter appear red or pink. Green glass and most other green gems appear green through the filter. Exceptions are demantoid garnet and a newly-discovered chromium-bearing tourmaline from Tanzania. Green fluorite and green zircon may exhibit a pink colour and care must be used in evaluating the results of this test since neither Indian nor South African emeralds show any colour change.

**Other observations.** Magnification by the microscope, the simple jeweller's loupe, or the hand lens may supply much information: uniformity, zoning, or patchiness of colour; diagnostic inclusions (e.g., the horsetail-like wisps in demantoid or the curved bands of bubble inclusions in synthetic corundum); double images of back facet edges that are indicative of double refraction; "feathers" along incipient cleavages; scratches and other signs of wear on the surface indicative of a relatively soft gem; the shape of nicks in the girdle indicating the nature of cleavage or fracture or both.

#### THE CUTTING OF GEMS

The first gemstone was doubtless picked up because it was attractive to look at and the finder was satisfied with it. In order not to lose it, he may have placed it in a pouch, pierced it, or put a groove around it so that he could tie it with a thong to his person. In time, handling of the object may have resulted in a semblance of a polish on the surface and the realization that polishing provided an improvement in appearance. The practice of polishing a lump without increasing the symmetry was long the vogue and became even more important when, in the course of time, gems took on the importance of a form of currency. Any diminution of the size and weight of the stone would therefore be a diminution in the asset. Most gemstones, however, contain inclusions or other flaws such as cleavage feathers and cracks. It was found subsequently that such faults could be hidden, at least in part, and the value of the stone upgraded if multitudes of tiny flat surfaces or facets were applied all over the surface of the stone, the weight being decreased very little in the process. Symmetrical arrangement of facets followed and eventually angles between major facets were carefully calculated to make the most of the optical properties of a particular gem.

There are still two schools of thought with reference to beauty in a gemstone. In the Orient, it is argued that the weight of a gemstone should be retained as much as possible even at the expense of beauty of colour and symmetry. In the Western world, however, beauty of colour and symmetry are paramount. As a result, many gems cut in the East have lumpy form, particularly below the girdle, and must be recut before being offered on the Western market. Unlike native-cut Ceylon stones, however, those of Thailand are magnificently cut. Some of the principal kinds of cuts are as follows:

**Cabochon.** The cabochon is a symmetrical derivation of the polished lump. It usually has one flat surface that may be circular or elliptical in plan and has a shallow to steep dome. It is used for opaque gems, such as turquoise; iridescent gems such as opal; chatoyant and asteriated stones; and opalescent material such as moonstone. Occasionally it may be produced as a double cabochon, the curvature of the lower portion being seldom as steep as that of the upper.

**Rose cuts.** One of the earliest symmetrical faceted forms is the rose cut. Basically it is a cabochon to which facets have been added, usually in two concentric zones. The standard rose cut consists of six triangular shallow facets on top, surrounded by a steeper zone of 12 facets, also triangular. Modifications may provide rose-cut beads and drops, or pendeloques. If the latter are circular in cross section they are called rose-cut briolettes. Rose cuts in various forms have been applied to all the transparent gems known in the past and may be seen in quantity and large size (even exceeding 100 carats) in such collections as those of Topkapı and Iran.

**The brilliant.** It is not known when faceting of diamond had its beginning, but by Tavernier's time in the middle of the 17th century many lapidaries in India were cutting this gem. Most were fashioned as rose cuts, which undoubtedly conserved the most weight from a cleavage fragment of diamond; however, attempts were made to polish the rather commonly occurring octahedral crystals. The faces of this form are the hardest and are almost impossible to polish. By slightly altering the angle of abrasion, however, the material may be ground and polished, using diamond dust. The first result was essentially an eight-faced polished octahedron called a diamond point. Then came the grinding away of one corner until the new flat surface, called the table, was half the width of the stone at the girdle, or broadest portion. The opposite tip was blunted to form a small face, called a culet, applied to prevent accidental splitting of the stone. This ten-faced form, still essentially an octahedron, was termed the table cut. Although used principally for diamond it was also used for spinel, which exhibits the same crystallographic habit. Toward the end of the 17th century a Venetian, Vincenti Peruzzi, produced the prototype of the modern brilliant. The brilliant cut is based on the table cut with the addition of more facets. The important feature, however, is that the index of refraction of the diamond is taken into account in calculating the angles between the crown and pavilion facets. In this way, white light entering crown facets is totally reflected from the pavilion facets and returned through the crown to the eye. Because diamond has strong dispersion or "fire," the farther the white light travels before re-emerging, the more the ray of white light will be spread into its spectral colours. The standard brilliant as now cut is only slightly modified from Peruzzi's original. It is based on eight-fold symmetry with 32 facets plus the table in the crown, or upper portion, and 24 facets plus a culet in the pavilion, or lower portion. Modifications, particularly in larger stones, may increase these numbers, but the major angles remain fixed. The brilliant form is used for many gems—both colourless and coloured. In such cases, however, the angles between crown and pavilion facets are adapted to the refractive index of the particular gem.

**Step cut or trap cut.** This popular style of cutting is most used on coloured gems. It consists, as in the brilliant, of a crown and pavilion; however, the facets are arranged in zones parallel to the girdle. The basic shape is square or rectangular in cross section but it may have the corners truncated (a form often called the emerald cut) or, indeed, have any cross section that the lapidary may choose. Other things being equal, the angles between crown and pavilion facets should take into account the refractive index of the gem in order to return as much light as possible through the crown and prevent "bleeding" of light out through the pavilion. Bad bleeding makes a stone appear to have a big hole in the pavilion. In practice, however, the depth of the stone is often adjusted to modify the colour; if a very dark stone it may be cut shallow, and, if a pale colour, it will be cut as deep as possible to increase the colour.

**Mixed cut.** Another popular cut is the mixed cut. Usually such stones have a brilliant-cut crown and step-cut pavilions but the reverse is sometimes seen.

#### COLOUR IMPROVEMENT

Because colour or lack of it has much to do with the beauty of gemstones, many practices have been developed to assist nature. The proper cutting of a gem, as mentioned above, may markedly benefit the final colour. In some gems, as in amethyst and sapphire, colour is patchy. A good cutter can often fashion such a stone so that, when viewed through the crown, its colour appears to be dispersed evenly throughout.

Some gemstones change colour when heated, and the practice is so old and the results often so permanent that it is accepted in the gem trade. The method varies somewhat for different species but is basically one of heating the raw material in a container to a predetermined temperature under controlled conditions. Thus amethyst be-

Enhancing  
the fire of  
diamond

Differing  
concepts  
of beauty  
in gems

comes yellow citrine and yellowish-brown topaz from Ouro Preto, Brazil, becomes a delightful rose pink. Brown zircons heated under reducing conditions turn colourless, blue, or blue green, but in an oxidizing atmosphere turn colourless, golden yellow, and occasionally red.

Changes in the colour of some gemstones also can be produced by exposure to radium or X-rays. Unfortunately the colour is usually either of short duration or fades on exposure to sunlight. Still another method of improving the colour of a gemstone is the application of a pigment or coloured foil to the pavilion facets. This adds to the colour and, in the case of the foil, assists in reflecting light from facets not cut at the proper angle.

#### GEM COLLECTIONS

#### National gem treasures

In past centuries gems and jewels belonging to royalty have served two purposes. In wearing and displaying them, the ruler proclaimed his wealth and, by implication, his power and his right to rule. They served also as a treasury with which to purchase supplies of all kinds both in peace and war, to reward friends, and if necessary to buy off an enemy. Much of a nation's history may be connected with its crown jewels. Today, displayed statically behind glass for citizen and foreign visitor alike to see, these gems recall the country's periods of glory and provide glimpses of the tastes and characters of those who developed them. Some collections, such as those of the British and Iranians, are still drawn on periodically for coronations and to lesser degree for state occasions. The Iranian collection still acts as a national treasury in that it provides a backing for a part of the note issue. With the passing of the monarchy in such countries as the U.S.S.R. and Turkey, crown jewels have become museum collections to serve only as objects of beauty and lessons in history.

**Crown jewels of Britain.** The crown jewels of Britain probably have been viewed by more people than those of any other country. Before 1968, they were displayed in the Wakefield Tower of the Tower of London, but in that year a new and bigger jewel house was located elsewhere in the Tower complex in order to give visitors more opportunity to view and to study them. The collection is most noted for the regalia, which includes the historic St. Edward's crown, the orb and sceptre (all used in the coronation ceremonies), and the Imperial State crown. Some of the world's finest gems are included in this collection. Cullinan I, the world's largest cut diamond, is set in the sceptre; Cullinan II, the second largest cut diamond, is in the State crown, as are the Black Prince's ruby and the Stuart sapphire. The *Küh-e Nūr*, the diamond with the longest recorded history and traditionally set in the crown of the queen consort, is at the present time set in the crown worn by the Queen Mother on state occasions.

**Crown jewels of Iran.** In 1960, the crown jewels of Iran were placed on public view in a specially constructed vault in the National Bank (Bank Melli) building in Tehrān. The bulk of the gems are the remnant of the booty acquired at the sack of Delhi by Nadir Shah in 1739. In their vast numbers, size, and quality they surpass any other collection of gems available to public view. Among the oldest objects are Nadir's gem-covered sword and buckler, but at least one gem, the *Daryā-i Nūr* diamond, seems to be traceable to 1642, when Tavernier saw it in Delhi. Most of the objects—throne, art objects, household wares, jewelry, arms, and armour—were made for the Qājār dynasty or were gifts to its members by other monarchs. With the coming of the Pahlavi dynasty in 1925, a new crown was produced and since that time a number of pieces of fine jewelry have been added. The most recent additions were the Empress' crown, jewelry, and other pieces, made for the occasion of the coronation in 1967 of Muhammad Reza Shah. The gems for all these items were drawn from older objects or from the large quantity of unset stones. Noteworthy among the gems are seven faceted diamonds of more than 100 carats each, five emeralds each in excess of 300 carats, the

world's largest and fourth largest red spinels, and a number of magnificent Burmese rubies in excess of 10 carats each. Here is displayed the greatest known aggregation of Indian diamonds, Colombian emeralds, Afghan spinels, and Burmese rubies. More gem-studded treasures, including a great bed-throne, are displayed in the Museum of the Golestān Palace, also in Tehrān.

**The Diamond Fund and other collections of the U.S.S.R.** The Diamond Fund of the U.S.S.R. is housed in the Kremlin in Moscow and has been available to the general public since 1967. The crowns and other regalia of the tsarist regime are displayed but of particular gemmological interest are the Orlov and the Shah diamonds, the "ruby" of Catherine the Great, blue sapphires of 258.8 and 200 carats, a 136.25-carat step-cut emerald, and many diamonds from the Siberian diamond field. Nearby, in the Armoury of the Kremlin, are other treasures: thrones, icons, arms, armour, and harness, richly set with gemstones. In the Hermitage Museum, the former winter palace of the tsars in Leningrad, other treasures and ornamental minerals remain in bountiful profusion.

**Crown jewels of Turkey.** The treasures of the Sultans of Turkey are now housed in four rooms of their former palace, the Topkapı Museum in Istanbul. They consist of gem-studded thrones, arms and armour, temple ornaments from Mecca, jikas and other personal jewelry, and various art objects. Noteworthy among the gemstones are an 86-carat pendeloque diamond, as well as large emeralds and red spinels.

**Other collections.** A number of other museums have been able to build quite substantial collections of gems and jewelry. The most notable of these are: American Museum of Natural History, New York; British Museum (Natural History), London; Field Museum of Natural History, Chicago; The Geological Museum, London; Royal Ontario Museum, Toronto; Smithsonian Institution, Washington; The Victoria and Albert Museum, London.

#### SYNTHETIC GEMSTONES

Synthetic gemstones are produced in several ways that are derived from two principal methods, growth from solution and growth from a melt. In crystal growth from solution, the chemical components of the crystal are dissolved in a suitable solvent to produce a saturated solution. By allowing the temperature to lower or the solvent to evaporate, the solution becomes supersaturated and crystals of the desired substance may be produced. In actual practice in the production of synthetic gem materials, the process is usually carried out under high temperature and pressure; the hydrothermal technique or high-melting "fluxes" are used to dissolve the components.

The most widely used melt technique is the one invented by Verneuil (about 1890). In it, powder of the appropriate chemical composition is fused in an intense oxy-hydrogen flame. Directed by the flame to a target, the fused matter gradually builds up a boule, a roughly cylindrical body, of sometimes several inches in length. The material of the boule has been known to crystallize as a single crystal, with the characteristic atomic structure and physical properties of the chemical substance, but because of the rapidity of growth, crystal faces are usually lacking. The production of boules requires that the chemicals and gases used be of exceptional purity. The desired colour is introduced by the addition of a small amount of foreign material. This method is used in the commercial production of synthetic corundum, spinel, rutile, and strontium titanate.

**Ruby and sapphire.** Ruby and sapphire may be produced by the Verneuil process, hydrothermally, and from flux. At the present time, the only economic method is the Verneuil technique. If made of pure aluminum oxide (alumina), the boule would be colourless. Suitable colours are obtained by the addition of small amounts of oxides, for example chromic oxide (about 8 percent) for ruby. Ruby and sapphire in most colours, except an ac-

Growth  
from  
solution  
and growth  
from melts

ceptable blue, are produced in this way. Blue sapphire is usually simulated by a suitably coloured spinel. Asteriated boules are produced by adding a trace (0.1 to 0.3 percent) of titanium oxide to the alumina powder. After manufacture, the boule is heat treated and the titanium oxide precipitates as rutile needles, arranged in three intersecting planes.

**Emerald.** For more than a century, attempts have been made to synthesize the beautiful and valuable emerald, primarily by hydrothermal crystallization. The best known to date has been the process of Carroll F. Chatham of San Francisco. The process is secret but is said to be hydrothermal, which seems likely judging from groups of crystals that have appeared on the market. It is said further that crushed beryl is used as raw material and that a small crystal may be used as a "seed" in a tungsten or molybdate melt. Further reports indicate that the usable crystals take about one year to grow.

The Chatham synthetic emerald, grown as a crystal, does not exhibit curved growth lines as do corundum boules from the Verneuil furnace. There are, however, inclusions, which, although similar to those of natural emerald, are sufficiently different to be recognized by an expert. They are veil-like feathers either like waving curtains or in parallel bands. The feathers contain many liquid- and gas-filled inclusions. Because of the rather high content of these light inclusions, synthetic emerald has a specific gravity of about 2.65, sufficiently less than natural emerald that it will float in a liquid in which natural emerald sinks.

**Spinel.** Only the red natural spinel has appreciable value as a gem, and synthetic spinel of this colour apparently has been difficult to achieve. A red synthetic spinel is now marketed, but the stones are small due to the severe fracturing of the boules. Synthetic spinel finds its greatest use as simulations of other gems. Blue spinel can be prepared that comes closer to the colour of blue sapphire than does synthetic blue corundum. Most synthetic blue sapphires on the market are synthetic spinel and therefore are really simulated blue sapphire. Pale-blue spinel is also used to simulate aquamarine, for which there is no commercial synthetic. Other colours may simulate other important gems.

**Rutile.** Rutile is an interesting synthetic because gem material of the mineral rutile ( $\text{TiO}_2$ ) is exceedingly rare. The synthetic appeared in 1948 and is a Verneuil product using purified titanium oxide powder. The usual colour is a very pale yellow, but other colours (yellow, orange, red, blue, and green) have been produced. It has very strong birefringence and cut stones exhibit marked doubling of back facet edges. The specific gravity is 4.25, heavier than corundum, and the dispersion—about six times that of diamond—is the most amazing feature of this material, providing it with phenomenal "fire." Unfortunately, it is relatively soft. As a material for personal adornment, it provides a fiery stone. As a simulation of diamond it is identified by lack of hardness, birefringence, specific gravity, and lack of the transparency that marks most of the diamonds. It has been marketed under the name Titania.

**Strontium titanate.** Still another synthetic is strontium titanate, a chemical as yet unknown in nature. It crystallizes in the isometric system, as does diamond, and is produced as water-clear, colourless boules. Cut stones show no doubling of back facet edges when viewed through the table, the index of refraction is 2.41, and the dispersion is four times as great as that of diamond. It is remarkably heavy, with a specific gravity of 5.13, but rather soft. Marketed under the names Fabulite and Starilian, it provides a remarkable simulation for diamond, far outdoing it in "fire." Its high specific gravity and softness provide ready identification.

**Diamond.** Diamond has not been synthesized in size suitable for gem use and little need be said here concerning it. Attempts at synthesis, with little or no success, have been recorded for a hundred years, but in 1955, the General Electric Company, announced successful synthesis of diamond. Since that time, other companies have

succeeded also, and gem-quality crystals as large as one-eighth of an inch have been produced. The method involves the melting of graphite with catalyst metals under high temperature ( $+ 2,000^\circ \text{C}$ ) and tremendous pressure ( $+ 1,000,000$  pounds per square inch). The crystals are very small but are excellent for cutting and grinding, and for some applications they are preferred to the crushed natural material.

#### IMITATION GEMSTONES

**Glass and plastic.** The first imitation gemstone was used in prehistoric times. In early Egypt, beads and other objects were made of faience, which consists of a vitreous glaze over a gritty core. Later Egyptians simulated a number of the colourful gems in glass. Indeed, glass still provides the bulk of material used to simulate gems for costume jewelry. Today there are two main types of glass used in gem simulation. The type known as bottle or window glass is used for the cheap, molded imitations. The better simulations are made from a glass containing lead oxide and sometimes salts of thallium. The lead and thallium increase the dispersion and brilliancy of the glass. The best of this type of glass is called strass, after its discoverer. The amount of polishing that these "gems" receive depends on the quality of the glass used and the market for which the simulation is prepared. In the cheapest, the table may be the only facet polished. Added brilliance may be obtained by coating the pavilion facets with a mirrorlike surface of evaporated metal. A new method of making glass (or paste) gemstones is to coat the pavilions of glass stones with a coloured pigment.

The glasses usually offer little trouble in identification. Except in the narrow range of beryl and topaz, specific gravities and refractive indices do not match those of natural gemstones. No gems in that range are isotropic as is glass. In addition, glass may show trapped bubbles and curved stria. Such identifying features are particularly present in the cheaper paste.

Plastics of various kinds may be coloured and are used for some simulations of gemstones. The low specific gravities, indices of refraction, and softness are immediate clues to their identity. Brown plastics are used to simulate amber, which is likewise organic, soft, and light.

**Simulated pearls.** Imitation or simulated pearls are produced in quantity by coating beads of opalescent glass (plastic beads may be used in cheaper varieties) with pearl essence. This material is made by dissolving a derivative of fish scales in nitrocellulose lacquer, an appropriate colour being added if desired. Up to ten coats of lacquer are applied in order to build up the lustre. If the beads are hollow, the specific gravity will be lower than that of natural or cultured pearls, and if solid, the specific gravity is usually higher. The surface looks like blotting paper, while the nacre of the true pearl shows tiny overlapping platelike crystals. The perforation shows the ragged edge of the coating and the glassy interior.

## Gene

Genes are the carriers of the genetic information passed on from generation to generation in the sex cells of all organisms, according to the principles discussed in the article HEREDITY.

The evidence is overwhelming that the basic genetic material constituting the gene is fundamentally the same in all living organisms: it consists of chainlike molecules of nucleic acids—deoxyribonucleic acid (DNA) in most organisms and ribonucleic acid (RNA) in certain viruses—and is usually associated in a linear arrangement that, in part, constitutes the chromosome.

The term gene no longer stands simply for a discrete structural unit of heredity of definite and invariable length. It is now thought of as an operational entity whose properties depend upon the mode of measurement. These refinements in definition of genetic material are explained below in the section *Nature of the gene*.

An account of the development of the gene concept precedes the discussion of gene structure and function according to the following outline:

- Development of the gene theory
  - Blood heredity versus particulate heredity
  - The concept of the gene
  - The reality of the gene
    - The parallel between chromosomes and genes
    - The linear order of genes
- Nature of the gene

## Development of the gene theory

### BLOOD HEREDITY VERSUS PARTICULATE HEREDITY

Before the time of the Austrian monk-naturalist Gregor Mendel, it was universally believed that heredity was carried by blood and that the bloods of the parents are blended in the offspring. Mendel proved that at least some traits that differentiate varieties of peas are inherited through factors that do not blend but actually segregate when the sex cells are formed. Although published in 1866, the work of Mendel was unappreciated until 1900. The British evolutionist Charles Darwin fully real-

ized that understanding the mechanism of heredity was of basic importance for his theory of organic evolution. In 1868 Darwin published *The Variation of Animals and Plants Under Domestication*, to which he added an appendix containing his "Provisional Hypothesis of Pangenesis." In this acknowledgedly speculative venture, he surmised that all cells of the body shed into the bloodstream minute particles called gemmules (or pangenes), which assemble to form the sex cells. A gemmule was imagined to be a representative, perhaps a tiny model, of the cell that produced it. When a body cell was altered by some environmental agency, it gave rise to altered gemmules. This detail was important to Darwin because, in common with his contemporaries, he believed in the inheritance of acquired characters. While the hypothesis of pangenesis seemed to explain adequately at the same time the transmission of inherited and of acquired traits, it was experimentally disproved.

In 1889 a Dutch botanist, Hugo de Vries, advanced the theory of intracellular pangenesis. By then, most biologists no longer regarded inheritance of acquired traits as a well-founded hypothesis, and evidence was rapidly accumulating that the chromosomes of cell nuclei were the carriers of the hereditary materials. De Vries proposed that the pangenes constituted the chromosomes and passed only from the nuclei into the cell cytoplasm, where they became active. Each cell was believed to contain many different pangenes, each of which could become active in different cells (thus explaining why cells become different in the developing organism).

August Weismann, a German biologist and one of the founders of the chromosomal theory of heredity (1892)—the forerunner of the gene theory—believed that the hereditary materials were composed of determinants that specified the characteristics of different cells. The sex cells were thought to contain sets of determinants for all cells, but, during the cleavage of a fertilized egg and the cell divisions in a developing embryo, the determinants were gradually sorted out, so that finally every cell retained only the determinants needed to specify the characteristics of a certain tissue or organ. The sex cells were the exception; they had to retain a full set of the determinants, which could be passed on to the offspring. These cells carried the germ plasma, which can be considered potentially immortal, since it may be transmitted from generation to generation without end (Figure 1). In every

Darwin's notion of "pangenesis"

The continuity of the germ plasma

Figure 1: Weismann's concept of the continuity of the germ plasma (see text).

generation the germ plasma constructs the somatoplasm (or soma), the body that is its temporary container and vehicle. The body is mortal; it dies after it transmits its germ plasma to the progeny. In unicellular organisms, which reproduce by simple fission, the separation of the germ plasma and the body does not exist; these organisms, themselves, are potentially immortal. Weismann's hypothesis was, thus, an antithesis of Darwin's hypothesis of pangenesis. Instead of the sex cells being compounded of the gemmules shed by the body, Weismann admitted only the passage of the determinants from the germ

plasma to the body. Quite consistently with this view, Weismann rejected the possibility that characters acquired by the body may be inherited.

From the vantage point of present-day knowledge, these pre-Mendelian speculations may appear naïve. Their historical importance is, however, unquestionable. They led to the abandonment of the notion that heredity is transmitted by blood and to the acceptance of the idea that the hereditary materials are particulate. The scientific climate had changed when Mendel's work was rediscovered in 1900, and his approach to the study of heredity was not so strange and unfamiliar as it was in 1866.

#### THE CONCEPT OF THE GENE

Gregor Mendel was by no means the first to experiment on plant heredity, but he did it in a systematic and inspired way. Mendel's data revealed to him that each parent contained pairs of factors but contributed only one member of each pair to its offspring. It was also clear that the factors retained their individuality from generation to generation, whether they asserted themselves or not, and united randomly in the offspring.

The gametes (ovules and pollen grains in plants, egg cells and spermatozoa in animals) of course do not display differentiating characters such as colours or shapes of flowers, seeds, eyes, hair, etc. And yet Mendel's experiments demonstrated that the gametes do contain some formative elements or factors that indeed are responsible for the appearance of characters in the organism. Mendel's results were confirmed and extended in 1900 and thereafter to many species of plants and animals, including man. A Danish biologist, Wilhelm Johannsen, proposed in 1909 to call the formative elements, or factors, genes, not to be confused with the speculative pangenes, determinants, etc.

Mendel's pea varieties with, for example, purple and white flowers carried alternative forms of one gene that allowed the plants to develop flowers of these colours; such alternative states of a single gene are now termed allelomorphs (or alleles). Each "pure" variety contained two similar alleles, or a double dose of genes for each trait, and was called a homozygote. Each hybrid variety, which is derived from crossing two pure varieties, necessarily had two unlike alleles for each trait and was called a heterozygote. When the heterozygote formed sex cells, the alternative alleles segregated and passed into different and equally numerous cells. The sex cells were "pure" since they contained only one allele for a character; for example, either the allele for purple or for white flowers but not both and not a mixture of the two. These considerations led to Mendel's law of segregation, or the law of the purity of the gametes: different alleles of genes do not mix or contaminate each other while they are present together in the body of a heterozygote. Here, then, is a basic difference between the blood theory and the gene theory of heredity.

It proved quite impossible to keep the gene concept purely symbolic and free from any hypotheses. In point of fact, the progress in studying genes came from making a sequence of hypotheses about the genes and submitting these hypotheses to test by experiments. As expected, some of the hypotheses proved to be wrong and had to be abandoned. Thus, it seemed temptingly simple to suppose that each gene represents in the sex cell a certain unit character and that the organism is an aggregate, a sort of a mosaic composed of such unit characters. In the development of an organism from a fertilized egg, each gene would add its proper unit character to those produced by other genes, until the body is fully formed. In a sense, this hypothesis was a throwback to something like Weismann's determinants, except that the unit characters were no longer thought of as representing body parts or single cells but rather as representing qualities, such as colour, pattern, shape, or size.

Because of their brevity, expressions such as "the gene for blue eyes" or "the gene for blood group A" are used even now; these expressions are likely to mislead a beginner into believing that there is a one-to-one relationship between each gene and an independent unit char-

acter, or trait, for which a given gene is responsible. This is actually not so. What looks like a trait controlled by a single gene is frequently the result of interaction of several or many genes (Figure 2). The variety of coat col-

Relation of genes to traits

Figure 2: The relationship between genes and traits (see text).

ours found in domestic dogs, cats, rabbits, horses, cattle, and other mammals, for example, results from often very complex interactions of many genes, some of them represented by several alternative forms (multiple alleles). The difference between the skin colours of Negroes and of whites is the result of the joint action of several genes, each of which increases or decreases the skin pigmentation relatively slightly. Conversely, many genes act on constellations of seemingly unrelated traits. Such genes are called pleiotropic. In man, many hereditary diseases are caused by single gene changes that produce combinations or syndromes of traits, some structural, others physiological or psychological. Thus, phenylketonuria is inherited as a simple recessive; the afflicted homozygotes have their mental development severely retarded, and their urine contains large amounts of phenylalanine and phenylpyruvic acid. In general, the development of an individual of any species is controlled by all the genes he carries; characters of traits are merely descriptive aspects of this unitary process.

#### THE REALITY OF THE GENE

Although genes were originally simply symbols useful to explain the observable facts of Mendelian segregation, it soon became evident that they had physical reality as component parts of the chromosomes of cell nuclei. A group of brilliant biologists, among them Theodor Boveri, Wilhelm Roux, and August Weismann in Germany and Edmund B. Wilson in the United States, inferred that the heredity transmitted from one generation to the next must be carried in the chromosomes of the sex cells. This inference had been reached in the closing decade of the 19th century; i.e., before the rediscovery of Mendel's laws. The question of whether the Mendelian genes were also carried in the chromosome logically presented itself.

**The parallel between chromosomes and genes.** The behaviour of the chromosomes during the processes of maturation of sex cells (meiosis) is precisely such that the Mendelian segregation of the genes carried in these chromosomes can be envisaged as a simple and necessary consequence. During meiosis the chromosomes unite in pairs, divide, exchange segments, and then disjoin and pass to different sex cells (gametes). Suppose, then, that the maternal chromosome of a given pair carries an allele of a gene different from that in the paternal member of the chromosome pair. These gene alleles will segregate, one-half of the gametes formed carrying one allele and the other half carrying the other. If female and male gametes unite at random at fertilization—i.e., if there is no tendency for sex cells with similar or with different gene alleles to seek out or to avoid each other—the segregation ratios observed by Mendel necessarily follow.

The correctness of the above reasoning was demonstrated experimentally by the renowned U.S. geneticists Thomas Hunt Morgan, Calvin B. Bridges, Hermann J. Muller, and Alfred H. Sturtevant. Morgan and his colleagues made use of the then new experimental material, the vinegar fly (often called fruit fly) *Drosophila melano-*

The "fruit fly" school of genetics

Linkage  
of genes

*gaster*. This fly has four pairs of chromosomes in each of its body cells, while its sex cells carry only four chromosomes, one representative of each pair. The chromosomes of maternal and paternal origins in different pairs are distributed randomly at meiosis, and the microscopically observed random distribution of the chromosomes is paralleled by the random assortment of genes discovered by Mendel. In *Drosophila*, however, more than four, and eventually several hundred, variant genes were discovered. Clearly then, a chromosome may contain several genes. If so, can the random assortment of the genes be an invariable rule? The genes carried on the same chromosomes do exhibit some tendency to remain together in inheritance. As the chromosome is transmitted, so are all its genes transmitted. This tendency, called linkage, was shown to parallel the chromosome assortment at meiosis. The known genes in *Drosophila* belong to four linkage groups, the same number as that of the chromosome pairs. Moreover, one linkage group consists of genes that express themselves in individuals of one sex—that is, they exhibit a sex-linked inheritance; this linkage group is carried in the X chromosome, which is also responsible for the determination of sex. Of the remaining three chromosome pairs, two are large and one very small; correspondingly, there are two linkage groups with many genes and one with relatively few, as demonstrated in the progenies of crosses.

The analysis of the relationship between the genes and the chromosomes can be carried further. In the formation of sex cells, genes located in different chromosomes are assorted at random; *i.e.*, by chance they remain together in the original parental combinations in 50 percent of the sex cells and, because of crossing-over (see below), form new combinations in the remaining 50 percent. This expectation, however, is not always realized, because genes carried on the same chromosome are linked in various degrees—quite tightly, loosely, or moderately—the frequency of new gene combinations ranging from near 0 to 50 percent. The closer together the genes are in the chromosomes, the tighter the linkage and the lower the frequency of recombination; conversely, the farther apart the genes are, the looser the linkage and the higher the frequency of recombination. Consequently, the degree of linkage may be used as a measure of the distance between the genes. The members of each chromosome pair twist around each other at meiosis, establishing points of contact called chiasmata (singular, chiasma), and exchange segments. This crossing-over and exchange of chromosome segments was pointed out by Morgan as the explanation of linkage and recombination. A chiasma will be formed less often between neighbouring genes than between genes far apart in the chromosome.

**The linear order of genes.** Morgan's idea was expanded into a theory of the linear arrangement of the genes in the chromosomes. When the frequencies of recombination (expressed in crossover units) between genes *A* and *B* and *B* and *C* are known, the frequency between *A* and *C* can be predicted (Figure 3). If crossing-

Figure 3: Crossing-over percentages used in establishing the linear order of genes in a chromosome (see text).

over between *A* and *B* occurs 5% of the time and crossing-over between *B* and *C* occurs 3% of the time, then, when the percentage of crossing-over between *A* and *C* is tested, it is either 8% ( $AB + BC$ ) or 2% ( $AB - BC$ ). This suggests that the genes are arranged in the chromosome in a linear file, either *ABC*, if crossing-over between *A* and *C* is 8%, or *ACB*, if crossing-over is 2%. When *AB* and *BC* are large (say, 10% or more), *AC* may be

less than  $AB + BC$ . This is explained by the occurrence in the chromosome of more than a single chiasma between the loci of remote genes. Knowing the degree of linkage of several genes in the same chromosome, it is possible to plot a genetic map of the chromosome. Genetic maps of the chromosomes of *Drosophila melanogaster* were first published in 1915 in *The Mechanism of Mendelian Heredity* by Morgan, Sturtevant, Muller, and Bridges. At present, genetic maps of various degrees of precision exist for several organisms.

The genetic, or linkage, maps of chromosomes are constructed entirely on the basis of statistical data concerning the frequencies of recombination between linked genes observed in various crossing experiments. In principle at least, such maps could as well be drawn had the actual, microscopically visible chromosomes never been discovered. A proof that the linear order of the genes shown on the genetic maps is really the same as their arrangement in the chromosomes became possible after the discoveries of various chromosomal aberrations in *Drosophila melanogaster*. Sections of chromosomes are sometimes lost (deficiency or deletion), reduplicated (duplication), transferred from one chromosome to another (translocation), or rotated by 180° in the same chromosome (inversion), as shown in Figure 4. Chromo-

W.B. Saunders Company, Philadelphia

Figure 4: Types of chromosomal mutations.

somal aberrations are generally rare, but their frequencies are increased in the progenies of parents treated with high-energy radiations. Using techniques developed chiefly in *Drosophila* and in corn, the chromosomal aberrations can be studied genetically. The blocks of genes that are lost, duplicated, translocated, or inverted can be delimited in terms of the sections of the genetic maps. Some chromosomal aberrations can also be discovered under the microscope, because they make certain chromosomes longer or shorter than normal, or fragmented. Extraordinary refinement in the study of the locations of genes in chromosomes became possible after the discovery of giant chromosomes in the cells of salivary glands of many flies, including *Drosophila*. They appear to consist of alternating dark (stainable by nuclear dyes) and light bands or disks; because the total length of the salivary-gland chromosomes is a hundred or more times greater than those in other *Drosophila* cells, it is possible to see chromosomal changes so minute that they escape detection in the normal-sized chromosomes. The first cytological maps, showing the location of certain genes of *Drosophila melanogaster*, were drawn at first for the chromosomes in the developing sex cells and nerve cells and subsequently, with far greater precision, in the giant chromosomes of the salivary glands.

The linear order of the genes as shown on the genetic maps coincides with that on cytological maps, but the relative distances are not always the same. This is explained by the more frequent occurrence of chiasmata in some parts of the chromosomes than in other parts. The salient fact, however, is that the symbolic genes finally were shown to be material particles in the chromosomes. The question inevitably arose whether the genes are absolutely discrete particles or only segments

the linear  
order of  
genes

Influence  
of genes on  
other  
genes

of some kind of a continuum. A chromosome with its genes has sometimes been likened to a string of beads. Many investigators found this simile much too crude and envisaged genetic variations as generalized changes in whole chromosomes. Molecular-level analysis of the genes (see below) eventually established that the actual situation lies somewhere between these extremes, but some evidence of interdependence of neighbouring or adjacent genes was obtained through the discovery of position effects. The functioning of a gene apparently depends not only on the intrinsic properties of that gene but on those of the neighbouring genes as well.

### Nature of the gene

Perhaps the most impressive and spectacular advance of biology in the 20th century was the discovery of the nature of the genetic material. The way information is encoded in the genes has been clarified, and much has been learned about the mechanisms that translate this information into the developmental processes of the organism.

### FUNCTIONAL ANALYSIS

While the pioneers of genetics used higher plants and animals as experimental materials, much of the work since the late 1940s has been done with micro-organisms—bacteria, viruses, and the mold *Neurospora crassa*. The great store of biochemical and physiological data accumulated by bacteriologists has been invaluable for clarifying genetic mechanisms, and the genetic studies have in turn helped to elucidate metabolic pathways in the experimental micro-organisms.

**Recombinational ability.** In 1947 it was proved that certain strains of the colon bacteria (*Escherichia coli*, usually abbreviated to *E. coli*) undergo conjugation, a true sexual process in which genetic recombination can occur. Another kind of genetic recombination is caused by transformation, in which a bacterial cell incorporates a segment of DNA received from the medium into its own chromosome. A still different mechanism of gene recombination is transduction, which involves the transfer of sections of chromosome from one bacterial cell to another by means of attachment to the chromosome of a bacteriophage (bacterial virus). A diagrammatic representation of these processes is shown in Figure 5.

The discovery of the sexual process (see below) was made possible by the availability of mutant strains differing in nutritional requirements. Ordinary strains of *E. coli* grow well on a minimal medium of a simple carbon source, usually the sugar glucose and several inorganic elements. Some mutants require particular carbon sources; for example, a mutant may grow well on a glucose medium but not on a medium containing the sugar galactose. Consider two strains of *E. coli*, each of which has two different mutants that change the nutritional requirements of their carriers. If the ordinary so-called wild-type *E. coli* carries the genes *ABCD*, the two mutant strains can be represented as *ABcd* and *abCD*, where the lowercase letters stand for variant gene alleles that result in the inability of their carriers to grow on the minimal medium. Thus, *ABCD* bacteria grow on the minimal medium well, while *ABcd* and *abCD* strains require mediums with certain chemical substances in addition to those in the minimal one. Cultures of *ABcd* and *abCD* bacteria were mixed together, and, after a short period of time, samples of the mixture were taken and placed on solid minimal medium in Petri dishes. Most of the bacteria failed to grow, but some colonies of cells did appear. These colonies consisted of cells carrying the genes *ABCD*, like the wild-type *E. coli*. The appearances of *ABCD* cells were far too numerous to be accounted for by simultaneous mutation. Their appearance in the mixtures must be the result of gene recombination.

Certain strains of *E. coli* manifest recombination through conjugation. Two mating types, conveniently referred to as "males" and "females," have been found. Male bacterial cells are determined by the presence of a genetic factor called F (for "fertility"), while female cells lack the F factor. Male cells are designated  $F^+$ ; female cells are designated  $F^-$ . In males, the F factor can exist in

Figure 5: Genetic transmission in bacteria.

From T. Watanabe, *Infectious Drug Resistance*. Copyright © 1967 by Scientific American, Inc. All rights reserved.

two states, either as an integral part of the male bacterial chromosome or as a free particle in the cytoplasm. Males with a free F factor can conjugate with an  $F^-$  cell, but only the F factor is transmitted to the  $F^-$  cell. But male cells with an integrated F factor always transfer parts of their chromosomes to the female cells. These male  $F^+$  cells are designated Hfr because they yield a high frequency of recombination with  $F^-$  cells.

A cross between  $F^+$  cells that are not Hfr and  $F^-$  cells results in conjugation, but only the previously mentioned F factor is transferred. Only  $F^+$  cells result from such matings. In crosses between Hfr cells and  $F^-$  cells, however, a portion of the bacterial chromosome is transferred; recombination occurs between the portion of the transferred chromosome and the  $F^-$  chromosome.

The observation that the F factor is rarely transferred in an Hfr  $\times$   $F^-$  cross led to the hypothesis that the F factor is the last piece of the chromosome to be transferred. Electron-microscope photographs revealed a cytoplasmic tube connecting bacteria of opposite mating types during conjugation of Hfr  $\times$   $F^-$  cells. The progress of chromosome transfer can be followed by recording which genes of the male cell appear in recombinants arising from the female cell. Suppose the Hfr cell has the genes *ABCDE* so arranged on its chromosome, *A* being transferred first. Suppose further that the  $F^-$  cell has the genes *abcde*. Recombinant bacteria resulting from this cross can be recognized by the presence of one or more genes originating from the Hfr cell. The experiment was performed by artificially interrupting the conjugation between bacterial pairs by violent agitation in a high-speed food blender (Figure 6). When conjugation was interrupted after five minutes, only a small portion of the male chromosome was transferred, and, inasmuch as the *A* gene was not located at the tip of the transferred portion of the chromosome, no recombinants were observed. When mating continued for 20 to 30 minutes, several or all genes were transferred, and recombinants were observed. Transfer of the entire male chromosome is rare, requiring about a two-hour mating. The F factor (not in diagram) was transferred last, thus confirming the hypothesis that it is located at the end of the chromosome.

From W. Hayes, *The Genetics of Bacteria and Their Viruses* (1964); John Wiley & Sons, Inc.

Data derived from the interrupted-mating experiment can be used to construct genetic maps of the bacterial chromosome. The length of time needed for a gene to be transferred is a measure of its position along the chromosome. Several Hfr strains have been found that transfer their genes in different orders. Analysis of these strains indicates that the bacterial chromosome is a circular structure. The various Hfr strains result from the integration of the F factor at different points along the circular chromosome. At the beginning of the conjugation, the chromosome breaks at the location of the F factor; the chromosome tip not containing F is transferred to the F<sup>-</sup> cell first.

**Information transferral.** The evidence that nucleic acids, especially deoxyribonucleic acid (DNA), act as the carriers of the genetic information came convergently and within a short period of time from several sources (for the chemistry of these complex molecules, see NUCLEIC ACIDS). The amounts of DNA per nucleus vary greatly in different animals. The amphibian *Amphiuma* has  $168 \times 10^{-9}$  milligrams of DNA per cell, while the jellyfish *Cassiopeia* has only  $1.43 \times 10^{-9}$  milligrams. Man is intermediate, with about  $6 \times 10^{-9}$  milligrams DNA per cell. There is, however, a remarkable constancy of DNA quantity in the nuclei of cells of different tissues in each species. The only exception to this rule is that the nuclei of gametes, such as spermatozoa in animals, have, within

the limits of error of the measurements, one-half of the amount of DNA present in body cells. This is exactly what one should expect, since meiosis results in the gametes being reduced to one set of chromosomes. No other cell constituents show such constancy.

Further evidence involving DNA as the genetic material was provided by the demonstration that the "transforming principle," which induces changes in the pneumonia bacteria (pneumococci), consists of DNA. The ability of pneumococci to cause infection, the virulence, depends on the presence of a polysaccharide (composed of sugar subunits) envelope surrounding the bacterial cells. When grown on laboratory culture mediums, virulent pneumococci produce large colonies that have a smooth, glistening surface. Bacteria from such cultures produce infection in mice. After many transfers on fresh laboratory mediums, however, the bacteria tend to lose their polysaccharide envelopes and their ability to infect mice; correlated with these changes is the change to small colonies with rough outlines. The smooth and the rough variants are designated S and R, respectively. Mice inoculated with either the living R pneumococci or the heat-killed S pneumococci remain free of infection, but mice inoculated with a mixture of living R and heat-killed S bacteria become infected. Living S pneumococcal cultures can be obtained from such animals, proof that the virulent S cells were reconstituted from the mixture inoculated. Some material derived from the dead S bacteria induced the transformation of R into S strains. This material was shown by extensive chemical tests to be DNA. Thus, it is the hereditary material from the dead bacteria that determines the genetic character induced in the living ones.

How does the DNA of the dead cells accomplish the transformation of the living ones? It evidently must penetrate the wall of the living cell. Once a section of the transforming DNA strand is inside the recipient cell, there apparently occurs a pairing between homologous regions of the bacterial chromosome and the transforming DNA. There must follow breakage and subsequent reunion of the bacterial chromosome and the transforming DNA. Thus a portion of the transforming DNA becomes integrated into the bacterial chromosome. If this model is valid, one would expect that genes located near each other on the transforming DNA would appear together more often in a transformed cell than will genes relatively far apart in the transforming DNA. This expectation is fulfilled, and the principle has been utilized as a means of mapping the donor cell chromosome.

Further evidence that DNA serves as the physical basis of heredity was obtained in the early 1950s, using bacteriophages that attack *E. coli*. The bacteriophage (or simply phage) is an ultramicroscopic tadpole-shaped body, with a hexagonal head, a cylindrical tail, an end plate, and six tail fibres (see VIRUSES). The head contains the DNA; the outer surface and the tail consist of protein. A phage particle attacking *E. coli* attaches itself by its tail plate to the surface of the host bacterial cell. The DNA from the head then passes through the tail and into the body of the host. The metabolic machinery of the bacterial cell is subverted to make phage DNA and phage protein. When a new generation of the phage particles is ready inside the bacterium, destruction (lysis) of the latter takes place, and a hundred or more new phage particles are released into the external medium, where they can attack other bacterial cells.

#### STRUCTURAL ANALYSIS

The remarkable properties of the nucleic acids, which qualify these substances to serve as the carriers of the genetic information, have claimed the attention of many investigators. The groundwork was laid by pioneer biochemists who found that nucleic acids are long chainlike molecules, the backbones of which consist of repeated sequences of phosphate and sugar linkages—ribose sugar in RNA and deoxyribose sugars in DNA (see NUCLEIC ACIDS). Attached to the sugar links in the backbone are two kinds of purines, adenine (A) and guanine (G), and two kinds of pyrimidines, cytosine (C) and thymine (T) in DNA or cytosine (C) and uracil (U) in RNA. A single

Effect of the DNA of dead bacteria on living bacteria

Evidence for DNA as the genetic material

purine or a pyrimidine is attached to each sugar, the compound being called a nucleotide. The nucleic acids extracted from different species of animals and plants have different proportions of the four nucleotides. Some are relatively richer in adenine and thymine, while others have more guanine and cytosine; however, the ratios of A to T, and also of G to C, are equal.

**Molecular structure.** On the basis of results of X-ray crystallography on DNA, James Watson and Francis Crick proposed in 1953 their now-famous model, which shows DNA as composed of two spirally wound (helical) chains, in which the A's (adenines) in one chain are always linked by hydrogen bonds to T's and the G's in one chain to C's in the other. This model fulfills the basic requirements—it makes it possible to envisage how genes replicate their precise structures when their copies are synthesized. It also makes it possible to explain how a gene can carry genetic information written in some chemical code. And, finally, it helps to envisage how mutational changes in the genes are produced.

The Watson-Crick model of the genetic material permits an explanation of the mechanism of precise replication of genes (Figure 7). The paired complementary

bility, termed semiconservative replication, would result in two molecules of DNA, each composed of one old and one new strand. Another possibility, conservative replication, is that the DNA molecules serve as templates for

From W. Braun, *Bacterial Genetics* (1965); W.B. Saunders Company, Philadelphia

Figure 8: Three possible modes of replication of DNA. Parental DNA is indicated in black; the newly synthesized DNA is indicated in white. The DNA strands are shown as straight for ease in representation.

Figure 7: A possible method for the replication of DNA according to Watson and Crick. The arrows indicate the direction of rotation.

strands of the DNA molecule may separate as a result of a breakage of the hydrogen bonds between the nucleotides. If free nucleotides (base + sugar + phosphate) are present in the medium surrounding the gene, they might pair with the complementary bases on the single strands of DNA. An enzyme, DNA polymerase, functions to form the phosphate bonds between the sugars in the DNA backbone. It has been used in the synthesis of DNA in vitro, in cell-free systems. The enzyme is extracted from rapidly dividing cells of the familiar bacterium *E. coli*. A supply of the four nucleotides, A, T, G, and C, is provided, as well as a source of energy, adenosine triphosphate (ATP). To start DNA synthesis another key component is added—a trace of DNA to serve as a primer. The kind of DNA that is synthesized depends on the primer. Even though the enzyme came from *E. coli*, if the primer is DNA of some quite different organism, such as cattle, the DNA that is synthesized is not *E. coli* but cattle DNA.

There were at least three possible ways to envisage the mechanism of replication of DNA (Figure 8). One possi-

the synthesis of new DNA without separation of the pairs of strands. The third possibility, dispersive replication, states that the parental DNA molecule breaks up into fragments, each of which is replicated separately. Results of many experiments are consistent with the semiconservative model of DNA replication and rule out the other models. Evidence indicates that the same mechanism of replication of DNA as found in bacteria occurs in higher organisms. Synthesis of new DNA occurs while the old chromosome is in the process of uncoiling.

**Changes in chromosomes.** Much of the information on the fine structure of genes has proceeded from studies of bacteriophages, because they mutate, or change genetically, very readily and because they exhibit several recombinational phenomena, including transduction, which consists of the transfer by bacteriophages of portions of chromosomes from one bacterial cell to another.

**Mutation.** Suppose that a drop of some substance suspected of containing bacteriophages is placed on the surface of a culture medium consisting of agar covered with a layer of *E. coli* bacteria. If phages are present, they will infect the bacteria and eventually cause their death. The bacteria layer will develop holes, or plaques, as a result of the destruction of the individual bacteria by lysis. Because each plaque develops from a single phage particle, the number of such plaques formed gives an estimate of the abundance of phages in the inoculum. Each type of phage forms a plaque of characteristic appearance; thus, mutations can be detected as variations in plaque form.

Crosses between mutant phages of different types can be made if a single bacterium is simultaneously infected with two phage mutants. A proportion of the progeny phage will be recombinants for the mutants in question. If a bacterium is infected with two types of phages, one having the genes *ab* and the other *AB*, recombination results in the appearance of some phage particles having the genes *ab* and *AB*. This method of crosses has been utilized to construct a genetic map of the bacteriophage designated T4 phage. The map is circular, indicating the physical continuity of the T4 chromosome.

Not all bacteriophages cause the destruction of their host cell by lysis. A class of phages termed temperate has the ability to enter into a symbiotic relationship with the bacterial host cell. The chromosome of the temperate phage becomes incorporated into the bacterial chromosome and is replicated only when the bacterial chromosome replicates. A bacterial cell in this state is termed lysogenic for the phage in question. If, however, the chromosome of a temperate phage becomes dissociated

Mutant phages that reveal a circular chromosome

from the bacterial chromosome, it is capable of autonomous replication, which results in the lysis of the host cell. A temperate phage can be artificially induced to enter an autonomous state through the action of such stimuli as ultraviolet light.

**Transduction.** The mechanism of transduction seems to be as follows. The chromosome of the phage particle is a ring-shaped structure. This chromosome pairs with a certain region of the bacterial chromosome. Both chromosomes then break, and the reunion of the broken ends results in the insertion of the phage chromosomal material into the bacterial chromosome.

Transduction has been utilized to construct a map of the bacterial chromosome. The genes that lie close together in the chromosome will usually undergo transduction together, and, if three or four genes are followed simultaneously, their order in the chromosome can be determined.

**Complementation.** The classical Morgan-Muller conception of the gene was defined as a unit of function (its mutants changing, for example, the eye colour, the wings, or the bristle shape in *Drosophila* flies); a unit of recombination (having a definite position on the genetic map); and a unit of mutation (similar mutational changes arising repeatedly). These three criteria of defining and delimiting the genes usually coincided and thus gave concordant results. Genetic experiments on *Drosophila* flies, however, deal with numbers of individuals generally several orders of magnitude smaller than are involved in many experiments with micro-organisms. Beginning in 1955, detailed studies on portions (the "rII region") of the chromosome of the bacteriophage T4 were responsible for a change in definition of the gene. A U.S. geneticist, Seymour Benzer, found a mutant (r) of the phage T4 that caused rapid lysis of one strain (B) of *E. coli* but could not lyse another strain (*E. coli* K12 [λ]). This latter strain, however, was lysogenic for the phage lambda (λ). This finding led to the development of complementation, or cis-trans, tests and to the detection of very small frequencies of recombination. When various combinations of rII mutants are used to infect *E. coli* K, two kinds of results are observed. In some combinations of mutants normal plaques are formed, while other combinations yield no plaques. The mutants belong to two groups called rIIA and rIIB, which have altered functionally different regions of the phage chromosome. When two mutants belong to different groups they complement each other, reciprocally compensate for each other's deficiency, and give viable phages that produce normal plaques.

According to the classical gene theory, the mutants that do not complement each other must be alleles of the same gene. But, since it can be determined by recombination mapping that all rIIA mutants do not occur at a single spot on the phage chromosome, the definition of a gene must be altered. The functional groups of mutants may be designated as cistrons (defined by cis-trans tests). All mutations that are functionally allelic are, therefore, members of a cistron.

This material also provides an extremely sensitive method for detecting recombination between mutants within a given cistron. *E. coli* B may be infected with two rIIA mutants that permit normal reproduction and crossing-over. After the cells are lysed, progeny phages are collected, and *E. coli* K and B are infected with known quantities of phage. If recombination occurs, a few small plaques representing wild-type phage appear on the K host. The number of plaques on the B host gives an estimate of the total number of phage particles used. The ratio of the number of plaques on K to the number on B hosts is an estimate of the amount of recombination between the two mutants in question. This method is sensitive enough to detect one recombination event in 100,000,000. The amount of recombination between two mutants is then used as an estimate of the distance between them in the chromosome. When many such mutants are crossed by this method, a map of the rII region of the bacteriophage chromosome emerges, on which all rIIA mutants, as determined by complementation tests,

fall into one segment, while all rIIB mutations fall in another segment.

To localize the some 3,000 mutants of the rII type on the chromosome map involves an enormous amount of time and labour, even though phage crosses can be made rapidly. The problem is more manageable with the aid of mutants that apparently result from deletions (deficiencies) of short sections of the phage chromosome. Utilizing deficiency mutants, sites at which mutation or recombination can occur are more easily mapped within the rII region of the chromosome. The names *muton* and *recon* have been proposed for the smallest units that can mutate and recombine. The rII region represents about 2 percent of the total length of the genetic map of the phage T4 chromosome, and the DNA composing this region is estimated to contain about 4,000 nucleotide pairs. The large number of mutation and recombination sites discovered in the rII region of the chromosome suggests that the mutation and recombination units may be the nucleotide pairs. The genetic units of function, recombination, and mutation thus do not coincide. The Morgan-Muller gene corresponds most closely to the modern conception of the cistron as a unit of function.

**Extranuclear genetic material.** Some characteristics of organisms do not show Mendelian segregation and, among higher organisms, are inherited through the maternal line only (see HEREDITY). Thus, the cells of green plants contain in their cytoplasm bodies called chloroplasts, which carry the green pigment chlorophyll. In corn (maize), variants are known whose leaves are striped green and yellow because of the absence of chlorophyll in the chloroplasts of some cells. Since no chloroplasts are present in pollen grains, the conclusion is that chloroplasts are self-replicating bodies in egg cells and in part control their own characteristics.

Similar conclusions of maternal inheritance have been drawn from studies of certain growth mutants in yeasts and in the bread mold *Neurospora crassa*. The presence of extranuclear genetic materials suggests that DNA must be present within the cellular bodies in question.

In the early 1960s the existence of DNA within chloroplasts and mitochondria was demonstrated. The subsequent discoveries of ribosomes, transfer RNAs, and other enzymes within mitochondria and chloroplasts suggest that these cytoplasmic bodies may synthesize part if not all their own proteins.

## Genes and development

### GENE ACTION

**The one gene-one enzyme hypothesis.** The study of mutations that alter metabolic processes has shed light on the mode of action of the genes in the development of the organism. The normal expression of a genetic trait (such as eye colour in *Drosophila* flies) involves a chain of chemical reactions transforming a substance A into B, B into C, C into D, etc. Each transformation is facilitated by a specific enzyme, and each enzyme is a product of a certain gene, hence the one gene-one enzyme hypothesis. A mutation, then, may stand for the absence of an enzyme.

In the early 1940s studies of biochemical mutants in the bread mold *N. crassa* were very significant in advancing knowledge of gene action. Most strains of this mold grow well on a minimal medium containing sugar, an inorganic nitrogen source, and the vitamin biotin. Some mutant strains, however, do not grow on the minimal medium and require for growth the addition of certain substances that normal *N. crassa* can synthesize itself. Among many mutants studied in *N. crassa*, those concerned with synthesis of the amino acid tryptophan proved particularly favourable for study. Tryptophan is synthesized as follows: anthranilic acid (A) → indole (B) → tryptophan (C). Mutants were found that blocked the step A → B, others that blocked B → C. Apparently, each step is facilitated by an enzyme produced by a separate gene, and a mutational change in the gene may cause a lack of the enzyme or may make it ineffective.

**The determination of protein structure and synthesis.** Proteins, basic components of living organisms, are con-

structed from nitrogen-containing compounds called amino acids. Some 20 amino acids are commonly found in naturally occurring proteins. The amino acids are linked together in the proteins by a specific chemical bond, the peptide bond, to form long chains. It is the sequence of the amino acids in a protein that is uniquely determined by the sequence of the four bases in DNA. The amino-acid sequence or primary structure of a protein usually determines the three-dimensional structure that the complete protein molecule will take. Interactions between various chemical groups on the amino-acid units of protein are responsible for the three-dimensional structure that results. Three groups of proteins can be recognized: (1) enzymes, or catalytic proteins, which participate in almost all chemical reactions that take place in cells of living bodies; (2) structural proteins, which form the building blocks of cellular components; and (3) regulatory, or control, proteins, which interact with genes or their products to control the amounts and presumably the times of production of still other protein molecules.

The amino-acid sequence of a protein such as human hemoglobin shows that these molecules are composed of several protein subunits, usually called polypeptide chains, linked together by chemical bonds. Normal hemoglobin (A) is composed of four polypeptide chains, two alphas ( $\alpha$ ) and two betas ( $\beta$ ), whose amino-acid sequences show considerable similarity.

An example of the difficulty encountered by the one gene-one enzyme hypothesis is provided by the variants in the human hemoglobin molecule. Genetic studies of individuals having mutant hemoglobins have shown that the alpha and beta chains of hemoglobin are controlled by two genes located on two different chromosomes. This suggests that the one gene-one enzyme hypothesis should be modified to a one gene-one polypeptide chain hypothesis.

Further studies of mutant hemoglobins have elucidated how the gene might control the specific amino-acid sequence of a polypeptide. A hereditary disease in humans, sickle-cell anemia, was first discovered in Africa and the Mediterranean regions of Europe and Asia. Clinical manifestations of this affliction include a change in the form of the red blood cells to a sicklelike shape. Chemical study of the hemoglobins of persons with sickle-cell anemia revealed the presence of an abnormal hemoglobin designated hemoglobin S. Hemoglobin S is composed of two normal alpha chains and two altered beta chains. A study of the amino-acid sequence of the mutant beta chain revealed a single amino-acid substitution: the glutamic acid at a certain position in the normal chain had been replaced by valine in the mutant chain. Several other mutant hemoglobins were discovered, and their analyses again showed a single amino-acid substitution, compared with the hemoglobin present in "normal" persons. The mutants responsible for these variant hemoglobins evidently alter the genes so that a single amino-acid difference appears in the mutant. Table 1 lists some of these abnormal hemoglobins. Hemoglobin I, for ex-

ample, shows a substitution of aspartic acid for lysine at position 16 in the alpha chain. The beta chain of hemoglobin C has a lysine substituted for glutamic acid at position 6.

Further evidence for the genetic control of the amino-acid sequences in polypeptide chains of proteins was obtained in 1964 in studies on *E. coli*. The enzyme tryptophan synthetase in *E. coli* consists of two polypeptide chains, designated A and B. A number of mutants exist that result in inactive forms of the enzyme, the result of amino-acid substitutions in the A chain. Precise genetic mapping of these mutants reveals a collinearity, an exact linear correspondence between the mutants on the genetic map and the positions of amino-acid substitutions in the altered A-chain polypeptides. The collinearity of the genetic map and the polypeptide chains is convincing evidence that specific regions of a gene encode for the sequence of amino acids in polypeptide chains.

THE GENETIC CODE

The discovery of the ways in which the sequence of the nucleotides in the DNA of a chromosome is translated into the sequence of amino acids in a protein is one of the outstanding achievements of molecular biology. This is often called the transcription function of DNA, to distinguish it from the duplication function, in which DNA replicates itself (see above).

**The "letters" of the genetic alphabet.** The information contained in DNA is first transcribed into an RNA molecule, from which the information is subsequently translated into protein. The hypothesis can be represented thus: DNA  $\rightarrow$  RNA  $\rightarrow$  protein. Reverse transfer does not occur; i.e., there is no storage of information in the protein molecules and no transcription of it back into nucleic acids. This is sometimes referred to as "the central dogma" of molecular genetics.

Tiny particles in the cytoplasm of cells have been identified as the sites of protein synthesis. These particles, called ribosomes, consist of both RNA and protein. Besides the ribosomal RNA, another kind of RNA, called messenger RNA (mRNA), found both in the nucleus and in the cytoplasm, serves as a carrier of the genetic information from the nuclear DNA to the ribosomal RNA. The sequence of the genetic letters, A (adenine), T (thymine), C (cytosine), and G (guanine), in the DNA is first transcribed into the corresponding sequence of the letters A, U (uracil), C, and G in the messenger RNA. This occurs through the action of the enzyme RNA polymerase. This enzyme synthesizes RNA in a test tube from a mixture of the A, U, C, and G bases, but it does so only in the presence of a primer DNA. The sequence of the bases in the primer is copied in the RNA. The steps involved in this process are: (1) the DNA double helix unwinds by breaking the hydrogen bonds between the corresponding bases in the paired strands; (2) the RNA polymerase forms the bonds between the RNA bases that are complementary to the bases in the DNA; and (3) the messenger RNA thus formed passes into the cytoplasm and becomes attached to a ribosome.

The process of protein synthesis is represented diagrammatically in Figure 9. The information contained in the sequence of the bases (letters) in the messenger RNA is then translated into a sequence of amino acids in a protein. This requires the presence of still another molecule that is capable of recognizing the code for a specific amino acid and selectively making the amino acid available at the right point in the protein synthesis, a soluble RNA fraction within cells that can bind amino acids. Soluble, or transfer, RNA (SRNA, or tRNA) is a single-stranded molecule that forms about 20 percent of the total cellular RNA. If amino acids and a source of energy (usually ATP) are added to a mixture of transfer RNA's, reversible binding of the amino acids to the RNA molecules occurs. Furthermore, each amino acid is bonded to a specific transfer RNA molecule by a specific activating enzyme. There are at least 20 different transfer RNA's and activating enzymes that correspond to the 20 amino acids commonly found in proteins. The amino acid-transfer RNA complex becomes attached to the ribosome with its messenger RNA

The one gene-one polypeptide chain

The central dogma of molecular genetics

Table 1: Amino Acid Substitutions in Abnormal Human Hemoglobins

hemoglobin type	substitution	position in chain
in the alpha chain:

Figure 9: Synthesis of protein.

(Top) The messenger RNA shown with a ribosome (in stages) "reading" its message, the translation occurring from left to right, and the polypeptide chain growing as the ribosome proceeds along the messenger RNA. (Bottom) A highly magnified ribosome in the process of "reading" a messenger RNA molecule. The ribosome has just "read" an AAG sequence off the messenger RNA, and a specific transfer RNA molecule (UUC) moves into place carrying the amino acid lysine (Lys), which is then added to the polypeptide chain. Next in position to be read is CCU, which draws a transfer RNA molecule carrying the amino acid proline (Pro) to be transferred to the growing polypeptide chain. The ribosome moves from left to right along the messenger RNA molecule. Each ribosome has two binding sites for transfer RNA: one that holds the growing polypeptide chain and a second for positioning a new transfer RNA molecule for processing.

From T. Jukes, *Molecules and Evolution* (1966); Columbia University Press

molecule; the addition of the amino acid to the growing polypeptide chain then occurs. A sequence of bases (anticodon) on the transfer RNA molecule pairs with a complementary sequence (codon) on the messenger RNA molecule, which is held in the correct position by the ribosome. Once the recognition has occurred, a peptide bond is formed between the amino acid bound to the transfer RNA and the growing polypeptide chain.

**Reading the code.** How do the four letters—A, T, C, and G—specify, or code, for 20 different amino acids? If a single letter coded for an amino acid, only four amino acids could be specified. If two bases were needed to specify an amino acid, then 16 different combinations could be constructed, again an insufficient number (20 amino acids must be accounted for). Combinations of three letters allow 64 different words to be constructed, more than the necessary minimal number. A three-letter, triplet, code could be constructed in at least three different ways: (1) with words overlapping; (2) with words not overlapping and punctuated; and (3) with words not overlapping and not punctuated. An overlapping code is composed of words that overlap each other—i.e., the letters of any given word may belong to one, two, or three words. The DNA might contain, for example, the sequence A G C G T T A C G; the first word is AGC, the second CGT, and so on. This type of code is improbable, because of the restrictions it would place upon the possible sequence of amino acids in protein. As the example above shows, if the first word is AGC, the second word must begin with C, etc. Examination of amino-acid sequences in a protein such as hemoglobin indicates that any amino acid can follow any other—a possibility not allowed for by an overlapping code.

If the code is nonoverlapping, a problem of distinguishing words from each other arises. DNA contains no spaces separating the words as in written sentences; therefore,

there must be other indications of specific starting points for messenger RNA synthesis. The base sequence AGC AGC AGC... could be punctuated by the presence of a fourth base, T, between each AGC triplet. This would reduce the number of possible triplets to 27. That a punctuated code of this type is not realized is seen from the evidence of the degeneracy in the code for some amino acids. The degeneracy means that some amino acids are coded for by more than one triplet, and a punctuated code does not allow enough words. A second objection to this type of code comes from a consideration of the effects of mutation on the coding sequence. If one of the punctuation marks mutates to another base, or a coding base mutates to a punctuation mark, the resulting sequence will be complete nonsense functionally.

The third possibility is a nonoverlapping, nonpunctuated code, in which the reading starts from a specific point. In all organisms studied in this respect this is the method of coding used. If the reading of the genetic message begins at a fixed place in a DNA strand, then the addition or the removal of a single letter will alter the message from that point on. Suppose that the DNA message read from left to right reveals the triplets GAC, TCA, and TTA (which are transcribed in the RNA code as CUG, AGU, AAU). Deletion of the first T alters the reading frame so that triplets GAC, CAT, TA... will be read. The first triplet is unchanged, but all the remaining triplets may specify wrong amino acids. The chemical addition of a base to the sequence likewise shifts the reading frame; such a mutant will also specify wrong amino acids beyond the point of the base addition. If an original mutant resulted from the deletion of a base from the DNA, the addition of a base at a point beyond the first mutation would restore the reading frame of the DNA sequence, and would result in nearly normal function. In the bacteriophage T4, assume that the original wild-type phage DNA sequence within the rII region reads ACT GGC TAG CTG TCA TCG... Deletion of the C in the second triplet results in the following triplets being read: ACT, GGT, AGC, TGT, CAT, CG... This is an rII mutant. The subsequent addition of a base (A) between the third and fourth mutant triplets results in the following sequence: ACT GGT AGC ATG TCA TCG... Note that the first, fifth, and sixth triplets are identical to those in the original wild-type phage. Only the second, third, and fourth triplets are altered, and the reading of the code from the fourth triplet on will be identical to that in the wild-type phage. Frequently, suppressor mutations occur in proximity to other mutations and restore the reading frame of the DNA sequence, thereby allowing a sequence of amino acids differing only slightly from the original one to be formed in the protein.

A knowledge of the base sequence in the messenger RNA and the resulting amino-acid sequence in protein reveals the code for each amino acid. The triplet UUU, for example, is the code for the amino acid phenylalanine, corresponding to the sequence AAA in the DNA. Poly-A (AAA) and poly-C (CCC) messenger RNA's code for lysine and proline, respectively.

Other triplets were tested for their coding abilities by synthesizing messenger RNA molecules with varying proportions of the two bases. If, for example, a mixture of the two bases U and C in a 5:1 proportion are synthesized into RNA, the possible triplets and their probable frequency in the synthetic messenger RNA can be easily determined. The triplet UUU will be most common and will appear with the frequency  $(\frac{5}{6} \times \frac{5}{6} \times \frac{5}{6})$ ; the triplets UUC, UCU, and CUU will appear in the frequencies of  $\frac{5}{6} \times \frac{5}{6} \times \frac{1}{6}$ ; the triplets UCC, CUC, and CCU will be the next most frequent and will appear with a frequency of  $\frac{5}{6} \times \frac{1}{6} \times \frac{1}{6}$ ; while the triplet CCC should appear only  $\frac{1}{216}$  of the time. A messenger RNA of this composition should result in the incorporation into protein of eight different amino acids. In fact, only four amino acids were present in the protein produced; this means that several of these triplets encode for the same amino acid and therefore that the code is degenerate.

The RNA code triplets (or codons) and the amino acids

Mutations as "misspellings" of the code

The words of the genetic code

for which they stand are shown in Table 2. Triplets have recently been discovered that encode for starting and for stopping the synthesis of protein chains in *E. coli*. Many

proteins of *E. coli* begin with the amino acid methionine. Two different transfer RNAs for methionine are known to exist, only one of which functions to initiate protein synthesis. After synthesis of the protein, an enzyme may remove a portion of the beginning of the chain to eliminate the obligatory methionine molecule. The second transfer RNA for methionine allows this amino acid to be incorporated into the middle of a polypeptide.

Termination of protein synthesis appears to be effected by three different RNA triplets: UAA, UAG, UGA. These triplets were discovered as mutations that produced premature cessation of protein synthesis in many different genes. The exact mechanism of polypeptide-chain termination is not known, although the action of a special transfer RNA molecule is suspected.

#### REGULATION OF GENES

**The operon system.** The evidence accumulated in genetics makes it virtually certain that not all the genes present in a cell are active in directing the specific processes of protein synthesis. Gene action can be switched on or off, depending on the position of a cell in the body and the stage of body development, as well as on the external environment.

The control of the gene activity has been elucidated in *E. coli*. A culture of these bacteria growing on a minimal medium is able to synthesize the amino acids needed to construct the proteins from carbohydrates and a nitrogen source. The synthesis requires the presence of certain enzymes whose activities can be detected in a growing culture. If the culture of bacteria is supplied with certain amino acids, the synthesis of the enzymes that synthesize these amino acids is quickly arrested. This phenomenon is known as repression, and the enzymes affected are repressible enzymes. The pathway for the synthesis of the amino acid arginine in *E. coli* is a good example. This

synthesis involves three steps and three separate enzymes:

When arginine is present in the medium, none of the three enzymes involved in this process are detected, but if arginine is removed all three enzymes rapidly appear. The end product of this pathway, arginine, controls the production of the intermediate enzymes, since the addition of either ornithine or citrulline to the medium has no effect. A related process involves the production of enzymes whose substrates are not always present in cells. The presence of lactose in the medium, for example, induces the synthesis of three enzymes that proceed to degrade lactose; this phenomenon is termed induction.

The classes of genes involved in regulating the expression of a gene—repressing its action or inducing it—are shown in Figure 10. The part of the chromosome con-

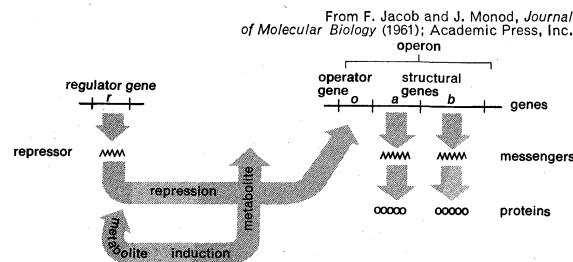

Figure 10: Model of the operon and its relation to the regulator gene.

taining the genes concerned is divided into two regions, one of which includes the operator and structural genes. This is termed an operon. The other part contains only the regulator gene. The regulator gene need not be located close to the operon. The regulator gene produces some substance, a repressor, which affects a second gene, an operator. There are several lines of evidence that suggest that the repressor substance is a protein molecule. It would be necessary for such a molecule to have at least two areas or sites that interact with the operator gene or a metabolite or both to influence structural genes (repress or induce their action, depending on given conditions).

**Other influences on genes.** The orderly complexity of the mechanism of cell division ensures that a dividing cell will give rise to two daughter cells with exactly similar chromosomes. Yet, as a fertilized egg cell gives rise to more and more body cells, these cells differentiate and become distinct from each other. A nerve cell, a muscle cell, a liver cell, and others are strikingly different; if each contains exactly the same chromosomes and genes, how are these differences explained? The same genes are present in all the daughter cells, but different genes become active in different types of cells.

The operon model (see above) furnishes a plausible explanation of how different genes may be active at different times in different tissues. Very suggestive evidence of such variable gene activity comes from observations of the giant chromosomes present in the cells of larval salivary glands and some other tissues of certain flies. At certain stages of the development of a larva, some of the stainable disks or bands in these chromosomes expand and at other stages contract again. The expansion is apparently caused by a localized uncoiling of the gene strings composing the giant chromosomes. The expanded portions of a chromosome are called puffs. There is good evidence that the bands in the giant chromosomes correspond to small groups of genes or even to single genes. Detailed observations on the giant chromosomes in different tissues of the larva of the midge *Chironomus* showed the banding patterns to be identical throughout but the puffing patterns to vary from tissue to tissue. A plausible conclusion is that all cells had identical complements of genes but that different genes were active in each tissue. The puffing patterns of a tissue also varied precisely with the development stage of the insect.

Variability of gene activity in different tissues

Ending the code

The study of the mechanisms of cellular differentiation was advanced by the discovery of nitrogen-rich proteins associated with DNA. These proteins, called histones, have the capability to affect the structure of the genetic material so as to allow or repress the gene activity. The lateral loops of the so-called lampbrush chromosomes (large, fuzzy-appearing chromosomes) in developing amphibian egg cells react to histones by contracting. The rate of RNA synthesis in lampbrush chromosomes is greatest when the lateral loops are fully expanded. The addition of histones to isolated calf-thymus nuclei inhibits various synthetic reactions, such as ATP and RNA synthesis. The removal of histones from nuclei results in enhanced RNA synthesis. Electron-microscopic examination of untreated nuclei shows that the genetic material exists in two discrete states: a compact, darkly staining mass and a diffuse, poorly staining matrix. It has been demonstrated that the overwhelming majority of RNA synthesis occurs in areas of diffuse genetic material. The addition of histones results in an increase in the amount of compact genetic material, while the removal of histones results in the dispersal of the genetic material. This work indicates that changes in the appearance of the genetic material will result in new patterns of RNA synthesis.

The mechanism of the histone effects was studied by examining chemical reactions that affect chemical groups other than the amino acids contained in histones. The attachment to histones of chemical groups called acetyl apparently causes some structural change in the genetic material that allows more genes to produce messenger RNA.

Reversible addition and subtraction of acetyl groups in histones may, then, control the gene action in development. Several problems remain to be solved. Histones may control the general gene activity, but development involves the activation and repression of specific gene systems. At present no mechanism is known that would give the needed specificity to histones. The reversible acetylation of histones controls its regulatory activity, but what controls the rate of histone acetylation? The operon model discussed above can be utilized as a first step in an approach to these problems. A combination of several operons into a complex regulatory system gives a system whose properties remotely approach those observed in differentiating cells. The inescapable conclusion is that an organism is a highly complex system, composed of many tissues, each of which interacts with the others and with the environment in a precise, predictable manner.

## Genealogy

The word genealogy comes from two Greek words—one meaning "race" or "family" and the other "to speak." Thus is derived "to trace ancestry," the science of studying family history. The term pedigree, used to describe a genealogy as set forth in chart or other written form, comes from the Latin *pes* ("foot") and *grus* ("crane") and is derived from a sign resembling a crane's foot, used to indicate lines of descent in early west European genealogies. Chart pedigrees, familiar to most people from school history books, include arrow shapes, parallel lines, a crinkled line denoting illegitimacy, and the sign = denoting marriage. Genealogy is a universal phenomenon and, in forms varying from the rudimentary to the com-

paratively complex, is found in all nations and periods. In this article the history of genealogy will be outlined, followed by an account of the work of modern genealogists, professional and amateur, and as organized in associations.

**Development of genealogical study.** The history of genealogy can be divided most easily into three stages. The first is that of oral tradition; the second, that in which certain pedigrees were committed to writing. The third stage comprises the period from approximately 1500 in western Europe and later in the English-speaking world, during which the whole basis of genealogy widened to such an extent that it is now possible for the majority of people in western Europe to trace their ancestry.

**Oral tradition and biblical sources.** In the early days of civilization, before written records were made, oral traditions were necessarily important. Without the art of writing, reliance must be placed on memory, aided possibly by mnemonic systems like that of knot arrangements used by the pre-Hispanic Peruvians, or beads employed by the Maori of New Zealand. The ancient Scottish sennachy, or royal bard, could recite the pedigree of the old Scots kings at the latter's inauguration, and the nobles of Peru, who boasted a common descent with the sovereign, were able to preserve their pedigrees despite the complexity resulting from the practice of polygamy. Oral transmission of genealogical information is almost always as a list of names—the lineages of the ancient Irish kings, for example. Events of outstanding importance are occasionally incorporated in such lists.

Numerous Oriental genealogies appear in the Old Testament. A cursory examination of these will reveal that they belong to the first and second stages in the history of genealogy, as described above. The systematic keeping of genealogical records, as in Europe since 1500, did not occur until very recently in Asia and Africa.

In southern India the ruling house of the maharajas of Travancore claimed to trace its descent, direct and unbroken, from the old Cēra kings of southern India (referred to as independent sovereigns in one of the edicts of Aśoka, the great Mauryan emperor of the 3rd century BC). A claim that inscriptions of the rulers of Travancore have been found from the 9th century AD comes from a statement issued by the secretariat of the maharaja of Travancore. Its reliability may be judged along with the genealogies of princes in northern India shown in Lt. Col. James Tod's monumental work, *Annals and Antiquities of Rajasthan* (1829, republished 1950). Referring to the lineages of Indian princes as being known since the early centuries BC, Tod wrote, "If, after all, these are fabricated genealogies of the ancient families of India, the fabrication is of ancient date, and they are all they know themselves upon the subject." The very long Oriental genealogies begin as oral pedigrees and were later written down, but they concern only princes or great persons.

In Africa the one instance of a claim to very long descent, that of the Emperor of Ethiopia, bears a similarity to Tod's Rājput genealogies. The Emperor is said to descend from the marriage of King Solomon with the Queen of Sheba. The tradition was written down more than 15 centuries ago; it is therefore older than the history of most European monarchies, but it cannot, of course, be substantiated by documentary proof.

Under European influence, the greater Oriental countries have adopted the practice of keeping systematic records for all citizens. In China, with its ancient system of ancestor worship, long, drawn-out pedigrees, including claims to descent from Confucius, are not unknown. The establishment of the Chinese Republic in 1911 brought with it registration of vital statistics.

In modern Japan, as might be expected from its thoroughgoing Westernization, the registration of vital statistics is regulated by law. The Family Registration Law of 1947, and later enactments, require a comprehensive registration of a Japanese national from his birth to his death. Such information, however, is kept in local registration offices, and there is no system in Japan for

Oriental  
genealogies

gathering together, recording, and preserving the information in one central place (although of course the results of statistics, such as the number of births, is known to the central authority). Such an exact system of registration covers only the era of modern Japan. The present-day pedigree of the Japanese emperors has a divine origin; it is mainly a string of names, easily recited and memorized, mixed with semifabulous legends and first written down in the early centuries of the Christian Era. Such pedigrees are concerned only with exalted persons, royal or noble.

#### Biblical genealogies

In the Old Testament there are many genealogies, the object of which is to show descent from Adam, Noah, and Abraham. By the time these genealogies had become part of the Jewish scriptures, the concept of racial purity had reinforced the keeping of family records. Genealogies of Jesus Christ in the New Testament aim at showing his descent from David, the one in St. Luke's Gospel going as far back as Adam, "who was the son of God." The idea of divine origin was reflected everywhere in a wildly polytheistic form among the Gentiles. Almost without exception, the heroes whose genealogies were recited by the bards had their paternity ascribed to the gods, or to persons such as Romulus who were regarded as having become divine. Greek fables abound in stories of great men begotten by gods and mortals.

In Roman genealogies heroes were always descended from gods. Julius Caesar, for example, was supposed to have sprung from the line of Aeneas, and thus from that of Venus. Among the Romans, traditions of descent remained vague even when written. Caesar's murderer, Brutus, was popularly supposed to be of the same family as an ancient Brutus, who had expelled the Tarquins, but no pedigree appears to have existed to substantiate the belief.

Among the northern nations that overwhelmed the western Roman Empire, belief in divine sonship was general. For Saxon rulers of the English kingdoms it was necessary to be descended from the god Woden.

*Early written records.* With the invention of writing, the oral became the written tradition. This occurred in Greece and Rome, where genealogies were recorded in poems and in histories. But genealogy did not at this stage become a science, because when writers dealt with it, they did so either incidentally in their narrative or because they were concerned with the family relationships of their gods.

#### Maximum length of genealogies

The historian Edward Gibbon's observation that "the proudest families are content to lose in the darkness of the middle ages, the tree of their pedigree" may be challenged in the light of recorded genealogies. The male line of Charlemagne has been traced to St. Arnulf, bishop of Metz, who died about 635. Several royal line descents are traceable to the 6th century, as, in England, is the tree of Louis Mountbatten, 1st Earl Mountbatten. The ancestry of Queen Elizabeth II goes to Egbert of Wessex (about 825), beyond him to Cerdic (c. 500), and, if another series of names is accepted, to Woden (an actual man later divinized by the Germans), in the 3rd century AD.

With the conversion of the barbarians to Christianity the recording of their regal traditions began. Examples occur in Ireland, Wales, and England. It was natural for the first chroniclers, who were mostly monks, to write down the oral pedigrees of the kings in whose realms they lived. Students of the Irish regal pedigrees are prepared to accept two or three generations before the time of St. Patrick (flourished 5th century AD) as genuine, and it is quite probable that name lists of the Irish kings are valid back to the 3rd century AD. Similarly, in Wales, the ancestry of the greatest Welsh families can be traced for a millennium. Among the Anglo-Saxons there were similar bardic pedigrees recorded by monastic scribes, and many of these might have survived but for the destruction of the Old English ruling class during the Norman Conquest. A regular feature of such old pedigrees recorded by monks was an attempt to link them with the genealogies of the Scriptures. In an Anglo-Saxon pedigree of great length—that of the kings of Wessex (the

ancestors of Elizabeth II)—the line is thus traced to Scef, "a son of Noah born in the Ark." In the process of working out the connection between scriptural and regal genealogies, the monks adopted a reverse technique to that of the 4th-century-BC Greek mythographer Euhemerus; *i.e.*, they downgraded the old gods to human status.

From roughly 1100 to 1500, the emphasis of genealogists was on pedigrees of royal and noble lines. Claims to a throne, as with the dozen or so claimants to the Scottish crown after the death of Alexander III in 1286 and of his direct heir, Margaret the Maid of Norway in 1290, frequently involved genealogical trees. The truth was sometimes bent to suit some political end, but, on the whole, medieval European records are genealogically valid. This is because they were not primarily intended to supply genealogical information but to record land transactions, taxation, and lawsuits. The facts of family history are incidental and are therefore generally reliable. Exact dates of birth, marriage, and death are rarely given. A man is said to be of age "by Michaelmas 1330."

This period also saw the emergence of pedigrees of lesser folk. Land transactions involved claims in the local courts of the lords. Serfdom gave way to villenage; the latter involved so many days of labour on the lord's demesne and also the inability to move from the estate without the lord's consent. There was strong inducement for a man to prove that he was not a villein and for the bailiff to show that he was. In several parts of England, pedigrees of villeins or persons claimed as such have been worked out over periods of 100–150 years.

It was during the third period in European genealogical history that records that came to include everyone began. This period extends from 1500 to the present. As feudalism gradually gave way, new classes of citizens arose. In England the appearance of a powerful mercantile and business community was reflected in the growth of the middle classes, from which was continually recruited a new nobility and gentry. In turn, owing to the English rule of inheritance by primogeniture and the fact that unlike the continental nobility English nobility has never extended beyond the reigning peer and his wife, the middle classes themselves continually received the younger children of peers and gentry. Two other factors leading to the proliferation of records were the enormous changes caused by the Reformation and the great re-emphasis on individual religion and the desire of Renaissance monarchs to have more exact information about all their subjects.

**Modern genealogy.** Amateurs in the subject of genealogy are almost always actuated by the desire to trace their own family history. In the course of so doing they discover and work with general principles which apply to pedigrees other than their own, though records other than those applicable to their own case do not interest them. The professional genealogist is concerned not with one family but with many, and with the principles of genealogical research which arise from a wide study. As there are no university courses in the subject and therefore no degrees or other certificates of professional proficiency, the professional must be largely self-taught.

The disciplines required of a professional genealogist include a deep knowledge of the history of the country with which he is concerned and of its neighbours. National history determines the form of national genealogy, and genealogy can illuminate many aspects of national history that might otherwise remain obscure. The Wars of the Roses, for example, are hard to grasp unless genealogical trees showing relationships of the contestants are studied, and the course of the American Revolution is easier to understand when the links between George Washington and his compeers with the old English landed families who overthrew the Stuarts are comprehended. An understanding of the principles of law, especially of land law, the ability to decipher court hand or medieval script, an understanding of heraldry, and an intimate knowledge of the study of surnames and place names are also essential to the genealogist. Variations in surname spelling can be bewildering. The key is in the

Qualifications of the professional genealogist

sound of the name, for a medieval scribe could not ask the illiterate person before him to spell his name.

The main task undertaken by the professional genealogist is the tracing of pedigrees for clients, this being the staple of his work. Clients often consult genealogists when they wish to establish their family background, or, when having tried to trace it, they have come to a stop.

The writing of private family histories by professionals is very common. The material has usually been worked out by others who wish it to be checked and written by a professional.

The amateur genealogist, as already mentioned, is usually concerned only with his own family. The standard of amateur work varies with the individual, from the truly bad to the excellent.

Amateur genealogical work has increased greatly since 1945. In the United States there has been a long interest in the subject. The New England Historic Genealogical Society, the Augustan Society (based in California) and many state societies are of note. The Mormons (the Church of Jesus Christ of Latter-day Saints) have built up in Salt Lake City, Utah, a microfilm library of genealogical records from Britain and continental Europe, which is probably unequalled. In Canada, Australia, New Zealand, and South Africa the study of genealogy by private persons and by associations is growing rapidly. In England there is a Society of Genealogists, and there are corresponding bodies for Ireland and Scotland. In Spain there is an International Institute of Genealogy and Heraldry, which since 1955 has organized international congresses held in many European capitals at intervals of two years. In Czechoslovakia, by way of contrast, the national Genealogical Society has been dissolved, and in general it has not been feasible to obtain genealogical details from Communist countries, though it is probable that changes are now occurring in this respect. Jewish records are in a separate class. With the establishment of the state of Israel in 1948, a very great effort has been made to centralize information about the Jews of continental Europe under the care and direction of the Jewish Historical Archives in Jerusalem.

In tracing family history, the worker follows certain rules. He works backward from the present. This is an elementary caution constantly put on one side by amateurs, who tend to trace forward from a person of the same name who may well be unrelated. As there cannot in the nature of things be a gap in a pedigree, no assumptions as to relationship can be allowed without very strong reason to accept them. Good and bad features in the ancestry have to be accepted: bastardy has to be allowed for, as well as regal ancestry by legitimate lines. An ancestor's wrongdoing must also be allowed for, though with passage of time this is usually taken in a romantic sense. Registration of birth, marriage, and death first became compulsory in England in 1837. Public records in most other Western countries began at varying dates in the 19th century. Census records are of great importance. They began in the U.S. as early as 1791; in Britain in 1801 (papers kept only from 1841); and even earlier in French Canada, in 1655-66. Parish registers began in England in 1538, though they are rarely preserved from that date. In most countries they begin later, but in Spain the oldest extant is dated 1394, and there are 1,636 parishes having records prior to 1570. In England, Nonconformist records have been kept by various bodies, and many are now held officially at Somerset House, London, or the Public Record Office. In America the settlers were generally trying to get away from established church and controlling state. They were vigorous individualists who kept careful records of their lives and of the organization of their new communities. Examples of detail in New England records can be seen in many of the 1,600 pedigrees contained in *American Families with British Ancestry* (500 page suppl. to John Burke's *Landed Gentry*, 1939); in A.M. Burke's *Prominent Families of the United States of America*, and in the many volumes of family history produced in the United States.

Wills are of the utmost importance as a source of genea-

logical information. Ships' lists of passengers are useful in supplying dates for immigrant ancestors' departure for the New World, but since they do not indicate place of origin, but only the port of departure, the original habitat must be sought elsewhere. Without a knowledge of the ancestor's place of origin in the home land it is useless in almost all cases to attempt a search.

With the aid of the type of record mentioned above, and with help from family Bibles, tombstones, and plaques and brasses in churches, it is as a rule possible for a person of English antecedents to trace some 250-300 years of ancestry. Before the 17th century, everything depends on the social position of the ancestors. Tax records, lawsuits, and purchases and sales of land are the chief sources for tracing a family before 1600. The Pipe Rolls extend from the reign of Henry II (1154-89) to that of Queen Victoria, with an interrupted beginning also in the time of Henry I (1100-35). Monastic records are of great importance as showing grants or ownership of land. The pleas of the crown deal with suits at law and contain much detail about families. There are many Rolls besides those of the Pipe which give a great deal of incidental genealogical information. *Inquisitiones post mortem* show the position of an heir; i.e., his age and other details. As the centuries are passed, the numbers of those who can prove a descent by the male line dwindles, until by the time of the Norman Conquest scarcely half a dozen pedigrees can be traced in the male line for either Saxon or Norman.

Regarding deposition of public records, two principles have been followed by archivists: that of centralization and that of diffused local holdings. The former has many obvious advantages and was adopted in Scotland and in Ireland. It has one disadvantage—destruction of the records at one stroke. This happened in Dublin on April 13, 1922, when Irish factions fighting with each other burned most of the Irish records. The second system, by which records are stored in a number of depositories, prevails to a considerable extent in England. Although the Public Record Office at Somerset House and the British Museum library are places of centralized record, the parish registers remain outside them, scattered in numerous parishes or county offices. County records contain masses of material not to be found in London.

From the 16th century there has been an increasing accumulation of written material, which deals either exclusively or incidentally with genealogy. William Camden (1551-1623), a learned English antiquary and historian, did much to raise the standards of genealogical research. He was the first English writer on surnames, and his work was not resumed for nearly 200 years. Sir William Dugdale, a younger contemporary of Camden, made a beginning with his *Antiquities of Warwickshire* to the great output of county histories written between the 17th and 19th centuries. The revolution in modern genealogy was the application to its study of canons of historical and literary criticism formulated in Europe from 1800. Their application to genealogy was fairly late, as is illustrated by the fact that the 19th-century English historian Thomas Macaulay, critically perceptive in most other spheres, accepted what amounted to family myths as true genealogy. Later writers, J.H. Round, W. Farrer, C. Lewis Loyd, C.T. Clay, and the editors of the *Complete Peerage* are of the greatest importance.

**BIBLIOGRAPHY.** For an outline of the sources and methods of procedure, see L.G. PINE, *Trace Your Ancestors*, 3rd ed. rev. (1964). Also useful is A.J. WILLIS, *Genealogy for Beginners* (1955). J. UNETT, *Making a Pedigree*, 2nd ed. (1961), contains information on medieval records. G. HAMILTON EDWARDS, *In Search of Ancestry* (1966), is a larger work with more detail, especially on naval and military sources. On American genealogy, see G.H. DOANE, *Searching for Your Ancestors: The How and Why of Genealogy*, 3rd ed. (1960); and J.S. SWEET, *Genealogy and Local History: An Archival and Bibliographical Guide*, 2nd rev. ed. (1959). See also L.G. PINE, *American Origins: A Handbook of Genealogical Sources Throughout Europe* (1960) and *The Genealogist's Encyclopedia* (1969).

(L.G.P.)

## Genetics

Genetics is the branch of biology concerned with heredity. Since prehistoric times, man has recognized the influence of heredity and has applied its principles to the improvement of cultivated crops and domestic animals. A Babylonian tablet more than 6,000 years old, for example, shows pedigrees of horses and indicates possible inherited characteristics; other old carvings show cross-pollination of date palm trees. Most of the mechanisms of heredity, however, remained a mystery until the 20th century, when scientifically supported information became available.

Genetics may be defined as the study of the way in which genes operate and the way in which they are transmitted from parents to offspring. Modern genetics involves study of the mechanism of gene action—the way in which the genetic material (deoxyribonucleic acid) affects physiological reactions within the cell. Although genes determine the features an individual may develop, the features that actually develop depend upon the complex interaction between genes and their environment. Normal green plants, for example, have genes containing the information necessary to synthesize the chlorophyll that gives them their green colour, and chlorophyll is synthesized in an environment containing light; *i.e.*, the gene for chlorophyll is expressed. If the plant is placed in a dark environment, chlorophyll synthesis stops; *i.e.*, the gene is no longer expressed.

### HISTORICAL BACKGROUND

The Greek philosopher Pythagoras speculated around 500 bc that human life begins with a blend of male and female fluids, or semens, originating in body parts. Aristotle later postulated that the semens are purified blood and that blood, therefore, is the element of heredity. That this later concept persisted in the Western world is indicated by such common phrases as blue blood, blood-will-tell, blood relative, bad blood, and royal blood.

About 1651, the English physician William Harvey disproved the Greek concept; his discovery that deer embryos have the appearance of a tiny ball during early developmental stages and resemble a deer only later in development led him to conclude that the origin of the tiny ball was a small egg. Before the end of the 17th century, it had been suggested that the female structures called ovaries are the source of eggs and that sperm might carry the hereditary material of the male.

Early in the 19th century, a French scientist, Jean-Baptiste Lamarck, suggested that acquired characteristics are inherited. Around 1865 Gregor Mendel (*q.v.*), an Austrian monk, reported his discoveries on inheritance in garden peas. A few years later, the deoxyribonucleic acid (DNA) component of genes was isolated from pus cells, and it was discovered that salmon sperm also contain considerable amounts of DNA. Late in the 19th century, a German physician, August Weismann, showed that reproductive cells (germ plasma) are independent of other body cells (somatoplasm), thus refuting earlier hypotheses of inheritance of acquired characteristics.

The concept of sudden changes in heredity (mutations) was introduced in the beginning of the 20th century. Discoveries concerning sex determination in insect chromosomes and gene linkage on a chromosome of sweet peas were made soon afterward in the U.S. and England. In 1908, an English mathematician and a German physician formulated the so-called Hardy-Weinberg principle, which provided the foundation for population genetics. The study of biochemical genetics was begun in 1909 in England with an effort to discover the way by which gene-induced enzyme deficiencies cause abnormalities.

Hermann J. Muller, a U.S. geneticist, induced mutations in the fruit fly with X-rays in 1927. Experiments on the mold *Neurospora* by two Nobel Prize-winning geneticists, George W. Beadle and Edward L. Tatum, proved that the function of most genes is to direct the synthesis of enzymes, which thus are the expression of many hereditary traits. By 1944 DNA had been proved to be the substance of heredity, and, in 1953, the Nobel Prize winners

James D. Watson and F.H.C. Crick reported a structure of DNA compatible with the capability for self-duplication. Two French Nobel Prize winners, François Jacob and Jacques Monod, discovered the mechanism by which hereditary information is transferred from genes to the site of protein (enzyme) synthesis. Their work resulted in the discovery of the genetic code, by which DNA is translated into protein.

### SCOPE

**Nature of the science.** Genetics overlaps many different branches of biology and many other sciences; *e.g.*, chemistry, physics, mathematics, sociology, psychology, and medicine. Microbiologists who study inheritance in micro-organisms are called microbial geneticists; cytologists who study the genetics of cells are called cytogeneticists. Biochemical, or molecular, geneticists investigate the chemical nature of the gene and its methods of action. Some physicists have applied their techniques to molecular genetics, and mathematicians may specialize in population genetics. Behavioral scientists also look to genetics to solve certain problems of human and animal behaviour. Specialists in medical genetics or genetic counselling now know that many of man's afflictions are hereditary.

**Topics of study.** *Classical genetics.* Classical genetics, which remains a basis for all other topics in genetics, is concerned primarily with the method by which genetic traits classified as dominant (always expressed), recessive (subordinate to a dominant trait), intermediate (partially expressed), or polygenic (due to multiple genes) are transmitted in plants and animals. These traits may be sex-linked (result from the action of a gene on the sex, or X, chromosome) or autosomal (result from the action of a gene on a chromosome other than a sex chromosome). Classical genetics began with Gregor Mendel's study of inheritance in garden peas and continues with studies of inheritance in many different plants and animals.

*Cytogenetics.* Cytogenetics blends the skills of cytologists, who study the structure and activities of cells, with those of geneticists, who study the relationship between the mechanism of heredity and cellular activities. Cytologists discovered chromosomes and the way in which they duplicate and separate during cell division at about the same time that geneticists began to understand the behaviour of genes at the cellular level. The close correlation between the two disciplines led to their combination.

Plant cytogenetics early became an important subdivision of cytogenetics because, as a general rule, plant chromosomes are larger than those of animals. Animal cytogenetics became important after the development of the so-called squash technique in which entire cells are pressed flat on a piece of glass and observed through a microscope; the human chromosomes have been numbered using this technique.

*Microbial genetics.* Micro-organisms were generally ignored by the early geneticists because they are small in size and were thought to lack variable traits and the sexual reproduction necessary for a mixing of genes from different organisms. After it was discovered that micro-organisms can have different physiological characteristics and also are able to reproduce sexually, they became objects of great interest to geneticists because they reproduce more rapidly than larger organisms; *i.e.*, a mutation, or change, occurs in a gene about one time in 10,000,000 gene duplications, and one bacterium may produce 10,000,000,000 offspring, among which are numerous mutants, in 48 hours.

Many discoveries in microbial genetics have been applied to other areas of genetics; for example, the way in which genes produce enzymes that function in turn to produce genetic traits has important applications to human genetics. Much of microbial genetics also applies to the study of the genetics of viruses.

*Molecular genetics.* Molecular genetics includes the study of the molecular nature of the gene and the method by which genes control the activities of the cell. Molecular geneticists have studied the molecular structure of a gene (*e.g.*, that involved in the synthesis of the human

Plant and  
animal  
cytoge-  
netics

20th-  
century  
discoveries

## Synthetic genes

blood pigment, hemoglobin) and determined the exact sequence of its components; in addition, they have created a synthetic gene by joining the components comprising a known gene in the correct sequence.

**Population genetics.** A study of genes in populations of animals provides information on past migrations, evolutionary relationships and extents of mixing among different varieties and species, and methods of adaptation to the environment. Statistical methods are used to analyze gene distributions and chromosomal variations in populations.

Human population geneticists have traced migration and invasion routes of man; genetic studies of present-day Europeans, for example, reveal routes of human migrations that occurred hundreds or thousands of years ago. The origin of the people inhabiting South Pacific islands and the degree of intermingling among mixed races also are studied by human population geneticists.

**Behavioral genetics.** Another aspect of genetics is the study of the influence of heredity on behaviour. Many characteristics once considered to be acquired behavioral patterns actually are of a hereditary nature. The role of heredity in instinctive patterns of behaviour among animals has long been recognized, but many of man's actions also have a hereditary explanation. The effect of various drugs (e.g., LSD) on behavioral patterns in animals, including man, is of particular interest.

**Human genetics.** Some geneticists specialize in human genetics. When classical geneticists first determined the principles of heredity in plants, fruit flies, mice, and other forms of life, they tried to interpret man's heredity in a similar way but found many traits that did not fit the patterns. As techniques improved, it was found that the method of inheritance of human characteristics is the same as that for other living things.

Some human geneticists, called genetic counsellors, advise individuals concerning the probabilities for the appearance of serious hereditary defects in their children. The counsellors usually have medical training because many traits are recognizable only after special diagnostic procedures. Medical genetics is another important application of human genetics. Many medical schools devote entire departments to medical genetics, which is the study of the treatment and prevention of inherited afflictions in man.

The prospects for the future of human genetics are promising; it is possible that man may someday control his heredity; even now functional genes can be transferred from one organism to another, and certain treatments are able to cause specific kinds of mutations.

Such manipulation of genes eventually may be useful in solving many human hereditary diseases; e.g., stopping the function of genes that are out of control, starting the function of nonfunctioning ones. Activation of nonfunctioning genes in some types of tissue may enable them to replace body parts that have been injured or destroyed. It is conceivable that man may someday learn to change harmful genes into normal ones.

#### THE STUDY OF GENETICS

## Hybrids

**Experimental breeding.** When animals that differ with respect to *one* primary trait are bred, and their offspring then are bred among themselves to give a second generation, the method of inheritance of the trait can be determined; the process is known as a monohybrid cross. A dihybrid cross involves breeding individuals that differ with respect to *two* traits; the results of such crosses show whether the genes are linked on the same chromosome or are on different chromosomes. If the genes are linked, the distance between them can be determined by the number of recombinations of traits obtained, an indication of the amount of crossing over between genes. By such crosses, geneticists have established elaborate chromosome maps of many organisms showing the location of many genes on the chromosomes.

A test cross may be used to determine if animals carry recessive genes; e.g., cocker spaniel dogs may be of solid colours or parti-coloured (spotted). Since the gene for parti-coloured is recessive, it may be carried (but not ex-

pressed) by some solid-coloured dogs. If a solid-coloured dog is suspected of carrying a recessive gene for parti-coloured, it is bred to a parti-coloured dog. Parti-coloured offspring indicate that the solid-coloured dog carries the recessive gene. This technique is used by animal breeders to eliminate undesirable recessive genes.

Experimental breeding is most successful in organisms with large numbers of offspring, a relatively short life cycle, and a number of variable characteristics. The fruit fly, *Drosophila*, meets these requirements and has been used extensively in breeding experiments; mice also have been used extensively.

**Cytogenetic techniques.** Cytogenetic techniques are closely associated with experimental breeding. Older cytogenetic techniques involve placing cells in paraffin wax, slicing thin sections, and preparing them for microscopic study. The newer and faster squash technique involves squashing entire cells and studying their chromosomes. Dyes that selectively stain various parts of the cell are used; the genes, for example, may be located by selectively staining the deoxyribonucleic acid (DNA) of which they are composed. Radioactive compounds also are valuable in determining the location of various components of the cell. Tissue-culture techniques may be used to grow cells before squashing; white blood cells can be grown from samples of human blood and studied with the squash technique.

**Biochemical techniques.** Biochemical techniques are used to determine the activities of genes within cells. Radioactive compounds are valuable in studies involving gene duplication and cell metabolism. Thymine is a compound found only in genes; if radioactive thymine is placed in a tissue-culture medium in which cells are growing, genes use it to duplicate themselves. When cells containing radioactive thymine are analyzed, the results show that, during duplication, genes split in half, and each half synthesizes its missing components. When radioactive uracil, a compound found only in the ribonucleic acid (RNA) component of cells, is incorporated into the RNA messengers of genes, their pathway from the chromosomes to the site of protein synthesis in the cytoplasm (ribosomes) is revealed.

Chemical tests are used to distinguish certain inherited characteristics of man; e.g., urinalysis and blood analysis reveal the presence of certain inherited abnormalities—phenylketonuria, cystinuria, alkaptonuria, gout, and galactosemia. Special techniques (e.g., chromatography, electrophoresis) are used to separate the components of proteins, so that inherited differences in their structures can be revealed; for example, more than 100 different kinds of human hemoglobin molecules have been identified.

**Physiological techniques.** Physiological techniques are used in genetic investigations. In micro-organisms, most genetic variations involve some important cell function. Some strains of one bacterium (*Escherichia coli*), for example, are able to synthesize the vitamin thiamine from simple compounds; others, which lack an enzyme necessary for this synthesis, cannot survive unless thiamine is present. The two strains can be distinguished by placing them on a thiamine-free mixture; those that grow have the gene for the enzyme, those that fail to grow do not. The technique also is applied to human cells since many inherited human abnormalities are caused by a faulty gene that fails to produce a vital enzyme; albinism, which results from an inability to produce the pigment melanin in the skin, hair, or iris of the eyes, is an example of an enzyme deficiency in man.

**Immunological techniques.** Many substances (e.g., proteins) are antigenic; i.e., when introduced into a vertebrate body, they stimulate the production of specific proteins called antibodies. Various antigens exist in red blood cells, including those that comprise the major blood groups of man (A,B,AB,O). Blood antigens of man include inherited variations, and the particular combination of antigens in an individual is almost as unique as fingerprints. Immunological techniques are used in blood-group determinations that precede blood transfusions and in determining Rh incompatibility in childbirth.

Radioactive thymine

Evolutionary relationships can be determined by immunological techniques. If protein from a specific fruit fly is injected into a guinea pig, and the guinea pig reacts by producing antibodies, and blood serum from the guinea pig is then mixed with proteins from the same fly, antigens and antibodies react to produce a cloudy mixture. Mixtures of guinea pig blood serum and proteins from other fruit-fly species cause various degrees of cloudiness, depending on their evolutionary relationship to the original species; e.g., the closer the relationship, the greater degree of cloudiness.

**Mathematical techniques.** Mathematical techniques are used extensively in genetics. The laws of probability are applicable to crossbreeding and are used to predict ratios concerning the appearance of specific traits in offspring. Geneticists also use statistical methods to determine the significance of deviations from expected results. In investigations involving possible mutagenic effects of factors such as high-energy radiation and drugs, statistical tests are used to establish the validity of conclusions; statistics are used in studies of the possible effects of LSD in producing chromosome aberrations in man, for example, to show whether differences found in cells of users and nonusers of the drug are significant.

Mathematics is used by population geneticists to evaluate the distribution of genes in populations. The Hardy-Weinberg principle, for example, is important in studying animals that carry a recessive gene; when the actual number of carriers is much greater than that calculated, it is concluded that some environmental factor favours the carriers. The gene for sickle-cell anemia in Africans, for instance, is found in more people than the frequency of those who have the anemia would indicate because people who carry the gene are more resistant to malaria than noncarriers and, therefore, have a better chance of survival.

#### APPLICATIONS

**Medicine.** Genetic techniques are used in medicine to diagnose and treat inherited human disorders. Knowledge of a family history of cancer or tuberculosis may indicate a hereditary tendency to develop these afflictions. Cells from embryonic membranes reveal certain genetic abnormalities, including enzyme deficiencies, that may be present in newborn babies, and thus permit early treatment. Many countries require a blood test of newborn babies to determine the presence of an enzyme necessary to convert an amino acid, phenylalanine, into simpler products. A condition known as phenylketonuria (PKU), which results from lack of the enzyme, causes permanent brain damage, if not treated soon after birth. The presence of about 40 different types of inherited abnormalities can be detected in embryos as young as 12 weeks; the procedure, called amniocentesis, involves removal and testing of a small amount of fluid from around the embryo.

**Agriculture and animal husbandry.** Agriculture and animal husbandry apply genetic techniques to improve plants and animals. Plant geneticists produce new species by special treatment; e.g., a hybrid grain has been produced from wheat and rye, and plants resistant to destruction by insect pests have been developed.

Plant breeders use the techniques of budding and grafting to maintain desirable gene combinations originally obtained from crossbreeding. The use of the chemical compound colchicine, which causes chromosomes to double in number, has resulted in many new varieties of fruits, vegetables, and flowers.

Animal breeders use artificial insemination to propagate the genes of prize bulls. Prize cows can transmit their genes to hundreds of offspring by hormone treatment, which stimulates the release of many eggs that are collected, fertilized, and transplanted to foster mothers.

**Industry.** Various industries employ geneticists; the brewing industry, for example, may use geneticists to obtain strains of yeast that produce large quantities of alcohol. The pharmaceutical industry has developed strains of molds, bacteria, and other micro-organisms high in antibiotic yield.

#### SOCIETIES AND PUBLICATIONS

Many countries have one or several genetic societies, most of which publish journals. The trend is to establish more societies and journals in the fields of molecular and human genetics. Most large countries have at least three or four societies dealing directly with the field of genetics, and each has its own journal. These are in addition to many local and regional societies. Some of the better known journals in the field of genetics are: *Annales de Genetique* (France); *American Journal of Human Genetics* (U.S.); *Atti Associazione Genetica Italiana* (Italy); *Canadian Journal of Genetics and Cytology* (Canada); *Genetics* (U.S.); *International Zeitschrift für Theoretische und Angewandte Genetik* (West Germany); and *Japanese Journal of Genetics* (Japan).

**BIBLIOGRAPHY.** A.G. DEBUSK, *Molecular Genetics* (1968), a paperback providing concise coverage of this subject; L.C. DUNN, *A Short History of Genetics* (1965), a paperback outlining the major features of the development of genetics; I.M. LERNER, *Heredity, Evolution and Society* (1968), a discussion of the problems of society as related to genetic discoveries; J.A. PETERS (ed.), *Classic Papers in Genetics* (1959), reprints of reports of important genetic discoveries; CURT STERN, *Principles of Human Genetics*, 3rd ed. (1971), a classic work in the field, thorough coverage; M.W. STRICKBERGER, *Genetics* (1968), a college-level treatment of modern genetics; R.P. WAGNER and H.K. MITCHELL, *Genetics and Metabolism*, 2nd ed. (1964), a comprehensive account of the relationship between genes and cellular activities; A.M. WINCHESTER, *Genetics* (1971), an introductory genetics text, including all principles of the subject, but slanted toward human genetics, *Heredity: An Introduction to Genetics*, 2nd ed. (1966), a paperback providing concise coverage of the subject in terms understandable to the general reader.

(A.M.W.)

## Genetics, Human

Genetics is the science of biological inheritance, the basic laws of which were discovered in the 19th century by an Austrian monk, Gregor Johann Mendel, who worked them out on pea plants grown in the garden of his Augustinian monastery. During the early part of this century, many more precise details were added during intensive study of other organisms, especially the fruit fly. Understanding of the chemical basis of genetics first began to come in the 1940s from the study of inheritance in bacteria and viruses. Since human genetics differs in no fundamental way from inheritance in other living things, the general articles HEREDITY and GENE provide relevant background material and discussions.

This article is divided into the following sections:

- I. General aspects of human genetics
  - The biological basis
  - Single-factor inheritance
  - Human blood
  - Heredity and environment (nature and nurture)
  - Chromosome variations
  - Mutation
- II. Applications of human genetics
  - Genetic counselling
  - Genes in populations
  - Genetics and the evolution of man

### I. General aspects of human genetics

#### THE BIOLOGICAL BASIS

*Egg and sperm (gametes).* A human individual arises from his biological parents through the union of two cells, an egg from the mother and a sperm from the father. The human egg cell, like that of other mammals, is barely visible to the naked eye. Eggs are shed, usually one at a time, from the ovary (female sex gland) and pass down tubes (oviducts) toward the uterus. Fertilization, the process in which the sperm enters the egg, occurs in the ducts; if it does not take place, the egg disintegrates in the uterus. Fertilization represents the major event in the genetic determination of the new individual; within the fertilized egg is contained all of the hereditary material that bridges the generations. (For developments after fertilization, see EMBRYOLOGY, HUMAN.)

*Chromosomes.* During the early part of the present century, cellular studies with ordinary microscopes that

Statistical  
methods

Budding  
and  
grafting

### The chemistry of genes

transmit light led to the conclusion that all cells, including egg and sperm, contain material within them that at times forms into a definite number of rodlike units called chromosomes. A series of elegant microscopic studies clarified the mode of reproduction of these chromosomes when new cells are formed through the splitting (mitosis) of pre-existing cells. Chromosomes are known to be the carriers of specific hereditary factors (genes), and it has become clear that all cellular organisms (microbe, insect, cabbage, and king) inherit from pre-existing parents in the same chromosomal way.

Methods for the chemical analysis of minute bits of biological material have been perfected to the point that the parallel study of biochemistry and genetics has proceeded most rapidly. The cell nucleus (with its chromosomal material) has been found to be made up of a chemical called deoxyribonucleic acid (DNA) in combination with protein compounds. Evidence is now overwhelming that the DNA component represents the physical basis of the hereditary material. Variations in the chemical structure of DNA molecules seem to determine differences in the mode of action of specific genes.

**Proliferation, differentiation, and growth.** Except in special cases, the two parents make essentially equal genetic contributions to the offspring at the time of fertilization. In humans, as in other animals, the change of the fertilized egg (zygote) into an adult individual is accomplished by processes of proliferation, differentiation, and growth. These processes are basically cellular; the zygote, a cell, proliferates by first forming two cells. These two then form four, these four, eight, and so on, until the recognizably human embryo containing billions of cells is produced. As proliferation proceeds, the cells differentiate; that is, some become specialized as muscle, some as nerve, some as liver, and so on. Prior to its division, a cell undergoes growth, manufacturing new living substance according to precise instructions from the genes (DNA) contained in the cell nucleus.

When a cell divides, the two resulting daughter cells receive materials from the mother cell. In particular, the hereditary materials of the original nucleus of the fertilized egg are duplicated during the process of mitosis. The nucleus of a normal human cell displays 46 chromosomes when it is dividing (Figure 1). One longitudinal

Figure 1: Normal human chromosomes. The cell, from a female, has been flattened and the 46 chromosomes stained.

half of each chromosome, representing a full set of all genes located there, reaches each daughter cell. Thus, each daughter cell normally has the same hereditary composition as that of the mother cell. In most cases, then, not only do all the cells of the body of a person have an equivalent set of genes but the genes present are duplicates of those that were present in the original fertilized egg.

**Gene action.** According to the principles just discussed, the hereditary material (DNA) with which each individual begins life finds its way into all his body cells.

The genes exert their influence on cellular processes by providing chemically coded information for the production of enzymes and other proteins. The translation of gene information to new protein is accomplished in an indirect manner; sections of the DNA in a chromosome are transcribed (or copied) into molecules of a complementary chemical called ribonucleic acid (RNA), which carry the hereditary information to the places in the cell at which specific proteins are synthesized. Such hereditary influences as those referring to eye colour, blood type, stature, and disease resistance relate directly or indirectly to the action of the genes contained within the individual cells.

**Meiosis.** The genetic relationship of the individual to his parents can be understood by examining in detail the origin of the gametes (egg and sperm) from which he arises. Close scrutiny of the 46 chromosomes of a normal human cell shows that there are different types that vary greatly in size and shape. Among the 46, moreover, each type is normally represented twice; thus, although there are indeed 46 chromosomes present (the so-called diploid number), they can be seen to consist of 23 pairs (Figure 2).

Chromosome pairs

Figure 2: Chromosome pairs. The chromosomes from Figure 1 have been arranged in pairs. The XX (23rd) pair identifies a female.

Normally the chromosome number in the cells of a child is the same as that of his parents, egg and sperm each contributing one member of any pair and containing half the chromosome number (haploid number). Pains-taking chromosome counts, for example, reveal that as each egg matures in the ovary, only one member of each of the 23 pairs of chromosomes reaches the final egg cell; a similar process occurs in the development of each sperm cell. Thus the 46 chromosomes of the normal child derive equally from the two parents. The father supplies 23 (one member of each pair) to the fertilized egg, while the other 23 come from the mother.

The cellular process that accomplishes the chromosome reduction (from the diploid to the haploid number) in the formation of gametes is called meiosis. This cycle of changes is initiated in certain diploid cells in the ovary (or testis). During meiosis the two members of each chromosome pair (homologous chromosomes) move close together in the cell. As they do this, they become greatly extended (uncoiled) and selectively exchange equivalent parts in a process called crossing-over.

Following crossing-over, two specialized cell divisions occur (the meiotic divisions). The net result of these is that one, and only one, of the strands making up the paired chromosomal unit reaches the future egg (or sperm) cell. When this occurs normally, not only is there reduction in chromosome number (46 to 23) but also the resulting single member of the chromosome pair is a new recombination (through crossing-over) of the genes present in the original diploid cell.

Recombination of genes through crossing-over and subsequent reassortment does not provide new genes. Rather, the variation already existing in the parent is

Trillions  
of com-  
binations

placed in new combinations as his gametes are formed. Fertilization normally involves the relatively random union of two parental cells, each containing a haploid number of chromosomes that carry new, unique combinations of old genes. The number of possible hereditary combinations is hard to grasp intuitively. Even if a gross underestimate of only two differing gene pairs per chromosome were assumed, each potential human parent would be capable of producing more than 19,000,000,000,000 genetically different kinds of sperm (or eggs). It is extremely unlikely that even one of these trillions of gene combinations would exactly duplicate that of any ancestor.

**Sex determination.** As a rule, the two members of each chromosome pair appear almost identical under the microscope with regard to size and shape. The single human exception to this rule is in just one pair of the 46 chromosomes normally found in the male; one of the members of one of these pairs is much shorter than the other. The comparable pair in female cells consists of two full-sized chromosomes. In view of the sexual difference, that particular pair is called the sex chromosomes. The larger chromosome is referred to as X and the smaller as Y. Thus, the normal human male has the chromosome formula XY and the female XX. Since only one member of each pair of sex chromosomes is transmitted through the gametes, normal human sperm are of two types (Y or X), whereas normal eggs all carry an X-chromosome. If a Y sperm fertilizes an egg, the result is XY and the fertilized egg begins to develop into a boy. Boys inherit their Y-chromosome from the father. When an X-bearing sperm reaches the egg first, the result is the start of a female embryo.

If X and Y sperm were produced in equal numbers, according to simple chance, then the sex ratio at conception (fertilization) would be expected to be half boys and half girls, or 1:1. Direct observation of sex ratios among newly fertilized human eggs is not yet feasible and sex-ratio data are typically collected at the time of birth. Reliably, in almost all human populations studied at birth, there is a slight excess of males; about 106 boys are born for each 100 girls. Throughout life, however, there is a slightly greater mortality of males; this slowly alters the sex ratio until, beyond the age of about 50 years, there is an excess of females. Other studies indicate that within the womb, embryo males suffer such a degree of relatively greater mortality that the sex ratio at conception might be expected to favour males even more than the 106:100 ratio observed at birth would suggest. Firm explanations for the apparent excess of male fertilizations have not been established; it is possible that Y sperm survive better than X or they may be a little more efficient in penetrating the egg. In any case, the sex differences are small, the statistical expectation for a boy (or girl) at any single birth still being close to one out of two.

#### SINGLE-FACTOR INHERITANCE

Genetic variation among individual people may arise from differences at one or more paired gene locations along the chromosomes. Although people tend to differ at many such points on their chromosomes, the observable effects of these gene differences are frequently so slight that it is difficult to identify the effect of each location separately. The principles of inheritance emerge more clearly when a difference at a single gene location produces conspicuous, unusual effects in the individual. Such striking departures from the norm frequently are classed as abnormalities. But it is also firmly supported that the mode of inheritance of a gene pair having a very slight effect, for example, on the height of an individual within the normal range is inherited according to the same rules as a pair causing a more drastic effect. Since the latter are easier to observe, however, examples are usually chosen for study from among them. Today the customary practice in genetics, as employed successfully by Mendel, is to simplify analysis by considering the effects of only one gene pair at a time.

**Dominant inheritance.** Some persons with generally dark hair show a streak of white (usually near the crown

of the head) present from their very first growth of hair. Known as white forelock (piebald trait), it is inherited in a pattern that is consistent with the notion that it involves a single gene pair (one gene for completely dark hair and another for the white-streak condition). The gene for white forelock apparently acts by interfering with pigment formation in some of the cells of the scalp, producing the white hair. Studies of families in which it occurs indicate it to be a dominant gene; that is, to dominate (or "swamp" the effect of) the gene for completely dark hair.

Figure 3 shows the inheritance of the piebald trait in

White  
forelock

Figure 3: Inheritance of white forelock through five generations of a family (see text).

a family through five generations. In pedigrees of this sort, the circles refer to females, and the squares to males; two symbols directly joined by a horizontal line represent a marriage, and children are shown in the next line below, with the birth order from left to right. Those individuals showing the trait are indicated by solid symbols. It may be seen from Figure 3 that the white-forelock trait is about equally present in men and women. It can go from the father to a child of either sex or from the mother to a child of either sex. In this pedigree it does not skip even one generation; that is, no marriage in which both parents lacked the white forelock produced children who had it. (In this particular family, the data are incomplete because the appearance of the mother in generation 1 is not recorded.)

The genetic explanation, dominant inheritance in this case, is as follows. Each affected individual has one chromosome that carries a gene that leads to white forelock, whereas the other homologous (partner) chromosome has a member of the gene pair that does not have this effect. Thus, using symbols, the gene *W* leads to white forelock and the gene *w* tends to produce the normal condition. An individual who inherited the white trait from only one parent (such as those in generation 3) must be *Ww* and is said to be heterozygous for the trait (capable of producing two different kinds of gametes; e.g., a *W* sperm and a *w* sperm). The condition of dominance means that one *W* gene is sufficient to overcome the darkening effect of *w*. When an affected man marries a normal woman (who must be *ww*), half of the resulting children on the average would be expected to exhibit the trait because half of his sperm carry *W* and half *w*. Since all of the eggs of the mother are the same in the sense that they all contain the gene *w* (Figure 4), she is said to be homozygous (homo, "same") for the normal trait.

If an individual were to carry two dominant genes,

Figure 4: Simple dominance.

Mating of a white-forelock man ( $Ww$ ) with a normal woman ( $ww$ ). The gene locations are shown on the chromosomes (vertical bars). The  $W$  gene will occur in half the sperm of the affected father; therefore, his children of either sex have a 50 percent chance of inheriting the trait.

Genotype  
and  
phenotype

having the homozygous gene formula  $WW$ , that person would of course show the piebald trait; a further consequence would be that none of the children would escape the white forelock, regardless of the genetic condition of the other parent.

The sight of a person with a white forelock can be attractively striking, and it is not unusual for someone with genetically normal hair colour to use bleach for cosmetic reasons. Careful examination of the hair to its very roots should help settle the matter. Furthermore, white hairs of the hereditary piebald trait are not confined to the head; a person carrying the white-forelock gene shows other spots of white hair and unpigmented skin in various parts of the body. Indeed, in conducting genetic studies it is most crucial to discover the degree to which the observable trait (called the phenotype) is attributable to the pattern of genes in the cells (the genotype) and to what extent it arises from environmental influence. The distinction between the contributions of heredity and environment is especially difficult to make in genetic studies of such traits as bodily stature, resistance to specific diseases, and level of intelligence (e.g., see INTELLIGENCE, DISTRIBUTION OF). At any rate, a white patch of hair on the head may be attributed wholly to the environment (if it is the result of peroxide); to the effect of the  $W$  gene on pigmentation patterns (if there is no cosmetic bleaching at all); or to both factors (if a carrier of the  $W$  gene undertakes to increase the extent or vividness of his white forelock with chemicals).

Examples of simple dominant inheritance are quite frequently encountered among human characteristics. More than 300 traits may be listed that clearly show this type of inheritance; a sampling is given in Table 1. Many of these are relatively rare, abnormal, pathological conditions that may be looked upon as hereditary diseases or defects.

In the study of pedigrees, some characteristics such as the webbed-toed condition (syndactyly) show strong evidence of dominant inheritance. Occasionally, however, it is found that the characteristic skips a generation. This may be attributed to what is called lack of penetrance; that is, a person may carry the gene for syndactyly, but the effect of the gene in some cases may be so slight (of such low penetrance) as to be undetectable by ordinary means. In other words, the evidence is that an individual may carry a gene that usually elicits a dominant phenotype, but for various reasons does not show it himself. (In a roughly similar way, people can harbour germs without falling ill themselves.)

A condition called achondroplasia also appears to be transmitted by a single dominant gene that acts to impair the growth of specific cartilages in the body as the bones

Table 1: Human Characteristics Often Attributable to a Single Dominant Gene

trait	conspicuous signs
Achondroplasia	abnormality of ossification centres in bones, resulting in dwarfism
Amyloidosis	congestive heart failure
Brachydactyly	short fingers and toes
Cataract	opacity of the lens of the eye
Cleft mentum	a bony peculiarity underlies a Y-shaped fissure in the chin
Huntington's chorea	degeneration of certain brain centres
Myotonic dystrophy	a type of muscular dystrophy with muscle wasting and loss of muscle tone
Piebald trait	white forelock of hair and other nonpigmented spots
Polydactyly	extra fingers
Ptosis	constricted or drooping eyelid
Syndactyly	"webbed" fingers or toes
Tuberous sclerosis	nodules in brain, viscera, and skin
Xeroderma pigmentosum	sensitivity to sunlight with likely development of skin cancer at an early age

are being formed. The result is a type of dwarfism in which the proportions of trunk and limbs are visibly abnormal; it is observed not only among people but in animals such as dachshunds. It must be distinguished from another type of dwarfism that produces a normally proportioned adult of very small size. The latter condition typically results from a malfunction of the pituitary gland, usually arising from injury or disease during a critical stage of the individual's early development. This may have the effect of impairing the pituitary gland's normal function of elaborating growth hormones (without which the person becomes stunted).

Single genes frequently have more than one obvious effect; a gene that causes deafness, for example, also produces abnormality of the fingernails. Called pleiotropy, such multiple effects of single genes are almost universal. Since genes operate by affecting developmental processes, a single gene change may eventually affect a number of bodily or behavioral characteristics. Thus, in achondroplasia, not only is the process of bone development altered but the consequent dwarfism affects the size, distribution, and function of the muscles and internal organs as well. It is frequently difficult to specify what effects are primary and what are secondary with regard to the action of a gene. Genetic conditions are usually named for their most easily recognized phenotypic sign (which serves as a convenient label, but by no means describes the full genotypic effect).

Not only may dominance be incomplete, as in the case of syndactyly; in addition, alleles (i.e., genes that may alternatively occupy the same location on a chromosome) may each produce a separate, different effect. Such a condition, called codominance, is exemplified in the human inheritance of so-called MN blood types. In this case, the blood type depends on chemical substances (antigens) in the red blood cells that are specified by a chromosome pair that can carry alternative genes (alleles) called  $M$  and  $N$ . Homozygous individuals may be  $MM$  or  $NN$ , in which cases the antigen in the blood cells is either  $M$  or  $N$ , respectively. A heterozygous  $MN$  person has both antigens in his red cells; that is, there is no dominance and each antigen is produced independently. At any rate, simple blood tests, using special chemicals that selectively make  $M$  cells or  $N$  cells agglutinate (stick together), can show whether a person is homozygous or heterozygous (see BLOOD GROUPS).

**Recessive inheritance.** More than 250 traits have been related to single genes that are recessive; that is, their effects are masked by dominant alleles and manifest themselves phenotypically only in homozygous individuals. A partial list is given in Table 2. Albinism, for example, in which the affected person lacks pigment in his skin, has white hair, and pink eyes, results only when a gene leading to albinism comes from both parents. This may result from several types of marriage. If  $A$  is a gene leading to normal pigmentation, and  $a$  is a gene leading to the albino condition, three kinds of genotypes can result:

Multiple  
effects

**Table 2: Human Characteristics Often Attributable to a Single Pair of Recessive Genes**

trait	conspicuous signs
Acheiropody	lack of hands and feet
Albinism	lack of pigment in skin, hair, and eyes
Alkaptonuria	defect of a tissue enzyme
Amaraotic idiocy	metabolic disorder of intelligence, with blindness
Cretinism	disturbance in function of thyroid glands
Deaf-mutism	deafness from birth
Galactosemia	enzyme deficiency that results in cataracts and mental retardation
Hartnup's disease	defect of protein (amino acid) metabolism
Hyperlipidemia	abnormal fat metabolism with retarded development
Keratosis palmo-plantaris	horny skin on palms and soles
Microcephaly	abnormally small head
Phenylketonuria	enzyme disorder leading to mental retardation
Phenylthiocarbamide taste blindness	inability to taste this substance as bitter
Thalassemia	abnormal type of hemoglobin in red blood cells

Albinos

*AA* and *Aa* exhibit normal pigmentation, and *aa* is albino. Thus, it frequently happens that both parents of an albino are phenotypically normal but are genotypically heterozygous (*Aa*), both carrying the albino gene *a*. The combinations that can occur in the children of such parents are *AA*, *Aa*, and *aa*. Only the *aa* genotype leads to albinism, and the chance of producing an albino child is one out of four. A carrier (*Aa*) married to an albino person (*aa*) will tend to have half albino children, while two albinos can produce only albino children.

Genes that are recessive are among the most common types known in man; as methods for detecting them are perfected, it is likely that those known will come to outnumber the dominants. Unlike the case of dominant inheritance, the person showing the results of having inherited a pair of recessive genes may not only have carrier parents who escaped the phenotypic trait but even his grandparents or great-grandparents may have failed to show it. The effectiveness of the recessive gene in producing the fully developed trait, however, is not affected even by a long sojourn, hidden over many generations in heterozygous individuals.

As in the case of dominant genes, most of the recessives listed in Table 2 lead to defects, producing observable characteristics that usually are recognized as diseases. These disorders predominate in such lists since they not only are important medically but they also serve as good examples of how inheritance operates. Thus, geneticists have tended to emphasize and record extensively those genes having conspicuous effects on people who inherit them. Nevertheless, most of the so-called normal variation among persons, such as in hair, eye, and skin colour, stature, facial features, and body build, are also clearly influenced by single genes. The inheritance of these traits, however, is complicated by two major factors. First, more than one gene, and frequently many gene locations on the chromosomes, may be involved in the determination of a trait. Second, many of these characters (*e.g.*, stature) are strongly influenced by environmental conditions (*e.g.*, amount of food available during critical growth stages). The interplay of these two factors leads to a complex situation that requires methods of study that go beyond simple inference from pedigrees; these are discussed below.

In the catalog of recessive traits, many conditions derive from disturbances in cellular chemical processes and have been called inborn (hereditary) errors of metabolism. With advances in biochemistry, many of these disorders have been found to be ascribable to the malfunction or absence of one or more major enzymes in the body. It is now clear that the synthesis within the body of enzymes (which themselves are protein in nature) is under the control of specific genes. If a gene is defective, then its coding system for regulating the synthesis of the particular protein involved is likewise impaired. This may affect every cell of the body, producing a variety of effects.

Errors of metabolism

A well-known example of an inborn metabolic error is the disorder called phenylketonuria, arising from a recessive gene *p* and found in individuals who are homozygous (*pp*). In the presence of the normal gene (*P*), a common amino acid (phenylalanine) found in many protein foods is transformed into another amino acid called tyrosine. The transformation from phenylalanine to tyrosine normally can be accomplished only in the presence of an enzyme called phenylalanine hydroxylase. In *pp* individuals, however, this enzyme is lacking; as a result, dietary phenylalanine either accumulates in the body or some of it is converted to a substance (phenylpyruvic acid) that normal people produce only in small quantities. Individuals with phenylketonuria tend to excrete large quantities of this acid, along with phenylalanine, in their urine, where these substances may be detected. When an infant develops high concentrations of phenylpyruvic acid and unconverted phenylalanine that accumulate in the blood, the tragic consequence may be feeble-mindedness. The mental deficiency appears to arise indirectly from an abnormal concentration of these substances in the brain. Fortunately, this very serious effect of phenylketonuria can be avoided by strict control of dietary phenylalanine, but dieting should begin as early in the infant's life as possible.

**Sex-linked inheritance.** The sex chromosomes (see above *Sex determination*), particularly the large X-chromosomes, carry a number of genes that are not related directly to the sexual traits of the individual. Since such genes are carried on the sex chromosomes, they are said to be sex-linked in their inheritance. More than 60 such genes have been recognized; a few of the more common are listed in Table 3. Sex-linked inheritance has special

**Table 3: Human Sex-Linked Characteristics**

trait	conspicuous signs
Colour blindness	red-green vision impaired
Ectodermal dysplasia	sweat glands absent or reduced
Hemophilia	hemorrhages; abnormal blood clotting
Ichthyosis simplex	scaly skin
Retinitis pigmentosa	degeneration of the retina of the eye

properties that may be seen in one form of hereditary colour blindness carried only by the X-chromosome.

If the recessive gene leading to the colour blindness is called *c*, and the normal allele is *C*, then human females having a pair of X-chromosomes may have three kinds of genotype: *CC* and *Cc* girls or women commonly have normal colour vision, whereas *cc* individuals are colour-blind. Typical males, on the other hand, are *XY* and have only a single X-chromosome and thus are either *CY* or *cY* genotypes. Since males receive their X-chromosomes only from their mothers, the father has no effect on the condition as found in his sons, contributing only the Y-chromosome, which carries no genes for colour vision. When a *cc* colour-blind woman marries a man who carries the *C* (colour-normal) gene on his X-chromosome, all the sons will be colour-blind and all the daughters will be phenotypically normal. In this case all the daughters will be heterozygous colour normal (*Cc*) and all the sons (*cY*) will be colour-blind. Sex-linked inheritance is distinguished from what is called autosomal inheritance, in which the genetic factors concerned are borne on a pair of the other chromosomes (autosomes), which are not related to the determination of sex.

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is also under the control of a sex-linked gene location. More than 20 alleles are known to be found at this location on the X-chromosome, some of which result in an enzymatic deficiency. Deficiency in G6PD, as produced by an allele that is common among people of black African ancestry, renders the person highly sensitive to the antimalarial drug primaquine. Another variant encountered among people of Mediterranean origin results in an unusual sensitivity to the common broad bean called *Vicia fava*. This reaction, called favism, results in a sometimes fatal anemia that develops when the person eats the raw beans or even inhales the pollen of this plant.

Colour blindness

Examination of cells from a normal human female (e.g., scraped from the inside of the mouth) reveals the presence of a small, darkly staining structure (Barr body) in the nucleus of those cells that are not dividing. This body is not observed in normal males and thus provides a way of telling the sex of the person by microscopic examination. Study has revealed that the material of the Barr body in the cell comes from one of the normal female's two X-chromosomes. Condensation of the chromosome to form the Barr body appears to inactivate the genes carried by that chromosome, effectively reducing the number of functional X-chromosomes in the female cell to one. (Inactivation also occurs in the case of rare, abnormal males who have one or more surplus X-chromosomes.) Although the significance of this finding is not wholly understood, it appears that now one, now the other, of the X-chromosomes becomes inactivated during the development of the normal female.

#### Mosaicism in women

According to one theory (the Lyon hypothesis), the tissues of some females (whose X-chromosomes are heterozygous) represent a mosaic of two kinds of cells present in approximately equal numbers because of the alternation in forming the Barr body. This appears to be borne out in studies of the cells of females who are heterozygous at the G6PD location. The two classes of cells that can be recognized actively manifest one or the other of the expected enzymatic variants. Other once-mystifying manifestations of sex-linked traits among human females also seem to be explained by mosaicism, providing additional evidence in support of the hypothesis.

**Lethal genes.** Some genes (e.g., those affecting hair form or eye colour) are of minor importance to the health of the person and to his ability to survive physiologically. Other genes, such as those that result in the defect or absence of an important enzyme, may lead to a frail individual whose chances of survival are reduced. The spectrum of such deleterious gene effects ranges from slight to lethally severe.

A number of known genes lead to the premature death of the individual who carries them, such lethal genes generally killing the embryo very early or at least before birth. In a number of cases, a category of sublethal genes is recognized for which death may be delayed into the years of childhood. In any event, to be classified as lethal or sublethal, the gene must prevent survival of the individual to the reproductive period.

In any given case of stillbirth (or of spontaneous abortion), the action of a dominant lethal gene is difficult to distinguish from environmentally produced death during embryonic life. Nevertheless, careful study has even revealed evidence that some genes are recessive in their lethal effects. When one particular recessive gene is present in the homozygous state, for example, there is an almost complete lack of development of brain tissue in the fetus. This condition (anencephaly) invariably has a lethal effect before birth; such fetuses are commonly aborted or are stillborn. In another recessive-gene disorder known as amaurotic idiocy, fatty deposits accumulate in the brain of the fetus. The child may be born alive, but there is progressive blindness and intellectual retardation, the physiological degeneration that underlies these symptoms resulting in early death.

#### HUMAN BLOOD

More is known about the genetics of the blood than about any other human tissue. One reason for this is that blood samples can be easily secured and subjected to biochemical analysis without harm or major discomfort to the person being tested. Perhaps a more cogent reason is that many chemical properties of human blood display relatively simple patterns of inheritance.

**Blood types.** Certain chemical substances within the red blood cells (such as the MN substances noted above) may serve as antigens. When cells that contain specific antigens are introduced into the body of an experimental animal such as a rabbit, the animal responds by producing highly specific proteins (antibodies) in its own blood. In this category is perhaps the best known of the human

blood groups, referred to as the ABO system. The synthesis of the two principal antigens in the ABO system is under control of genes occurring at what is apparently a single chromosome location (designated *I*). Three alleles exist at this *I* locus: one (*I<sup>A</sup>*) leads to the formation of what is called antigen A, another (*I<sup>B</sup>*) leads to B antigen, while the third allele (*I<sup>O</sup>*) results in blood cells lacking either antigen. *I<sup>A</sup>* and *I<sup>B</sup>* are codominant but *I<sup>O</sup>* is recessive. The various possible genotypes at this locus and the phenotypes they produce are given in Table 4. In

#### The ABO blood system

Table 4: The ABO Blood Groups

common designation of blood groups	genotypes	phenotypes (antigens present in blood cells)
A	<i>I<sup>A</sup> I<sup>A</sup></i> or <i>I<sup>A</sup> I<sup>O</sup></i>	antigen A
B	<i>I<sup>B</sup> I<sup>B</sup></i> or <i>I<sup>B</sup> I<sup>O</sup></i>	antigen B
AB	<i>I<sup>A</sup> I<sup>B</sup></i>	antigen A and antigen B
O	<i>I<sup>O</sup> I<sup>O</sup></i>	neither A nor B present

addition to the ABO system of the *I* locus, there are about 15 gene systems known (including MN and the well-known Rh) associated with other chromosome locations.

**Rh incompatibility.** The Rh antigens are of particular importance in human medicine. Curiously, however, their existence was discovered in monkeys (which resemble people in many ways). When blood from the rhesus monkey (hence the designation Rh) is injected into rabbits, the rabbits produce so-called Rh antibodies that will agglutinate not only the red blood cells of the monkey but the cells of a large proportion of human beings as well. Some people (Rh-negative individuals), however, lack the Rh antigen; the proportion of such persons varies from one human population to another. Akin to data concerning the ABO system, the evidence for Rh genes indicates that only a single chromosome locus (called *r*) is involved. At least eight Rh alleles are known for the *r* location; basically the Rh-negative condition is recessive.

A medical problem may arise when a woman who is Rh-negative carries a fetus that is Rh-positive. The first such child may have no difficulty, but later similar pregnancies may produce severely anemic newborn infants. The first Rh-positive fetus appears to immunize the Rh-negative mother; that is, she develops antibodies that may produce permanent (sometimes fatal) brain damage in any subsequent Rh-positive fetus. Damage arises from the scarcity of oxygen reaching the fetal brain because of the severe destruction of red blood cells. Measures are available for avoiding the severe effects of Rh incompatibility by transfusions to the fetus within the uterus; however, genetic counselling before marriage is especially desirable in such cases to forestall the need.

**Abnormal hemoglobin.** Several types of hemoglobin (the oxygen-carrying pigment in red blood cells) are known to be under the control of a single chromosome locus (called *Hb*). An especially interesting allele (*Hb<sup>s</sup>*) at this locus specifies an abnormal condition called sickle-cell anemia. The disorder was named from the peculiar sicklelike shape assumed by red blood cells of affected individuals. Persons who are homozygous *Hb<sup>s</sup> Hb<sup>s</sup>* are affected by a very severe anemia that is usually fatal in early life. Those who are heterozygous for *Hb<sup>s</sup>*, carrying one of the alleles for a normal hemoglobin (e.g., one called hemoglobin A), have no anemia; nevertheless, they may show the sickle-cell trait on microscopic examination of their blood.

The biochemical basis for sickling came to be understood when it was discovered that hemoglobin S and hemoglobin A move at different rates in an electrical field. Such means of chemical study have shown that the difference between the two hemoglobins depends on only one of nearly 600 amino acids that make up the complex protein molecule of hemoglobin. The *Hb<sup>s</sup>* gene, which is held responsible for this small chemical difference, is a very good example of how a gene that changes a body protein only very slightly can have far-reaching effects

Hemophilia

on a person's very life. The  $Hb^s$  gene is especially common in some populations of African origin; reasons for this high incidence will be discussed below.

**Abnormal blood clotting.** In clotting, which serves to prevent excess loss of blood after an injury, a complex protein called fibrin is normally formed. Persons with a genetic impairment of the clotting reaction are popularly known as bleeders. A common form of this disorder (hemophilia) displays simple sex-linked inheritance. The peculiar features of this type of inheritance were described in records dating from the second century AD. Ancient Hebrew laws codified in the Talmud contain special provisions (for male infants born into families of bleeders) that authorize that the ritual of circumcision may be omitted according to a complicated set of rules governing pedigree. Study of these rules shows them to be consistent with modern understanding of the mode of sex-linked inheritance. Sex-linked hemophilia frequently has affected members of European royalty. The evidence is strong that London-born Queen Victoria, for example, was heterozygous for the trait; she bore a son who suffered from hemophilia, and the disorder appeared among the male descendants of three of her daughters.

**Serum proteins.** Human serum, the fluid portion of the blood that remains after clotting, contains various proteins that have been shown to be under genetic control. Study of genetic influences has flourished since the development of precise methods for separating and identifying serum proteins. These move at different rates under the impetus of an electrical field (electrophoresis), as do proteins from many other sources (e.g., muscle or nerve). Since many genes act by specifying the synthesis of proteins, biochemical studies based on electrophoresis permit direct study of tissue substances that are only a metabolic step or two away from the genes themselves.

Most attention in the genetics of substances in the blood has been centred on serum proteins called haptoglobins, transferrins (which transport iron), and gamma globulins (a number of which are known to immunize against infectious diseases). Haptoglobins appear to relate to two common alleles at a single chromosome locus; the mode of inheritance of the other two seems more complicated, about 15 kinds of transferrins having been described. Like blood-cell antigen genes, serum-protein genes are distributed worldwide in the human population in a way that permits their use in tracing the origin and migration of different groups of people.

#### HEREDITY AND ENVIRONMENT (NATURE AND NURTURE)

It is a primary axiom in modern genetics that what is inherited from one's ancestors is a set of nucleic acid determiners (genes). To cite an example, it may be noted that blue eye colour shows recessive inheritance. The common notion that a child has "inherited" his brown eyes from his father rather than from his blue-eyed mother should be recognized for the shortcut statement that it is. Only the genes (e.g., the potential for eye colour) are inherited; the actualized phenotypic trait (e.g., brown eyes) is the outcome of the manner in which the pertinent gene or genes interact with the environment during the growth and development of the individual. An embryo deprived of nourishment from the environment will die before it can develop any eyes at all.

Another way of saying this is that no trait can exist or become actual without an environmental contribution. Thus, the old question of which is more important, heredity or environment, is without meaning. Both nature (heredity) and nurture (environment) are always important for every human attribute.

But this is not to say that the separate contributions of heredity and environment are equivalent for each characteristic. Dark pigmentation of the iris of the eye, for example, is under hereditary control in that one or more genes specify the synthesis and deposition in the iris of the pigment (melanin). This is one character that is relatively independent of such environmental factors as diet or climate; thus, individual differences in eye colour tend to be largely attributable to hereditary factors rather than to ordinary environmental change.

On the other hand, it is unwarranted to assume that other traits (such as height, weight, or intelligence) are as little affected by environment as in the case of eye colour. It is very easy to gather information that tall parents tend, on the average, to have tall children (and that short parents tend to produce short children), properly indicating a hereditary contribution to height. Nevertheless, it is equally manifest that growth can be stunted in the environmental absence of adequate nutrition. The dilemma arises that only the combined, final result of this nature-nurture interaction can be directly observed. There is no accurate way (in the case of a single individual) to gauge the separate contributions of heredity and environment to such a characteristic as height. An inferential way out of this dilemma is provided by studies of twins, however.

**Fraternal twins.** Usually a fertile human female produces a single egg about once a month. Should fertilization occur (a zygote is formed), growth of the individual child normally proceeds after the fertilized egg has become implanted in the wall of the uterus (womb). In the unusual circumstance that two unfertilized eggs are simultaneously released by the ovaries, each egg may be fertilized by a different sperm cell at about the same time, become implanted, and both grow, to result in the birth of twins.

Twins formed from separate eggs and different sperm cells can be of the same sex or of either. No matter what their sex, they are designated as fraternal twins. This terminology is used to emphasize that fraternal twins are genetically no more alike than are siblings (brothers or sisters) born years apart. Basically they differ from ordinary siblings only in having grown side by side in the womb and in having been born at approximately the same time.

**Identical twins.** In a major nonfraternal type of twinning, only one egg is fertilized; but during the cleavage of this single zygote into two cells, the resulting pair somehow become separated. Each of the two cells may implant in the uterus separately and grow into a complete, whole individual. In laboratory studies with the zygotes of many animal species, it has been found that in the two-celled stage (and later) a portion of the embryo, if separated under the microscope by the experimenter, may develop into a perfect, whole individual. Such splitting occurs spontaneously at the four-cell stage in some organisms (e.g., the armadillo) and has been accomplished experimentally with the embryos of salamanders, among others.

The net result of splitting at an early embryonic stage may be to produce so-called identical twins. Since such twins derive from the same fertilized egg, the hereditary material from which they originate is absolutely identical in every way, down to the last gene locus. While developmental and genetic differences between one "identical" twin and another still may arise through a number of processes (e.g., mutation), these twins are always found to be of the same sex. They are often breathtakingly similar in appearance, frequently down to very fine anatomic and biochemical details (although their fingerprints are differentiable).

**Diagnosis of twin types.** Since the initial event in the mother's body (either splitting of a single egg or two separate fertilizations) is not observed directly, inferential means are employed for diagnosing a set of twins as fraternal or identical. The birth of fraternal twins is most frequently characterized by the passage of two separate afterbirths. In many instances, identical twins are followed by only a single afterbirth, but exceptions to this phenomenon are so common that this is not a reliable method of diagnosis.

The most trustworthy method for inferring twin type is based on the determination of genetic similarity. By selecting those traits that display the least variation attributable to environmental influences (such as eye colour and blood types), it is feasible, if enough separate chromosome loci are considered, to make the diagnosis of twin type with high confidence.

**Inferences from twin studies.** *Metric (quantitative) traits.* By measuring the heights of a large number of or-

Split embryos

The interaction of heredity and environment

Figure 5: Measured differences between identical (one-egg) twins, between like-sexed fraternal (two-egg) twins, and between like-sexed ordinary siblings.

Adapted from H.L. Carson, *Heredity and Human Life* (1963); Columbia University Press

ordinary siblings (brothers and sisters) and of twin pairs, it may be shown that the average difference between identical twins is less than half the difference for all other siblings (see Figure 5). Any average differences between groups of identical twins are attributable with considerable confidence to the environment. Thus, since the sample of identical twins (given in Figure 5) who were reared apart (in different homes) differed little in height from identicals who were raised together, it appears that environmental-genetic influences on that trait tended to be similar for both groups.

Yet, the data for like-sexed fraternal twins reveal a much greater average difference in height (about the same as that found for ordinary siblings reared in the same home at different ages). Apparently the fraternal twins were more dissimilar than identicals (even though reared together) because the fraternal twins differed more among themselves in genotype. This emphasizes the great genetic similarity among identicals. Such studies can be particularly enlightening when the effects of individual genes are obscured by the influence of the environment on quantitative (measurable) traits (e.g., height, weight, and intelligence).

Any trait that can be objectively measured among identical and fraternal twins can be scrutinized for the particular combination of hereditary and environmental influences that impinge upon it. The effect of environment on identical twins reared apart (Figure 5) is suggested by their relatively great average difference in body weight as compared with identical twins reared together. Weight would appear to be more strongly modified by the environment than is height.

Study of comparable characteristics among farm animals and plants suggests that such quantitative human traits as height and weight are affected by allelic differences at a number of chromosome locations: that they are not simply affected by genes at a single locus. Investigation of these gene systems with multiple locations (polygenic systems) is carried out largely through selective-breeding experiments among large groups of plants and lower animals. Human beings select their mates in a much freer fashion, and polygenic studies among people are thus severely limited.

Intelligence is a very complex human trait; but even roughly measured as IQ, intelligence shows (Figure 5) a strong contribution from the environment. Fraternal twins, however, show relatively great dissimilarity in IQ, suggesting an important contribution from heredity as well. Twin studies involving psychological traits should be viewed with caution; for example, since identical twins tend to be singled out for special attention, their environment should not be considered equivalent even to that of other children raised in their own family.

**Other traits.** For traits of a more qualitative (all-or-none) nature, the twin method can also be used in efforts to assess the degree of hereditary contribution. Such investigations are based on an examination of cases in

which at least one member of the twin pair shows the trait. It is found, for example, that in about 80 percent of all identical twin pairs in which one twin shows symptoms of a psychiatric disorder called schizophrenia, the other member of the pair also shows them (that is, the two are concordant for the schizophrenic trait). In the remaining 20 percent, the twins are discordant (that is, one lacks the trait). Since identical twins often have similar environments, this information by itself does not distinguish between the effects of heredity and environment. When pairs of like-sexed fraternal twins reared together are studied, however, concordance for schizophrenia is very much lower—only about 15 percent (Figure 6).

Adapted from H.L. Carson, *Heredity and Human Life* (1963); Columbia University Press

Figure 6: Concordance rates for identical (one-egg) twins and for fraternal (two-egg) twins for cases in which at least one twin shows the trait.

Schizophrenia clearly develops much more easily in some genotypes than among others; this indicates a strong hereditary predisposition to the development of the trait. The schizophrenic trait also serves as a good example of variable penetrance, in that identical twins may differ in whether they express it or not.

Studies of concordance and discordance between identical and fraternal twins have been carried out for many other human characteristics, a few of which are also summarized in Figure 6. It has, for example, been known for many years that tuberculosis is a bacterial infection of environmental origin. Yet identical twins raised in the same home show concordance for the disease far more often than do fraternal twins. This finding seems to be explained by the high degree of genetic similarity among the identical twins. While the tuberculosis germ is not inherited, one's heredity does seem to make him more (or less) susceptible to this particular infection. Thus the genes of one individual may provide the chemical basis for immunity to a disease, while the genes of another may fail to do so.

Indeed, there seem to be genetic differences among disease germs themselves that result in differences in their virulence. Thus, whether a genetically susceptible person actually develops a disease also depends in part on the heredity of the particular strain of bacteria or virus with which he must cope. Consequently, unless environmental factors such as these are adequately evaluated, the conclusions drawn from susceptibility studies can be unfortunately misleading.

Some human traits, such as susceptibility to measles, show a small (but nonetheless distinct) hereditary component. Social disorders (criminality, for example) frequently give evidence of being affected by hereditary factors. This is not to say that there is an invariably specific "criminal" gene (or gene combination) that dooms one to a career of crime. The evidence is, rather, that human personality is to some degree shaped by a number of genes, each of which may have an individually small effect. Under conditions of social pressure, genetically based personality types may turn to crime. If the pressure is absent or slight, such a person will no more fall into criminality than he will exhibit susceptibility to tuberculosis unless he happens to come in contact with a virulent germ.

## CHROMOSOME VARIATIONS

Under unusual circumstances a human egg or sperm may contain an abnormal set of chromosomes; e.g., too many or too few. Imbalances of this sort may be associated with abnormal appearance and behaviour.

**Abnormal number of sex chromosomes.** In some instances (about 1 in 3,500 female human births) a girl infant is born with only one X-chromosome instead of the usual pair (the XO condition). Such a child exhibits a total of 45 chromosomes instead of the normal 46. Development is abnormal, although the individual has female external genitalia. Nevertheless, her ovaries, uterus, and breasts fail to develop normally, and she is almost always incapable of reproduction; this disorder is called Turner's syndrome.

Somewhat more frequently, about one in 400 male births, infants are born with one or more surplus X-chromosomes (producing a group of symptoms called Klinefelter's syndrome). Thus, the chromosome number is 47 in an XXY child rather than 46; in addition to the normally "female" XX condition, there is a Y-chromosome present. The person shows external male genitalia but has very small testes and somewhat feminized breasts; there is also proneness to mental retardation. Klinefelter's syndrome provides evidence for the male-determining tendency of even a single Y-chromosome.

A rarer abnormality in the number of sex chromosomes has been recognized as the XYY male. Men with this genetic endowment are unusually tall and tend to display psychological disturbances, frequently being aggressive and sometimes mentally deficient. While men with extra Y-chromosomes have been found to comprise a small percentage of inmates of penal institutions surveyed, as might be expected in the case of any complex psychological trait, other XYY individuals have achieved normal social adjustment. At any rate, the practice of calling such men "supermales" seems unwarranted.

**Abnormalities related to the autosomes.** Occasionally a gamete is formed that contains an extra autosome (a chromosome other than X or Y). This can result in a person with three rather than the usual pair of autosomes. (In Figure 2, all pairs numbered 1 through 22 are autosomes.) If one of the larger autosomes is involved it is likely that the zygote will die before development, perhaps because there is no autosomal mechanism similar to that of X-chromosome inactivation.

One of the smallest chromosomes (from pair 21) is sometimes represented twice instead of once in the gamete (egg or sperm). After fertilization, individuals with three of these small chromosomes survive well and are recognized phenotypically as sufferers of Down's syndrome (sometimes called mongoloid idiocy). In addition to mental retardation, such individuals are short and have stubby hands and feet and abnormalities of the heart. They exhibit a peculiarity of the eyelid that gives them a superficial resemblance to Asians, hence the term mongoloid idiocy.

Down's syndrome is one of the most frequently observed serious human genetic disorders, being found in about one out of 600 live births and in all racial groups. The incidence is highest when older mothers give birth, suggesting that abnormal movement of chromosome 21 may occur as the effect of maternal aging on the formation of the egg. The risk is about 100 times less among mothers in their 20s than it is for women over 45.

Some persons with typical signs of Down's syndrome even show the normal number of 46 chromosomes. Examinations indicate that, in addition to the normal pair 21, there is still a third chromosome 21 attached (translocated) to one of the larger autosomes (probably to pair 14). These cases usually involve one parent who can be shown to carry a translocation, although the parent is himself phenotypically normal. The probability for the production of a child with Down's syndrome appears to be about one out of three if the mother is the carrier, but apparently it is less if the father is the carrier.

In most cases the zygote's loss of an entire chromosome is lethal; embryonic survival is more likely when there is loss of only a small portion of one chromosome. When

part of the short arm of chromosome 5 is deleted, for example, the infant survives with a distinctive syndrome called *cri du chat* (French: "cry of the cat"). The affected individual shows mental retardation and skeletal deformities that include widely set eyes. Vocalization includes a catlike sound that is so characteristic that it serves to name the syndrome.

## MUTATION

Under most mitotic and meiotic circumstances newly formed chromosomes and their genes are very exact, complete, and perfect reproductions of the originals. As a cell grows and undergoes division, the DNA molecules of the nucleus tend to be faithfully reproduced by a process of self-copying. This remarkable adaptation contributes to the continuity of living species, generation after generation, for each specific characteristic encoded by the genes. Ordinary environmental changes such as gradual variation in temperature, barometric pressure, diet, or muscular activity seem to have no effect on the exactness of the process.

On occasion, however (e.g., in response to environmental radioactivity), imperfect self-reproduction of chromosomal DNA molecules may occur to produce the potential for new traits; this is called mutation. Even when only a single gene in one cell is mutated, the copying process tends faithfully to reproduce the changed DNA in all the descendants of that particular cell. Indeed, mutation appears to be a basic cellular mechanism underlying the evolution (e.g., descent with change) of living beings.

**Somatic mutation.** Mutation in any cell of the body except a germ cell (egg or sperm) is called somatic mutation. A common result of what seems to be somatic mutation is observable among blue-eyed people. Blue colour in the eyes of a person is attributable generally to a lack of pigment; possibly a single chromosome locus is involved; at any rate, the genes that produce this trait are recessive to those that generate pigment. If *b* represents the gene (allele) for blue eyes and *B* an allele coding for brown eyes, then a person with blue eyes would be represented by *bb*. Occasionally, however, blue-eyed persons are observed to have a small sector (or flecks) of brown (usually in one eye). This is probably the result of somatic mutation (mutation of a cell within the eye itself) of one of the *b* alleles to *B*. It is inferred that this mutation from *b* to *B* occurred in one of the embryonic cells that normally give rise to the iris of the eye, all cells descending from this one showing the brown pigment of the dominant *B* gene. The iris of the eye of such a person is a genetic mosaic, with most of its cells *bb* (blue) and a small sector of cells descended from the mutant *Bb* (brown). Such localized mutations do not affect the germ cells and thus are not transmitted to the next generation.

**Germinal mutation.** Although such mutations as the one just described cannot be inherited, if the same DNA change were to occur in an egg or sperm (germ cell), there would be a definite probability (perhaps small) that the newly mutated gene would be passed on to the next generation. In other words, it is at least theoretically possible that two *bb* (blue-eyed) parents could produce *Bb* (brown-eyed) children through germ-cell mutation. Such germinal mutations are the object of careful search by investigators, since they facilitate the study of the laws of inheritance as well as providing clues to the future direction of human evolution.

**Mutation rates.** Detectable results of germinal mutation among people are only very rarely encountered. Thus, the actual rate of mutation in human chromosomes defies full measurement. A major reason for this is that most mutations seem to be recessive and thus tend to be masked for generations. Efforts to measure mutation rate therefore are most conveniently directed toward selected dominant or codominant mutations for which phenotypic recognition is easier; indirect (inferential) methods of measurement are still required.

One dominant gene that is useful for studying human mutation rate produces the form of dwarfism called achondroplasia (Table 1). When an affected child appears in a family in which both parents are normal, the proper-

Studies of achondroplasia

"Supermales"

Down's syndrome

ly diagnosed condition can be ascribed to the occurrence of one new mutation. The frequency of such an event is customarily calculated on the basis of the number of gametes (egg and sperm cells) produced by the parents in one generation; for human achondroplasia, the mutation rate has been inferred to be 4.2 per 100,000 gametes. Analyses of a number of different gene loci in man and in such experimental organisms as corn (maize) and *Drosophila* (fruit fly) show that the average mutation rate among living beings is on the order of one in 100,000 gametes ( $10^{-5}$ ). Nevertheless, each gene studied shows its unique mutational probability; the neurological disorder called Huntington's chorea shows only about 0.5 mutation per 100,000 gametes, whereas the figure for neurofibromatosis (a disorder with soft tumours distributed over the whole body) is from 13 to 25 per 100,000. The general average in man is about the same as for achondroplasia, roughly four per 100,000 gametes.

The word mutation may be applied to alterations in chromosome number and breakage of chromosomes (as in translocation) as well as to gene changes. The frequency of these chromosome mutations may or may not be the same as that of gene mutations. In any event, the spontaneous rate of mutation is manifestly very low by almost any criteria. Nevertheless, while the processes of heredity are conservative and generally resist change, there are environmental factors that can increase the rate of mutation.

*Spontaneous and induced mutation.* In all living things that have been studied, including man, there is a low level of mutation that occurs independently of the investigator's intervention and so has been generally labelled spontaneous. It is hard to ascribe any specific cause to these; spontaneous mutations are generally thought to be copying errors that are inevitable in so intricate and delicate a mechanism. Perhaps some of them may arise from relatively random events in the environment (such as cosmic rays from outer space), since it is now known that certain environmental agents will greatly increase the frequency of mutations. Paramount among these mutagens (mutation producers) are ionizing radiations of all sorts (including cosmic rays), as well as chemicals such as mustard gas and formaldehyde.

To be actively mutagenic, the agent must reach the cells themselves; for example, ultraviolet radiation (e.g., the tanning rays of the sun) is mutagenic, but its low penetrating ability renders it essentially ineffective as a germinal mutagen in man. Nevertheless, sunlight seems to be a somatic mutagen; heavily tanned people are found to be prone to skin cancers, the abnormal growth presumably stemming from skin cells mutated by the sun's ultraviolet rays. By contrast, penetrating ionizing radiations such as X-rays and those that result from atomic explosions are among the most powerful germinal mutagens found; no living organism is known to have body tissues adequate to shield the germ cells from their penetration.

*Radiation hazards.* It was a stroke of good fortune that the damaging genetic effects of ionizing radiation were already partially known in the 1930s, a decade before the use of atomic energy burst upon the world. The obvious dangers of increasing the germinal mutation rate, already tragically high in the human species, were widely discussed during the 1950s. These genetic arguments had much to do with the suspension of atmospheric testing of atomic weapons by a number of countries.

Radioactive materials such as strontium-90 and iodine-131 are released in considerable quantities into the atmosphere by such tests. These mutagenic materials become distributed throughout the upper atmosphere and filter back to earth as radioactive fallout. Strontium-90, in particular, has created great concern because it remains active for a long time and because it readily replaces calcium in teeth and bones. This brings the mutagenic radiation close to such sensitive tissues as bone marrow, where blood cells originate. As a result, the danger of a form of blood cancer called leukemia rises. Since most powerful mutagens are also likely to induce cancer, many investigators seek to relate this disease to a basically genetic cause. Apparently irreversible cellular changes that are

associated with senescence suggest somatic mutation as a basis for the process of aging as well.

There appears to be a direct relationship between the dose of radiation received and the number of mutations induced among living cells. The more radiation (or mutagenic chemical) affecting a cell, the greater the number of expected mutations will be. At low levels of radiation, it becomes increasingly difficult to demonstrate that a proportionately small number of mutations is still being induced. Nevertheless, the adoption of an arbitrary "safe" level, below which no medical or hereditary hazard can be expected, is clearly untenable, and the safest position in this regard is that the less radiation to both germinal and somatic tissues, the better. When radiation is used for medical or dental diagnosis and treatment, the anticipated benefits should be weighed against the hazards, however small their probability.

Customarily, the risk associated with exposure to radiation is expressed as the radioactive dose (in roentgen units) that is found by experimentation to double the spontaneous germinal (hereditary) mutation rate. Among laboratory mice it has been calculated that doubling ensues at about 45 roentgen units administered as a single dose of relatively intense radiation. Such a dose given all at once apparently produces more damage than does the same dose when it accumulates over a longer period from a source of lower intensity. Thus if the source is chronic, low-level radiation (such as from dispersed fallout), the doubling dose in mice may be as high as 200 roentgen units. There is good reason to expect similar results among people; the hazards (among other objections) prohibit such experimental studies with human beings. If such studies were feasible, a radiation dose could be specified that would double the probability that the affected person will produce a child carrying a new, presumably deleterious, mutation.

General exposure to man-made radiation has not reached such high doses; present radiation levels are, nevertheless, more mutagenic than they would have been had atomic explosions never occurred. While authorities may differ as to what constitutes an "acceptable" level of man-made radiation, there is general dread that a doubling dose of radiation to the human population of the world would end in major calamity. In addition, calculations indicate that unavoidable background radiation (about 3 roentgens over 30 years) received by the average person is not sufficient to account for all the mutations that are continually arising spontaneously. There must be other, unknown factors that affect the basic rate of mutation. Until these factors are understood, the prospects for their control remain bleak.

## II. Applications of human genetics

### GENETIC COUNSELLING

The term genetic counselling is applied to a service, typically available in medical settings, in which prospective parents are provided with estimates of the probability that they will produce children with genetically controlled defects. Considering the great increase in understanding of human genetics, it seems likely that such counselling will be sought by an increasingly large number of persons. Genetic disorders have attracted growing attention in medical practice, especially since the urgencies of infectious disease have been reduced through such developments as antibiotic control.

Genetic counselling has been, and probably will continue to be, desired mostly by persons who seek a rational basis for deciding whether or not to limit their reproduction. Accordingly, the role of the genetic counsellor is to collect the relevant evidence by making a pedigree study of the couple concerned and then, by applying established principles of inheritance to estimate the risk, or probability, of genetic defect among their offspring. The counsellor ordinarily is in a position to estimate only the probability of trouble, leaving the final decision to the couple themselves.

That human chromosomes carry a large store ("genetic load") of recessive, potentially harmful genes is well documented; indeed, about 4 percent of live human births

Skin  
cancer

show defects of medical concern, at least half of which are attributable to major genetic influence. The most common situation that prompts people to seek a genetic counsellor is one in which a phenotypically normal couple produce a first child suffering from a major defect. The parents understandably want to know what the chances are that subsequent children will also be affected.

**Simple inheritance.** A typical example might involve an albino child born to a couple who are themselves normally pigmented. Since an albino person may face health and social problems, the parents in all likelihood will be concerned to know the probability that their next child also will be albino.

After examining the child and making sure of the diagnosis, the genetic counsellor can ascertain that albinism results in an individual who carries a pair of recessive genes for the trait; *i.e.*, the child is homozygous for albinism. Accordingly, one albino allele must come from each parent; that is, both parents must carry the gene (must be heterozygous for it). In this case no further pedigree study is needed to give the couple the answer to their question. The probability that their next child will be albino is one out of four, one-quarter, or 25 percent; this is readily deduced from the principles of simple recessive inheritance. What the parents do with this information is their responsibility alone; they may share a powerful desire for a second child or they may feel that an albino child still can find much reward in his life. On the other hand, they may decide (for any of a number of human reasons) that they consider the risk, even at 25 percent, as too high.

If the defect under consideration were a more threatening recessive trait (such as phenylketonuria, which poses difficulty in treatment and a serious risk of mental deficiency), a decision against taking the chance would perhaps be more likely.

Should the mother of an albino child die, the heterozygous father may plan a second marriage. He might ask the genetic counsellor to estimate the probability that this second marriage will result in another albino child. The likely case is that, in the counsellor's study of the pedigree of the prospective new wife, no history of albinism can be found in her family, since human albinism is very rare indeed. What the counsellor still needs to estimate are the maximum chances (however unlikely) that the second wife still may be heterozygous for albinism, since recessive genes may remain undetected for generations. This can be estimated from data concerning the frequency of albinism in the population (beyond the family) from which the presumed second wife is herself drawn. On a world population basis, heterozygous carriers of the recessive gene for albinism have been found to number about one in 50 persons. Accordingly, the estimate that the proposed wife might be heterozygous is the probability  $\frac{1}{50}$ . Since the probability is  $\frac{1}{2}$  that each parent will pass on the gene if present, the probability for the production of an albino child could therefore be calculated as  $\frac{1}{50} \times \frac{1}{4} = \frac{1}{200}$ . This is only 0.5 percent and suggests that the chances of producing an albino child in the proposed marriage are quite remote.

The estimate made in the preceding case can be made more specific if the counsellor can find data on the particular subgroup of people from which his clients come. Genes for albinism, like many others, occur more or less frequently in different human groups. Homozygous (albino) individuals are observed only at a rate of about one in 20,000 among Europeans, one in 3,000 among black Nigerians, and one in 132 among the San Blas Indians of Panama. Clearly the frequency of carriers of albino genes is less than the world average (one out of 50) among Europeans and much higher among San Blas Indians. At any rate, the counsellor should base his estimates on the most pertinent data available.

**Complex inheritance.** In cases such as those just described (in which the mode of inheritance is simple), the counsellor usually can answer the questions prospective parents ask with enough confidence to cite a specific probability. This is not as readily accomplished when the genetic basis is more complicated or when the expression

(*e.g.*, penetrance) of the gene is irregular. Congenital (present at birth) dislocation of the hip, for example, is a rare condition. It has been found that about 41 percent of identical twins are concordant for the trait but only about 3 percent of fraternal twins show concordance. This suggests a strong hereditary basis for the condition; nevertheless, since the 41-percent concordance of identical twins is by no means complete, the appearance of the trait is attributed in part to nongenetic factors. The problem is further complicated; examination of pedigrees for infants with congenital dislocation of the hip has failed to establish a simple mode of inheritance.

Although lacking a firmly defined hereditary mode on which to base deductions, the counsellor still can resort to purely empirical statistics to make an estimate of risk. If, for example, a woman who exhibits dislocation wishes to marry and asks what the chances are that her children will also be affected, figures available for answer will include the fact that in one sample of 219 women known to have had the condition and who bore a total of 48 sons and 45 daughters, none of the sons showed the trait but five of the 45 daughters did. These empirical figures based on previous medical records can be used to estimate the risk even without the availability of a theoretical genetic mechanism for transmission. Medical records for a growing number of medically important human traits are constantly being augmented, and empirical risk figures are being widely used as valuable guides in genetic counselling.

**Identification of carriers.** Under ordinary circumstances the presence of a recessive gene is fully hidden by its normal allele, and its heterozygous carrier cannot be told by direct observation from a person who is homozygous normal for the trait. In some instances the heterozygote carrier can be recognized, and thus the counsellor's task is facilitated. Biochemical tests can sometimes help identify heterozygous carriers of the recessive phenylketonuria gene, for example.

Huntington's chorea is one disorder for which as yet no heterozygote test has been developed. This incurable nervous disease is produced by a dominant gene that usually does not manifest itself until well past the age of reproduction, the average age of the patient at the time of the first symptom being about 50 years. Accordingly, a person who has the gene rarely knows it until after his children are born. A test that could identify carriers early in their lives would help alleviate much human suffering, since such people tend to pass the offending gene on to half of their children. The gene that gives rise to Huntington's chorea apparently was introduced into North America by just three immigrant families of British origin. Nevertheless, it has been estimated that at the present time there are approximately 7,000 affected individuals among their descendants.

The genetic counsellor often is presented with a vague or diverse series of symptoms. These often may arise from one or several genes, from environmental events, or from a combination of factors. Pedigrees based on reports given by family descendants themselves are notoriously inaccurate, and frequently the genetic counsellor may be hard put to separate fancy or hearsay from fact. This problem is especially difficult to overcome in counselling clients who are concerned with such complex psychological characteristics as neurotic behaviour.

**Eugenics.** The term eugenics has been applied to theories and practices ostensibly designed to improve the human condition from the genetic point of view. Genetic counselling typically is a form of so-called negative eugenics, in that it tends to improve man as a species by discouraging reproduction among those deemed likely to perpetuate genes that lead to medical defects. Since so much human tragedy is attributable to such genes, there is widespread agreement that mankind would be far better off without them. Sterilization (*e.g.*, of certain insane people) is legally required in some cases, although local laws vary greatly, even within given countries. By and large, negative eugenics is most widely acceptable when it is practiced through counselling.

On the other hand, the question of positive eugenics is

Congenital  
hip dis-  
location

Parental  
responsi-  
bility

Failure of  
large-scale  
programs  
of positive  
eugenics

quite another matter. Such attempts are designed to identify "good" genes and thereby improve man by encouraging the reproduction of those persons who are thought to carry them. All too often, however, the desirability of particular hereditary human traits (such as skin colour or shape of nose) is as subjective and controversial a matter as is one's taste in music. Judgments clash over whether intelligence is preferable to calmness or originality to obedient tractability. Even if agreement were possible, such attributes are most unreliably measured, and finding the relative contribution of heredity and environment to each of them is most frustrating.

The difficulties appear so great that attempts to advance positive eugenics on a broad scale have been abortive. Unfortunately, efforts of governments (as in Nazi Germany) to favour the reproduction of "superior" groups of people rested on a pseudoscientific approach in which the magnitude of the role of the genes in producing desirable human attributes was grossly overstated. The Nazi slaughter of millions in the name of eugenics is a tragic chapter in history. Subtle and more disguised forms of genetic selection may be accomplished by withholding jobs, opportunities, housing, and health care from particular groups of people; such tactics may be observed in all societies. The power to isolate and deprive individuals and groups is also the power to limit their reproduction and their survival as human subspecies. Conversely, reproduction of human groups can be selectively encouraged by such measures as government subsidies for having borne children.

Large-scale programs of positive eugenics inevitably seem to become deeply embroiled in economic, social, and political struggle. To the extent that they are thus embroiled, their failure becomes assured. A major stumbling block is the clear evidence that enormous genetic differences exist among individuals within any large racial or ethnic group; each group exhibits genetically defective as well as genetically gifted members. The differences between groups, in contrast, are substantially smaller (if they exist at all) with regard to the genetic basis of intelligence and personality. In addition, group differences tend to be exaggerated or concealed by the considerable impact of environmental variations. Accordingly, the statement can be categorically made that there is no scientific basis on which any kind of genetic racism can be built. Thus, while lower socioeconomic classes of people traditionally have outproduced more privileged groups, there appears to be no reason to expect genetic deterioration of the human species because of this.

**Genetic engineering.** Although slow in its effects, negative eugenics (based on identifying defective individuals rather than on a futile search for "inferior" groups) seems to be the most promising way in which modern human genetics can be applied for man's benefit. Indeed, fundamental discoveries in basic genetics have provided the theoretical basis upon which a science of individual genetic engineering, or intervention, can be built.

Artificial insemination is perhaps the most widely used engineering practice at the present time to circumvent male sterility in barren marriages. Sperm can be collected from fertile donors (if need be, frozen and used at a later time) to effect fertilization in a normal female whose husband cannot father children. By having his sperm stored, a man may become a father years after he has died.

The theoretical possibility has existed for a long time that human X and Y spermatozoa safely could be separated by a number of possible techniques (e.g., under the influence of an electrical field). Such separation, used in conjunction with artificial insemination, would result in the possibility of controlling the sex of the offspring. Despite repeated reports of success (e.g., among rabbits) optimism for human sex control seems premature; a successful, acceptable technique remains to be developed for use with people.

Some geneticists have urged that positive-eugenic use be made of the presently available technique of human artificial insemination. In this view, the spermatozoa of men with presumably "outstanding" genetic endowment could

be stored in "sperm banks" for long periods and then could be used to effect fertilizations with prospective mothers who desired it. Unfortunately, fathers who have earned high social esteem for their achievements all too often produce children whom others judge mediocre or inferior. Such common disappointments are attributable to a number of factors. First, genetic recombination in the formation of the man's gametes (spermatozoa) yields a high probability that a "good" combination of genes will be broken up (if, indeed, such a combination exists in the first place). The sperm cells a man produces all can be expected to differ from the unique one his father contributed toward his existence. Then, the male parent provides only half of the child's genetic endowment, so the result is in doubt from the mother's side as well. In addition, those who achieve distinction may, like anyone else, carry genes that tend to produce undesirable effects: epilepsy, bodily malformations, blindness, or schizophrenic behaviour. Thus, the sperm-bank approach to positive eugenics seems to entail definite risk of failure; the prediction that great benefits would automatically accrue is debatable.

Optimistic predictions of the use of engineering practices in human genetics are frequently made. Although many genetic interventions are theoretically possible or have been accomplished in lower organisms, their adaptation to the special human condition has not yet been made. Perhaps the most promising of these is amniocentesis, in which cells from an embryo (or very early fetus) can be removed from within the mother (e.g., hypodermically) and tested long before the birth of the child. If an abnormal chromosome, defective enzyme, or other deleterious genetic condition can be diagnosed by tests on such cells, the laws of many communities may permit abortion. Amniocentesis may become a major step toward avoiding such tragic genetic disorders as Down's syndrome (mongolian idiocy).

The human ovum has been successfully fertilized outside of the potential mother's body and, indeed, has been cultured in laboratory glassware to a many-celled stage. If desired, such an embryo can be placed in a receptive uterus and will implant. One may hope that, with the use of proper tests, implantation could be accomplished only with those embryos lacking diagnosable defects. Even this hopeful possibility should be approached with caution, however, since the number of serious human genetic diseases that can be diagnosed using cell samples is at present very small indeed.

Somewhat more remote, but still possible, is a technique that would replace a defective or lethal gene locus with one that is normal. This possibility is based on the discovery that engineered gene replacements are feasible in bacteria. Comparable manipulation of the genes in a mammalian cell (e.g., from a dog or a person) has not been accomplished and practical use of this technique toward human betterment seems far away indeed.

Another sensational possibility is the replacement of the normal (biparental) nucleus of a fertilized egg with the nucleus of a somatic cell taken from anywhere in the body of just one person. Such replacements have been accomplished in experimental animals; in the human case, this sort of one-parent embryo might be implanted in a receptive uterus. An infant born of the implanted pregnancy would be expected to have the same genetic characteristics as the donor individual.

#### GENES IN POPULATIONS

Population genetics is a branch of genetic science that concerns the frequency and fate of gene differences within groups (populations) of individuals. The meaning of gene frequency can be illustrated by a system with two alleles such as those for the M and N blood types. When the homozygous individual is *MM* he shows only the M antigen in his cells; when he is *NN*, he shows only the N antigen. Heterozygous *MN* individuals show both antigens. If a village of 1,000 people is found to include 810 *MM*, 180 *MN*, and 10 *NN* individuals, it would mean that the N antigen is much rarer than the M; this may be expressed in precise terms as the gene frequency of N. Of

New genes  
for old

Control  
of the  
embryo's  
sex

a total of 2,000 alleles for this trait (each of the 1,000 people has two alleles), 200 are *N*: two from each of the 10 *NN* individuals (20) plus one more from each of the 180 *MN* heterozygotes. Thus the gene frequency of *N* is  $\frac{200}{2,000}$ , or 10 percent; *M* makes up the remainder and is therefore 90 percent.

**The Hardy-Weinberg equilibrium.** If the entire population of the village discussed above randomly forms couples and children are born, the same *M* and *N* gene frequency tends to appear in both generations. At reproduction, the gametes form a so-called gene pool in which 90% tend to be *M* and 10% *N*. The law of genetic equilibrium (Hardy-Weinberg law) states that, given any pair of frequencies *p* and *q* for two alleles (in this case *p* = 90% and *q* = 10%), the frequencies among the zygotes of the offspring will tend to be in accordance with the ratio *p*<sup>2</sup> (for *MM*): 2 *pq* (for *MN*): *q*<sup>2</sup> (for *NN*). Substituting the village's values for *p* and *q*, one would expect to find (among every 1,000 children) 810 *MM*, 180 *MN*, and 10 *NN*, the same as in the previous generation. Such theoretical predictions are closely verified in laboratory experiments, although chance factors are likely to produce some variation from the expected gene frequencies. The Hardy-Weinberg law tends to hold experimentally regardless of the initial gene frequency: for example, when *p* and *q* are 60% and 40%. It is to be noted that *p* plus *q* always equal one (or 100%).

The law also holds for dominant-recessive gene pairs (alleles). In most cases, as pointed out earlier, the recessive *a* gene (for albino) is very rare compared with the dominant *A* (for normal pigment) in human populations. Only albino (*aa*) and normal phenotypes (*Aa* or *AA*) can actually be observed. If in a population of 1,000 people there are found to be 10 albino (*aa*) individuals (*q*<sup>2</sup> = 1%, or .01), by applying the law, it may be inferred that the gene pool for these people is 10% *a* (*q* =  $\sqrt{q^2}$ ) and that the remaining 90% is *A*. Once *p* and *q* have been established (in this case as 90% and 10%), one can then calculate the expected number of *Aa* carriers (2*pq*) and homozygous (*AA*) normals (*p*<sup>2</sup>) as in the previous example. Even though the gene is dominant, the frequency of the normal *A* allele will not tend to increase when mating is random but will tend to remain at equilibrium. For purposes of genetic counselling, if a population is at Hardy-Weinberg equilibrium, one can calculate the probable frequency of the carriers of any hidden recessive gene if one knows the frequency of the double recessives (e.g., albinos). In this case, it turns out that about 19% of the normals will be expected to be carriers of the *a* gene. As a further example, for a population in which the gene frequency for phenylketonuria is  $\frac{1}{200}$ , one may estimate the number of carriers to be about  $\frac{1}{100}$ , or 1%.

**Conditions that favour the Hardy-Weinberg equilibrium.** A population is most likely to remain at equilibrium if it contains a large number of individuals. If it is small, departures from random mating may result in considerable deviations from expectation. Thus, if the law is to hold, the various matings should be made according to chance; that is, they should not be selective with regard to any particular genotype. While genes such as those for the *M* and *N* blood groups show practically no evidence of affecting one's choice of a mate, it is conceivable, for example, that albinos in a population might tend to marry albinos. If such selective mating occurred, the Hardy-Weinberg equilibrium for the albino gene would be upset.

Equilibrium also is favoured by the operation of the 1:1 gametic ratio in heterozygotes expected in simple inheritance. If, for example, *MN* individuals were prone to produce more *M* gametes than *N* gametes, the equilibrium would be disturbed.

Unless all relevant genotypes (e.g., *MM*, *MN*, and *NN*) have equivalent fitness to reproduce, equilibrium tends to be broken. In other words, to preserve equilibrium, the presence of *N* in the homozygous state should not impair or enhance in any way the ability of its carrier to reproduce relative to the other two genotypes.

**Natural selection and random drift.** By now it should be clear that sexual reproduction under simple (Mende-

lian) inheritance is a conservative force that tends to maintain the genetic status quo in a population. If a gene frequency is 1 percent in a population, it tends to remain at 1 percent indefinitely unless some force acts to change it. Outside of the laboratory, the most powerful force for changing gene frequencies is natural selection. In genetic terms, natural selection means that some genotypes leave more offspring than others. The capacity for the production of offspring is spoken of as Darwinian fitness or, simply, fitness. If the fitness of the three genotypes from a gene pair are all the same, then the gene frequencies will tend to remain stable in the next generation. Should the homozygous recessive genotype be lethal or produce sterile individuals (with zero fitness), then the recessive gene will tend to be underrepresented in the next generation. The result will be a change in the gene frequency.

If such a process goes on generation after generation, the recessive gene tends slowly to be eliminated. But as the gene becomes rarer, the probability of the production of sterile (zero-fitness) individuals will also be decreased, tending to slow the rate at which that gene is removed from the population pool. The rate of decline is even slower if the homozygous genotype is not completely sterile but, as is indeed the case with albinos (*aa*), partially fertile. Since it is found that albino people typically produce fewer children than do normals, this contributes to natural selection against the albino *a* gene.

If any population is relatively small, the effects of chance may result in the total elimination of the *a* gene from that population, so that all members are *AA*. Such an event is spoken of as a fixation for gene *A*. Chance alone, which particularly operates through fluctuations in population size, can strikingly alter gene frequencies at intermediate levels as well. This effect is called random drift and, along with natural selection, is a powerful process of genetic change within populations. Both processes can be expressed mathematically and the rates of change of gene frequency (from generation to generation) can be calculated. Calculations also take into account evidence of definite mutation rates for given genes. Thus, if natural selection and random drift are operating to eliminate a gene such as *a* (albinism), the computations also should reflect the frequency with which *a* genes are arising as mutations. Thus, what happens to a gene in an isolated (closed) population depends on the interrelationships of natural selection, random drift, and mutation rate.

**Evolution.** Change in gene frequency (and thus the genetic composition of a population) is the essence of the evolutionary process. As a classic example, increase in the frequency of a gene leading to a black body colour has occurred among some populations of moths in England during the past century. The phenomenon is called industrial melanism (pigmentation), since it has been attributed to the effects of factory smoke. Moths homozygous for the "dark" gene are less conspicuous on soot-blackened surfaces such as tree trunks than are moths that carry the normal gene for light-gray mottled colour. Over the decades, the gene leading to dark colour has nearly replaced the other in heavily industrialized regions of England. Apparently, dark moths are protectively coloured and less likely to be eaten by birds. This is an example of adaptive evolution on a limited, local scale (microevolution). Human populations are also subject to microevolution, but the changes emerge more slowly since a human generation is longer than that for moths. Genes that confer increased Darwinian fitness on their carriers are expected to increase in frequency, just as those that are deleterious should tend to decrease. Even if a gene contributes only slightly to increased fitness, there will nonetheless tend to be a progressive increase in gene frequency in its favour. Although the process may be very slow, calculations over 100 to 1,000 generations indicate that even very small increases in fitness may bring about powerful changes in the composition of populations.

**Genetic polymorphism.** Although progressive evolutionary change may eliminate one member of a pair of alleles from a population, in some cases (known as balanced polymorphism) counteracting selective forces lead

Darwinian  
fitness

Inferring  
gene fre-  
quencies

Micro-  
evolution

to stable gene frequencies in which both alleles are maintained. An example of balanced polymorphism is the case of the gene leading to sickle-cell anemia among some tribes of Africa. The sickling gene produces a specific type of hemoglobin ( $Hb^s$ ), while normal hemoglobin is related to another allele ( $Hb^A$ ). Accordingly, the possible genotypes are  $Hb^A Hb^A$ ,  $Hb^A Hb^s$ , and  $Hb^s Hb^s$ . The latter people are homozygous for the sickle-cell gene and especially prone to develop severe anemia. While the condition is not lethal before birth, such individuals rarely survive long enough to exhibit more than minimal fitness in the Darwinian sense of capacity to reproduce. On these grounds it might be concluded that natural selection eventually should drive the frequency of the  $Hb^s$  gene to complete elimination or at least down to the one in 100,000 level of the mutation rate. One would theorize a transient polymorphism; that is, one on the way out, toward fixation of the favoured allele.

Evidence, however, seems to contradict theory since, in a number of African tribes living in their ancestral tropical lowlands where one form of malaria is widespread, the  $Hb^s$  (sickling) gene is very common indeed. On the other hand, the same gene is rare in genetically related but isolated tribes living in highlands that are free of mosquitoes that transmit this (tertian) type of malaria. This discrepancy between lowland and highland people has led to the hypothesis that the  $Hb^A Hb^s$  heterozygote is more fit and capable of leaving more offspring than is the homozygous normal  $Hb^A Hb^A$  in a highly malarious environment. Although the exact way in which this extra measure of protection is provided is not understood, the hypothesis seems to be borne out by the observations. Calculations indicate that when any heterozygote is favoured over both homozygotes, both alleles will tend to be retained in the population. Equilibrium gene frequencies for both  $Hb^A$  and  $Hb^s$  are expected to maintain balanced polymorphism as long as the environmental agent (malaria) remains.

Populations of African origin in malaria-free regions of the Americas, whose ancestors came from villages with high frequencies of  $Hb^s$ , exhibit much lower frequencies of the gene than do those who remain genetically balanced in the ancestral villages. Apparently there is an ongoing microevolutionary change among all such populations that are no longer subject to substantial natural selection from the effects of tertian malaria.

**Genetic load.** Much of the genetic polymorphism in man appears to be transient rather than balanced. In practice, it is difficult to identify all of the alleles that any given chromosome location may carry. Nevertheless, the search continues for recessive genes that produce severe effects (as homozygotes). Sometimes called the mutational load, these genes are identified as concealed mutants carried by heterozygous individuals.

Natural selection, although it may work regularly to eliminate mutations that are unfavourable for reproduction, frequently cannot consummate the elimination fast enough. The result is that these "bad" genes may accumulate in human populations. They constitute a hidden load of mutations that mankind carries as part of the price of biological existence. Almost all living organisms carry comparable genes, but among humans, for whom every defective or stillborn child may impose a poignant burden, the matter is especially serious.

More optimistically, the enormous genetic variability carried by human populations by no means consists only of deleterious recessives. Many genes individually have little effect; since they function in combination with genes at other chromosome locations, they are called polygenes. Recent estimates of polygenes that combine to affect the enzymes of human blood suggest that, as has been found in other organisms, about a third of the chromosome loci are polymorphic (as is the sickle-cell gene). Using a fairly conservative figure of genes at 10,000 chromosome locations for man, this suggests that about 3,300 locations are polymorphic in the human species.

How such great variability is maintained is a subject of active investigation and theoretical controversy. One popular theory is that much of the genetic variability is main-

tained specifically because it provides superior heterozygous combinations (the balance hypothesis). Balanced polymorphism, as in the case of sickle-cell anemia, may provide increased fitness for the heterozygote, but the homozygous individual still suffers.

Consideration of the relative importance of mutational and balance loads has centred around the possibility that some genetic differences exist in which the two homozygotes and the heterozygote are neutral from the point of view of natural selection. This view is not favoured in more traditional selection theory, which holds that no two genotypes can be absolutely identical in producing reproductive fitness.

#### GENETICS AND THE EVOLUTION OF MAN

**The origin of the human species.** Human genetics, especially when considered in terms of populations, has contributed much to theories on the origin of the human species (see HOMINIDAE). Theories of man's origins are considered in detail in other articles, but suffice it to say that in many cases the evolutionary emergence of any species is associated with geographical isolation of a population. Subsequently, this population comes to represent a unique gene pool that arises when its members fail to interbreed with other contemporary groups because of the persistence of isolating mechanisms, geographical, cultural, or otherwise.

Fossil and archaeological data indicate the likelihood that man emerged as a genetic isolate from prehuman ancestors on continental Africa; limited evidence suggests the early Pleistocene age (which began more than 2,000,000 years ago). Subsequently, the human species (*Homo sapiens*) spread to almost all habitable parts of the world. At the dawn of recorded history, the human species had already reached all continents except possibly Antarctica. From the location and character of their remains, it appears that the spread of these ancient people was accomplished by small bands, migrating groups that moved on foot (and later with the aid of horses or small, primitive rafts or boats).

The human species up to recorded history was apparently made up of many semi-isolated, relatively small population groups, with only minor interconnecting migration. This ancient population in many parts of the world came to form a complex mosaic of villages or settlements, much as has been observed in more recent times among the peoples in New Guinea.

This spread was likely to have been accompanied by a combination of natural selection and random drift, which, with a high mutation rate and growing numbers of people within isolated communities, would produce and spread great genetic variability both within groups and from one isolated population to the next.

**Genetic aspects of race.** According to one definition, a race is a geographical subdivision of a species that differs genetically from other races (subspecies) in the frequency of one or more alleles. Some theorists, imagining the human population of the world as it might have been about 4000 BC, speculate that there were perhaps five major races, one for each inhabited major land mass.

If contemporary human groups are any indication, however, within any major racial division there were large numbers of small subdivisions. The many human population segments of today blend at the edges and frequently defy description. Systematic biological distinctions among them are difficult to make. Blood-group and other gene-frequency differences, for example, show that all Indians of the Western Hemisphere manifest major genetic similarities; nevertheless, great variability exists from one group to the next, beginning in the American Arctic and proceeding to Tierra del Fuego at the tip of South America. Only where isolation has been rigorous is an occasional group found that is genetically distinct enough to tempt specific classification (see RACES OF MANKIND).

However one chooses to distinguish the "races" of man (e.g., by skin colour, hair form, stature, facial features, or whatever), it is grossly evident that they can and do mate successfully one with the other. This ready interfertility

Man as a genetic isolate

The survival of "bad" genes

among all human subgroups heavily endorses their designation as a single animal species, *Homo sapiens*. Mating between any of the "races," no matter how superficially different, produces children who have biologically sound heredities and who are fully fertile.

The continuing genetic recombination within what is identified as a single human species provides great diversity in modern man. Many feel that this diversity provides a source of great biological strength for the future of man.

(H.L.C.)

## Geneva

One of Europe's most unusual cities, Geneva has served as a model for the so-called city-state and owes its pre-eminence to the triumph of human, rather than geographic, factors. It developed a cosmopolitan character from the 16th century onward, when, as the dynamic centre of the Calvinist Reformation, it became the "Protestant Rome." Its contemporary economic and cultural prestige, too, are out of proportion to its physical size (Genève canton has a total area of 109 square miles [282

square kilometres], of which 62 square miles are in the city proper) and population, nearly 174,000 by 1970 with a population of over 321,000 in the metropolitan area. Territorial isolation has, in fact, been a basic feature of this economic and political entity, which did not establish its definitive frontiers until 1815, after long historical vicissitudes. Cut off, after the Reformation, from its natural geographic surroundings in France and Savoy, Geneva was forced to establish a distant but powerful network of intellectual and economic relationships, linking it with the European continent and with emerging regions overseas.

An aristocratic republic, governed first by an elite of bankers and scholars and then, after a radical insurrection in 1846-47, by an emergent liberal bourgeoisie, Geneva has functioned primarily as a centre of commerce, in contact with both Germanic and Mediterranean countries. Badly endowed in relation to the heavy industry associated with the Industrial Revolution, Geneva became instead a centre for capital accumulation and for such specialized manufacture as watchmaking. Contemporary Geneva is, above all, a service metropolis, specializing in financial activity and housing the headquarters of many public and private international organizations.

The Geneva of the early 1970s was plagued by problems stemming from its unique traditions: there is a very high proportion of foreigners in its population; there are manpower difficulties; its limited overall area is being rapidly consumed by urban growth; the German-Swiss element in the economy is exerting increasing influence; there is poor integration with neighbouring French territories; and rail and highway facilities are inadequate. Yet the city's uniqueness remains the key to its continued prosperity. Geneva has always justified the comment of the great French statesman Talleyrand: "There are five continents, and then there is Geneva." (For further information, see SWITZERLAND; SWITZERLAND, HISTORY OF.)

## HISTORY

Geneva grew up in the centre of a natural basin clearly delimited by encircling mountains. The excellent location, besides commanding the important Swiss corridor between the Alps and the Jura Mountains, is also the

Territorial isolation

By courtesy of the Swiss National Tourist Office

Geneva in its lake setting, with the International Labour Office and the Parc Villa Barton in the foreground.

focus of Alpine passes leading into Italy and, along the Saône-Rhône axis, of routes to the Mediterranean. The local climate is tempered by the presence of Lake Geneva (Lac Léman), while the Jura create a screen that diminishes rainfall.

**Foundation and early growth.** The original site of the city was an easily defended hill dominating the lake outlet near a convenient crossing point. Human occupation began in the Paleolithic Period and further developed in the Neolithic, which witnessed the growth of a vast lake-dwelling community built on piles. The original name of Genava (or Geneva) undoubtedly dates back to the pre-Celtic Ligurian peoples. In about 500 BC, at the time of the Roman conquest, Geneva was a fortified settlement of the Allobrogian Celts, and as early as 58 BC, Geneva served as a departure point for Caesar's campaign against the Helvetians. By 379 it was a Roman city, Christianized, and the seat of a bishop. After the Germanic invasions it became the capital of the Burgundian kingdom (443–534).

During the period of the birth of feudalism, however, Geneva—which had belonged to Lotharingia and then again to Burgundy (888–1034)—was in the centre of the lands belonging to the Genevese counts, who became hereditary after 1034. With the final extinction of the line of Genevese counts in 1401, the bishop—who was the direct vassal of the Holy Roman emperor and invested with temporal power—became pre-eminent, in spite of the ambitions of the House of Savoy, which was tightening its hold on the neighbouring territories. Geneva was now a regional centre exercising influence over a vast bishopric and, through its trade fairs, entering into the economic life of Europe. A decline began toward 1450, however, owing to competition from Lyons and to the growing power of the great national states. The fairs—which disappeared completely in the 16th century—nevertheless coincided with initial urban expansion; the town grew from its original hill site, with commercial quarters springing up along the banks of the lake and the Rhône. A foothold was also established north of the river, in the suburb of Saint-Gervais.

**The Reformation.** The economic diversity of this early period prepared the way for the Reformation. Religious unrest enhanced the desire of the inhabitants to escape the power of the bishop-prince (who, from the start of the 15th century, was finally bound politically to the House of Savoy) and also to expand their participation in politics, which had been inaugurated with the granting of certain franchises in 1387. In 1536 the citizens of Geneva embraced the Reformation and proclaimed a republic, supported by John Calvin between 1541 and 1564. Geneva was saved from the Duke of Savoy's counterattack by France and its Swiss allies, particularly Bern. The republic continued to defend its independence in a series of campaigns between 1589 and 1601, but, by the Treaty of Lyons (1601), Savoy ceded the Pays de Gex to France, thus severing Geneva from Switzerland. The Duke of Savoy also made an abortive attempt to take the city by surprise during the night of December 11–12, 1602, but the action of France and the Swiss cantons led to the further recognition of Geneva's independence in the Treaty of Saint-Julien (July 11, 1603).

The effect  
of the  
Reforma-  
tion

The Reformation period marked a vital turning point in Genevan history, for as early as 1530 the city had razed its outlying areas and enclosed itself in a formidable system of fortifications. The inhabitants, cut off from the bishop's former territories of Jussy on the east and Peney on the west, turned to banking and to such remunerative trades as watchmaking, introduced by the French Huguenots. The influx of other refugees from Italy, Germany, and, above all, France infused the republic with new blood. They gave the "Protestant Rome" a continental dimension and brought with them a high level of culture, attested to both by the prosperity of the printing industry and by the founding of the Academy in 1559.

**The modern period.** The 18th century was a calm period, during which Geneva—which had benefitted from

a further influx of French Protestants following the revocation of the toleration granted by the Edict of Nantes in 1685—consolidated its economic power and extended its territory through agreements with France and Sardinia. A modus vivendi was established with the House of Savoy, which continued to maintain a close watch on the city and tried, with the creation of the town of Carouge in 1772, to set up a rival commercial and religious (Catholic) bastion at the gates of the city. The oligarchic republic of Geneva was at the zenith of its prosperity, with branches of its banking houses in every country and its financial power ranging far and wide, from the court of Versailles to the new United States. Material wealth stimulated a burst of culture and artistic creativity. Although still enclosed within its walls, the city adorned itself with beautiful private mansions and public buildings, while the patricians built sumptuous country houses. Local political life was intense, featuring a seething controversy that opposed the bourgeoisie and working-class elements, the natifs, to the dominant aristocracy, a conflict that reached sufficient intensity to provoke interventions from both Paris and Turin. The birthplace of Rousseau and the sanctuary of Voltaire, Geneva was a centre of attraction for the elite of the Enlightenment and was one of the places where the new political science, derived from natural law, was developed.

In 1798, with the aid of local Jacobins, Geneva was annexed to the "Grande Nation" of the French Directory. The city was reduced to a subservient role in the Département du Léman and submitted, in 1802, to the protection of Napoleon I. The Emperor distrusted Geneva, "that city where they know English too well" (which was indeed harbouring a secret liberal and Anglophile opposition), and the French period became an era of demographic stagnation and economic recession.

The effect  
of the  
French  
Revolution

As early as 1813 Geneva threw in its lot with France's enemies and was thus able to claim indemnities upon the fall of the empire. The aristocratic republic was restored and undertook negotiations with the Swiss cantons to join the Helvetic Confederation and also with the Great Powers at the Congress of Vienna. On September 12, 1814, the republic was admitted to the ranks of the Swiss cantons. Through the cession of 12 Savoyard communes of the Pays de Gex in the Second Treaty of Paris (November 20, 1815), it "rounded out" its territories into a single block, linked to the rest of Switzerland. The French and Sardinian customs line was pushed back to create a free zone that constituted an economic, if not a political, hinterland.

The Restoration brought back the aristocracy, which experienced a further quarter century of glory. "Swiss Geneva" had ceased to be an autonomous political entity, and its relations with neighbouring countries were the responsibility of the federal authority. Gradually, however, the bourgeoisie and the common people began to question the aristocratic regime. They obtained concessions in 1841, but trouble broke out again in 1843. The civil war of the Sonderbund, which began in 1846 between Catholic and Protestant Swiss cantons, permitted the radicals, led by James Fazy, to go on the offensive. On October 7, 1846, the working-class suburb of Saint-Gervais revolted, and the conservative government was overthrown. The radicals, who drew up the new constitution of 1847, were thereafter masters of Geneva. James Fazy dominated the political scene until 1861. He was in many ways the founder of modern Geneva, having opened the canton to railway lines, created the Bank of Geneva, and, above all, having made widespread urban expansion possible by demolishing the fortifications.

The  
creation of  
"Swiss  
Geneva"

In 1860 Geneva lost its last chance for territorial growth. With the annexation of northern Savoy by France, a greater free zone was created out of the Chablais, the Faucigny, and part of Genevan territory. The city regained, and until 1914 held, its role as a regional economic capital. It also continued to assert its international influence—the Red Cross was founded in 1864, and the League of Nations was installed in 1919. In 1923, however, France suppressed the free zone in a blow that

was only partially compensated by the re-establishment of the petites zones (of 1815 and 1816) in 1923. The lack of a larger free zone further accentuated Geneva's international role. In the city itself, Fazy's successors inaugurated and pursued a violently anticlerical policy, and in 1907 the separation of church and state was established by popular vote. In the late 19th century, hydroelectric power inaugurated a new industrial era, but this was hindered both by World War I and by the world financial crisis of 1929. It was not until after 1945 that the contemporary phase of demographic and economic growth got under way, signs of a prosperity that has brought problems of its own.

#### THE CONTEMPORARY CITY

**Layout and urban structure.** Geneva exhibits the classic pattern of old European cities, with a concentric arrangement of neighbourhoods in more or less continuous belts around the original nucleus. The Haute-ville, centred on the hill and marked by the Cathedral of St. Peter, is the historic heart of Geneva. The route from the rue de l'Hôtel-de-Ville to the Grand-Rue marks the crest of the Celtic settlement, and the Bourg-de-Four marks the city's first extension outside its walls. The houses here are typical of the Middle Ages and the Renaissance, and building density is high. This neighbourhood also has experienced relative depopulation in favor of such luxury businesses as antiques and interior decoration; government office buildings; and high-rise apartments and offices.

At the foot of the hill an area reclaimed from the lake and the Rhône forms a low-lying shopping district featuring big department stores and places of entertainment. On the site of the old fortifications—mostly to the south of the Rhône—suburbs, dating from the second half of the 19th century, have grown up. These are lifeless, exhibiting a uniform style, with specialized streets (one for doctors, one for banks); public buildings (museums, the Grand Théâtre, the university); and such green areas as the Promenade des Bastions. Beyond these suburbs is a new, irregular belt of working-class residential areas, close to the railway stations (Eaux-Vives, Grottes, Saint-Gervais), and industrial zones. The latter—Acacias, Jonction, Servette, Charmilles, and Secheron—exhibit little or no planning. A well-to-do residential area follows on the southern plateau (Malagnou, Champel), while the quarter housing such international agencies as the Red Cross, the International Labour Office, and the World Health Organization rises on old patrician properties north of the Rhône. The old Savoyard city of Carouge is joined to Geneva by the populous and commercial rue de Carouge. Finally, since 1945, such new satellite settlements as Onex, Meyrin, Le Ligon, and La Grabelle have sprung up in the surrounding countryside. By the 1970s the canton included 45 communes, 16 of which were united with Geneva in the city proper.

The canton's frontier has undergone a long formative process. Agreements with neighbouring states gradually brought closer together, and finally united, the scattered elements of the area's feudal mosaic. The principal mechanisms were the treaties of Paris (1749), with France, and of Turin (1754), with Sardinia, and, with these same two countries, agreements of 1815 and 1816. The current isolation of Geneva is almost complete; of the 45 roads that radiate out of Geneva, only three link the city to the rest of Switzerland. The others are intersected by the frontier. The frontier with France covers 64 miles (102 kilometres), as compared with only 3 miles shared with the neighbouring Swiss canton of Vaud.

**Demography.** It was not until after 1945 that the city's population began to register rapid growth, owing to the admission of other Swiss citizens and foreigners. By 1970 it reached 173,618. Natural growth was only two per thousand, compared with 20 per thousand lost through emigration. Persons over 65 years represent 18 percent of the native Genevan population, 12 percent of other Swiss residents, and only 5 percent of foreign residents. Persons under 21 years of age are approximately equally distributed. A large foreign population is one of

the constants of Genevan demography. Since the 1820s the proportion of foreigners has not dropped below 16 percent, and in 1970 it stood at 34 percent. Native Genevans make up about 30 percent of the population, and the remainder are Swiss from other cantons. By the 1970s immigration to Geneva was characterized not only by the traditional contingents from Italy and France but also by a rising number from the Iberian Peninsula, the Americas, Asia, and Africa. Among the native population and in the professional classes, the Protestant element is in the majority, but, within the population as a whole, Geneva is no longer the "Protestant Rome." Roman Catholics, in fact, make up slightly more than half the population.

**Economic life.** Geneva has a tertiary, or service, economy; well over two thirds of the population is employed in service industries and less than 1 percent in agriculture. The latter is in decline because of the lack of land and is protected by the government. It supplies such commodities as wheat, rapeseed, dairy products, and wine.

Industry is characterized by lack of space and raw materials and by distance from vital mineral sources. Geneva has always had quality labour and internationally oriented commercial management, as well as an early start in capital accumulation. Certain older activities, such as cotton-textile manufacture, have disappeared, but watchmaking has a continuing tradition of precision and quality. Industrial production is diversified and is, above all, oriented toward export. By the 1970s the largest industry was that of precision machinery and instrument manufacture, employing approximately 16,000 workers. Principal specialties are equipment for hydraulic plants (turbines and alternators), electrical equipment, machine tools, and measuring devices. Watchmaking and jewelry making, with more than 70 firms and 4,000 employees, have lost first place in the area of mass production to those of the Jura region but are still in the forefront with respect to the creation of high-quality articles. The chemical industry, with two dozen firms and 2,500 employees, is the second largest in Switzerland, after Basel. It supplies luxury items—such as fragrances and bases for perfume—as well as medicines. The food-processing industry is well represented, with 2,000 persons employed, and Geneva also manufactures almost half of all Swiss-made cigarettes. Outside the city an industrial zone of 9,700,000 square feet has been set up at La Praille and at the Acacias, along the railway. The manpower shortage has necessitated the influx of foreign workers. Finally, recent decades have witnessed a process of concentration through mergers and the passage to German-Swiss control of a number of large businesses in electromechanical construction, precision metallurgy, and chemicals.

**Administration and services.** The republic and canton of Geneva is governed by the Constitution of 1847 (as modified by later laws), which established a democracy based on universal male suffrage and extended the vote to women in 1960. Local cantonal government is exercised by an executive power, the Council of State (consisting of seven members, who are elected for four years), and by a legislature, the Great Council, which is composed of 100 deputies, who are also elected for four years by proportional ballot. Each constituent commune has its own communal assembly, administrative council, and mayor. On both communal and cantonal levels, citizens have the right of legislative initiative and of referendum. To represent it in the federal government, the canton elects two deputies to the Council of States and a number of national councillors, which varies according to population. Since 1936, power has been exercised by a coalition of national parties, excluding the Labour Party (Communist) and including the independent Christian Socialist Party (Catholic), the Liberals, Radicals, and Socialists. The rate of voter participation is one of the lowest in Switzerland and rarely attains 50 percent of those registered.

Service activities are an expression of Geneva's cosmopolitan character and its commercial and financial vocation. Commerce, banking, and insurance employ more

Industry

Residential  
areas

Financial  
role

than 30,000 persons; hotels, 8,000; and public and private services, 26,000. The handling of capital has long been the prime mover in the city's prosperity, and banking and the stock exchange have more than 3,000 employees. Although Geneva is second to Zürich in total volume of financial transactions, it has retained a position of worldwide importance. When compared with the branches of the large Swiss banks of German-Swiss origin and with the numerous affiliates of foreign firms, the local private banks have specialized in the management of fortunes. Geneva is one of the principal sanctuaries for capital, and it has been estimated that its banks hold more than half the total amount of foreign capital in the country. Many international institutions have found a home in the city as a result of centuries-old orientation to the outside world and of the security brought by Swiss neutrality. In 1945 Geneva became the European headquarters of the United Nations and of the numerous organizations attached to it. In addition, there are more than 150 international headquarters for such private organizations as the League of Red Cross Societies, the Inter-Parliamentary Union, and the World Council of Churches. Operating on a European level and extending its activity into the industrial and technological area, CERN (the European Nuclear Research Council) appropriately juts out, territorially, onto French soil.

In the area of communications, success has been uneven. It has been said that Geneva lost the battle of the railroads in the 19th century, and the two railway stations of Cornavin and Eaux-Vives do not, in fact, link up. Geneva has been connected with Lausanne and with the Swiss highway system by a multilane expressway since 1964. The city also contributed labour and financing to the construction of the highway tunnel beneath Mt. Blanc and the Route-Blanche (White Way) to Italy. Cointrin airport, however, the second largest in Switzerland, has been more successful, and its traffic is rising continuously. Transport difficulties are aggravated by the ever increasing number of daily migrant workers who cross Geneva's borders.

**Cultural life.** Geneva has an ancient cultural tradition. A scholarly elite cultivated theology, philosophy, literature, and, especially since the 17th century, the exact and natural sciences. Geneva has been in the avant-garde of geology, botany, and mountaineering (both sporting and scientific). In 1872 the Academy was transformed into a university, which now has more than 8,000 students, nearly half of them foreigners. Its outstanding reputation in certain specialties (international studies, botany, the educational sciences) draws a large audience to the city. Geneva's cultural life is intense, revolving around its museums; the music conservatory and international musical performance competitions; the Orchestre de la Suisse Romande; the Théâtre; and the proceedings of international meetings held in the city.

**BIBLIOGRAPHY.** The collective volume, *Genève, Carrefour des Nations* (1963), provides a good introduction. *Genève, le Pays et les Hommes* (1958); PAUL GUICHONNET, *Genève: Réflexions sur un destin urbain* (1965); and CLAUDE RAFFESTIN, *Genève: Essai de géographie industrielle* (1968), covers the present-day geography and economy. Urban evolution is the subject of two significant books: LOUIS BLONDEL, *Le développement urbain de Genève à travers les siècles* (1946); and ANDRE CORBOZ, *Invention de Carouge* (1968). The historical literature is extraordinarily rich, particularly for political and religious facts and for the period previous to 1798. PAUL F. GEISENDORF, *Bibliographie raisonnée de l'histoire de Genève des origines à 1798* (1966), offers an appropriate orientation. Two general histories are P.E. MARTIN (ed.), *Histoire de Genève*, 2 vol. (1951-56); and FRANÇOIS RUCHON, *Histoire politique de la République de Genève . . .* (1953). ANTHONY BABEL, *Histoire économique de Genève, des origines au début du XVI<sup>e</sup> siècle* (1963); JEAN-FRANÇOIS BERGIER, *Genève et l'économie européenne de la Renaissance* (1963); and ANNE-MARIE PIUZ, *Affaires et politique: Recherches sur le commerce de Genève au XVII<sup>e</sup> siècle* (1964), cover economic history. See also WALDEMAR DEONNA, *Les Arts à Genève des origines à la fin du XVIII<sup>e</sup> siècle* (1942); and ALFRED BERTCHOLD, *La Suisse romande au cap du XX<sup>e</sup> siècle* (1963); *Histoire des sciences à Genève* (1955).

(P.G.)

## Genghis Khan

Genghis Khan (Chingis Khan), the son of a Mongolian chieftain, was a warrior and ruler of genius who, starting from obscure and insignificant beginnings, brought all the nomadic tribes of Mongolia under the rule of himself and his family in a rigidly disciplined military state. He then turned his attention toward the settled peoples beyond the borders of his nomadic realm and began the series of campaigns of plunder and conquest that eventually carried the Mongol armies as far as the Adriatic Sea in one direction and the Pacific coast of China in the other, leading to the establishment of the great Mongol Empire.

Taipei, Taiwan, Republic of China

Genghis Khan, ink and colour on silk by an unknown Chinese artist.

**Historical background.** With the exception of the saga-like *Secret History of the Mongols* (1240?), only non-Mongol sources provide near-contemporary information about the life of Genghis Khan. Almost all writers, even those who were in the Mongol service, have dwelt on the enormous destruction wrought by the Mongol invasions. One Arab historian openly expressed his horror at the recollection of them. Beyond the reach of the Mongols and relying on second-hand information, the 13th-century chronicler Matthew Paris called them a "detestable nation of Satan that poured out like devils from Tartarus so that they are rightly called Tartars." He was making a play on words with the classical word Tartarus (Hell) and the ancient tribal name of Tatar borne by some of the nomads, but his account catches the terror that the Mongols evoked. As the founder of the Mongol nation, the organizer of the Mongol armies, and the genius behind their campaigns, Genghis Khan must share the reputation of his people, even though his generals were frequently operating on their own, far from direct supervision. Nevertheless, it would be mistaken to see the Mongol campaigns as haphazard incursions by bands of marauding savages. Nor is it true, as some have supposed, that these campaigns were somehow brought about by a progressive desiccation of Inner Asia that compelled the nomads to look for new pastures. Nor, again, were the Mongol invasions a unique event. Genghis Khan was neither the first nor the last nomadic conqueror to burst out of the steppe and terrorize the settled periphery of Eurasia. His campaigns were merely larger in scale, more successful, and more lasting in effect than those of other leaders. They impinged more violently upon those sedentary peoples who had the habit of recording events in writing, and they affected a greater part of the Eurasian continent and a variety of different societies.

Two societies were in constant contact, two societies that were mutually hostile, if only because of their diametrically opposed ways of life, and yet these societies

Struggles  
between  
nomadic  
and  
sedentary  
societies

were interdependent. The nomads needed some of the staple products of the south and coveted its luxuries. These could be had by trade, by taxing transient caravans, or by armed raids. The settled peoples of China needed the products of the steppe to a lesser extent, but they could not ignore the presence of the nomadic barbarians and were forever preoccupied with resisting encroachment by one means or another. A strong dynasty, such as the 17th-century Manchu, could extend its military power directly over all Inner Asia. At other times the Chinese would have to play off one set of barbarians against another, transferring their support and juggling their alliances so as to prevent any one tribe from becoming too strong.

The cycle of dynastic strength and weakness in China was accompanied by another cycle, that of unity and fragmentation amongst the peoples of the steppe. At the peak of their power, a nomadic tribe under a determined leader could subjugate the other tribes to its will and, if the situation in China was one of weakness, might extend its power well beyond the steppe. In the end this extension of nomadic power over the incompatible, sedentary culture of the south brought its own nemesis. The nomads lost their traditional basis of superiority—that lightning mobility that required little in the way of supply and fodder—and were swallowed up by the Chinese they had conquered. The cycle would then be resumed; a powerful China would re-emerge, and disarray and petty squabbling among ephemeral chieftains would be the new pattern of life among the nomads. The history of the Mongol conquests illustrates this analysis perfectly, and it is against this background of political contrasts and tensions that the life of Genghis Khan must be evaluated. His campaigns were not an inexplicable natural or even God-given catastrophe but the outcome of a set of circumstances manipulated by a soldier of ambition, determination, and genius. He found his tribal world ready for unification, at a time when China and other settled states were, for one reason or another, simultaneously in decline, and he exploited the situation.

**Early struggles.** Various dates are given for the birth of Temüjin, as Genghis Khan was named—after a leader who was defeated by his father, Yesügei, when Temüjin was born. The chronology of Temüjin's early life is uncertain. He may have been born in 1155, in 1162 (the date favoured today in Mongolia), or in 1167. According to legend, his birth was auspicious, because he came into the world holding a clot of blood in his hand. He is also said to have been of divine origin, his first ancestor having been a gray wolf, "born with a destiny from heaven on high." Yet his early years were anything but promising. When he was nine, Yesügei, a member of the royal Borjigin clan of the Mongols, was poisoned by a band of Tatars, another nomadic people, in continuance of an old feud.

Cast out  
by his clan

With Yesügei dead, the remainder of the clan, led by the rival Taychiut family, abandoned his widow, Höelün, and her children, considering them too weak to exercise leadership and seizing the opportunity to usurp power. For a time the small family led a life of extreme poverty, eating roots and fish instead of the normal nomad diet of mutton and mare's milk. Two anecdotes illustrate both Temüjin's straitened circumstances and, more significantly, the power he already had of attracting supporters through sheer force of personality. Once he was captured by the Taychiut, who, rather than killing him, kept him around their camps, wearing a wooden collar. One night, when they were feasting, Temüjin, noticing that he was being ineptly guarded, knocked down the sentry with a blow from his wooden collar and fled. The Taychiut searched all night for him, and he was seen by one of their people, who, impressed by the fire in his eyes, did not denounce him but helped him escape at the risk of his own life. On another occasion horse thieves came and stole eight of the nine horses that the small family owned. Temüjin pursued them. On the way he stopped to ask a young stranger, called Bo'orchu, if he had seen the horses. Bo'orchu immediately left the milking he was engaged in, gave Temüjin a fresh horse, and set out

with him to help recover the lost beasts. He refused any reward but, recognizing Temüjin's authority, attached himself irrevocably to him as a *nökör*, or free companion, abandoning his own family.

Temüjin and his family apparently preserved a considerable fund of prestige as members of the royal Borjigin clan, in spite of their rejection by it. Among other things, he was able to claim the wife to whom Yesügei had betrothed him just before his death. But the Merkit people, a tribe living in north Mongolia, bore Temüjin a grudge, because Yesügei had stolen his own wife, Höelün, from one of their men, and in their turn they ravished Temüjin's wife Börte. Temüjin felt able to appeal to Toghrii, Khan of the Kereit tribe, with whom Yesügei had had the relationship of *anda*, or sworn brother, and at that time the most powerful Mongol prince, for help in recovering Börte. He had had the foresight to rekindle this friendship by presenting Toghrii with a sable skin, which he himself had received as a bridal gift. He seems to have had nothing else to offer; yet, in exchange, Toghrii promised to reunite Temüjin's scattered people, and he is said to have redeemed his promise by furnishing 20,000 men and persuading Jamuka, a boyhood friend of Temüjin's, to supply an army as well. The contrast between Temüjin's destitution and the huge army furnished by his allies is hard to explain, and no authority other than the narrative of the *Secret History* is available.

**Rise to power.** With powerful allies and a force of his own, Temüjin routed the Merkit, with the help of a strategy by which Temüjin was regularly to scotch the seeds of future rebellion. He tried never to leave an enemy in his rear; years later, before attacking China, he would first make sure that no nomad leader survived to stab him in the back. Not long after the destruction of the Merkit, he treated the nobility of the Jürkin clan in the same way. These princes, supposedly his allies, had profited by his absence on a raid against the Tatars to plunder his property. Temüjin exterminated the clan nobility and took the common people as his own soldiery and servants. When his power had grown sufficiently for him to risk a final showdown with the formidable Tatars, he first defeated them in battle and then slaughtered all those taller than the height of a cart axle. Presumably the children could be expected to grow up ignorant of their past identity and to become loyal followers of the Mongols. When the alliance with Toghrii of the Kereit at last broke down and Temüjin had to dispose of this obstacle to supreme power, he dispersed the Kereit people among the Mongols as servants and troops. This ruthlessness was not mere wanton cruelty. Temüjin intended to leave alive none of the old, rival aristocrats, who might prove a focus of resistance; to provide himself with a fighting force; and, above all, to crush the sense of clan loyalties that favoured fragmentation and to unite all the nomads in personal obedience to his family. And when, in 1206, he was accepted as emperor of all the steppe people, he was to distribute thousands of families to the custody of his own relatives and companions, replacing the existing pattern of tribes and clans by something closer to a feudal structure.

Destruction  
of the  
Merkit

At least from the time of the defeat of the Merkits, Temüjin was aiming at supremacy in the steppes for himself. The renewed friendship with Jamuka lasted only a year and a half. Then, one day while the two friends were on the march, Jamuka uttered an enigmatic remark about the choice of camping site, which provoked Temüjin's wife Börte to advise him that it was high time for the two friends to go their separate ways. What lies behind this episode is difficult to see. The story in the *Secret History* is too puzzling in its brevity and its allusive language to permit a reliable explanation. It has been suggested that Jamuka was trying to provoke a crisis in the leadership. Equally, it may be that the language is deliberately obscure to gloss over the fact that Temüjin was about to desert his comrade. In any event, Temüjin took Börte's advice. Many of Jamuka's own men also abandoned him, probably seeing in Temüjin the man they thought more likely to win in the end. The *Secret History*

justifies their action in epic terms. One of the men tells Temüjin of a vision that had appeared to him and that could only be interpreted as meaning that Heaven and Earth had agreed that Temüjin should be lord of the empire. Looking at the situation in a more down-to-earth way, the interplay of the vacillating loyalties of the steppe may be discerned. The clansmen knew what was afoot, and some of them hastened to move over to Temüjin's side, realizing that a strong leader was in the offing and that it would be prudent to declare for him early on.

The break with Jamuka brought about a polarization within the Mongol world that was to be resolved only with the disappearance of one or the other of the rivals. Jamuka has no advocate in history. The *Secret History* has much to tell about him, not always unsympathetically, but it is essentially the chronicle of Temüjin's family; and Jamuka appears as the enemy, albeit sometimes a reluctant one. He is an enigma, a man of sufficient force of personality to lead a rival coalition of princes and to get himself elected *gur-khān*, or supreme Khan, by them. Yet he was an intriguer, a man to take the short view, ready to desert his friends, even turn on them, for the sake of a quick profit. But for Temüjin, it might have been within Jamuka's power to dominate the Mongols, but Temüjin was incomparably the greater man; and the rivalry broke Jamuka.

Gathering  
of the  
clans  
around  
Temüjin  
and  
Jamuka

Clan leaders began to group themselves around Temüjin and Jamuka, and, a few years before the turn of the century, some of them proposed to make Temüjin Khan of the Mongols. The terms in which they did so, promising him loyalty in war and the hunt, suggest that all they were looking for was a reliable general, certainly not the overlord he was to become. Indeed, later on, some of them were to desert him. Even at this time, Temüjin was only a minor chieftain, as is shown by the next important event narrated by the *Secret History*, a brawl at a feast, provoked by his nominal allies the Jürkin princes, whom he later massacred. The Chin emperor in north China, too, looked on him as of no great consequence. In one of the reversals of policy characteristic of their manipulation of the nomads, the Chin attacked their onetime allies the Tatars. Together with Toghril, Temüjin seized the opportunity of continuing the clan feud and took the Tatars in the rear. The Chin emperor rewarded Toghril with the Chinese title of *wang*, or prince, and gave Temüjin an even less exalted one. And, indeed, for the next few years the Chin had nothing to fear from Temüjin. He was fully occupied in building up his power in the steppe and posed no obvious threat to China.

Temüjin now set about systematically eliminating all rivals. Successive coalitions formed by Jamuka were defeated. The Tatars were exterminated. Toghril allowed himself to be manoeuvred by Jamuka's intrigues and by his own son's ambitions and suspicions into outright war against Temüjin, and he and his Kereit people were destroyed. Finally, in the west, the Naiman ruler, fearful of the rising power of the Mongols, tried to form yet another coalition, with the participation of Jamuka, but was utterly defeated and lost his kingdom. Jamuka, inconstant as ever, deserted the Naiman Khan at the last moment. These campaigns took place in the few years before 1206 and left Temüjin master of the steppes. In that year a great assembly was held by the River Onon, and Temüjin was proclaimed Genghis Khan: the title probably meant Universal Ruler.

**Unification of the Mongol nation.** The year 1206 is a turning point in the history of the Mongols and in world history: the moment when the Mongols were first ready to move out beyond the steppe. Mongolia itself took on a new shape. The petty tribal quarrels and raids were a thing of the past. Either the familiar tribe and clan names have fallen out of use or those bearing them are to be found, subsequently, scattered all over the Mongol world, testifying to the wreck of the traditional clan and tribe system. A unified Mongol nation came into existence as the personal creation of Genghis Khan and, through many vicissitudes (feudal disintegration, incipient retribalization, colonial occupation), survives to the present day. Mongol ambitions looked beyond the steppe.

Genghis Khan was ready to start on his great adventure of world conquest. The new nation was organized, above all, for war. Genghis Khan's troops were divided up on the decimal system, were rigidly disciplined, and were well equipped and supplied. The generals were his own sons or picked men, absolutely loyal to him.

Beginning  
of the  
conquest  
of Asia

Genghis Khan's military genius could adapt itself to rapidly changing circumstances. Initially his troops were exclusively cavalry, riding the hardy, grass-fed Mongol pony that needs no fodder. With such an army, other nomads can be defeated, but cities cannot be taken. Yet before long the Mongols were able to undertake the siege of large cities, using mangonels, catapults, ladders, burning oil, and so forth and even diverting rivers. It was only gradually, through contact with men from the more civilized states, that Genghis Khan came to realize that there were more sophisticated ways of enjoying power than simply raiding, destroying, and plundering. It was a minister of the Khan of the Naiman, the last important Mongol tribe to resist Genghis Khan, who taught him the uses of literacy and helped reduce the Mongol language to writing. The *Secret History* reports it was only after the war against the Muslim empire of Khwārezm, in the region of the Amu Darya (Oxus) and Syr Darya (Jaxartes), probably in late 1222, that Genghis Khan learned from Muslim advisers the "meaning and importance of towns." And it was another adviser, formerly in the service of the Chin emperor, who explained to him the uses of peasants and craftsmen as producers of taxable goods. He had intended to turn the cultivated fields of north China into grazing land for his horses.

The great conquests of the Mongols, which would transform them into a world power, were still to come. China was the main goal. Genghis Khan first secured his western flank by a tough campaign against the Tangut kingdom of Hsi Hsia, a northwestern border state of China, and then fell upon the Chin empire of north China in 1211. In 1214 he allowed himself to be bought off, temporarily, with a huge amount of booty, but in 1215 operations were resumed, and Peking was taken. Subsequently, the more systematic subjugation of north China was in the hands of his general Muqali. Genghis Khan himself was compelled to turn aside from China and carry out the conquest of Khwārezm. This war was provoked by the governor of the city of Otrar, who massacred a caravan of Muslim merchants who were under Genghis Khan's protection. The Khwārezmian shah refused satisfaction. War with Khwārezm would doubtless have come sooner or later, but now it could not be deferred. It was in this war that the Mongols earned their reputation for savagery and terror. City after city was stormed, the inhabitants massacred or forced to serve as advance troops for the Mongols against their own people. Fields and gardens were laid waste and irrigation works destroyed as Genghis Khan pursued his implacable vengeance against the royal house of Khwārezm. He finally withdrew in 1223 and did not lead his armies into war again until the final campaign against Hsi Hsia in 1226–27. He died on August 18, 1227.

Subjuga-  
tion of  
China

**Assessment.** As far as can be judged from the disparate sources, Genghis Khan's personality was a complex one. He had great physical strength, tenacity of purpose, and an unbreakable will. He was not obstinate and would listen to advice from others, including his wives and mother. He was flexible. He could deceive but was not petty. He had a sense of the value of loyalty, unlike Toghril or Jamuka. Enemies guilty of treachery toward their lords could expect short shrift from him, but he would exploit their treachery at the same time. He was religiously minded, carried along by his sense of a divine mission, and in moments of crisis he would reverently worship the Eternal Blue Heaven, the supreme deity of the Mongols. So much is true of his early life. The picture becomes less harmonious as he moves out of his familiar sphere and comes into contact with the strange, settled world beyond the steppe. At first he could not see beyond the immediate gains to be got from massacre and rapine and, at times, was consumed by a passion for revenge. Yet all his life he could attract the

loyalties of men willing to serve him, both fellow nomads and civilized men from the settled world. His fame could even persuade the aged Taoist sage Ch'ang-ch'un to journey the length of Asia to discourse upon religious matters. He was above all adaptable, a man who could learn.

Organization, discipline, mobility, and ruthlessness of purpose were the fundamental factors in his military successes. Massacres of defeated populations, with the resultant terror, were weapons he regularly used. His practice of summoning cities to surrender, and organizing the methodical slaughter of those who did not submit, has been described as psychological warfare, but his methods were crude compared with those of the 20th century; and although it was undoubtedly policy to sap resistance by fostering terror, massacre was employed for its own sake. The standard Mongol practice, especially in the war against Khwārezm, was to send agents to demoralize and divide the garrison and populace of an enemy city, mixing threats with promises. The Mongols' reputation for frightfulness often paralyzed their captives, who allowed themselves to be killed in circumstances where resistance or flight was not impossible. With fortified cities, psychological pressure was not decisive, though it saved some troublesome sieges. Many cities resisted, some for as long as six months, relying on their strength or perhaps not believing the Mongol propaganda. Indeed, the Mongols were unaccountable. Resistance brought certain destruction, but at Balkh, now in Afghanistan, the population was slaughtered in spite of a prompt surrender, for tactical reasons.

His achievements were grandiose. He united all the nomadic tribes, and with numerically inferior armies he defeated great empires, such as Khwārezm and the even more powerful Chin state. Yet he did not exhaust his people. He chose his successor, his son Ögödei, with great care, ensured that his other sons would obey him, and passed on to him an army and a state in full vigour. At the time of his death, Genghis Khan had conquered the land mass from Peking to the Caspian Sea, and his generals had raided Persia and Russia. His successors would extend their power over the whole of China, Persia, and most of Russia. They did what he did not achieve and perhaps never really intended—that is, to weld their conquests into a tightly organized empire. The destruction brought about by Genghis Khan survives in popular memory, but far more significant, these conquests were but the first stage of the Mongol Empire, greatest continental empire of medieval and modern times.

**BIBLIOGRAPHY.** For general reading, LEONARDO OLSCHKI, *L'Asia di Marco Polo* (1957; Eng. trans., *Marco Polo's Asia*, 1960), is recommended. The relevant pages from RENE GROUSSET, *L'Empire des steppes: Attila, Gengis-Khan, Tamerlan* (1939; Eng. trans., *The Empire of the Steppes: A History of Central Asia*, 1970), is still the best concise account of the subject, and the whole book may be read with

profit. The most accessible, and perhaps the best, biography also by Grousset: *Le Conquérant du monde, Gengis-Khan* (1944; Eng. trans., *Conqueror of the World*, 1966), contains a critical bibliography. Other serious biographies are: B. VLADIMIRTSOV, *The Life of Chingis-Khan* (1930; orig. pub. in Russian, 1922); RALPH W. FOX, *Genghis Khan* (1936); and H. DESMOND MARTIN, *The Rise of Chingis Khan and His Conquest of North China* (1950.)

## Genoa

Genoa (Genova), an important port city, is the capital of Genoa (Genova) Province (*provincia*), in the Liguria Region (*regione*) of northwestern Italy; it stands at the head of a large gulf, close to the Lombard Plain and the Alpine passes leading north.

**Origins and early history (to the 10th century).** In ancient times, Genoa was first the site of a Ligurian fort, and in the 5th and 4th centuries BC its fine natural harbour made it a commercial emporium with Etruscan, Phoenician, and Greek contacts. From the 3rd century BC it was a major Roman station on the coastal route to Provence; another road led into Lombardy. The barbarians who overran Italy when the Roman Empire dissolved were defeated by the Byzantine general Belisarius in the mid-6th century AD, and Genoa remained under Byzantine rule until its conquest in about 643 by the Lombards, who destroyed its walls and allowed its trade to decay. Yet even in the 10th century, when Genoa was repeatedly sacked by the Saracens, a bare minimum of urban life and overseas trade still survived.

**The city in the 10th–19th centuries.** These Muslim raids provoked the local nobles to lead Genoa's fishermen and farmers, often in alliance with Pisa, in retaliatory attacks against the Muslims in Corsica, Sardinia, Sicily, and the Balearics. From the 11th century onward, the spoils were invested in new ventures in Naples, and Amalfi, in Sicily, Spain, and North Africa. After 1097 participation in the Crusades brought the Genoese profitable opportunities to hire out shipping and lend money, and Genoa secured trading quarters and privileges in Syrian and Byzantine ports. The Genoese extended their dominion eastward and westward along the coast, developed business activities inland, and supplemented meagre local produce by importing foodstuffs and raw materials; they became experts and innovators in shipbuilding, navigation, and cartography, in industrial and banking techniques, and in types of contracts that enabled even poor men to form partnerships and invest capital in lucrative overseas trade.

**The commune of Genoa.** The gradual evolution of the commune of Genoa, whose autonomy received recognition from the Holy Roman Emperor in 1162, provided a form of government that alleviated social tension and assisted the landed nobility and the flourishing bourgeoisie to collaborate in foreign enterprises. Perpetual

Genoese  
expansion

strife among the magnates, however, led in 1191 to the appointment of a foreign podesta (chief magistrate). Despite further innovations, such as a local *capitano del popolo* ("captain of the people") in 1257, internal dissensions continued to encourage foreign intervention. In 1339 the Genoese Simone Boccanegra became the first of a series of local rulers, called "doges," who were chosen for life but could seldom diminish faction and disorder.

**Trade rivalries.** Genoa's remarkable expansion involved constant struggles with trade rivals. In 1204 the Venetians manipulated the Fourth Crusade to secure predominance in Byzantium; but the Genoese reversed the position by assisting the exiled emperor Michael Palaeologus to recapture Constantinople in 1261. In 1284 Genoa's fleet destroyed Pisan sea power at the Battle of Meloria. Corsica and Sardinia were long-established spheres of influence and colonization, but Genoese merchants were able to penetrate to distant India and England; to set up colonies in the Crimea, at Phocaea with its alum monopoly, and on Chios with its mastic; to bring back slaves and gold from North Africa; and to establish commercial communities in Cyprus and Castile.

Genoa became one of Europe's largest cities; by 1300 its population possibly approached 100,000. It had strong walls, grand patrician palaces, and churches built in black and white marble stripes. Luxurious living standards were based, in part, on imported domestic slaves.

In the 14th century, European colonial rivalries were heightened by a general economic recession and, from 1348, onward, by the disastrous visitations of the Black Death (plague). A series of bitter wars against the Aragonese, who secured control of Sardinia, and against the Venetians came to a climax in 1380, when the Genoese narrowly failed to capture Venice itself.

Genoa was as successful overseas as Venice even though the Genoese lacked the disciplined constitution and public spirit that enabled Venice to run a rigidly state-controlled colonial empire, and despite Genoa's weakness in the face of public bankruptcy and private individualism. From 1396, however, internal disorder resulted in repeated submission to foreign rule by the French and by Milan. The amalgamation in 1405 of many government creditors to form the independent Banco di San Giorgio saved the Genoese government by taking over the disastrous national debt; but the bank secured so many privileges that it came to rival the state itself. After 1453 the Genoese lost all their Black Sea and Levantine colonies except Chios to the Turks, yet they found the resilience to diversify their activities and shift them westward, discovering new commodities and markets. Genoese entrepreneurs intensified their initiatives in Aragon, Castile, and Portugal and participated in new ventures along the African coast and in the Atlantic isles. Christopher Columbus, the discoverer of America in 1492, was a Genoese.

**Alliance with Spain.** In 1528, in the midst of a great European struggle for supremacy, the famous Genoese admiral Andrea Doria shifted his service from France to the Holy Roman Emperor Charles V (Charles I of Spain); Genoa escaped French domination through a Spanish alliance that allowed Genoese financiers, the great specialists in exchange operations, to handle huge sums for the Spanish crown. The Genoese controlled Spanish and Neapolitan trade, and Peruvian silver poured into their banks; by about 1570 they were the principal bankers of Catholic Europe. Also in 1528 Andrea Doria introduced a new constitution giving power to the magnates, with doges elected for two-year periods. This regime provided an era of more stable though increasingly oligarchic government.

**Loss of independence.** Real decadence came as Genoa was increasingly excluded from the prosperous Northern and Atlantic economy. Its fortunes were dictated by the great European succession wars. The city was ruinously bombarded by the French in 1684; was occupied in 1746 by the Austrians, against whom there was a popular uprising; and lost its last Mediterranean colony, Corsica, to France in 1768. In 1796 Napoleonic troops occupied Genoa, which sustained a terrible Austrian siege

in 1800. The Genoese expelled the French in 1814, but the next year's peace treaty gave Genoa to Piedmont. The resulting discontent, both republican and anti-Piedmontese, shaped Genoa-born Giuseppe Mazzini, the great prophet of the Italian Risorgimento. In 1860 Giuseppe Garibaldi sailed for Sicily from Genoa with his army of liberation.

**Genoa since 1860.** Genoa became the major port of the new unified Italy, rivalling Marseilles in France. Railway building, industrial development, and shipbuilding yards all inserted Genoa into the great industrial complex of northern Italy, while the Simplon and other Alpine tunnels greatly enlarged its hinterland. The city's population rose from 130,000 in 1871 to about 800,000 in the 1960s. Genoa has an important university and the other attributes of a great modern city. Its revolutionary traditions erupted in a successful insurrection against the Germans in April 1945. The heavy damage sustained during World War II was repaired, and Genoa has remained one of Italy's greatest towns.

**BIBLIOGRAPHY.** There is no good modern general history of Genoa, since N. LAMBOGLIA *et al.*, *Storia di Genova*, 3 vol. (1941-42), reached only to c. 1200. V. VITALE, *Breviario della storia di Genova*, 2 vol. (1955-56), provides an indispensable outline and a guide to the voluminous specialist literature for the period to 1815; for the subsequent period, see his "Genova," in *Enciclopedia Italiana*, vol. 16 (1932). Many useful articles and monographs appear in the *Atti della Società ligure di storia patria*, vol. 1 (1861- ). See also R.S. LOPEZ, "Market Expansion: The Case of Genoa," *Journal of Economic History*, 24:445-464 (1964); E. BACH, *La cité de Gênes au XII<sup>e</sup> siècle* (1955); and J. HEERS, *Gênes au XV<sup>e</sup> siècle: activité économique et problèmes sociaux* (1961).

(A.T.L.)

## Gentianales

Gentianales is an order of flowering plants that includes more than 12,000 species in five large families and less than 150 species in six smaller ones. Although widely distributed, representatives of the order are most abundant in tropical and subtropical areas. The gentian family (Gentianaceae) is exceptional, however, in having its greatest development in the north Temperate Zone.

**Economic importance.** Plants noted for their economic importance are found in several families of the order. Species are important sources of food, particularly beverages; others furnish drugs, rubber, and fibres. Many plants, because of their showy flowers or peculiar structure, have gained importance as cultivated garden plants. Some are well-known because of the poisonous qualities of their seeds or vegetative portions.

**Food.** Coffee is the most widely used product obtained from any representative of the order Gentianales. The genus *Coffea* is a member of the family Rubiaceae, and the number of species considered in the genus varies with the interpretation given the group. One recent study places the species number at about 100; of these, only four are of commercial value. The most important species is *Coffea arabica*. Although the scientific name indicates the Arabian Peninsula as the source of coffee, some botanists now look to Ethiopia as its original home. Introduced into the Americas on the island of Martinique and French Guiana in the early part of the 18th century, it then spread to Brazil and, before the end of the century, was distributed throughout Latin America.

**Drugs.** Bark from trees of *Cinchona*, also of the family Rubiaceae, yield the drug quinine, which once was used throughout the world to treat malaria. The trees are native in the Andes of South America, and, although more than 40 species are known, only four are of commercial value as sources of quinine. A dwindling supply of bark, resulting from the destruction of *Cinchona* forests, led to cultivation of the species in India, Java, and Ceylon in the mid-19th century. The production of synthetic substitutes for quinine now has relieved much of the need for *Cinchona*.

*Rauwolfia serpentina*, a native of India in the family Apocynaceae and long used as a minor drug plant, came into prominence when it was shown to be effective in reducing high blood pressure. When demand for the roots

Foreign  
influence

Coffee  
species

became so great that depletion of the wild plants was threatened, the government of India placed an embargo on the exportation of the roots. Research has led to the isolation of the active ingredient, an alkaloid called reserpine. An intensive survey of *Rauwolfia* species, prompted by the Indian embargo, demonstrated that reserpine is available in many of the 86 species of the genus, especially *Rauwolfia vomitoria* from tropical Africa and *Rauwolfia tetraphylla* from Central and South America.

**Rubber.** Rubber is one constituent of the milky juice, or latex, that is found in the well-developed system of tubes common in many species of the families Apocynaceae and Asclepiadaceae. A total of 74 genera and 258 species in the Apocynaceae and 24 genera and 90 species in the Asclepiadaceae contain measurable amounts of rubber. None approaches the importance of *Hevea*, a genus in the family Euphorbiaceae (order Euphorbiales, q.v.), although *Funtumia elastica* in the Apocynaceae is extensively planted for its latex throughout tropical Africa, where the climate is too dry for the successful cultivation of *Hevea*. The 20 years of growth necessary before commercial yields of latex are available, however, is an economic disadvantage of *Funtumia*. Species of many other genera in the Apocynaceae, such as *Mascarenhasia elastica*, *Landolphia owariensis*, and *Clitandra elastica* in Africa; *Hancornia speciosa* in Brazil; and *Plumeria rubra* in Mexico, have been exploited for rubber without cultivation.

In the family Asclepiadaceae, *Cryptostegia grandiflora*, originally from Africa, has been distributed to the warmer parts of the world for its rubber content. Extensive investigations of its cultivation and potential as a commercial source of rubber have been made, but difficulties encountered in collecting the latex have thus far retarded its commercial expansion.

**Fibres.** The fibres from plants of the milkweed genus *Asclepias* of the family Asclepiadaceae were known and utilized by the American Indians prior to the settlement of North America. The milkweeds were introduced as ornamental plants into Europe, where the fibres were rediscovered and used in Germany. No extensive exploitation of *Asclepias* fibres was made, however, because they lack the strength of other materials, such as flax and hemp.

The floss fibres on milkweed seeds have been found to contain properties comparable to kapok, the material obtained from seeds of the genus *Ceiba* in the family Bombacaceae (order Malvales, q.v.). The *Asclepias* floss has good insulating qualities; surface waxes and oils provide the floss with a buoyancy that could make it commercially valuable.

**Ornamentals.** Several members of the order Gentianales are prized as ornamentals or curiosities. Species of the genus *Gentiana* (family Gentianaceae) are frequently cultivated and highly recommended as rock garden or wildflower garden plants. The carrion flowers, species of the genus *Stapelia* in the family Asclepiadaceae, have peculiar angular and fleshy or succulent stems and are common representatives in gardens of succulents. Among the herbaceous members of the order Gentianales in cultivation are the species of *Vinca*, or the periwinkles (family Apocynaceae) and the butterfly weed (*Asclepias*) of the family Asclepiadaceae. The shrubs include the yellow Carolina jessimine (*Gelsemium*) and the butterfly bush (*Buddleja*) of the family Loganiaceae. The oleander (*Nerium*) is commonly grown in the hot, dry desert regions, along with the tropical yellow oleander (*Thevetia*); both are in the family Apocynaceae. *Bouvardia* and *Gardenia*, shrubby members of the family Rubiaceae, are cultivated in warm climates. *Allamanda* (Apocynaceae) is a tropical vine grown for its large yellow flowers. *Cryptostegia* is grown for its large, showy, lilac-coloured flowers, in addition to its value as a source of rubber.

**Poisons.** Poisonous chemicals are common in the family Loganiaceae. The bark of any of 12 species of *Strychnos* serves as the main or secondary ingredient used in the preparation of the arrow poison, curare. The

poisonous alkaloids strychnine and brucine are obtained from the Indian species *Strychnos nux-vomica*. The alkaloids of the Saint-Ignatius'-bean of the Philippines (*Strychnos ignatii*) are valued as a remedy for cholera.

The family Apocynaceae is also noted for the poisonous qualities of many of its members. *Nerium oleander*, the oleander commonly planted as an ornamental in arid regions, is highly toxic in the fresh or dry state; poisoning results from eating parts of the plant. Several toxic chemicals have been isolated from the oleander; the glucoside (a sugar-containing substance) oleandrin is the main constituent. Likewise, *Thevetia peruviana*, the yellow oleander, is toxic if ingested, and thevetin is one of many glycosides that has been isolated as an active ingredient.

**Structural diversity.** Trees and shrubs predominate in the families Rubiaceae, Loganiaceae, and Apocynaceae. Herbs are the common growth form in the Gentianaceae and Menyanthaceae, and both shrubs and herbs are found in the Asclepiadaceae.

The genera *Voyria*, *Leiphaimos*, *Bartonia*, and *Obolaria* of the Gentianaceae are saprophytes, plants that do not produce their own food by photosynthesis but absorb it from dead organic matter. The genus *Dischidia* of the Asclepiadaceae is an epiphyte—a plant that lives upon the branches of trees not as parasites but only for support. To insure a source of water *Dischidia rafflesiana* has developed fleshy leaves modified into pitchers that hold rainwater and debris carried there by ants. Within these pitchers a root system develops to utilize the accumulated water.

Epiphytes also occur in the peculiar genus *Myrmecodia* of the Rubiaceae. The swollen stem of this Malaysian genus is penetrated by numerous irregular galleries that house ants. The adaptive value of this ant-to-plant relationship is not yet understood.

A similar symbiotic plant and ant relationship is found in the genera *Nauclea* and *Duroia* of the Rubiaceae. Swollen hollow internodes (stem segments) inhabited by ants occur just below the flowers in species of these genera. The position suggests that the ants protect the flowers from unwanted visitors. Species of *Duroia* and *Remijia* have flask-shaped swellings on the leaf bases that are regularly inhabited by ants.

Vines are found in the families Loganiaceae, Apocynaceae, Asclepiadaceae, and Rubiaceae. Some of the American species of *Strychnos* are vines that may attain lengths of 160 feet (50 metres) or more; the common term bushrope is applied to them. In the Apocynaceae the vines, or lianas, may be supported by the twining stem, but in the genera *Landolphia* and *Clitandra* the flower stalks become tendril-like. Both herbaceous and woody vines are common in the family Asclepiadaceae. The frequently cultivated indoor or greenhouse wax plant, *Hoya carnosa*, and *Cryptostegia grandiflora* are climbing representatives of the milkweed family.

Although the family Rubiaceae is composed for the most part of trees and shrubs, the climbing habit is represented by both herbaceous and woody twiners in the genus *Manettia*. In the same family, members of the genus *Uncaria* climb by means of branches that are converted into hooks.

The only truly aquatic representatives of the order are found in the family Menyanthaceae. *Limnanthemum* is a floating aquatic plant; *Menyanthes*, the bogbean, is a marsh plant.

**Natural history.** Some representatives of the family Gentianaceae depend for normal development on the presence of mycorrhizal fungi—i.e., fungi that live in the roots of the plant (the host) and enter the cells to obtain nutrients by absorbing cell sap. At the same time the fungi provide some nutritive advantage for the host, which digests portions of the fungus.

Methods of pollination in most members of the order are not unusual except for the milkweed family, Asclepiadaceae, in which pollination is complex and unique. In most members of this family the pollen grains are clustered into globules, or sacs, called pollinia. Each stamen (male sexual structure) produces two pollinia, and the

Symbiotic relationships between ants and plants

Milkweed floss

Vegetative and floral features of three of the largest families in the order Gentianales.

Drawing by M. Pahl

pollinia in adjacent anthers (pollen sacs) are connected by a structure called a translator. The translator consists of two arms and an enlarged knob, or corpusculum. The length and form of the arms vary widely and are useful in distinguishing genera.

An insect visiting the flower catches its legs in the slit between the adjacent anthers and contacts the corpusculum. As the insect leaves the flower the sticky corpusculum, arms, and pollinia adhere to the leg and are withdrawn with it, to be deposited upon the more adhesive receptive stigmatic surface (pollen-receiving region of the female structure) of the next flower.

In some members of the family Asclepiadaceae, pollination is similar to that just described, but the pollen is in clusters of four grains, or tetrads, instead of pollinia and is carried from one flower to another in open cornucopia-shaped structures.

Several genera in the Asclepiadaceae that are adapted to desert conditions have developed a fleshy or succulent form. The genus *Stapelia* from Africa and several related genera have fleshy green stems and leaves reduced to scales.

**Classification.** *Distinguishing taxonomic features.* With few exceptions, the families of this order form a natural group. All except the family Menyanthaceae possess simple, opposite leaves. Most species have the four or five petals of each flower united to form a gamopetalous, or fused tubular, corolla. The presence of phloem, the food-conducting cells, toward the centre of the stem (intraxylary phloem), in addition to its usual position external to the xylem, or water-conducting cells, is characteristic of all the families except the Rubiaceae, Menyanthaceae, and Dialypetalanthaceae. The ovary is superior—located above the sepals, petals, and stamens—in most families; although representatives with inferior or half-inferior ovaries can be found. In the large family Rubiaceae the

ovary is normally inferior, but a few species have superior or half-inferior ovaries. The ovules have a single integument, or covering cell layer, and a single-layered nucellus, the central region of the ovule.

The five major families in the order Gentianales—Loganiaceae, Apocynaceae, Asclepiadaceae, Gentianaceae, and Rubiaceae—form a unit through the presence of opposite leaves, radially symmetrical corollas, ovaries composed of two carpels, or ovule-bearing segments, and the single integument and one-layered nucellus of the ovules. The six smaller families are mostly composed of genera that were formerly contained in the larger families; thus, for the most part, they have the same major characteristics as the large families.

Within the order the inferior position of the ovary, associated with the absence of internal phloem, is important in distinguishing the families Rubiaceae and Dialypetalanthaceae. The unusual stamen–pistil structure associated with the complex pollination mechanism separates the family Asclepiadaceae from the other families. The two separate ovaries united by a common style and stigma delimits the family Apocynaceae. The presence of a latex system points to the close association of Asclepiadaceae and Apocynaceae and separates these two families from the Gentianaceae and the Loganiaceae. The members of the Gentianaceae are primarily herbaceous, and the ovaries have parietal placentation; *i.e.*, the ovules are attached to the ovary walls. These two characters help to distinguish the Gentianaceae from the predominantly woody Loganiaceae, in which the placentation is axile—the ovules attach along the central axis of the ovary.

**Annotated classification.** The position of the ovary has long been considered a fundamental character suitable for placing plant families into orders. Although various authorities have discussed the affinities of the family Rubiaceae to other members of the Gentianales, the classification presented here upsets a tradition of long standing because it combines the orders Rubiales and Gentianales of most systems into the one order, Gentianales.

Three small families whose affinities are not clear also are included in the order. The Desfontainiaceae shows some relationship to the Loganiaceae, but the connection is not yet well-known enough to place the family definitely. The Menyanthaceae, long considered a part of the Gentianaceae, seems misplaced in this order. The compound leaves with alternate arrangement and absence of an internal phloem tend to set this family apart from the order Gentianales. The Dialypetalanthaceae, with its free petals, absence of internal phloem, numerous stamens, and inferior ovary, is also questionably placed in the Gentianales; further study of its single species may reveal a closer relationship to another order.

#### ORDER GENTIANALES

Trees, shrubs, and herbs with simple opposite leaves, except in the family Menyanthaceae. Phloem (food-conducting tissues) intraxylary—positioned toward the centre of the stem—except in the Menyanthaceae and Rubiaceae. Flowers perfect and hypogynous (with a superior ovary) except in the Rubiaceae. Corolla (collection of petals) of fused petals with 4 or 5 radially symmetrical lobes. Pistil (female structure) of 2 carpels (ovule-bearing components or segments of the pistil) with placentation—ovule attachment—to the ovary walls (parietal) or along the central axis of the ovary (axile); ovules usually numerous with 1 integument (covering) and a 1-layered nucellus (interior). Eleven families with more than 12,000 species distributed mainly in the tropics and subtropics of the world.

##### Family Loganiaceae

Predominantly woody plants, including lianas. Stipules (leaf-like appendages at the base of leafstalks) present but variously developed. Flowers in terminal cymes (clusters that mature from the top downward). Corolla tubular, with 4 or 5 imbricated (overlapping) lobes. Ovary superior or half inferior in *Mitreola*; 2-celled with axile placentation and numerous anatropous (inverted and straight) ovules. Seeds wingless or winged, fruit a capsule. Twenty-one genera and about 500 species, distributed mostly in the tropics.

##### Family Antoniaceae

With the characters of Loganiaceae except with numerous overlapping scales subtending the calyx (collection of sepals);

Recognition of families

corolla lobes valvate (not overlapping but touching edge to edge); seeds winged at each end or all around. Four genera and 8 species distributed in Malay Peninsula, tropical America, and tropical Africa.

#### Family Potialiaceae

With the characters of Loganiaceae except corolla contorted, of 5 to 16 lobes; fruit, a berry. Three genera and 65 species with tropical distribution.

#### Family Desfontainiaceae

With the characters of Loganiaceae except leaves spinose; flowers solitary or few and located terminally on stems; pistil 5-carpelled, 5-loculed (chambered). One genus and 5 species distributed in tropical South America.

#### Family Apocynaceae (dogbane family)

Trees, shrubs, and herbs, usually with a well-developed latex (milky-juice) system. Stipules absent. Inflorescence many-flowered, rarely of solitary flowers. Calyx lobes parted nearly to the base. Corolla salverform (trumpet-shaped) or funnel-form, the lobes contorted in the bud. Corona (a raised structure) or appendages of hairs or scales commonly found in the corolla throat or tube. Stamens attached to the petals (epipetalous) with anthers that open toward the central axis of the flower (introrse) on short filaments. Pistil of 2 carpels with free (not fused) ovaries united by a common style (the narrow upper part of the pistil) and a club-shaped stigma (pollen-receiving surface). Fruit commonly follicular (a pod that splits open) with one or both carpels maturing; rarely berrylike. Seeds numerous, comose (bearing a tuft of soft hairs) or winged. Nectar-producing glands common at base of ovary. There are 155 genera and 1,000 species distributed mainly in tropical and subtropical regions.

#### Family Plocospermataceae

Similar to Apocynaceae but pistil 1-loculed with 2 parietal placentae; style twice-bifid (bisected or parted into 2 branches) with 4 small clavate (club-shaped) stigmas; 2 ovules in each carpel. One genus with 3 species distributed in Mexico and Central America.

#### Family Asclepiadaceae (milkweed family)

Herbs or commonly herbaceous or shrubby climbers, rarely shrubs or trees; with well-developed latex system. Sepals 5 and deeply divided. Petals 5, united; lobes contorted or less commonly valvate. Stamens 5, epipetalous; filaments short and occasionally, along with corolla, bearing appendages and elaborated into complex structures. Corona single or double. Pistil 2-carpelled, with the 2 superior ovaries and styles free and the 2 stigmas united into an enlarged and flattened, conical or beaked stigmatic head. Cohering with the stigmatic head are the 5 anthers, which reduce the pollen-receiving portion of the stigma to 5 lines between the anthers. Fruit follicular with occasionally only 1 of the 2 carpels maturing. Seeds commonly comose. There are 280 genera and 2,000 species distributed mainly in the tropics.

#### Family Gentianaceae (gentian family)

Annual or perennial herbs, rarely shrubs, with opposite leaves that lack stipules. Sepals 4 or 5, variously divided. Petals 4 or 5 united but often deeply divided, the lobes usually contorted in the bud; hairs or scales common in corolla throat. Nectar-secreting pits with fringed margins often present near the base of the perianth segments (sepals and petals). Stamens epipetalous, anthers opening introrsely by longitudinal slits or, in *Exacum*, by terminal pores. Pistil of 2 carpels with a single style and 2-lobed stigma. Ovary with 1 locule and parietal placentae except in tribe Exacineae, which has a 2-loculed ovary and axile placentation. Ovules numerous and variously marked and winged. There are 65 genera and 1,100 species distributed mainly in the northern temperate zones of the world.

#### Family Menyanthaceae

Aquatic or marsh herbs with alternate, entire or trifoliate (of 3 leaflets) leaves that have sheathing petioles (leafstalks). Intraxylary phloem absent. Sepals 5. Petals 5, united, valvate. Stamens 5; epipetalous near the base of the corolla tube or between the corolla lobes. Pistil of 2 carpels with a 1-loculed ovary and 2 parietal placentae; ovary superior except in *Vilarsia*, which is half-inferior; style 1; stigmas 2; ovules numerous. There are 5 genera and 33 species distributed in the northern and southern temperate regions of the world.

#### Family Dialypetalanthaceae

Tree with opposite leaves. Intraxylary phloem absent. Flowers in bracteate (furnished with bracts—small scalelike appendages) many-flowered terminal inflorescences (clusters). Calyx of 4 sepals adnate (fused) to the ovary. Petals 4, free. Stamens numerous, ranging from 16 to 25, free from the corolla. Pistil of 2 carpels; 2 locules. Ovary inferior with axile placentation and numerous ovules. The family contains only 1 genus and 1 species (*Dialypetalanthus fuscescens*) distributed in Brazil.

#### Family Rubiaceae (madder family)

Mostly trees and shrubs, a few herbs, and some climbers. Leaves opposite or whorled; usually with conspicuous persistent stipules. Intraxylary phloem absent. Inflorescence varies from 1 large flower to many small flowers aggregated into a head. Calyx lobes 4 or 5. Corolla of 4 or 5 united petals, mostly with radial symmetry but tending to bilateral symmetry in some. Stamens 4 or 5 and epipetalous. Ovary, with few exceptions, inferior, of 2 carpels and 1 to many anatropous ovules. Fruit fleshy or dry. There are 500 genera and 6,500 species with worldwide distribution; however, they are most abundant in the tropics.

**Critical appraisal.** In addition to the usual taxonomic problems of species delimitation, a number of other questions remain unsolved. The family Loganiaceae, in its original interpretation, is considered an artificial grouping of several families. Most modern authorities consider the genus *Buddleja*, originally of the Loganiaceae, and its related genera as misplaced when associated with *Logania*, and so the family Buddlejaceae has been recognized. The Buddlejaceae is placed in the order Scrophulariales in the system followed here. In addition to the Buddlejaceae other workers recognize four other families now segregated from the Loganiaceae: the Strychnaceae, Spigeliaceae, Antoniaceae, and Potialiaceae. The classification system presented here accepts this interpretation insofar as the families Antoniaceae and Potialiaceae are concerned, but it does not recognize the families Strychnaceae and Spigeliaceae. In addition, the genus *Desfontainia* is here separated from the Potialiaceae and recognized as the family Desfontainiaceae.

The family Antoniaceae as interpreted here includes the Malaysian genus *Norrisia*, the tropical South American genera *Bonyunia* and *Antonia*, and the tropical West African genus *Usteria*. The genus *Peltanthera*, sometimes considered as part of the Antoniaceae, is here placed in the Buddlejaceae.

The family Menyanthaceae, long considered a subfamily (Menyanthoideae) of the Gentianaceae, has been shown on anatomical evidence to warrant familial status. It is here kept as a member of the order Gentianales with the recognition that its relationships are not altogether clear. Some other classification systems, however, associate the Menyanthaceae with the order Polemoniales, justifying this move more on its differences from the Gentianales than its similarities to the Polemoniales.

The monotypic (containing a single genus and species) family Dialypetalanthaceae is also a family of questionable relationships. It is here kept in the Gentianales although there are few characters to warrant the association. Some workers consider it a second family, along with Rubiaceae, in the order Rubiales. Still others question its relationship but consider it best placed in the order Myrtales.

The placement of the family Rubiaceae into the order Gentianales, as is done here, represents a break from the long-standing tradition of separating families with superior ovaries from those with inferior ovaries. Although the close relationship of the Rubiaceae to the Loganiaceae is recognized by many prominent taxonomists, most continue to maintain the order Rubiales separate from the Gentianales.

To accept the Gentianales as outlined above will require a reappraisal of the generally accepted fundamental nature of the position of the ovary. The importance of intraxylary phloem, a single integument, and the thin nucellar tissue as ordinal characters all need further evaluation under this scheme of classification.

## Gentz, Friedrich von

A passionate opponent of the French Revolution and Napoleon and a confidential adviser to the conservative Austrian statesman Clemens von Metternich, Friedrich von Gentz may also be counted among the most cogent thinkers and best stylists in the German language. His works remain a rich source for the history of Europe in the Napoleonic and post-Napoleonic era.

Copyright reserved

Gentz, portrait by Sir Thomas Lawrence (1769-1830). In Windsor Castle, Berkshire.

Gentz was born on May 2, 1764, in Breslau, then part of Prussian Silesia. His father was a Prussian civil servant; his mother came from the French Huguenot colony of Berlin, with which young Gentz liked to associate. Up to an advanced age, he wrote his diaries in French, which he wrote with the same limpid elegance that distinguished his German. Gentz studied under the great German philosopher Immanuel Kant in Königsberg. Although Gentz soon rejected the philosopher's republican idealism, radicalism, and pacifism, Kant was to have a lasting influence on his thought. Essentially self-taught, Gentz acquired his historical, juridical, and economic knowledge from books, chiefly English works.

In 1785 Gentz entered the Prussian civil service in Berlin, and in 1793 he became a secretary in the Generaldirektorium (War Office). Dissatisfied with his position, Gentz threw himself into the social life of the capital. For a brief period in the 1790s, Berlin—with its admixture of French émigrés, Russian, English, and Austrian aristocrats, writers, and bohemian artists from all over Germany—formed one of the intellectual centres of Europe. In this somewhat dissolute society Gentz gained a reputation as a brilliant conversationalist, ladies' man, gambler, and spendthrift. His marriage dissolved after a few years, and Gentz, who lacked the family man's temperament, did not marry again.

With the outbreak of the French Revolution, Gentz began his career as a political writer. As a pupil of Kant, he had at first hailed the Revolution as the "awakening of mankind." But he soon began to criticize the Revolution and ended by combatting it. In 1793 he published a German translation of Edmund Burke's *Reflections on the Revolution in France*; thereafter, Burke, the great

English conservative, remained for Gentz the master whose ideas most closely reflected his own and whose style he admired and imitated. In two periodicals he acquired or founded anew, *Neue deutsche Monatsschrift* and *Historisches Journal*, as well as in brochures published at irregular intervals from 1800 on, Gentz continued to analyze the great drama that unfolded in France: internal affairs and foreign policy and their correlation; the imperialism of the Jacobin extremists; and the affairs of the Directory and Napoleon. Gentz's writings of 1795-1802 are still uncannily topical. His attitude, which would now be called that of a conservative liberal, made him advocate the preservation of civic liberties against autocratic egalitarianism, the defense of the rule of law throughout Europe against illegitimate imperialism, and the maintenance of the equilibrium of powers against the encroachments of the one universal state, which, in his view, all French governments after 1793 were bound to strive for. In particular, Gentz pointed out the differences between the American and the French revolutions, seeing in the former a defense of historical rights against British usurpation, in the latter on anti-historical, aggressive, ideology-laden undertaking. This view found expression in various articles, notably in Gentz's reflections on the death of George Washington, probably the soundest European comment on that event. These political investigations were complemented by economic research, as in the great essay *Über die britische Finanzverwaltung*, which, translated into English, aroused the admiration of the British statesman William Pitt the younger.

As a politician, Gentz strove for a coalition of "Free Europe" against French despotism, a new and a better coalition after the failure of the old one. But, since Prussia observed a policy of strict neutrality during the period 1795-1806, Gentz's position in Berlin became increasingly untenable. In 1803 he accordingly moved to Vienna, the centre, as he hoped, of the Continent's resistance to Napoleon. He had visited London the year before and had been warmly welcomed as an ally by the royal family, the Cabinet, the opposition, and the press. Henceforth, he received sizable financial support from England, as he later did from many European rulers and governments. His acceptance of subsidies, however, does not necessarily imply that he was corrupt. For, while it is true that he liked to live in grand style, he accepted money only from those whose views were more or less in harmony with his own. In return, he gave his supporters the benefit, orally or in writing, of his free and independent opinion; if they wanted anything else, he broke off his connection with them.

As an independent adviser to the foreign ministry in Vienna, Gentz continued to propagandize his idea of a great European alliance that would act as one body in war or peace: "If war breaks out anywhere in Europe, you may be assured that it was I who started it." The net result of his efforts, however, was a series of disappointments: the War of the Third Coalition (1805-07) ended with the allied defeat at the Battle of Austerlitz and a rapprochement between Russia and France, and the Fourth Coalition ended with a Franco-Austrian alliance cemented by Napoleon's marriage to a Habsburg archduchess. Napoleon's decree of 1806, excluding English goods from the Continent, had the effect of jeopardizing Gentz's contacts with England, so that funds and messages from that country reached him only rarely and in insufficient measure. Gentz found himself in a state of melancholy isolation; by 1810 his advocacy of European freedom had begun to weaken.

Gentz's friendship with the new Austrian foreign minister, Metternich, helped him gain access to the Vienna state chancery, this time with the regular title of *Hofrat* (privy councillor). Metternich, whom he admired as a sceptical, worldly-wise man of affairs and a pragmatic politician, became his mentor; Gentz, in turn, became the all-powerful minister's propagandist and confidential adviser.

The War of Liberation that began with Napoleon's catastrophe in Russia and ended with his overthrow evoked

Association with Metternich

Influence of Burke

little enthusiasm in Gentz's tired spirit. He who had so long called Europe to arms against the French now wished to maintain Napoleon on his throne. He feared that Napoleon's fall would result in France in a new outbreak of radical Jacobinism and in Europe in the ascendancy of Russia—a state of affairs that he abhorred perhaps even more than French hegemony.

Gentz reached the peak of success at a time when his energies had already begun to flag. He was allowed to officiate as secretary general of the great congresses of the immediate post-Napoleonic era—those held at Vienna, Aachen (Aix-la-Chapelle), Troppau, Laibach, and Verona. It was a position that entailed many advantages by way of orders and decorations, influence, and money. As he had earlier formulated the Austrian and Prussian war manifestos against Napoleon, so he now wrote up, with the same untiring skill, the protocols of these European congresses. Yet these belated successes, unprecedented for a mere literary man, do not seem to have given him any lasting satisfaction; on the contrary, one often encounters in his diaries for this period a sense of bitterness and disillusionment, sometimes of outright cynicism. In measure as the "European System" (the post-Napoleonic alliances) weakened and finally broke down, Gentz's activities, which had at one time encompassed the Continent, were now restricted to Austria alone.

These activities were of a rigidly conservative and purely defensive nature. The idea of "European freedom" was replaced by the old order of the Continent, an idealized 18th century, which Gentz defended against the 19th. Whether it was a question of Greeks and Serbs rising up against the Turks, Spanish liberals against Bourbon absolutism, Latin Americans against Spain, German students against the German police state, or Italians fighting against the pope, the Austrians, and their own native rulers, Gentz, by lending his pen to Metternich's policy of intervention, would invariably be found on the side of the threatened old powers. He had, to be sure, demonstrated his courage in the struggle against Napoleon; but in his innermost heart he was a nervous and timid man, not without neurotic traits, who feared nothing so much as a repetition of the French Revolution. It is likely that he also felt that his own cultural background, let alone his way of life, was bound up with the old order of Europe. To his friends, he justified his attitude by arguing that, while the new—liberalism, democracy, nationalism—would surely prevail in the end, there also had to be those who did their best to retard and soften their impact. His own nature, he intimated, had predestined him for this historical service of fighting mere rearward actions.

The last chapter in Gentz's life was a personal one: his liaison, at the age of 66, with young Fanny Elssler, a ballerina immortalized on a Vienna monument as "the smile of her century." It was his final triumph and his first complete happiness, and, when it paled, it was time for him to die (June 9, 1832). His possessions had to be auctioned off in order to satisfy the creditors. Metternich paid for the funeral.

In the eyes of a majority of his contemporaries, the mature Gentz was a shameless reactionary, a hireling of the kings, and a traitor to his own youthful convictions. The publication of his collected works and of his astoundingly extensive correspondence mitigated this verdict in the opinion of those who had a feeling for quality. Gentz's most personal documents reveal him as a man of high integrity who scorned hyperbole and demagogic falsehood and unsparingly criticized both himself and those on whose behalf he laboured. Scholars have disputed among themselves as to whether he was actually a Romantic or perhaps a Rationalist; but the question is badly put, for he was too intelligent a man to follow blindly the doctrines of any school.

## Geochemical Equilibria at High Temperatures and Pressures

Earth scientists engaged in experimental studies are usually concerned either with geochemical reactions occurring near the surface of the Earth or with reactions occurring within the Earth. Sediments are deposited within the ocean or the hydrosphere (that is, the water portion of the Earth, as distinguished from the solid part) or beneath the atmosphere. The ocean provides a near-surface environment with a restricted range of temperature and pressure, compared with that for the formation of igneous rocks, which are produced by partial melting of material at depth, and metamorphic rocks, which are altered by high temperature and pressure after their original formation (see Figure 1). Another distinction between geochemical equilibria under these two rather disparate sets of conditions is that reactions occurring at or near the surface of the Earth are dominated by solutions. They are controlled more by changes in composition of the solutions than by changes in temperature and pressure, which are the main variables influencing deep-seated geochemical reactions.

The Earth is a chemical system that responds to changes in physical factors; that is, in the values of the physical properties that determine its characteristics and behaviour. Geochemistry, the study of the Earth's chemistry, is concerned with the distribution and migration of elements in the Earth, with the factors controlling their migrations, and with the history of the migrations. The classical geochemical approach is to study rocks now exposed at the surface and to deduce their history at or during the time they were buried within the Earth. This approach has been increasingly supplemented since 1950 by laboratory experiments. By applying appropriate pressures and temperatures to selected minerals and rocks and examining the products of this simulation of conditions believed to exist within the Earth, the reactions that can occur are determined directly. This approach provides an experimental probe through the crust of the Earth and into the upper part of the mantle. The results clarify and evaluate those from the classical approach and facilitate comparison of rival hypotheses.

The range of pressures and temperatures that occurs within the Earth's upper 100 kilometres (60 miles) can be reproduced in the laboratory with reasonable precision. Some apparatus can reproduce conditions at depths of about 600 kilometres (370 miles) but with less precision. The pressure-temperature ( $P$ - $T$ ) ranges of some geological and geophysical reactions are shown in Figure 1.

Figure 1: Ranges of pressure and temperature within which major geological processes occur. Dotted lines are estimated geotherms showing temperatures at specific depths beneath the oceans and beneath the continental shields (see text).

Metamorphism occurs up to pressures of about 10,000 atmospheres (one atmosphere is the pressure at sea level, 14.7 pounds per square inch), corresponding to the Moho depth—about 35 kilometres (22 miles) beneath the average continental crust. Line A marks the beginning of magma (*i.e.*, partially or completely melted rock materials) generation at higher temperatures. The upper mantle is believed to have a chemical composition between the plutonic rock types gabbro and peridotite. The subsolidus mineralogical changes occurring in gabbro and peridotite at pressures above 10,000 atmospheres are correlated with physical properties and boundaries within the Earth determined by geophysical methods. The zone above the line B shows conditions for the generation of basaltic magmas by partial fusion of mantle peridotite. Incipient melting can occur between the lines B and C in the mantle if traces of water are present. Geochemical reactions, like other chemical reactions, may be reversible; that is, the products of the reaction may themselves react to reform the original substances. If the rate of formation of the products and the rate of reformation of the original reactants are equal, the reaction is in equilibrium. The rate of a chemical reaction is expressed in terms of concentration, and the ratio of the two rates is embodied in what is known as the law of mass action, which is used to interpret the phenomena of geochemical equilibrium. See GEOCHEMICAL EQUILIBRIA AT LOW TEMPERATURES AND PRESSURES; HIGH-PRESSURE PHENOMENA; PHASE CHANGES AND EQUILIBRIA; THERMODYNAMICS, PRINCIPLES OF; ACID-BASE REACTIONS AND EQUILIBRIA; and EARTH, STRUCTURE AND COMPOSITION OF. For additional information on Earth materials and environments, see also MINERALS; IGNEOUS ROCKS; METAMORPHIC ROCKS; SEDIMENTARY ROCKS; ORE DEPOSITS; and ELEMENTS, GEOCHEMICAL DISTRIBUTION OF.

#### THERMODYNAMIC PRINCIPLES RELEVANT TO GEOLOGICAL—GEOPHYSICAL STUDIES

**Systems, phases, and components.** A system is any portion of the universe selected for consideration. In the thermodynamic sense, a system is an assemblage of material bodies interacting among themselves and distinguished from the surrounding medium by certain characteristics. Conditions in the Earth do not correspond precisely to those of ideal thermodynamic systems, but the latter provide concepts for the study of natural systems.

Closed and open systems

A closed system is one with walls that permit exchange of heat with the surroundings but no exchange of matter and is characterized by a fixed chemical composition. An open system can exchange heat and matter with the surrounding medium under controlled conditions. In geochemistry, the word system is usually used to describe the whole range of compositions that can be produced by mixing specified end-members (components).

The material within a system can exist in solid, liquid, or vapour state, given appropriate conditions of  $P$  and  $T$ . Each homogeneous portion of a system differing in composition or state and bounded by a surface is called a phase. Phases can theoretically be separated from each other by mechanical methods.

Components are defined as the smallest number of independently variable composition terms that are necessary and sufficient to express algebraically the compositions of all phases present in a system at equilibrium. Systems may be classified as one-component (unary), two-component (binary), etc., or multi-component, according to the number of components required to express the compositions of the phases present through the  $P$ - $T$  range under consideration.

**Phase diagrams and the phase rule.** When minerals are heated they may change into other polymorphic forms (*i.e.*, they may change in crystalline structure), they may dissociate into two phases, or they may melt; at high pressures, many minerals are transformed into dense polymorphs. All of these transformations are called phase changes. The most successful method yet devised for recording phase changes is the use of phase diagrams, which show the equilibrium relationships among various phases in terms of the variables  $T$ ,  $P$ , and concentrations

of components ( $X$ ). These are intensive parameters (*i.e.*, specific properties), the magnitudes of which do not depend on the size of the system.

For material of a given composition, such as granite or gabbro in the crust or peridotite in the mantle, the composition is defined. The phase changes can then be plotted on a  $P$ - $T$  diagram. In order to show the compositions of the phases at various points, supplemental diagrams are required. There are  $(n - 1)$  independent concentration variables in an  $n$ -component system,  $n$  representing any given number. Graphical representation of phase compositions in a four-component system thus requires three dimensions, or a tetrahedron; for more complex systems, graphical representation is difficult.

The number of the variables  $P$ ,  $T$ , and  $X$ , which must be arbitrarily fixed in order to define completely the state of a system at equilibrium, is called the number of degrees of freedom ( $f$ ), or the variance of the system. The variance is the largest number of intensive parameters that can change independently of each other without decreasing the number of coexisting phases. A divariant ( $f = 2$ ; that is, there are two degrees of freedom) phase assemblage occupies an area on a  $P$ - $T$  phase diagram;  $P$  and  $T$  can be changed independently of each other, and the number of phases does not change. At a given  $P$  and  $T$ , however, the compositions of the phases are fixed because there are no more degrees of freedom. A univariant ( $f = 1$ ) phase assemblage traces a line, and an invariant ( $f = 0$ ) phase assemblage can occur only at a single point on a  $P$ - $T$  diagram.

The variance of a system is defined for  $p$  coexistent phases, each of which contains the same  $c$  independently variable components, by the Gibbs phase rule:  $f = c - p + 2$ . The number 2 arises from two assumptions: (1) that the state of the system is defined by the concentration variables and only two others, namely,  $P$  and  $T$ —if other variables have to be taken into account, such as the force of gravity, electrical fields, or surface effects, then the number 2 has to be modified; (2) that the pressure is constant throughout the system, in particular across each interface. The second assumption is not true in the case of osmotic equilibrium between two liquids, and it is possible to have a system in which the pressure on the fluid phase is less than the pressure on solid phases; these conditions occur within the Earth. If there are two independent pressure variables in a system, then the "operating" phase rule becomes  $f = c - p + 3$ .

**The mineralogical phase rule.** The mineralogy of rocks suggests that a close approach to chemical equilibrium is attained during many deep-seated processes. Consider a block of the crust of uniform composition with the same assemblage of minerals throughout; this assemblage may be treated as a system. During its formation the pressure varied from the top to the bottom of the block. The geotherms (lines showing the temperatures at specific depths) in Figure 1 indicate that the temperature also would have varied, as a function of pressure. The mineral assemblage present is therefore at least divariant. For a divariant closed rock system with  $P$  and  $T$  the only intensive variables, the Gibbs phase rule becomes:  $2 = c - p + 2$ , or  $p = c$ . The variance may be greater than 2, and, for equilibrium mineral assemblages formed in finite rock masses within the Earth, the Norwegian mineralogist Victor Moritz Goldschmidt stated the mineralogical phase rule:  $p \leq c$  ( $p$  is less than or equal to  $c$ ), or the maximum number of minerals that can coexist in rocks in stable equilibrium is equal to the number of components.

**The phase rule for open systems.** When solutions and magmas migrate within the Earth, geochemical reactions and equilibria can be represented in terms of open rather than closed systems. In a thermodynamic model for an open system there are two kinds of components: inert and mobile. Inert components,  $c_i$ , remain within the system; their concentrations are defined by the initial conditions. Perfectly mobile components,  $c_m$ , can migrate in or out of the system during reactions; the chemical potentials of the mobile components are defined by conditions external to the system, regardless of what happens in the system. The state of an open system is defined in

Systems in the Earth's crust

terms of  $P$ ,  $T$ ,  $x_i$  for the inert components and the chemical potentials of the mobile components. The phase rule for such a system is  $f = c_i - p + (2 + c_m)$ . A finite rock mass at equilibrium under these conditions has at least  $2 + c_m$  degrees of freedom, and the mineralogical phase rule for an open system therefore becomes  $p \leq c_i$ , or the maximum number of minerals that can coexist in rocks is equal to the number of inert components. The number of mobile components in a rock system, according to this rule, equals the difference between the total number of components ( $c_m + c_i$ ) and the maximum number of minerals observed in the rock.

Many rock systems have been open to components such as water ( $H_2O$ ) and carbon dioxide ( $CO_2$ ), but it is probably rare for conditions to approach those of the model thermodynamic open system. Rocks are usually permeated by a limited amount of pore fluid (*i.e.*, a film, varying in thickness and nature, between the grains of a rock), and reaction of the fluid with the minerals changes its composition and the chemical potentials of the mobile components in the fluid. Only if large quantities of fluid flow through a rock, as in metasomatic processes (*i.e.*, replacement processes, in which new minerals of different chemical composition are produced by the introduction of material from external sources), are conditions in the thermodynamic open systems likely to be approximated. Components may be mobile but only rarely perfectly mobile.

**Reaction kinetics and available time.** Thermodynamics is concerned only with systems at equilibrium. Phase diagrams provide no information about the stages through which a system may pass nor anything about the rate of attainment of equilibrium. One of the major difficulties in experimental geochemistry is the attainment and recognition of stable equilibrium conditions during the short times that runs may be made in laboratory apparatus.

During the immense span of geological time, even very sluggish reactions have a good prospect of going to completion, and there is evidence that a close approach to equilibrium was achieved during the formation of many metamorphic and igneous rocks at high pressures. Equilibrium conditions are not maintained, however, as shown by the fact that rocks formed within the Earth have become exposed at the surface, with little or no change in mineralogy resulting from the large decrease in  $P$  and  $T$ . This phenomenon relates to factors such as reaction rates under conditions of decreasing  $T$  and  $P$  and the availability of fluxes such as water.

#### PHASE EQUILIBRIA IN MINERAL SYSTEMS

**One-component, two-component, and multi-component systems.** There are several approaches to the use of phase equilibria concepts that apply to petrological (*i.e.*, ore, mineral, and rock) and geochemical investigations. One approach is to study the phase relationships of a single mineral. For example, Figure 2 shows univariant phase transition boundaries for the one-component systems silicon dioxide ( $SiO_2$ ), calcium carbonate ( $CaCO_3$ ), and aluminum silicate ( $Al_2SiO_5$ ). These boundaries provide limits for the conditions of formation of rocks containing the polymorphs involved. Another approach is to study a synthetic mineral assemblage or system, as a model for the more complex rock system under consideration. A third approach is to work with whole-rock multi-component systems and to determine the conditions for the occurrence of specific reactions; the conditions can be plotted on  $P$ - $T$  diagrams, but the compositions of phases involved have to be represented separately.

**Solid-solid reactions.** Several types of solid-solid mineral reactions are shown in Figure 2. There are polymorphic transitions in unary systems as mentioned above. Minerals that are stable in the Earth's crust may become unstable at high pressures, as shown by the breakdown of plagioclase feldspar (albite-anorthite solid solutions) to yield quartz and the dense minerals jadeite, kyanite, and zoisite. The stability range may be affected considerably if other minerals are involved. The reaction of anorthite with forsterite is shown at pressures much lower

Figure 2: Solid-solid phase transitions in simple mineral systems. Abbreviations: cpx—clinopyroxene; opx—orthopyroxene; sa—sapphirine; si—sillimanite.

than the breakdown of anorthite alone. Many minerals can form stably only at high pressures, as illustrated by the formation of pyrope garnet from three other minerals. Changes of temperature or pressure may affect the compositions of coexisting minerals, and this is another important type of solid-solid reaction, one that cannot be illustrated conveniently on a  $P$ - $T$  diagram.

The reactions in Figure 2 are all univariant. In multi-component rock systems, many similar reactions are divariant or multi-variant, and they occur through a transition interval. One of the most significant is the transformation of gabbro, a rock which generally consists of calcic plagioclase and augite (a clinopyroxene), to eclogite, a rock with the same composition but different mineralogy. This transformation involves transitions similar to the reactions plotted in Figure 2; plagioclase and augite become unstable, and jadeitic pyroxene and pyrope are produced at their expense. Experimental determination of this complex transformation is difficult because reaction rates become extremely slow at temperatures below  $900^\circ C$  ( $1,650^\circ F$ ).

**Dissociation reactions.** Carbonates and hydrous minerals (*i.e.*, minerals with the hydroxyl group in their structure) are stable only to their dissociation temperatures. The general shape of univariant dehydration reactions is shown in Figure 3 by the curves for serpentine, muscovite, amphibole, and phlogopite; and the curve for magnesite is the sole example given of a decarbonation reaction. The dissociation temperatures of individual minerals are lowered if other minerals become involved, as shown by the curves for serpentine + brucite and muscovite + quartz.

The curves for hydrous or carbonated minerals and assemblages show the maximum temperatures for their stability under subsolidus conditions (*i.e.*, below the melting temperatures of the chemical system). Dissociation temperatures are lowered if the partial pressure of the volatile component involved, water ( $H_2O$ ) or carbon dioxide ( $CO_2$ ), respectively, is decreased compared to the total pressure on the solid minerals. This condition can arise in natural rock systems if the pore fluid contains additional components or if the pore fluid pressure is less than the load pressure, a condition that could occur if the vapour released migrates away from the rock. The dashed line for total pressures greater than 2,000 atmospheres shows the dissociation of muscovite + quartz if  $P_{H_2O}$  is maintained constant at 2,000 atmospheres. This line is a contour for constant  $P_{H_2O}$  on a divariant surface for the reaction in a system in which there are three independent variables,  $P_{total}$ ,  $P_{H_2O}$ , and  $T$  (see discussion of open systems).

# Behaviour of rock-forming minerals

The temperature of dissociation increases with pressure, and for many minerals melting temperatures may be reached. Invariant points in Figure 3 show the pressures above which phlogopite, muscovite, and muscovite + quartz dissociate to yield a liquid rather than a vapour phase. Some amphibole minerals behave the same. In the presence of a liquid phase, in contrast with the subsolidus dissociation reactions, the stability temperatures for hydrous minerals are increased if the partial pressure of water ( $H_2O$ ) is decreased compared with the total pressure, shown by the curves for phlogopite in Figure 3.

With increasing pressure, the slope of the curve ( $dP/dT$ ) of dissociation reactions, representing the rate of change of Pressure with Temperature, also increases toward the vertical. The slope for the dissociation curve of amphibole changes from positive to negative at pressures above about 18,000 atmospheres, in which region magnesian garnet and jadeitic pyroxene are produced; the change in slope from positive to negative is thus related to the gabbro-eclogite phase transition and the formation of dense minerals.

Geological processes include not only dissociation reactions but also hydration and carbonation reactions. The

Figure 3: Dehydration and decarbonation relations in mineral systems.

univariant curves and associated divariant surfaces for open systems provide  $P$ ,  $T$ , and composition limits for these reactions. The proportions of water and carbon dioxide in migrating solutions determine whether an assemblage including hydrous minerals becomes carbonated or whether an assemblage including carbonates becomes hydrated. Experimental determination of these reactions in the laboratory establishes values for equivalent reactions occurring in open systems in the Earth.

**Melting reactions.** In Figure 4B the univariant melting curve for a one-component system, albite, is shown. At fixed pressure albite melts completely at constant temperature. The effect of pressure is to increase the melting temperature; the slope of the melting curve ( $dP/dT$ ) is steep and positive. The subsolidus curve for the breakdown of albite to form jadeite + quartz meets the albite melting curve at an invariant point; at higher pressures the system becomes binary, and the melting reaction becomes jadeite + quartz  $\rightleftharpoons$  liquid. This reaction is univariant, but for mixtures of jadeite and quartz that do not have the composition of the liquid produced (this is fixed at a given  $P$  and  $T$ , as shown by application of the phase rule), the mineral assemblage melts through a temperature interval, beginning at the univariant curve. (The reverse curvature for the albite melting curve below the invariant point is part of a complex series of changes.)

Figure 4: Phase relationships for composition on the join albite-water.

(A) Variations in composition of phases for the reaction albite + vapour = liquid. (B) Univariant melting curves and solid-liquid transitions (see text).

From A. Boettcher and P. Wyllie, "Phase Relationships in the System  $NaAlSi_3O_8-H_2O$  to 35 Kilobars Pressure," *American Journal of Science*, Vol. 267 (1969)

Multi-component rock systems also have melting intervals. The curve for the beginning of melting of peridotite is shown in Figure 5, with a steep positive slope. The melting interval for peridotite is indicated in Figure 1 between the lines B and D. The composition of the liquid produced by partial melting of the peridotite, within a temperature interval above the solidus, corresponds in composition to basaltic magmas; the composition varies with temperature above the solidus, and with pressure.

**Melting in the presence of water.** Also shown in Figure 4B is the effect of water vapour under pressure on the melting temperature of albite. There is initially a marked decrease in melting temperature; this effect is reduced above a few thousand atmospheres, but the slope ( $dP/dT$ ) of the univariant reaction remains negative until albite breaks down. At the invariant point generated by the formation of jadeite and quartz, the solidus curve for mixtures in the albite-water composition range changes slope, becomes ternary, and with increasing pressure the temperature of melting for jadeite and quartz in the presence of water vapour increases. Another invariant point is generated where quartz is transformed to coesite. If there is enough water to saturate the liquid (see Figure 4A), melting is completed on the univariant curve for the binary mineral-water system, but for the ternary system, the univariant solidus curve is the beginning of melting; only mixtures corresponding to the first liquid produced melt at one temperature.

This melting pattern is general for minerals in the presence of excess water. The effect of water vapour under pressure on the temperatures of beginning of melting of the major crustal rock types is shown in Figure 5. These reactions follow the same pattern; there is a low-

Effect of excess water

Figure 5: Melting points of major rock types in the presence of water with  $H_2O = P_{total}$ , compared with the solidus for dry peridotite.

pressure regime, where the solidus curves trend to lower temperatures, and at pressures above about 15,000 atmospheres, where plagioclase feldspar becomes unstable, the solidus temperatures increase with increasing pressure, with slope approximating those for dry minerals and rocks. The solidus curve for peridotite in the presence of excess water exhibits a somewhat different pattern; the small proportion of plagioclase feldspar that may be present at low pressures reacts with olivine to yield aluminous pyroxenes and spinel at about 10,000 atmospheres (Figure 2). At higher pressures there is a gradual change in slope from negative to positive, associated with the formation of garnet peridotite from spinel peridotite (see pyrope formation in Figure 2).

If conditions are such that  $P_{H_2O} < P_{total}$ , then the melting temperatures are increased, as is illustrated for a simple system in Figure 4B. The dashed line for total pressures greater than 5,000 atmospheres shows the melting curve for albite (or jadeite + quartz at high pressures) in the presence of vapour with  $P_{H_2O}$  maintained constant at 5,000 atmospheres. This curve is approximately parallel with the univariant curves for dry melting, which correspond to conditions where  $P_{H_2O} = 0$ . This dashed curve is a contour on a divariant surface. There are as yet few experimental data on the positions of these contour lines.

The main changes in phase relationships produced if excess water is added to a dry rock are that solidus and liquidus temperatures are lowered, the melting interval between solidus and liquidus is increased, and hydrous minerals such as mica and amphibole are stabilized; these relationships become involved in reactions including a liquid (see Figure 3). For a granodiorite (a plutonic rock) with excess water at a fixed pressure of 2,000 atmospheres, Figure 6 shows the successive equilibrium assemblages, bounded by isothermal reaction lines, within the melting interval (see composition IV); the temperature interval is 270° C (490° F). For the dehydrated granodiorite composition (I), the melting interval is only 130° C (230° F), between  $n'$  and  $n$ .

Most natural conditions are water deficient, and the sequence of reactions through the melting interval of a rock is more like those illustrated for compositions II or III in Figure 6. The shaded area left of line a-b-c-d is vapour absent; there is insufficient water to saturate the liquid and hydrous minerals in the assemblages. The main changes caused by passing from the vapour-present

phase fields into the vapour-absent phase fields, with progressive decrease in water content (and in  $P_{H_2O}$ ), are that the liquidus temperature increases, the temperature interval between solidus and liquidus increases, the temperature stabilities of the hydrous minerals (biotite and hornblende) increase, and the amount of liquid within a given temperature interval above the solidus decreases. In composition II, containing no vapour-phase subsolidus, the temperature of beginning of melting is about 160° C (290° F) higher than for subsolidus assemblages with vapour; melting does not begin until biotite begins to dissociate, releasing water to dissolve in the liquid.

In the  $P$ - $X$  diagram of Figure 4A are shown the compositions of the three phases, albite (Ab), liquid (L), and vapour (V), involved in the univariant melting reaction  $Ab + V \rightleftharpoons L$ , at pressures up to the invariant point at which albite breaks down. The line for the liquid composition gives the solubility of water ( $H_2O$ ) in the silicate liquid as a function of pressure, and similarly the line for the vapour composition gives the solubility of the solid components in the vapour phase; the temperature varies along these curves, as shown by the corresponding reaction curve in Figure 4B. Experimental data are sparse, but the general pattern for other silicate minerals and rocks at pressures up to 10,000 atmospheres appears to be similar to that illustrated, although specific solubility values vary with the composition of the minerals and rocks involved. The solid components usually dissolve in the vapour phase in proportions different from their proportions in the mineral or rock, an effect that becomes more marked as the total solubility increases. At a given pressure, the solubility of water in silicate liquids decreases as the temperature increases, and the solubility of solid components in the vapour phase increases.

**Reactions involving other volatile constituents.** The dashed line in Figure 4B shows the effect of insoluble volatile components on the melting temperatures. If other volatile components more soluble in the silicate liquid than water are added, then melting temperatures are lowered. Experiments have been conducted using dilute acids or salt solutions. Experimental techniques have been developed for controlling oxygen fugacities (the pressure of a perfect gas is called the fugacity; it may be derived mathematically from measured pressure) at low levels of the order of  $10^{-30}$  atmospheres while  $P_{H_2O}$  is controlled independently at pressures up to several thousand atmospheres. These techniques make possible evaluation of the effect of oxygen fugacity and the oxidation state of iron on the stability ranges and melting reactions of iron-bearing minerals and rocks. The study of systems containing sulfur as a component has bearing on the origin of ore deposits, and attention has been directed toward experimental determination of the solubilities of sulfides in solutions. Another type of experimental study deals with the distribution of oxygen isotopes among minerals and fluids as a function of temperature.

#### AREAS OF APPLICATION OF HIGH-TEMPERATURE, HIGH-PRESSURE STUDIES

**Phase transitions in the Earth's interior.** It has been determined experimentally that peridotite believed to approximate the upper mantle in composition undergoes a series of phase transitions with increasing pressure. At low pressures the peridotite consists dominantly of olivine, with two pyroxenes and plagioclase. With increasing pressure the plagioclase is replaced by spinel, which may dissolve in aluminous pyroxenes, and then by pyrope-rich garnet (see simple reactions in Figure 2). The garnet peridotite undergoes a major phase transformation at  $P$ - $T$  conditions corresponding to the depth interval near 400–450 kilometres, which coincides closely with the seismic discontinuity (i.e., a discontinuity within the Earth that separates materials in which Earth vibrations travel at significantly different velocities) at the beginning of the mantle transition zone. Olivine changes to a spinel-like mineral and the pyroxenes dissolve in the garnet.

The phase transformation of gabbro into eclogite is related to the univariant reactions of Figure 2 involving the breakdown of albite and anorthite and the formation of

Silicate minerals and rocks

Effect of water deficiency

pyrope. There is a continuing debate about whether the gabbro-eclogite phase transformation is a cause of the Moho seismic discontinuity in some geologically active regions. Conflicting experimental results have been published and extrapolation from experiments at 1,000° C (1,800° F) to temperatures in the range 600° to 300° C (1,100° to 550° F), which approximates the natural conditions for this transition, produces conflicting interpretations of several major geophysical and petrological problems.

**Metamorphic petrology: mineral reaction series and mineralogical facies.** Metamorphic rocks provide a guide to temperatures and temperature gradients in the earth during the mountain-building cycle. During the burial, deformation, and metamorphism of rocks, a series of dehydration and decarbonation reactions occurs, as well as solid-solid transitions. Examples of these are plotted in Figures 2 and 3. If these two figures are superimposed, the dissociation reactions tend to cut across the solid-solid reactions, producing a grid of reaction lines bounding pigeonholes for mineral assemblages. If a rock experiences changes in *P* and *T* represented by a geotherm (see Figure 1), it will cross a series of reaction lines, and if equilibrium is maintained it undergoes a series of mineral reactions. Successive mineral assemblages are produced with progressive metamorphism. The metamorphic assemblages, or groups of metamorphic assemblages for rocks of different compositions within similar *P-T* intervals, are called metamorphic facies.

The concept of a petrogenetic grid, a *P-T* diagram traversed by experimentally determined reaction lines, was developed in 1940. Experimental studies have now turned this into an effective instrument for determining the depths and temperatures of origin of metamorphic rocks. Such calibration of observed metamorphic rocks indicates that metamorphism occurs through a wide range of conditions. It is shown in Figure 1 that some rocks are metamorphosed at moderate pressures and high temperatures, whereas others are metamorphosed at high pressures and low temperatures, possibly related to the down-sinking of a cold lithosphere slab beneath an island arc or continental margin. Geotherms and geothermal gradients during mountain-building processes may thus depart significantly from the average estimates shown in Figure 1. The line A in Figure 1 for the solidus of granite-water (see Figure 5) shows that partial melting begins in high-temperature metamorphism, with the formation of migmatites (*i.e.*, altered rocks consisting of thin alternating layers of different compositions).

**Igneous petrology: magma generation and crystallization.** Magmas, mutual solutions of silicates with small proportions of dissolved volatile components, are generated whenever the temperature at a given depth exceeds the solidus temperature for the material present. The solidus temperature for a dry rock is much higher than for a rock in the presence of an aqueous pore fluid (Figures 1, 4B, 5, and 6, one igneous and the other metamorphic).

In the mantle, basaltic magma is derived by partial fusion of peridotite. Conditions for the melting of peridotite dry and in the presence of excess water are shown in Figure 5. For dry mantle, basaltic magma is generated in the depth-temperature range shown in Figure 1. Experimental studies have shown that the composition of the liquid produced varies as a function of the mineralogy of the peridotite, as a function of depth, and with the temperature interval above the solidus. A significant change with increasing pressure is the increased solubility of olivine in the liquid. Note that for the formation of basaltic magma at depths less than 100 kilometres (60 miles), temperatures must become considerably higher than the two estimated geotherms plotted in Figure 1. The geotherms do pass through the *P-T* area for incipient melting if traces of water are present, and this phenomena provides a possible interpretation for the low-velocity zone of the upper mantle identified from seismic studies. The curve C in Figure 1 differs from the solidus for peridotite-water in Figure 5, because up to pressures of about 27,000 atmospheres it is assumed that the water is stored in amphi-

bole, and melting begins only when this mineral dissociates (Figure 3, melting of Type II in Figure 6).

The crystallization sequence of magmas, once generated, can be traced on phase diagrams. Equilibrium or fractional crystallization may occur, although usually the actual conditions would be between these two extremes. Fractional crystallization may occur continuously during uprise of the magma, or it may occur at a given pressure during a temporary halt in its upwards path. The composition of the liquid eventually emplaced into the crust, or erupted as a lava, is formulated during a complex history. Experimental determination of the effect of various *P-T* paths on the composition of the liquid is required for explanation of the origin of basaltic magma types.

It has been experimentally established that crustal rocks with a wide range of composition, in the presence of an aqueous pore fluid, will begin to melt within a few tens of degrees of the line A in Figure 1 (compare Figures 5 and 6, composition III). Normal magma generation in the crust appears to be limited to the formation of a crystal mush containing water-undersaturated liquid of granite composition. The granite liquid may be capable of separation and independent intrusion. It is doubtful that the amount of pore fluid in a deep-seated rock would exceed 1 percent by weight, and Figure 6 shows that all of it dissolves in the granite liquid within a few degrees of the solidus. The temperature of beginning of melting is controlled by  $PH_2O$ , and the amount of liquid is controlled by the proportion of granitic minerals in the rock and by the amount of water.

It is shown in Figure 6 that in order to produce liquids of intermediate composition, temperatures approaching 1,100° C (2,000° F) are required. It therefore appears that andesite and diorite liquid magmas are not produced within the crust during metamorphism unless temperatures are considerably higher than those normally considered likely. Alternative explanations involve formation by fractional crystallization of basalts with high oxygen fugacity and derivation from the mantle as primary magmas.

If slabs of lithosphere are sinking beneath island arcs and some continental margins, as required by the hypotheses of sea-floor spreading and plate tectonics (concept that the Earth's major structural features result from the collisions and general interaction of a relatively small number of large, 100-kilometre-thick lithosphere plates that form the outer layer of the Earth and move over the Earth's interior), then the study of geochemical reactions in crustal materials at pressures greater than 10,000 atmospheres is required for explanation of the evolution of island arcs and mountain chains.

**Geological thermometry and barometry.** The concept of a petrogenetic grid has been reviewed in the foregoing section on metamorphic petrology. A *P-T* phase diagram based on mineral reactions measured in the laboratory is an effective means of estimating temperatures and pressures of formation of rocks on the basis of their mineralogy. Some reactions are suitable for estimating temperatures, and others for estimating pressures; ideally, a mineral assemblage can be delineated on the petrogenetic grid in terms of both temperature and pressure.

Other aspects of geochemical reactions or equilibria provide similar information. The compositions of coexisting minerals, for example, are usually sensitive to changes in temperature and only slightly changed by pressure. Calibration of these values by experimental studies provides temperature estimates within specific mineral facies. Other mineral combinations are sensitive to pressure changes. The distribution of oxygen isotopes among coexisting minerals is a function of temperature, and this fact provides another geological thermometer that has been calibrated by high pressure geochemical experimentation.

There is always a question as to just what an estimated temperature and pressure means. Rocks have histories, and the estimated values represent simply the stage at which the *P-T* record became frozen in because of increasingly slow reaction rates. The petrographic study of relict and retrograde reactions occurring, respectively,

Production  
of liquid  
magmas

Origin of  
meta-  
morph  
ic  
rocks

before and after the major formation process of a rock provides information about a portion of the high- $P$ - $T$  history of the rock. Equilibrium phase diagrams determined in the laboratory can be used to calibrate the history deduced from the nonequilibrium mineralogical relationships preserved. Slow reaction rates in the rocks and in laboratory experiments cause many interpretive problems, but, on the other hand, if reactions in response to the changing  $P$ - $T$  conditions did not cease at some stage, there would be no historical record to examine. Eventually, with sufficient experimental, petrographical, and geological data, it may be possible to determine the complete depth-temperature-time relationships for various parts of a complex mountain range.

## Geochemical Equilibria at Low Temperatures and Pressures

Geochemical equilibria are involved in most natural geological and hydrological processes at or near the surface of the Earth. In any geochemical system or assemblage of phases (*i.e.*, states or forms) of matter, equilibrium exists when the phases of the system do not undergo any changes of properties with the passage of time. In addition, the phases must have the same properties after any temporary disturbance of the system is followed by return to the initial conditions. Low-temperature, low-pressure studies of chemical equilibria are concerned with the processes that take place between the lowest temperature on Earth and approximately 400° C (750° F), and between near vacuum and several kilobars of pressure (one bar = 0.987 atmosphere = 14.504 pounds per square inch).

Within these limits, low-temperature, low-pressure geochemistry involves the application of the fundamentals of chemistry, especially chemical thermodynamics (*i.e.*, the mathematical treatment of the relationship of heat and work and other forms of energy to equilibrium in chemical reactions and changes of state) to the analysis and explanation of Earth processes. Such studies are useful in ecology, corrosion control, hydrology, oceanography, waste disposal, and determination of the occurrence and origin of some mineral deposits.

The ultimate goal of low-temperature, low-pressure equilibria studies is to describe the various Earth environments—*i.e.*, the combinations of such external conditions as air, light, moisture, temperature, soil, and organisms—that may influence Earth materials and water by reason of naturally or artificially imposed geochemical stresses. The parameters that have proven useful for environmental description are (1) the electromotive force or potential of reactions (Eh), (2) acidity (pH), (3) pressure, (4) temperature, (5) solubility of minerals, and (6) the chemistry of pore solutions (*i.e.*, liquids in the pores or voids and interstices) in rocks. The fundamental factors that affect these parameters are the minerals that make up the Earth's crust and the amounts of organic material and water that are present in that crust. The amount of water is controlled primarily by climate and topography. Achievement of the basic goal requires the investigation of all of the possible variations of any basic parameter and the synthesis of the results. An environment may exhibit a relatively wide range of temperatures at the Earth's surface, for example; solutions present may range

from highly acidic to highly alkaline; the area may be humid, in which case the materials may be leached, or it may be arid, in which case the soluble minerals remain for long periods of time. A unified description of the Earth's environments becomes possible only when the several important parameters and their variations are examined from the viewpoint of thermodynamics. Included in this article is consideration of the principles of thermodynamics that are of special relevance to understanding geochemical equilibria at low temperatures and pressures and of geochemical diagrams that are employed to delimit environmental conditions. Additionally, there is consideration of several specific equilibria that are of significance in nature. These include carbonate, iron, and uranium systems, soil conditions, and osmotic equilibria. See also THERMODYNAMICS, PRINCIPLES OF; CHEMICAL EQUILIBRIA; and GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES.

### PRINCIPLES AND TECHNIQUES

**Law of mass action and the equilibrium constant.** The energy distribution within all chemical systems is such that all processes strive to achieve equilibrium. All chemical reactions are reversible; that is, the products of the reaction may themselves react to reform the original substances; at equilibrium the rate of formation of the products and the rate of reformation of the original reactants are equal. The law of mass action states that the driving force of a chemical reaction is proportional to the concentration of the reacting substances at a particular time. For a system at equilibrium, for example, the reaction of  $a$  moles ( $a$  mole is the molecular weight of a substance in grams) of  $A$  with  $b$  moles of  $B$  to form  $c$  moles of  $C$  and  $d$  moles of  $D$  is:  $aA + bB \rightleftharpoons cC + dD$ , in which the rates to the right and left are equal. The product of the activities (concentrations, in the nonthermodynamic sense) of the reaction products  $C$  and  $D$  raised to the powers of their numerical coefficients ( $c$ ,  $d$ ), divided by the product of the activities of the reactants  $A$  and  $B$  raised to the powers of their numerical coefficients ( $a$ ,  $b$ ), is a constant at a given temperature. This is the so-called thermodynamic equilibrium constant,  $K_{eq}$ ; in this case it is

$$K_{eq} = \frac{\alpha_C^c \alpha_D^d}{\alpha_A^a \alpha_B^b}$$

in which the Greek letter alpha,  $\alpha$ , denotes thermodynamic concentration or activity, and  $a$ ,  $b$ ,  $c$ ,  $d$  are the numbers of moles of substances  $A$ ,  $B$ ,  $C$ ,  $D$  as before.

The relation is valid for reactions between solid, liquid, and gaseous phases or combinations of these phases. Activity is a measure of the effective or active concentration of any phase involved in a reaction. One example is a reaction involving one or more solid phases (minerals) and a solution (water) phase. In infinitely dilute solutions activity is virtually equal to chemical concentration, but as a solution becomes more concentrated (contains more dissolved solids), the dissolved components in the solution and the solvent (generally water) cease behaving ideally; their effective concentrations, or activities, do not change proportionally with their chemical concentrations. A correction for deviations from the ideal is required by the fact that as the concentration of a solution is increased, ions (atoms that have gained or lost electrons and thus are positively or negatively charged) interact with one another and with water molecules. For this reason it is necessary to change from standard units of chemical concentration to those of activity in order that ion-activity products,  $K_{iap}$ , the actual equilibrium constants, may be compared with laboratory-determined thermodynamic equilibrium constants,  $K_{eq}$ , to ascertain which minerals are in equilibrium with, and therefore presumably controlling, the chemistry of a natural water.

The six parameters of environmental description

Most chemical analyses of waters are expressed in units of milligrams per litre (mg/l) or milliequivalents per litre (meq/l). To convert these values to activity, it is necessary to change them to units of molality. A one-molal solution is defined as one that contains a mole (an amount of a substance in grams that corresponds to the sum of the atomic weights of all the atoms in the molecule) of solute in 1,000 grams of water. Molar concentrations are not used in thermodynamic studies (molar solutions are referred to a litre volume of solution) because of the temperature dependency of the volume and, hence, the concentration of such solutions.

**Standard state, activity, and activity coefficient.** A standard state for a given substance is the sum of its physical and chemical properties at an arbitrarily chosen set of reference conditions; a standard state may be varied for convenience, depending on the problem being studied. In its standard state, the activity of a pure phase is defined as unity.

Problems in defining the standard state of a gaseous phase

The standard state of a pure solid phase (whether an element or compound) is generally chosen at a specified temperature and, usually, at one atmosphere total pressure. Thus, the standard state of the mineral corundum,  $\text{Al}_2\text{O}_3$ , at 308.16° K (35° C or 95° F) would be written  $\text{Al}_2\text{O}_3$  corundum, 308.16° and would have unit activity.

The standard state of a gaseous phase is more difficult to define because only perfect gases (those that obey the ideal gas law) have unit activity at the specified temperature and one atmosphere pressure. Thus, the activity of a perfect gas is equal to the pressure:  $a_{\text{gas}} = P_{\text{gas}}$ . Real gases generally deviate from the ideal gas law; therefore, the standard state of a real gas is defined to have unit activity at a specified temperature and at that pressure at which the gas pressure would be one atmosphere if the gas obeyed the ideal gas law. As pressure on a real gas is lowered, it approaches the behaviour of an ideal gas. But at higher pressures the activity is not equal to the pressure ( $a_{\text{gas}} \neq P_{\text{gas}}$ ), and it is necessary to add an additional term  $\phi$ , the gas-activity coefficient to equate activity to pressure, namely:  $a_{\text{gas}} = P\phi_{\text{gas}}$ .

The standard state of a pure liquid (such as the element mercury, Hg, or the compound water,  $\text{H}_2\text{O}$ ) is generally defined as its state at a specified temperature and at one atmosphere pressure. If the standard state of water is chosen as one atmosphere pressure and 323.16° K (50° C, or 122° F), for example, then it has unit activity under these conditions.

The standard state of a substance dissolved in a solvent, as an ion or as an uncharged species in water (e.g., calcium ion,  $\text{Ca}^{2+}$ , and aqueous carbon dioxide,  $\text{CO}_{2(aq)}$ ), is defined by extrapolation to unit activity from behaviour in an infinitely dilute solution, in which the dissolved species acts ideally. In dilute solutions, molality is nearly equal to activity; for more concentrated solutions, a correction factor must be used. The correction factor, which provides a connection between activity,  $a_i$ , and molality,  $m_i$ , of the individual ionic species, is given by the equation

$$a_i = \gamma_i m_i, \quad \text{or} \quad \gamma_i = \frac{a_i}{m_i},$$

in which the Greek letter gamma (sub-i),  $\gamma_i$ , is the activity coefficient of component i. The activity coefficient for various ions may be calculated from standard water analyses by use of an empirical (the Debye-Hückel) equation, which equates the logarithm of the activity coefficient to the ionic charge, ionic diameter, and ionic strength of solution, namely:

$$\log \gamma_i = \frac{-Az_i^2\Gamma^{1/2}}{1 + a_i\Gamma^{1/2}}$$

in which A and B are temperature-dependent constants,  $z_i$  is the charge on the ion,  $a_i$  represents the effective diameter of the ion in solution, and the Greek letter gamma,  $\Gamma$ , is the ionic strength of the solution. Values for A, B, and  $a_i$  are given in standard textbooks on physical chemistry or solution chemistry. The Debye-Hückel equation gives reasonable values for activity coefficients up to an ionic strength of about 0.1, which corresponds to concentrations of dissolved solids in typical natural

waters of about 5,000 to 8,000 milligrams per litre. Drinking-water supplies contain less than 2,000 milligrams per litre and usually less than 1,000 milligrams per litre, whereas ocean water contains about 35,000 milligrams per litre dissolved solids.

**Free energy and equilibrium.** If a system is not at equilibrium, it will tend to react spontaneously with a release of energy. The so-called Gibbs free-energy function,  $\Delta G$ , provides a true measure of the driving force of a chemical reaction because free energy connotes the available work that can be done by a system. The Gibbs free energy of reaction is the sum of the free energies of formation of products less the sum of the free energies of formation of reactants; that is:

$$\Delta G_R^\circ = \sum \Delta G_f^\circ \text{ products} - \sum \Delta G_f^\circ \text{ reactants},$$

in which  $G_R^\circ$  is the free energy of the reaction and the Greek letter sigma,  $\Sigma$ , represents a summation. When  $\Delta G_R^\circ$  is zero, there is no net chemical work obtainable; the system is at equilibrium. If  $\Delta G_R^\circ$  is negative, the process may proceed spontaneously; a positive value means that work (energy) must be put into the system for the reaction to proceed. The equilibrium constant can be calculated from  $\Delta G_R^\circ$  according to the relation

$$\Delta G_R^\circ = -RT \ln K_{eq},$$

in which  $R$  is a constant,  $T$  is temperature, and  $\ln K_{eq}$  is the natural logarithm of the equilibrium constant.

The standard state for the calculation of free-energy values is commonly taken as that of the pure substance at 25° C or 77° F (298.16° K) and one atmosphere total pressure. Because natural systems of interest are commonly at some temperature other than 25° C, it is necessary to extrapolate free-energy data from 25° C to the temperature of the natural system. This may be done by using an equation (Gibbs-Helmholtz), which states that at constant pressure the free energy equals the heat of reaction plus the product of temperature and the rate of change of free energy with temperature, namely:

$$\Delta G = \Delta H + \left( \frac{\partial \Delta G}{\partial T} \right)_P,$$

in which  $\Delta H$  is enthalpy or heat of reaction (enthalpy is the heat change during a chemical process at constant

pressure) and  $\left( \frac{\partial \Delta G}{\partial T} \right)_P$  is the rate of change of free en-

ergy with temperature at constant pressure. By mathematical operations on the last two equations, the so-called van't Hoff equation relating the change in equilibrium constant with change in temperature to the enthalpy and absolute temperature is obtained:

$$\left( \frac{\partial \ln K_{eq}}{\partial T} \right)_P = \frac{\Delta H}{RT^2},$$

in which the symbols are as previously defined. This equation may be used to calculate equilibrium constants at temperatures other than 25° C. It generally provides a fair approximation only if the actual temperature is not far from 25° C. For larger variations, the assumption that  $\Delta H$  is independent of temperature (which is explicit in the van't Hoff equation) is invalid.

Pressure changes also affect the rate of change of the Gibbs free-energy function. The rate of change of free energy with change of pressure at constant temperature is equal to the change in volume, namely:

$$\left( \frac{\partial \Delta G}{\partial P} \right)_T = \Delta V_R,$$

in which  $\Delta V_R$  is the molal volume change of the reaction. It is calculated in a manner similar to the Gibbs free energy of reaction.

In most natural systems both temperature and pressure are subject to change. If the compositions of the phases do not change during a reaction (e.g., during congruent dissolution) and if the system remains at equilibrium, then the Clausius-Clapeyron equation, which defines the rate of change of pressure with respect to temperature is useful. This can be expressed

Gibbs free energy

$$\frac{dP}{dT} = \frac{\Delta H_R}{T\Delta V_R},$$

in which  $\Delta H_R$  is the total enthalpy change of the reaction,  $T$  is absolute temperature, and  $\Delta V_R$  is again the molal volume change.

**Nernst equation and Eh-pH relation.** In order to understand chemical reactions that involve an exchange of electrons, it is necessary to measure the electromotive force (emf) of the reaction. If the reaction is reversible, then the reversible emf,  $E^0$ , is related to the Gibbs free energy of reaction  $\Delta G_R^0$  by the expression

$$\Delta G_R^0 = nE^0F,$$

in which  $n$  is the number of electrons involved in the reaction,  $E^0$  is the calculated potential of the cell when all species are at unit activity, and  $F$  is the faraday (*i.e.*, the quantity of electricity transferred per equivalent weight of an element or ion). The cell potential can be shown to be related to the natural logarithm of the equilibrium constant by:

$$E^0 = -(RT/nF)\ln K,$$

in which  $K$  is the equilibrium constant,  $T$  is absolute temperature,  $R$  is a constant, and  $n$  and  $F$  are as defined above. In most chemical reactions the activity of all species is generally not unity, in which case the free-energy function equals the free energy of the reaction plus the product of temperature and the logarithm of the equilibrium constant:

$$\Delta G = \Delta G_R^0 + RT\ln K,$$

in which  $\Delta G$  is the free energy function,  $\Delta G_R^0$  is the free energy of the reaction,  $T$  is temperature,  $R$  is a constant, and  $K$  is the equilibrium constant.

The cell potential can be related to the equilibrium constant by:

$$Eh = E^0 + (RT/nF)\ln K,$$

in which  $Eh$  is the potential measured against the standard hydrogen-electrode reaction involving the decomposition of hydrogen to hydrogen ions plus electrons (which, by convention, has an emf equal to zero) and  $E^0$  is again the potential when all ionic species are at unity activity. This is a form of the Nernst equation; at standard pressure (one atmosphere) and temperature (298.16° K), the factor  $(RT/nF)$  can be reduced and

$$Eh = E^0 + \frac{0.05916}{n} \log K.$$

Many chemical elements are capable of existing in more than one valence state (*i.e.*, combining capacity, the numerical expression of which represents the number of electrons an atom can gain, lose, or share in a chemical reaction). Thus, iron may exist as metallic iron with no net charge, as the ferrous ion with a net charge of plus two, or as the ferric ion with a net charge of plus three. In addition, complex ions, such as the iron hydroxide ions  $\text{Fe}(\text{OH})^{2+}$ ,  $\text{Fe}(\text{OH})^{+3}$ , and  $\text{FeO}(\text{OH})^-$ , are possible under appropriate conditions of oxidation-reduction potential (redox, or  $Eh$ ) and pH. The pH of a solution is defined as the negative logarithm of the hydrogen-ion activity. Thus, if the activity of the hydrogen ion is  $10^{-7.3}$ , then the pH of the solution is plus 7.3. Because of the large number of similarly behaving elements, many chemical reactions in geologic environments may be expressed in terms of  $Eh$ , or pH, or by a combination of  $Eh$  and pH. For this reason,  $Eh$ -pH diagrams (the plotted relations of  $Eh$  and pH) provide an excellent pictorial method for portraying such reactions. By drawing lines on these diagrams to denote the activity of each possible dissolved species, the oxidation-reduction potential of the environment can be estimated from study of the solid phases present and from determination of the activity of dissolved species in equilibrium with the solid phases.

**Reaction types.** One of the primary tasks of low-temperature studies is to determine which minerals are in

equilibrium with their physical and chemical environment. This can be done by means of simple calculations that utilize the equations cited thus far. Examples of the several types of reactions are considered below.

**Solid-solid reactions.** There are many reactions involving only solids that are geologically important. Any reaction for which free-energy data exist can be tested by means of the Gibbs free-energy equation. The reaction of calcite,  $\text{CaCO}_3$ , with magnesite,  $\text{MgCO}_3$ , to produce dolomite,  $\text{CaMg}(\text{CO}_3)_2$ , provides a common example. If the reaction occurs at 25° C and one atmosphere pressure and if the solids are pure, then they are in their standard states and have unit activity. Under these conditions, the reaction can be written

Applying the relation that the free energy of reaction is equal to the free energy of the products (dolomite) minus the free energy of the reactants (calcite and magnesite) yields:

$$\Delta G_R^0 = \Delta G^0_{\text{dolomite}} - (\Delta G^0_{\text{calcite}} + \Delta G^0_{\text{magnesite}});$$

and substituting the appropriate free energy values at 25° C and one atmosphere of pressure:

$$\Delta G_R^0 = (-516.56) - (-269.98 - 246.11) = -0.47 \text{ kilocalorie.}$$

Because the free energy of reaction is negative, this means that dolomite is the stable mineral at the given conditions of temperature and pressure. That is, it would require an input of +0.47 kilocalorie to drive the reaction in the opposite direction, converting dolomite to calcite and magnesite.

**Solids and pure water.** Reactions that involve only solids and pure water can be treated similarly to solid-solid reactions, because the activity of pure water is unity. An example of importance in nature is the reaction: anhydrite,  $\text{CaSO}_4$ , plus water,  $\text{H}_2\text{O}$ , to yield gypsum,  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ . This is written

Applying again the relation that the free energy of the reaction is equal to the free energy of the products minus the free energy of the reactants:

$$\begin{aligned} \Delta G_R^0 &= \Delta G^0_{\text{gypsum}} - (\Delta G^0_{\text{anhydrite}} + 2\Delta G^0_{\text{water}}) \\ \Delta G_R^0 &= 429.19 - (-315.56 + 2(-56.9)) \end{aligned}$$

In this instance, the free energy of the reaction

$$\Delta G_R^0 = -0.25 \text{ kilocalorie.}$$

Thus, this reaction also tends to go in the direction of the product (gypsum) at 25° C and one atmosphere pressure. One of the reasons that the hydration (addition of water) of anhydrite is important is that a mole of gypsum is much less dense than a mole of anhydrite. If, therefore, hydration occurs in confined space, as in the subsurface environment, the pressure may be significantly increased. Also, the reaction gives off heat and consequently changes both the pressure and the temperature of the system.

**Gases and solids or solutions reactions.** Reactions between gases and solids or solutions are geologically common and are readily handled thermodynamically. The reaction between a solution that contains calcium ions and  $\text{CO}_2$  gas, that reacts to produce calcium carbonate ( $\text{CaCO}_3$ ) and hydrogen ion ( $\text{H}^+$ ), for example, can be written

The equilibrium constant for this reaction is obtained by dividing the products by the reactants as before:

$$K = \frac{\alpha_{\text{CaCO}_3} \cdot (\alpha_{\text{H}^+})^2}{\alpha_{\text{Ca}^{2+}} \cdot \alpha_{\text{H}_2\text{O}} \cdot P_{\text{CO}_2}},$$

in which the Greek letter alpha ( $\alpha$ ) represents activity and  $P_{\text{CO}_2}$  represents the pressure of carbon dioxide in the solution. Because the activities of pure water and solids are unit, the expression reduces to:

Use of  
Eh-pH  
diagrams  
to depict  
elements  
in more  
than one  
valence  
state

This equation says that equilibrium between the given

$$K = \frac{(\alpha_{H^+})^2}{\alpha_{Ca^{2+}} \cdot P_{CO_2}}$$

solution (calcium ions and water) and a gas (such as the Earth's atmosphere) is a function of the amount of calcium ( $\alpha_{Ca^{2+}}$ ), the square of the amount of hydrogen (expressed either as  $\alpha_{H^+}$  or as pH), and the pressure of the gas ( $P_{CO_2}$ ).

**Geochemical diagrams. Partial-pressure diagrams.** It is often convenient to portray diagrammatically the relations between mineral species in order to better understand their origin and mode of occurrence. One such diagram of broad practical value is the partial-pressure diagram. Any reaction that can be written so as to include a gas phase can be illustrated on such a diagram. As shown in Figure 1, which portrays the copper-sulfur-

Figure 1: Partial-pressure diagram of the Cu-S-O system with water as a mobile excess compound, at 25°C and one atmosphere total pressure (see text).

oxygen system, the lines on the diagram that separate solid phases represent the equilibrium condition between the two minerals. The reaction whereby native copper, Cu, reacts with sulfur, S, to produce chalcocite,  $Cu_2S$ , for instance is expressed by:

and the equilibrium constant ( $K$ ) is

$$K = \frac{1}{\sqrt{P_{S_2}}}$$

in which  $P_{S_2}$  is the partial pressure of sulfur gas in the system. The free energy of this reaction is -30.2 kilocalories, and the equilibrium constant,  $K$ , is  $10^{22.34}$ ; for this value of  $K$ , the partial pressure of sulfur at which the two minerals, Cu and  $Cu_2S$ , are in equilibrium is therefore  $10^{-44.28}$ . This is the position of the phase boundary on Figure 1. In like manner, boundaries involving oxides can also be calculated. Those reactions that involve only oxygen or sulfur in the gas phase plot as either horizontal or vertical lines on the figure. Those reactions that involve both gases plot as slanted lines. The slope depends on the relative amounts of the two gases involved. The diagram indicates that one could find Cu and  $Cu_2O$  in the same geological environment but that the pair Cu plus CuO is not geochemically stable; the two phases should always be separated by  $Cu_2O$ . The diagram also indicates that  $Cu_2O$ , CuO, and  $Cu_4(OH)_6SO_4$  can coexist at a unique combination of gas pressures. The point where all three phases occur is commonly called a triple point.

**Eh-pH diagrams.** Another commonly used geochemical diagram is the Eh-pH plot illustrated in Figure 2. By means of the Nernst equation, which relates the potential electromotive force of a reaction to the equilibrium constant, it is possible to construct a picture of mineral relations for elements that commonly exist in several valence states. Copper provides a useful example because it can exist in nature as the element  $Cu^0$  and in both the cuprous ( $Cu^+$ ) and cupric ( $Cu^{2+}$ ) states.

The upper slanted boundary on Figure 2 represents the conditions under which water decomposes to oxygen.

Figure 2: Eh-pH diagram of stability relations in the system Cu-S-C-H<sub>2</sub>O at 25°C and one atmosphere pressure (see text).

The reaction, at one atmosphere pressure and 298.16° K (25° C, or 77° F) is

in which the products of decomposition are four hydrogen ions ( $H^+$ ) and four electrons ( $e^-$ ), in addition to oxygen ( $O_2$ ). The equilibrium constant in this case is simply the logarithm of the activity of the hydrogen ions ( $\alpha_{H^+}$ ) raised to the fourth power because four ions are present. Thus, the Nernst equation relating cell potential and the equilibrium constant is:

$$Eh = E^0 + \frac{0.059}{4} \log (\alpha_{H^+})^4,$$

in which Eh is the potential of the reaction measured against the hydrogen electrode half cell (emf = 0), and  $E^0$  is the potential when all ionic species are at unit activity. Because pH is defined as the negative logarithm of the activity of the hydrogen ion ( $-\log \alpha_{H^+}$ ):

$$Eh = E^0 - 0.059 \text{ pH}.$$

This basic relationship defines the slope; by using the free energy relationship to cell potential previously given ( $\Delta G_R^0 = nE^0F$ ) it is possible to solve  $E^0$  and obtain:

$$Eh = 1.23 - 0.059 \text{ pH}.$$

In like manner, it is possible to solve for the intercept and slope of the bottom boundary on Figure 2, which represents the conditions under which water breaks down to hydrogen gas at one atmosphere pressure.

Lines between various pairs of copper-bearing minerals on Figure 2 represent equilibrium conditions between those pairs. Considering the conditions under which native copper is oxidized to cuprite,  $Cu_2O$ , for example:

in which  $Cu^0$  is native copper, reacting with water to produce cuprite, hydrogen ions, and two electrons ( $e^-$ ). The slope and intercept on the diagram can be determined in the manner given above for the  $H_2O:O_2$  relation.

Those reactions that do not involve a change in valence state (*i.e.*, only involve dissolved species but no electrons)

have phase boundaries that plot as vertical lines on the diagram. This means the reaction is independent of Eh and occurs only at a given concentration of dissolved species and fixed pH. The equilibrium boundary between the copper minerals tenorite, CuO, and malachite, Cu<sub>2</sub>(OH)<sub>2</sub>CO<sub>3</sub>, can be obtained from the reaction

in which malachite dissociates to produce cuprite, bicarbonate ion (HCO<sub>3</sub><sup>-</sup>), and hydrogen ion (H<sup>+</sup>). The free energy of the reaction and the equilibrium constant can be obtained as before, and because the activity of total carbon species is fixed for the entire diagram, the pH can readily be computed.

Use of  
geochemical  
diagrams  
with ore  
deposits

Diagrams such as these are exceedingly useful in understanding ore deposits. Under increasingly oxidizing conditions, for instance, but without much change in pH, a buried deposit that consists of copper, Cu, and copper sulfide, Cu<sub>2</sub>S, will change to malachite (Cu<sub>2</sub>(OH)<sub>2</sub>CO<sub>3</sub>) and possibly also brochantite (Cu<sub>4</sub>(OH)<sub>6</sub>SO<sub>4</sub>) toward the surface of the Earth. This is because the geochemical conditions become increasingly oxidizing (the Eh increases) from deep within the Earth's crust toward its surface. Thus, the occurrence at or near land surface of the secondary enrichment minerals, such as brochantite, antlerite, malachite, azurite, or tenorite, may be indicative of a large copper deposit lying hidden below.

Other diagrams also are useful and their variety is limited only by the available thermodynamic data and the ingenuity of the constructor. Some other examples are included in the next section on significant equilibria in nature.

#### GEOCHEMICAL EQUILIBRIA OF SIGNIFICANCE IN NATURE

**Carbonate equilibria in water.** The principal significance of the equilibrium constant in geochemistry is that it provides a means of calculating departure from equilibrium between the aqueous phase and solid mineralogic phases. Departure is determined by comparison of the thermodynamic equilibrium constant,  $K_{eq}$ , with the ion-activity product,  $K_{iap}$ , which is calculated from chemical analysis of water. Equilibrium studies identify the minerals that control the chemistry of water and assist in predicting changes that may occur with time or as a result of stress upon hydrologic systems. Determination of whether water is in equilibrium with a particular mineral requires knowledge of the equilibrium constant,  $K_{\text{mineral}}$ , which is obtained from physical-chemical laboratories, and the ion activity product,  $K_{iap}$ , which is calculated from chemical analysis of water. For example, in the solution of calcite to produce calcium and carbonate ions

in which CaCO<sub>3</sub> is calcite, Ca<sup>2+</sup> is calcium ion, and CO<sub>3</sub><sup>2-</sup> is carbonate ion, the equilibrium constant would be

$$K_{\text{calcite}} = \frac{\alpha_{\text{Ca}^{2+}} \cdot \alpha_{\text{CO}_3^{2-}}}{\alpha_{\text{CaCO}_3}},$$

in which the Greek letter alpha (α) again represents activity—of the calcium and carbonate ions and of calcite. The ion-activity product, as its name suggests, is equal to the product of the ions, namely:

$$K_{iap} = \alpha_{\text{Ca}^{2+}} \cdot \alpha_{\text{CO}_3^{2-}}.$$

The activities are calculated from chemical analysis of water, but because the dominant carbonate species in solution in water is bicarbonate rather than carbonate ion, the required reaction is bicarbonate dissociating to produce hydrogen ion and carbonate ion

in which HCO<sub>3</sub><sup>-</sup> is bicarbonate, H<sup>+</sup> is hydrogen ion, and CO<sub>3</sub><sup>2-</sup> is carbonate ion. The equilibrium constant for this reaction is given by

$$K_{\text{HCO}_3^-} = \frac{\alpha_{\text{H}^+} \cdot \alpha_{\text{CO}_3^{2-}}}{\alpha_{\text{HCO}_3^-}},$$

in which  $K_{\text{HCO}_3^-}$  is the equilibrium constant and the Greek letter (α) is activity of hydrogen, carbonate, and bicarbonate ions. Rearranging this equation to obtain the activity of the carbonate ion (α<sub>CO<sub>3</sub><sup>2-</sup></sub>):

$$\alpha_{\text{CO}_3^{2-}} = \frac{K_{\text{HCO}_3^-} \cdot \alpha_{\text{HCO}_3^-}}{\alpha_{\text{H}^+}},$$

in which  $K_{\text{HCO}_3^-}$  is a thermodynamic constant at a given temperature, activity of the bicarbonate (HCO<sub>3</sub><sup>-</sup>) is calculated from chemical analysis of the water, and activity of the hydrogen ion is determined from the pH of the water.

By making temperature corrections, the ion-activity product for calcite (CaCO<sub>3</sub>) can be calculated from activities of calcium and carbonate ions and compared with the equilibrium constant  $K_{\text{calcite}}$ . Because all systems in nature tend toward equilibrium, it is well established that where water is undersaturated with respect to a mineral, that mineral is being dissolved. Because of kinetic effects, however, it cannot be said categorically that where the water is supersaturated with respect to a mineral, that mineral is necessarily being precipitated. Groundwater in many areas attains supersaturation greater than 200 percent, and water from lakes and streams has been found to be even higher.

The complex chemistry of calcite, CaCO<sub>3</sub>, in the ocean involves interactions between the hydrosphere, atmosphere, lithosphere, and biosphere. This complexity is caused in part by the carbon dioxide (CO<sub>2</sub>) reacting with the seawater to form carbonic acid, H<sub>2</sub>CO<sub>3</sub>, which, in turn, dissociates to form CO<sub>3</sub><sup>2-</sup> and HCO<sub>3</sub><sup>-</sup>. At the pH of ocean water, as with most other water, the dissolved carbonate is in the form of HCO<sub>3</sub><sup>-</sup>. Because carbon dioxide, CO<sub>2</sub>, is involved in photosynthesis, its partial pressure exhibits systematic diurnal and seasonal cycles, which are reflected in changes of CaCO<sub>3</sub> equilibrium. Both mineral forms of CaCO<sub>3</sub> (calcite and aragonite) are found in the sea, with calcite being the more abundant. Aragonite is precipitated primarily by organisms, is metastable (an intermediate condition) with respect to calcite, and is converted to calcite under normal marine conditions.

Warm surface water of the ocean is supersaturated with respect to calcite. Values as high as 300 percent of saturation are common in the equatorial Atlantic Ocean. In the polar regions, the supersaturation is generally less than 150 percent. Studies of the waters off Bermuda indicate that only the deepest water is in equilibrium with the sediment present, in this case an ooze containing aragonite, and that the bulk of the water is supersaturated with respect to calcite. Factors such as particle size and magnesium content of the sediments seem to be important in controlling the degree of saturation. Low-magnesium calcite is the least soluble; calcite with 20 to 30 percent magnesium carbonate, MgCO<sub>3</sub>, is the most soluble; and aragonite is intermediate.

Calcite  
saturation  
in the  
Atlantic  
and  
Pacific  
oceans

In the Pacific Ocean, except for surface water, the water mass is undersaturated with respect to calcite. Pacific water with a temperature of about 14° C (57° F) tends to be saturated with respect to calcite; waters warmer than 20° C (68° F) are saturated with respect to aragonite.

Although ocean water is sometimes supersaturated with respect to a few other minerals, notably the apatites of the Pacific Ocean, it is undersaturated with respect to most minerals. A great amount of investigative work has been done, but the carbonate equilibrium of the oceans is still imperfectly understood, and fundamental questions about the rates of reactions remain.

**Iron equilibria.** Several geochemical principles that are involved in chemical weathering and sedimentation processes can be examined in terms of the behaviour of iron, which is typical of the elements in nature that exist in more than one valence state. The iron phases that are stable at near-surface conditions are native iron and the iron oxides hematite (Fe<sub>2</sub>O<sub>3</sub>) and magnetite (Fe<sub>3</sub>O<sub>4</sub>). One of the early fundamental tasks was determination of the activities of various dissolved ionic species involving iron, oxygen, and water [Fe<sup>2+</sup>, Fe(OH)<sup>2+</sup>, Fe(OH)<sub>3</sub><sup>2+</sup>, FeO<sub>2</sub><sup>-</sup>,

$\text{Fe}(\text{OH})^+$ ,  $\text{HFeO}_2^-$ , and  $\text{Fe}^{2+}$ ], and a few others (for which free-energy data are not available) that are in equilibrium with the solid oxides.

Both the number of solid phases and dissolved species are greatly increased when carbon dioxide, dissolved sulfur, and silica are added to the system. These relations have been described and explained largely by use of Eh-pH diagrams. A summary of the type of understanding gained from this approach is as follows:

Ion  
formation  
during  
weather-  
ing of  
igneous  
rocks

During weathering, part of the iron in the minerals of igneous rocks (those derived from silicate melts at high temperatures and pressures) is oxidized to cause the familiar brown, yellow, and red discoloration to the rock surface, and part of the iron is dissolved as ferrous ion,  $\text{Fe}^{2+}$ . The ferrous ion can be transported for long distances if the solutions remain slightly acidic and reducing, and if they do not contain other ions that would cause precipitation. The most common ions are carbonate, sulfide, and silicate; the precipitation reaction for any of these is aided by an increase in alkalinity of the solution. Primary controls on the precipitation of iron compounds are: the concentration of various ions; the acidity or alkalinity of the solution; and the degree of reduction of the environment. Iron sulfide, for example, precipitates only under extreme reducing conditions or from a solution in which the concentration of sulfide is great. The precipitation of iron carbonate and iron silicate depends primarily on the relative concentrations of bicarbonate and silicate ions. Ferrous iron oxidizes to hematite most readily under alkaline conditions (*i.e.*, conditions of pH greater than 7). The metal stays in solution as long as conditions remain constant and precipitates as any one of a number of minerals when conditions change. The precipitation reactions can occur in many different geologic situations, as summarized by the American geochemist K.B. Krauskopf (*Introduction to Geochemistry*, McGraw-Hill Book Co., 1967):

... by oxidation at the site of the original iron mineral, before any transportation has taken place; by oxidation in soil derived from the original rock, after only minor movement within the soil layer; by oxidation in streams, lakes, or swamps, when the water is aerated and loses its contained organic matter; in seawater, as oxide if the water is aerated, as carbonate or silicate if the water is mildly reducing, as sulfide if the redox potential is low and sulfur is abundant.

In some situations in which iron could be expected to precipitate, ferric oxide instead remains in suspension as an iron colloid and can be carried for long distances. This is the form in which iron is transported in aerated surface water. In some geologic environments, bacteria act as iron-precipitating agents by using the oxidation of iron compounds as an energy-producing reaction for their life processes.

Use of  
iron-equi-  
librium  
studies in  
ground-  
water  
chemistry

In addition to their contribution to the understanding of the occurrence of iron-ore minerals, iron-equilibrium studies have been extremely important in groundwater chemistry. A serious problem for many water users is objectionably high concentrations of dissolved iron that make the water unusable for many purposes. Another equally serious problem is the corrosion of well casings and pumps, which causes a great deal of maintenance expense. An adequate description of the local environment based on Eh, pH, mineralogy of aquifers (water-bearing strata) and direction of groundwater movement has made it possible in many places to predict the concentration of dissolved iron and to outline methods of treatment in potential water supplies before construction of wells. Similarly, the first step in developing a corrosion-abatement program is such a description of the chemical system in order to identify the deleterious corrosion and concomitant encrustation processes.

**Uranium-vanadium equilibrium.** The search for radioactive materials after World War II provided a great impetus for scientists to study chemical equilibrium because of complex problems associated with the origin and occurrence of uranium ores. Principles of modern low-temperature geochemistry were largely developed during this period of exploration for radioactive ores. Before about 1950, the chief uranium ore in the United States was

carnotite, a hydrated, potassium-bearing uranium, and vanadium oxide compound ( $\text{K}_2(\text{UO}_2)_2\text{V}_2\text{O}_8 \cdot 0 \text{ to } 3\text{H}_2\text{O}$ ), and it was believed to be a primary mineral precipitated during deposition of the surrounding sediments. The mineral is fully oxidized; uranium has a valence of six ( $\text{U}^{6+}$ ) and vanadium a valence of five ( $\text{V}^{5+}$ ). In deeper deposits, however, ore was found in which the valence states  $\text{U}^{4+}$  and  $\text{V}^{3+}$  existed, indicating a lesser degree of oxidation. Further search and study ultimately proved that uraninite ( $\text{UO}_2$ ), in which uranium has a valence of four, is the primary mineral, and carnotite is the secondary mineral resulting from oxidation processes. Before this conclusion was reached, several important questions had to be resolved in order to develop a consistent theory that led to a successful exploration program. The American geochemists R.M. Garrels and C.L. Christ have succinctly stated the problem as follows,

... if an unoxidized uranium ore consists of uraninite, monazite, and pyrite, with some sphalerite and galena, will oxidation yield the complex mineral assemblages observed? What oxidation products can coexist stably? Which minerals will oxidize first under near equilibrium conditions?

The solution was achieved by superposition of various Eh-pH diagrams constructed in the manner described in the foregoing discussion.

Details of uranium chemistry explain much of the origin and occurrence of its ore minerals. Although uranium has many valence states (+2, +3, +4, +5, and +6), only the +4 and +6 states are of geologic interest. Vanadium exists in the natural state in valences of +3, +4, and +5 and is complicated further by the great variety of complex ions. Uranium in its two lowest valence states is a sufficiently powerful reducing agent to decompose water to form hydrogen gas; in the presence of water, the +5 valence state is unstable with respect to +4 and +6 as follows:

in which  $\text{UO}_2^+$  is uranium oxide containing uranium in the +5 state and  $\text{UO}_2^{+2}$  is uranium oxide containing uranium in the +6 state. The transition from valence state +4 to +6 occurs in the following reaction:

in which uranium in the +4 state combines with water to produce  $\text{U}^{6+}$ -bearing uranium oxide, from hydrogen ions ( $\text{H}^+$ ) and two electrons ( $\text{e}^-$ ). The reaction has a potential ( $E^\circ = +0.33$  volt) that is within the normal range for redox potentials in nature. By obtaining equilibrium constants from free-energy data for various reactions, as discussed in the section on principles and techniques, it is quite easy to explain why the particular minerals are stable in the selected environments in which the ores exist.

**Kaolinite-gibbsite equilibria.** The distribution, origin, and formation of clay minerals demonstrate another group of chemical reactions that occur in nature. Clay minerals are hydrous aluminum silicates, and many contain other metals, primarily magnesium, iron, calcium, sodium, and potassium. The chemical composition of clay does not determine its properties, such as degree of plasticity and capacity for ion exchange. The primary control on clay properties is structure of the clay minerals, which may be examined by X-ray-diffraction cameras and electron microscopes. Many intriguing and unanswered questions of geochemistry remain centred around the origin of clay minerals. It is generally believed that clay is the stable product of weathering; that is, the minerals that represent final attainment of equilibrium between the original constituents of rock-forming minerals and conditions at the Earth's surface. It has not been clearly demonstrated whether the different clay minerals represent adjustments to slightly different weathering environments, or whether some of the minerals represent metastable intermediate varieties that are formed during weathering and ultimately are converted to other clay minerals. Experimental laboratory work suggests that acid solutions (pH less than 7) favour formation of kaolinite, and that basic or alkaline solutions

The geo-  
chemistry  
of clay  
minerals

(pH greater than 7) favour formation of montmorillonite. This conclusion is partly corroborated by data on the geologic occurrence of the two minerals.

Kaolinite is commonly the chief clay mineral in soils that occur on well-drained slopes in humid climates, where abundant vegetation makes soil solutions acid and where cations are effectively leached away (leaching is the percolating action of groundwater). Montmorillonite is characteristic of soils in less humid climates, where soil solutions are mainly alkaline and where cations are moved less rapidly. Illite is formed in environments that contain a high concentration of potassium ion and can be formed from montmorillonite. Illite is the common clay mineral in alkaline soils of desert areas.

The formation of bauxite

Another question of long standing has been the formation of bauxite, the important aluminum ore. The essence of the problem of origin of bauxite lies in the relation between kaolinite,  $H_4Al_2Si_2O_9$ , and gibbsite,  $Al_2O_3 \cdot 3H_2O$ . In many geological areas, kaolinite is the mineral that precedes the final dissolution of solids by agents of weathering. In other areas, the persistent mineral is gibbsite.

If equilibrium between kaolinite, gibbsite, dissolved silica, and water is assumed, then the following reaction can be written:

Severe leaching conditions generally are accepted as required for the formation of gibbsite, and the pore water must be reasonably pure; its activity therefore is fixed at unity. The equilibrium constant for the reaction is  $K_{eq} = [H_4SiO_4]^2$ , and the free energy of the reaction is +12.7 kilocalories. Equilibrium is attained between gibbsite and kaolinite at a fixed value of the activity (= concentration) of dissolved silica of about two parts per million of dissolved silica. At any lower value of dissolved silica, kaolinite should tend to dissolve, leaving a residuum of gibbsite.

The stability of gibbsite ( $Al_2O_3$ ) can be shown (Figure 3)

Figure 3: Gibbsite-kaolinite solution relations at 25° C and one atmosphere pressure, for acid conditions (see text).

as a volume on a diagram using pH,  $Al^{3+}$ , and dissolved silica ( $H_4SiO_4$ ) as variables, even though its stability alone is independent of  $H_4SiO_4$ . The boundary between gibbsite and kaolinite is a plane representing a fixed activity of  $H_4SiO_4$ . At  $H_4SiO_4$  activities greater than this value, kaolinite can be expected to dissolve congruently and thus leave no gibbsite residue. The prevalence of kaolinite in the upper levels of most soils formed under strong leaching conditions leads to the prediction that most soil-solution compositions are toward the rear of Figure 3.

The dashed arrows show the change in solution composition that results if kaolinite dissolves at a fixed pH. Under such conditions, the ratio of  $H_4SiO_4$  to  $Al^{3+}$  in solution is maintained at unity. If a kaolinite soil is subjected to leaching by rainwater, with pH fixed at 4, perhaps by living plants or decomposing organic materials that release carbon dioxide,  $CO_2$ , to the soil water, the solution composition will change along the line indicated by arrow 1, and the soil field intersected is that of kaolinite. In other words, kaolinite dissolves congruently to leave a kaolinite residue. On the other hand, if there is no pH buffering (i.e., stabilizing action by dissolved substances that release hydrogen ion) hydrogen ion ( $H^+$ ) will be used up when kaolinite dissolves, and the solution composition will change along a path similar to that shown by arrow 2, indicating incongruent solution of kaolinite to produce a gibbsite residue.

The diagram thus leads to a hypothesis concerning some major controls on the formation of bauxite and serves to show the utility of such methods of representation as stimuli to the collection of data about relations that might not otherwise be deduced. Most soils in areas of high rainfall and concomitant high leaching rates are kaolinitic; they also tend to have low pH values. The low pH apparently results in part from a high carbon dioxide content in the soil atmosphere, an effect induced by decomposition of organic materials in the soil and in part from pH lowering at the surfaces of roots. Perhaps under exceptional conditions of high rainfall and high temperature, bacterial decomposition is so rapid that carbon dioxide resulting from organic decomposition passes directly into the atmosphere, and the soils are so heavily leached that plant ground cover is relatively sparse. If these conditions occur, rainwater descending through the soil will be relatively unbuffered, and gibbsite residue could result. Whatever the details of the explanation, it does appear that the requirement of abundant unbuffered soil water for bauxite formation is in accordance with the occurrence of low silica-high alumina soil residues.

**Osmotic equilibria.** Certain earth materials, such as compacted clay minerals (shale), can act as semipermeable membranes; these materials restrict or prevent the passage of ions while allowing relatively unrestricted flow of neutral species, such as the water molecule. Among the phenomena resulting from the ion-exclusion properties of membranes are hyperfiltration and the development of osmotic pressure and of differences in electrical potential across them.

Hyperfiltration occurs when an electrolyte solution flows through a semipermeable membrane. As a result of ion exclusion, the effluent is less concentrated than the original solution.

Movement of water across a semipermeable membrane in the absence of an externally applied pressure differential may result from the existence of different salt concentrations on opposite sides of the membrane, from the existence of an electrical potential across the membrane, and also from the existence of different thermal-energy levels on either side of the membrane. Such phenomena are termed, respectively, chemical osmosis, electro-osmosis, and thermo-osmosis. Any one or a combination of these phenomena may cause pressure differentials across a membrane.

The phenomenon of chemical osmosis will occur when two aqueous phases having different salt concentrations (that is, different activities of water) are separated by a semipermeable membrane. At constant temperature, a greater net transfer of water will occur from the less saline solution (in which the activity of water is higher) through the membrane into the more saline solution (lower activity of water), causing the pressure to increase in the more saline solution and to decrease in the less saline, if the two solutions are confined. The pressure that must be applied to the more saline side of the membrane to cause the passage of water in both directions to be equal is termed osmotic pressure. An equation to express the relation between osmotic pressure and solution concentration, derived from thermodynamic arguments, is

Chemical osmosis, electro-osmosis, and thermo-osmosis

$$\pi = \frac{RT}{V_{H_2O}} \ln \frac{\alpha^I_{H_2O}}{\alpha^{II}_{H_2O}},$$

in which  $\pi$  (pi) is osmotic pressure,  $V_{H_2O}$  is the molar volume of pure water,  $\alpha^I_{H_2O}$  and  $\alpha^{II}_{H_2O}$  are the activities of water in solutions I and II, respectively,  $R$  is a constant, and  $T$  is absolute temperature.

The flow of water through the membrane to establish osmotic equilibrium is accompanied by ion-exclusion effects, which will increase the salinity of the solution on the low-pressure side of the membrane. The solution that passes through the membrane is less saline than that on either side and will tend to decrease the salinity on the high-pressure side of the membrane.

Some pressure and salinity data regarding water-bearing sedimentary rocks cannot be explained by simple gravitational flow of water or by solution of minerals. Certain of such geological relations can be explained by osmotically induced cross-formational movement of water, through shale that serves as a semipermeable membrane, from an aquifer in which water has a low concentration of dissolved salts to one in which water is more concentrated. Similarly, an externally applied pressure differential on the fluid phase may cause cross-formational water flow through a semipermeable shale membrane, with resultant ion-exclusion effects commonly referred to as salt filtering or hyperfiltration.

It has been postulated that salt filtering by clay or shale membranes may account for the formation of brine, some of which has a dissolved solids concentration greatly exceeding that of seawater. These various speculations are supported by experimental laboratory investigations.

The exact mechanism by which ion-exclusion occurs is not fully understood. One widely held hypothesis involves the fact that clay minerals have a net charge deficiency. To maintain overall electrical neutrality, the clay absorbs a large number of cations and some anions. As the clay is compacted, the absorbed ions from either side of a pore or channel overlap, so that the pore becomes positively charged. This charged channel repels cations from entering, and, in order to maintain electric neutrality across the membrane, anions are also restricted from moving through the membrane pores.

## Geography

Geography—*geō*, meaning "the earth," and *graphein*, "to write"—is the science that describes the Earth's surface. The concept of the discipline is simple, its study complex. The content is enormous and is constantly changing in both space and time. Since the features of the Earth's surface cannot be considered apart from the atmosphere above and the outer layers of the crust below, a zone of considerable vertical extent must be held in view, and all the phenomena, natural and man-made, that occur within it must be examined. This article falls into three parts. The first part is a short introduction that states in general terms the nature of geography as a discipline, outlines its interrelationship with other sciences, and notes briefly the changing role of the geographer from early times to the present day. The second part is a survey of geographical exploration that reveals how much of the world was known and therefore studied in

times past. The third part presents a discussion of modern geographical concepts. There are separate articles on CLIMATE; CLIMATIC CHANGE; CONTINENTAL DRIFT; CONTINENTAL SHELF AND SLOPE; CONTINENTS, DEVELOPMENT OF; MAPS AND MAPPING; OCEAN BASINS; OCEAN CURRENTS; OCEANIC RIDGES; OCEANS AND SEAS; and OCEANS, DEVELOPMENT OF; and also on individual continents, countries, cities, states, and physical features, as well as biographical articles on individual explorers. Articles on related disciplines within the physical, biological, and social sciences may also be consulted.

**The aims of geography and its relationship to other sciences.** The aim of the geographer is not merely to paint a word picture, however vivid, of the surface features of the Earth nor merely to map them, however accurately. While he must do these things, his work begins, not ends, with the collection and depiction of data and with the perception of the spatial patterns they make. To understand the patterns, he must analyze the location of the elements, establish the networks that link them, and seek to identify the processes that bring them about and subsequently alter them. The patterns are studied not as separate designs but, rather, as they occur together in close interrelationship. Furthermore, areas and places cannot be studied in isolation if reality is to be preserved. The city of London, for example; must be looked at within the context of England, England within Europe, and Europe within the world. Nature has few sharp boundaries, and man—increasingly mobile, his communication lines ever more speedy, efficient, and far-flung—is realizing more and more forcibly the unity of the world. So vast a field demands from its students clarity of purpose, patient and objective investigation, and integrity of interpretation if progress in its understanding is to be made.

If the subject itself is logically indivisible, its study must be subdivided if it is to be manageable. There are two ways of doing this: either the Earth's surface may be considered part by part, the approach of regional geography; or the elements that create the spatial patterns may be grouped like with like, the approach of systematic geography.

In the first half of the 20th century, the regional approach was perhaps predominant. The examination of all the geographical elements within a chosen area, as they interacted to give the area a unique character, and thus to differentiate it from other areas, was considered the ultimate aim of the geographer. In the second half of the century, however, it was thought by some that, since the Industrial Revolution began, there has been so rapid a spread of ideals, ideas, and techniques that regional differences have become of less importance than regional similarities. Thus, there has been a trend in favour of the systematic approach that represents an endeavour to form hypotheses to explain those features of spatial patterns that many areas share in common.

Systematic geography may be conveniently subdivided into physical geography, including climatology, hydrography, and the study of landforms; biogeography, the geography of soils and of plant, animal, and human populations; and human geography, the geography of the economic, political, and social activities of man in organized communities. Historical geography is concerned primarily with the human geography of the past and is of importance because so many of the present spatial patterns owe much to earlier ones.

Each of the groups of elements that the geographer examines in their association in spatial patterns is in its own right the subject of study of another specialist. Thus, there are close links between the geographer and the meteorologist, geologist, biologist, demographer, economist, political scientist, sociologist, and historian. The geographer even has links with the psychologist, philosopher, and theologian, because ideas as well as material things often find geographical expression. The geographer also needs a knowledge of the science and art of surveying and of cartography, for the map is the record of geographical data, and its constant study is second in importance only to work on the ground itself. By the early 1970s, statistical techniques, with the help of com-

The interrelationship of spatial patterns

Relationship to other subjects of study

puters and the building of models, had become fashionable aids to geographical analysis. In all these disciplines the geographer is a learner, not an investigator; he acquires from other scientists specific knowledge about each group of elements in which he is interested and, in return, gives them information about their spatial relationships with other phenomena.

It is, perhaps, the ecologist and the geographer who have the most in common. The unit of the ecologist is the ecosystem, a functional unit that includes both organisms and their nonliving environment. An ecosystem may vary in size and complexity from a pond to an ocean or from a copse to a forest. Some geographers have, indeed, defined their study as being that of human ecology, but this definition is not wholly valid: the ecologist's aim is the study of the functioning of his unit; the geographer's aim is the study of the distribution of functional units and of the spatial patterns that they form.

**The evolution of the role of the geographer.** The geographer has played many roles—as an explorer of the unknown world; as a map maker recording the geographical facts; as a scientist collating and arranging information to guide the search for more; and as a teacher educating his pupils the better to understand and appreciate the world of which they are a part.

In ancient Babylonia and Egypt, the geographer was most valued as a surveyor, remapping the boundaries that so often were obliterated by floods. In Greece, the geographer, then synonymous with the cosmographer, was a universal scientist since the specialist sciences, both natural and social, were as yet undifferentiated. Pythagoras and Aristotle, the Greek philosophers of the 6th century and 4th century BC, respectively, believed the Earth to be a sphere, and Pythagoras taught that it revolved around a central fire. Herodotus, the Greek historian of the 5th century BC, prefaced his history with a description of his world, speculated about the causes of volcanic eruptions and earthquakes, and discussed the courses of the major rivers and the reasons for the Nile floods. The Romans, essentially a practical people, were little interested in cosmographical hypotheses or geographical conundrums, but they needed roadbooks and road maps to guide soldiers and administrators throughout their empire: the Roman geographers were again the surveyors.

During the long years of internal dissension and external attack that followed the breakup of the Roman Empire in the West, scholars congregating in remote places looked inward, not outward; they studied the Bible, not the world, so that geographers became the henchmen of the theologians. The maps they produced were not attempts to portray reality but, in modern parlance, were “models,” illustrating theological concepts. In these centuries, the Muslims, not the Christians, were the scientists; Arab geographers in the 11th and 12th centuries preserved, added to, and handed on the Greek learning that early Christendom had first ignored and then lost.

Stimulated by this fruitful contact with the Arabs, Western geographers shook themselves free from the bondage of the medieval Christian Church, only to be enthralled anew—by Greek ideas, in general, and by the concepts of Ptolemy, the 2nd-century Greek geographer and astronomer, in particular. Because these geographers were not original thinkers but mere popularizers of Greek ideas, they even discarded Arab additions and corrections. Ptolemy's maps, drawn from tables constructed in the 2nd century AD, were regarded as authoritative until the 16th century. It was, indeed, belief in Ptolemy's exaggerated representation of the west-east extent of Asia that encouraged Christopher Columbus and fellow adventurers to sail westward on their momentous voyages.

The role of the geographers in the 15th- and 16th-century Age of Discovery was twofold: to promote exploration and to record the new knowledge on new maps. Of the men who backed the voyages some were scholars: among these were the Portuguese prince Henry the Navigator and, in England, the mathematician John Dee, the translator Richard Eden (both Cambridge dons), and the

Oxford geographer Richard Hakluyt. Others—including the Englishmen Roger Barlow, Robert Thorne, and John Frampton—were merchants. The map makers were equally important; the maps of the Venetian Contarini (1506), the German Martin Waldseemüller (1507), and the Dutch cartographer Johann Ruysch (1508) show early attempts to fit the new discoveries into Ptolemy's scheme. The great Dutch cartographers—Gerardus Mercator and Abraham Ortelius in the 16th century and Jodocus Hondius and Willem Blaeu in the late 16th and early 17th centuries—supported by the interests of a still growing empire, produced up-to-date atlases that at last outmoded the Ptolemies.

In the course of the 18th century, the governments of the day and the learned societies replaced individual geographers as patrons of explorers, and the central authorities, with the aid of professional surveyors and cartographers, took their place as map makers. The function of the geographers became primarily the study of the ever-increasing knowledge of the features of the Earth's surface.

The emergence of geography as an independent discipline in the universities was presaged by the interest taken in the subject by the 18th-century philosophers. The German writer Johann Wolfgang von Goethe, the German poet Friederich Schiller, and the German philosopher Friederich Hegel, by their interest in nature, the French philosopher Baron Charles de Montesquieu, by his discussion of the effects of the environment on nations in his book *De l'esprit des lois* (“The Spirit of Law”), published in 1748, and the German philosopher Immanuel Kant, through the lectures he gave on physical geography as a “part of the theory of knowledge,” all stimulated the study of geography.

Two Germans of the late 18th and early 19th centuries—Alexander von Humboldt, a natural scientist, and Carl Ritter, a historian—were the first to write and teach as academic geographers. Both attempted—Humboldt in *Kosmos* (“Cosmos”), Ritter in *Die Erdkunde* (“Geography”)—to write books that would order and arrange all geographical knowledge in a systematic fashion: both died with their mammoth works unfinished, although their concepts laid the foundation of modern geography. The essential role of the geographer since their day has been that of the scholar, the scientist, and the teacher.

But the geographer has not lost his practical functions. With increasing confidence he emerges from the seclusion of the university to take his part in public life. Contemporary geographers, developing specialized studies, play a role in a society that is much concerned with planning the proper use of its environment.

### A survey of geographical exploration

The world as known to the Incas of Peru in the 15th century must have had little in common with the world as known to their contemporaries the Italians. A survey of geographical exploration must therefore be made from a particular viewpoint; in this article the viewpoint is that of Europe.

The motives that spur men to examine their environment are many. Strong among them are the satisfaction of curiosity, the pursuit of trade, the conversion of the heathen, and the desire for security and political power. At different times and in different places, different motives are dominant; sometimes one motive inspires the promoters of discovery, another, the men who carry out the search.

The threads of geographical exploration are continuous and, being entwined one with another, are difficult to break or separate; three major sections may nevertheless be recognized. The first is the exploration of the Old World centred on the Mediterranean Sea; the second is the Age of Discovery, during which, in the search for sea routes to Cathay (the name by which China became known to medieval Europe), a New World was found; the third is the establishment of the geographical relationships of the New World to the Old and the elucidation of the major physical features of the continental interiors—in short, the delineation of the modern world.

Emergence  
of the  
geograph-  
ical  
discipline

A comparative study of the maps of the world illustrating this article and one in any modern atlas reveals vividly the progress that man has made in the exploration of the Earth.

#### THE EXPLORATION OF THE OLD WORLD

The period from the earliest recorded history to the beginning of the 15th century sees knowledge of the world widen from a river valley surrounded by mountains or desert (the views of Babylonia and Egypt) to a Mediterranean world with hinterlands extending from the Sahara to the Gobi deserts and from the Atlantic to the Indian oceans (the view of Greece and Rome), and later expand again to include the far northern lands beyond the Baltic and another and dazzling civilization in the Far East (the medieval view).

By courtesy of the Library of Congress, Washington, D.C.

Map showing the geographical knowledge of the world derived from the writings of Hecataeus of Miletus, c. 500 BC.

The earliest known map

The earliest known surviving map, dating probably from the time of Sargon of Akkad (about 2334–2279 BC), shows canals or rivers—perhaps the Tigris and a tributary—and surrounding mountains. The rapid colonization of the shores of the Mediterranean and of the Black Sea by Phoenicia and the Greek city-states in the first millennium BC must have been accompanied by the exploration of their hinterlands by countless unknown soldiers and traders. Herodotus prefaces his *History* (written in the 5th century BC) with a geographical description of the then known world: it reveals that the coastlines of the Mediterranean and the Black Sea had by then been explored. (See the Herodotus map in the article MAPS AND MAPPING.)

Stories survive of a few men who are credited with bringing new knowledge from distant journeys. Herodotus tells of five young adventurers of the tribe of the Nasamones living on the desert edge of Cyrenaica in North Africa, who journeyed southwest for many months across the desert, reaching a great river flowing from west to east; this presumably was the Niger, although Herodotus thought it to be the Upper Nile.

**Exploration of the Atlantic coastlines.** Beyond the Pillars of Hercules (the Strait of Gibraltar), the Carthaginians (from the Phoenician city of Carthage in what is now Tunisia), holding both shores of the strait, early ventured out into the Atlantic. A Greek translation of a Punic (Carthaginian) inscription states that Hanno, a Carthaginian, was sent forth about 500 BC with 60 ships

and 30,000 colonists “to found cities.” Even allowing for a possible great exaggeration of numbers, this expedition, if it occurred, can hardly have been the first exploratory voyage along the coast of West Africa. Some think that Hanno reached only the desert edge south of the Atlas, others identify the “deep river infested with crocodiles and hippopotamuses” with the Sénégal River, and the island where men “scampered up steep rocks and pelted us with stones” with one off the coast of Sierra Leone. There is no record that Hanno’s voyage was followed up before the era of Henry the Navigator.

About the same time, Himilico, another Carthaginian, set forth on a voyage northward; he explored the coast of Spain, reached Brittany, and in his four-month cruise may have visited Britain. Two centuries later, about 300 BC, Carthaginian power at the gate of the Mediterranean temporarily slackened as a result of squabbles with the Greek city of Syracuse on the island of Sicily, so Pytheas, a Greek explorer of Massilia (Marseille), sailed through. His story is only known from fragments of the work of a contemporary historian, Timaeus (who lived in the 4th and 3rd centuries BC), as retold by the Roman savant Pliny the Elder, the Greek geographer Strabo, and the Greek historian Diodorus Siculus, all of whom were critical of its truth. It is probable that Pytheas, having coasted the shores of the Bay of Biscay, crossed from the island of Ouessant (Ushant), off the French coast of Brittany, to Cornwall in southwest England, perhaps seeking tin. He may have sailed round Britain; he describes it as a triangle and also relates that the inhabitants “harvest grain crops by cutting off the ears . . . and storing them in covered granges.” Around Thule, “the northernmost of the British Isles, six days sail from Britain,” there is “neither sea nor air but a mixture like sea-lung . . . binds everything together,” a reference perhaps to drift ice or dense sea fog. Thule has been identified with Iceland (too far north), with Mainland island of the Shetland group (too far south), and perhaps, most plausibly, with Norway. Pytheas returned to Brittany and explored “beyond the Rhine”; he may have reached the Elbe. The voyage of Pytheas, like that of Hanno, does not seem to have been followed up. Herodotus concludes by saying “whether the sea girds Europe round on the north none can tell.”

It was not Mediterranean folk but Northmen from Scandinavia, emigrating from their difficult lands centuries later, who carried exploration farther in the North Atlantic. From the 8th to the 11th century bands of Northmen, mainly Swedish, trading southeastward across the Russian plains, were active under the name of Varangians in the ports of the Black Sea. At the same time other groups, mainly Danish, raiding, trading, and settling along the coasts of the North Sea, arrived in the Mediterranean in the guise of Normans. Neither these Swedes nor Danes were exploring lands which were unknown to civilized Europeans, but doubtless they brought to these Europeans new knowledge of the distant northern lands.

It was the Norsemen of Norway who were the true explorers although, since little of their exploits was known to contemporaries and that little soon forgotten, they perhaps added less to the common store of Europe’s knowledge than their less adventurous compatriots. About AD 890, Othere of Norway, “desirous to try how far that country extended north,” sailed round the North Cape, along the coast of Lapland to the White Sea. But most Norsemen sailing in high latitudes explored not eastward but westward. Sweeping down the outer edge of Britain, settling in Orkney, Shetland, the Hebrides, and Ireland, they then voyaged on to Iceland, where in 870 they settled among Irish colonists who had preceded them by some two centuries. The Norsemen may well have arrived piloted by Irish sailors; and Irish refugees from Iceland, fleeing before the Norsemen, may have been the first discoverers of Greenland and Newfoundland, although this is mere surmise. The saga of Eric the Red (*Eiriks saga rauða*; also called *Thorfinns saga Karlsefnis*), a Norwegian, gives the story of the discovery of Greenland in 982; the west coast was ex-

The Northmen

plored, and at least two settlements were established on it. About AD 1000, one Bjarni Herjulfsson, on his way from Iceland to Greenland, was blown off course far to the southwest; he saw an unknown shore and returned to tell his tale. Leif, Eric's son, together with some 30 others, set out in 1001 to explore. They probably reached the coasts of Labrador and Newfoundland; some think that the farthest point south reached by the settlers, as described in the sagas, fits best with Maryland or Virginia, but others contend that the lands about the Gulf of St. Lawrence are more probably designated. The area was named Vinland, as grapes grew there, but it has been suggested that the "grapes" referred to were in fact cranberries. Attempts at colonization were unsuccessful, the Norsemen withdrew, and, although the Greenland colonies lingered on for some four centuries, little knowledge of these first discoveries came down to colour the vision of the seamen of Cádiz or Bristol; the voyages of Christopher Columbus and John Cabot had their strongest inspirations in quite other traditions.

**The exploration of the coastlines of the Indian Ocean and the China Sea.** Trade, across the land bridges and through the gulfs linking those parts of Asia, Africa, and Europe that lie between the Mediterranean and Arabian seas, was actively pursued from very early times. It is therefore not surprising that exploratory voyages early revealed the coastlines of the Indian Ocean. Herodotus wrote of Necho II, king of Egypt in the late 7th and early 6th centuries BC, that "when he stopped digging the canal . . . from the Nile to the Arabian Gulf . . . [he] sent forth Phoenician men in ships ordering them to sail back by the Pillars of Hercules." According to the story, this, in three years, they did. Upon their return, "they told things . . . unbelievable by me," says Herodotus, "namely that in sailing round Libya they had the sun on the right hand." Whatever he thought of the story of the sun, Herodotus was inclined to believe in the voyage: "Libya, that is Africa, shows that it has sea all round except the part that borders on Asia." Strabo records another story with the same theme: one Eudoxus, returning from a voyage to India in about 108 BC, was blown far to the south of Cape Guardafui. Where he landed he found a wooden prow with a horse carved on it, and he was told by the Africans that it came from a wrecked ship of men from the west.

About 510 BC, Darius the Great, king of Persia, sent one of his officers, Scylax of Caria, to explore the Indus. Scylax travelled overland to the Kabul River, reached the Indus, followed it to the sea, sailed westward, and, passing by the Persian Gulf (which was already well-known), explored the Red Sea, finally arriving at Arsinoë, near modern Suez. The greater part of the campaigns of the famous conqueror Alexander the Great were military exploratory journeys. The earlier expeditions through Babylonia and Persia were through regions already familiar to the Greeks, but later ones through the great tract of land from the south of the Caspian Sea to the mountains of the Hindu Kush brought the Greeks much new geographical knowledge. Alexander and his army crossed the mountains to the Indus Valley and then made a westward march from the lower Indus to Susa through the desolate country along the southern edge of the Iranian plateau; Nearchus, his admiral, in command of the naval forces of the expedition, waited for the favourable monsoon and then sailed from the mouth of the Indus to the mouth of the Euphrates, exploring the Asiatic coast of the Persian Gulf on his way.

As Roman power grew, increasing wealth brought increasing demands for Oriental luxuries; this led to great commercial activity in the eastern seas. As the coasts became well-known, the seasonal character of the monsoonal winds was skillfully used; the southwest monsoon was long known as Hippalus, named for a sailor who was credited with being the first to sail with it direct from the Gulf of Aden to the coast of the Indian peninsula. During the reign of the Roman emperor Hadrian in the 1st century BC, Western traders reached Siam (now Thailand), Cambodia, Sumatra, and Java; a few seem also to have penetrated northward to the coast of China. In AD 161,

according to Chinese records, an "embassy" came from the Roman emperor Marcus Aurelius to the emperor Huan Ti, bearing goods that Huan Ti gratefully received as "tribute." Ptolemy, however, does not know of these voyages: he sweeps his peninsula of Colmorgo (Malay) southwestward to join the eastward trend of his coast of Africa, thus creating a closed Indian Ocean (see the map of Ptolemy in the article MAPS AND MAPPING). He presumably did not believe the story of the circumnavigation of Africa. As the 2nd century AD passed, and Roman power declined, trade with the eastern seas did not cease but was gradually taken over by Ethiopians, Parthians, and Arabs. The Arabs, most successful of all, dominated eastern sea routes from the 3rd to the 15th century. In the tales of derring-do of Sindbad the Sailor (a hero of the collection of Arabian tales of unknown date and authorship called *The Thousand and One Nights*), there may be found, behind the fiction, the knowledge of these adventurous Arab sailors and traders, supplying detail to fill in the outline of the geography of the Indian Ocean.

**The land routes of Central Asia.** The prelude to the Age of Discovery, however, is to be found neither in the Norse explorations in the Atlantic nor in the Arab activities in the Indian Ocean but, rather, in the land journeys of Italian missionaries and merchants that linked the Mediterranean coasts to the China Sea. Cosmas Indicopleustes, an Alexandrian geographer writing in the 6th century, knew that Tzinitza (China) could be reached by sailing eastward, but he added: "one who comes by the overland route from Tzinitza to Persia makes a very short cut." Goods had certainly passed this way since Roman times, but they usually changed hands at many a mart, for disorganized and often warring tribes lived along the routes. In the 13th century the political geography changed. In 1216 a Mongol chief assumed the title of Gengis Khan and, after campaigns in China that gave him control there, turned his conquering armies westward. He and his successors built up an enormous empire until, in the late 13th century, one of them, Kublai Khan, reigned supreme from the Black Sea to the Yellow Sea. Europeans of perspicacity saw the opportunities that friendship with the Mongol power might bring. If Christian Europe could only convert the Mongols, this would at one and the same time heavily tip the scales against Muslim and in favour of Christian power and also give political protection to Christian merchants along the silk routes to the legendary sources of wealth in China. With these opportunities in mind, Pope Innocent IV sent friars to "diligently search out all things that concerned the state of the Tartars," and to exhort them "to give over their bloodie slaughter of mankind and to receive the Christian faith." Among others, Giovanni da Pian del Carpine in 1245 and Willem van Ruysbroeck in 1253 went forth to follow these instructions. Travelling the great caravan routes from southern Russia, north of the Caspian and Aral seas and north of the Tien Shan, they eventually reached the court of the emperor at Karakorum. Carpine returned confident that the Emperor was about to become a Christian; Ruysbroeck told of the city in Cathay "having walls of silver and towers of golde"; he had not seen it but had been "credibly informed" of it.

But the greatest of the 13th-century travellers in Asia were the Polos, wealthy merchants of Venice. In 1260 the brothers Nicolo and Maffeo Polo set out on a trading expedition to the Crimea. After two years they were ready to return to Venice, but, finding the way home blocked by war, they travelled eastward to Bukhara (now in the Uzbek Soviet Socialist Republic in the Soviet Union), where they spent another three years. They then accepted an invitation to accompany a party of Tatar envoys returning to the court of Kublai Khan at Cambaluc, near Peking. The Khan received them well, provided them with a gold tablet as a safe-conduct back to Europe, and gave them a letter begging the Pope to send "some hundred wise men, learned in the law of Christ and conversant with the seven Arts to preach to his people." The Polos arrived home, "having toiled three years on the way," to find that Pope Clement IV was dead. Two years

The campaigns of Alexander the Great

Travels of the Polos

later they set off again, without the wise men, but taking with them Nicolo's son, Marco Polo, then a youth of 17. (Marco kept detailed notes of all he saw and, late in life when a captive of the Genoese, dictated to a fellow prisoner a book containing an account of his travels.) This time the Polos took a different route: starting from the port of Ormuz on the Persian Gulf, they crossed Persia to the Pamirs and then followed a caravan route along the southern edge of the Tarim Basin and Gobi Desert to Cambaluc. Knowledge of the route is interesting, but the great contribution of Marco Polo to the geographical knowledge of the West lay in his vivid descriptions of the East. He had great opportunities of seeing China and appreciating its life, for he was taken into the service of the Khan and was sent as an administrator to great cities, busy ports, and remote provinces, with instructions to write full reports. In his book he described how, upon every main highroad, at a distance apart of 25 or 30 miles (40 to 50 kilometres), there were stations, with houses of accommodation for travellers, with 400 good horses kept in constant readiness at each station. He also reported that, along the roads, the Grand Khan had caused trees to be planted, both to provide shade in summer and to mark the route in winter when the ground was covered with snow. Marco Polo lived and worked in western China, visiting the provinces of Shensi, Szechwan, and Yunnan, as well as the borders of Burma. He frequently visited "the noble and magnificent city of Quinsay [Hangchow], a name that signifies the Celestial City and which it merits from its pre-eminence to all others in the world in point of grandeur and beauty." Cipango (Japan) he did not visit but heard about it from merchants and sailors: "it is situated at a distance of 1,500 miles from the mainland . . . They have gold in the greatest abundance its sources being inexhaustible." The most detailed descriptions and the greatest superlatives were reserved for Cambaluc, capital of Cathay, whose splendours were beyond compare; to this city, he said,

everything that is most rare and valuable in all parts of the world finds its way: . . . for not fewer than 1,000 carriages and pack-horses loaded with raw silk make their daily entry; and gold tissues and silks of various kinds are manufactured to an immense extent.

No wonder that, when Europe learned of these things, it became enthralled. After 17 years, the Venetians were permitted to depart; they returned to Europe by sea. After visiting Java they sailed through the Strait of Malacca (again proving the error of Ptolemy) and, landing at Ormuz, they travelled cross-country to Armenia, and so home to Venice, which they reached in 1295.

A few travellers followed the Polos. Giovanni da Montecorvino, a Franciscan friar from Italy, became archbishop of Peking and lived in China from 1294 to 1328. Friar Oderic of Pordenone, an Italian monk, became a missionary, journeying throughout the greater part of Asia between 1316 and 1330. He reached Peking by way of India and Malaya, then travelled by sea to Canton; he returned to Europe by way of Central Asia, visiting Tibet in 1325—the first European to do so. Friar Oderic's account of his journeys had considerable influence in his day: it was from it that the spurious traveller, the English writer Sir John Mandeville, quarried most of his stories.

Ibn Batṭūṭah, an Arab of Tangier, journeyed farther perhaps than any other medieval traveller. In 1325 he set out to make the traditional pilgrimage to Mecca and in some 30 years he visited the greater part of the Old World, covering, it has been said, more than 75,000 miles. He was the first to explore much of Arabia; he travelled extensively in India; he reached Java and Southeast Asia. Then toward the end of his life he returned to the west where, after visiting Spain, he explored western Sudan "to the northernmost province of the Negroes." He reached the Niger, which he calls the Nile, and was astonished by the huge hippopotamuses "taking them to be elephants." When he finally returned to Fez in Morocco he "kissed the hand of the Commander of the Faithful the Sultan . . . and settled down under the wing of his bounty." He wrote a vivid and perspicacious account of his travels but his book did not become known

to Christian Europe for centuries. It was Marco Polo's book that was the most popular of all. Some 138 manuscripts of it survive: it was translated before 1500 into Latin, German, and Spanish, and the first English translation was published in 1577. For centuries Europe's maps of the Far East were based on the information provided by Marco Polo; even as late as 1533 Johannes Schöner, the German maker of globes, wrote:

Behind the Sinae and the Ceres [legendary cities of Central Asia] . . . many countries were discovered by one Marco Polo . . . and the sea coasts of these countries have now recently again been explored by Columbus and Amerigo Vespucci in navigating the Indian Ocean.

Columbus possessed and annotated a copy of the Latin edition (1483–85) of Marco Polo's book, and in his journal he identified many of his own discoveries with places that Marco Polo describes.

Thus, with Ptolemy in one hand and Marco Polo in the other, the European explorers of the Age of Discovery set forth to try to reach Cathay and Cipango by new ways; Ptolemy promised that the way was short, Marco Polo that the reward was great.

#### THE AGE OF DISCOVERY

In the 100 years from the mid-15th to the mid-16th century, a combination of circumstances stimulated men to seek new routes; and it was new routes rather than new lands that filled the minds of kings and commoners, scholars and seamen. First, toward the end of the 14th century, the vast empire of the Mongols was breaking up; thus, Western merchants could no longer be ensured of safe-conduct along the land routes. Secondly, the growing power of the Ottoman Turks, who were hostile to Christians, blocked yet more firmly the outlets to the Mediterranean of the ancient sea routes from the East. Thirdly, new nations on the Atlantic shores of Europe were now ready to seek overseas trade and adventure.

**The sea route east by south to Cathay.** Henry the Navigator, prince of Portugal, initiated the first great enterprise of the Age of Discovery—the search for a sea route east by south to Cathay. His motives were mixed. He was curious about the world; he was interested in new navigational aids and better ship design and was anxious to test them; he was also a crusader and hoped that, by sailing south and then east along the coast of Africa, Arab power in North Africa could be attacked from the rear. The promotion of profitable trade was yet another motive; he aimed to divert the Guinea trade in gold and ivory away from its routes across the Sahara to the Moors of Barbary (North Africa) and instead channel it via the sea route to Portugal. How soon the idea of finding a new sea route to Cathay came consciously into Henry's mind is not clear; but certainly by his death in 1460 he had formulated this aim.

Expedition after expedition was sent forth throughout the 15th century to explore the coast of Africa. In 1445, the Portuguese navigator Dinas Dias reached the mouth of the Sénégal, which "men say comes from the Nile, being one of the most glorious rivers of Earth, flowing from the Garden of Eden and the earthly paradise." Once the desert coast had been passed, the sailors pushed on: in 1455 and 1456 Alvise Ca' da mosto made voyages to Gambia and the Cape Verde Islands. All seemed promising; trade was good with the riverine peoples, and the coast was trending hopefully eastward. Then the disappointing fact was realized: the head of a great gulf had been reached, and, beyond, the coast seemed to stretch endlessly southward. Yet, when Columbus sought backing for his plan to sail westward across the Atlantic to the Indies, he was refused—"seeing that King John II [Henry's successor] ordered the coast of Africa to be explored with the intention of going by that route to India."

King John II sought to establish two routes: the first, a land and sea route through Egypt and Ethiopia to the Red Sea and the Indian Ocean and, the second, a sea route around the southern shores of Africa, the latter an act of faith, since Ptolemy's map showed a landlocked Indian Ocean. In 1487, a Portuguese emissary, Pêro da Covilhã, successfully followed the first route but, on re-

Henry the Navigator

The search for routes to Asia

Other European travellers in Asia

turning to Cairo he reported that, in order to travel to India, the Portuguese "could navigate by their coasts and the seas of Guinea." In the same year another Portuguese navigator, Bartolomeu Dias, found encouraging evidence that this was so. In 1487 he rounded the Cape of Storms in such bad weather that he did not see it, but he satisfied himself that the coast was now trending northeastward; before turning back, he reached the Great Fish River, in what is now South Africa. On the return voyage, he sighted the Cape and set up a pillar upon it to mark its discovery.

The seaway was now open, but eight years were to elapse before it was exploited. In 1492 Columbus had apparently reached the East by a much easier route. By the end of the decade, however, doubts of the validity of Columbus' claim were current. Interest was therefore renewed in establishing the sea route south by east to the known riches of India. In 1497 a Portuguese captain, Vasco da Gama, sailed in command of a fleet under instructions to reach Calicut, on India's west coast. This he did after a magnificent voyage around the Cape of Storms (which he renamed the Cape of Good Hope) and along the unknown coast of East Africa. Yet another Portuguese fleet set out in 1500, this one being under the command of Pedro Alvarez Cabral; on the advice of da Gama, Cabral steered southwestward to avoid the calms of the Guinea coast; thus, en route for Calicut, Brazil was discovered. Soon trading depots, known as factories, were built along the African coast, at the strategic entrances to the Red Sea and the Persian Gulf, and along the shores of the Indian peninsula. In 1511 the Portuguese established a base at Malacca, commanding the straits into the China Sea; in 1511 and 1512, the Moluccas, or Spice Islands, and Java were reached; in 1557 the trading port of Macau was founded at the mouth of the

Canton River. Europe had arrived in the East. It was in the end the Portuguese, not the Turks, who destroyed the commercial supremacy of the Italian cities, which had been based on a monopoly of Europe's trade with the East by land. But Portugal was soon overextended; it was therefore the Dutch, the English, and the French who in the long run reaped the harvest of her enterprise.

Some idea of the knowledge that these trading explorers brought to the common store may be gained by a study of contemporary maps. The map of the German Henricus Martellus, published in 1492, shows the shores of North Africa and of the Gulf of Guinea more or less correctly and was probably taken from numerous seamen's charts. The delineation of the west coast of southern Africa from the Guinea Gulf to the Cape suggests a knowledge of the charts of the expedition of Bartolomeu Dias. The coastlines of the Indian Ocean are largely Ptolemaic with two exceptions: first, the Indian Ocean is no longer landlocked; and second, the Malay Peninsula is shown twice—once according to Ptolemy and once again, presumably, according to Marco Polo. The Contarini map of 1506 shows further advances; the shape of Africa is generally accurate, and there is new knowledge of the Indian Ocean, although it is curiously treated. Peninsular India (on which Cananor and Calicut are named) is shown; although too small, it is, however, recognizable. There is even an indication to the east of it of the Bay of Bengal, with a great river running into it. Eastward of this is Ptolemy's India, with the huge island of Taprobane—a muddled representation of the Indian peninsula and Ceylon. East again, as on the map of Henricus Martellus, the Malay Peninsula appears twice. Ptolemy's bonds were hard to break.

**The sea route west to Cathay.** It is not known when the idea originated of sailing westward in order to reach

World map by J.M. Contarini, 1506, depicting the expanding horizons becoming known to European geographers in the Age of Discovery.

### The voyages of Columbus

Cathay. Many sailors set forth searching for islands in the west; and it was a commonplace among scientists that the east could be reached by sailing west, but to believe this a practicable voyage was an entirely different matter. Christopher Columbus, a Genoese or Spaniard who had settled in Lisbon about 1477, argued that Cipango lay a mere 2,500 nautical miles west of the Canary Islands in the eastern Atlantic. He took 45 instead of 60 nautical miles as the value of a degree; he accepted Ptolemy's exaggerated west-east extent of Asia and then added to it the lands described by Marco Polo, thus reducing the true distance between the Canaries and Cipango by about one-third. He could not convince the Portuguese scientists nor the merchants of Lisbon that his idea was worth backing; but eventually he obtained the support of King Ferdinand and Queen Isabella of Spain. The sovereigns probably argued that the cost of equipping the expedition would not be very great; the loss, if it failed, could be borne; the gain, should it succeed, was incalculable—indeed, it might divert to Spain all the wealth of Asia.

On August 3, 1492, Columbus sailed from Palos, Spain, with three small ships manned by Spaniards. From the Canaries he sailed westward, for, on the evidence of the globes and maps in which he had faith, Japan was on the same latitude. If Japan should be missed, Columbus thought that the route adopted would land him, only a little further on, on the coast of China itself. Fair winds favoured him, the sea was calm, and, on October 12, landfall was made on an island now generally identified as Watling Island in the Bahamas. With the help of Amerindians, the ships reached Cuba and then Haiti. Although there was no sign of the wealth of the lands of Kublai Khan, Columbus nevertheless seemed convinced that he had reached China, since, according to his reckoning, he was beyond Japan. A second voyage in 1493 and 1494, searching fruitlessly for the court of Kublai Khan, further explored the islands of "the Indies." Doubts seem to have arisen among the would-be colonists as to the identity of the islands since Columbus made all take an oath that Cuba was the southeast promontory of Asia—the Golden Chersonese. On his third voyage, in 1498, Columbus sighted Trinidad, entered the Gulf of Paria, on the coast of what is now Venezuela, and annexed for Spain "a very great continent . . . until today unknown." On a fourth voyage, from 1502 to 1504, he coasted Central America from Honduras to Darien on the Isthmus of Panama, seeking a navigable passage to the west. What passage he had in mind is obscure; if he still believed he had reached Asia, perhaps he sought a way through Ptolemy's Golden Chersonese into the Indian Ocean.

The tenacity, the courage, the skill in navigation that Columbus showed makes him stand out among the very few explorers who have changed substantially men's ideas about the world. At the time, however, his efforts must have seemed ill-rewarded: he found no emperor's court rich in spices, silks, gold, or precious stones but had to contend with mutinous sailors, dissident colonists, and disappointed sovereigns. He died at Valladolid in 1506. Did he believe to the end that he had reached Cathay, or did he dimly perceive that he had found a New World?

Whatever Columbus thought, it was clear to others that there was much to be investigated, and probably much to be gained, by exploration westward. Not only in Lisbon and Cádiz but also in other Atlantic ports, groups of men congregated in hopes of joining in the search. In England, Bristol, with its western outlook and Icelandic trade, was the port best placed to nurture adventurous seamen. In the latter part of the 15th century, John Cabot, with his wife and three sons, came to Bristol from Genoa or Venice. His project to sail west gained support, and with one small ship, the "Matthew," he set out in May 1497, taking a course due west from Dursey Head, Ireland. His landfall on the other side of the ocean was probably on the northern peninsula of what is now known as Newfoundland. From here, Cabot explored southward, perhaps encouraged to do so, even if seeking a westward passage, by ice in the Strait of Belle Isle. Little is known of John Cabot's first voyage, and almost nothing

of his second, in 1498, from which he did not return, but his voyages in high latitudes represented almost as great a navigational feat as those of Columbus.

The coasts between the landfalls of Columbus and of John Cabot were charted in the first quarter of the 16th century by Italian, French, Spanish, and Portuguese sailors. Sebastian Cabot, son of John, gained a great reputation as a navigator and promoter of Atlantic exploration, but whether this was based primarily on his own experience or on the achievements of his father is uncertain. In 1499 Amerigo Vespucci, an Italian merchant living in Seville, together with the Spanish explorer Alonso de Ojeda, explored the north coast of South America from Surinam to the Golfo de Venezuela. His lively and embellished description of these lands became popular, and Waldseemüller, on his map of 1507, gave the name America to the southern part of the continent.

The 1506 map of Contarini represented a brave attempt to collate the mass of new information, true and false, that accrued from these western voyages. The land explored by Columbus on his third voyage and by Vespucci and de Ojeda in 1499 is shown at the bottom left of the map as a promontory of a great northern bulge of a continent extending far to the south. The northeast coast of Asia at the top left is pulled out into a great peninsula on which is shown a big river and some mountains representing Contarini's concept of Newfoundland and the lands found by the Cabots and others. In the wide sea that separates these northern lands from South America, the West Indies are shown. Halfway between the Indies and the coast of Asia, Japan is drawn. A legend placed between Japan and China reveals the state of opinion among at least some contemporary geographers; it presumably refers to the fourth voyage of Columbus in 1502 and may be an addition to the map. It runs:

Christopher Columbus, Viceroy of Spain, sailing westwards, reached the Spanish islands after many hardships and dangers. Weighing anchor thence he sailed to the province called Ciambra [a province which then adjoined Cochinchina].

Others did not agree with Contarini's interpretation. To more and more men it was becoming plain that a New World had been found, although for a long time there was little inclination to explore it but instead a great determination to find a way past it to the wealth of Asia. Yet the voyage of the Portuguese navigator Ferdinand Magellan, from 1519 to 1521, dispelled two long-cherished illusions: first, that there was an easy way through the barrier and, second, that, once the barrier was passed, Cathay was near at hand.

Ferdinand Magellan had served in the East Indies as a young man. Familiar with the long sea route to Asia eastward from Europe via the Cape of Good Hope, he was convinced that there must be an easier sea route westward. His plan was in accord with Spanish hopes; five Spanish ships were fitted out in Seville, and in August 1519 they sailed under his command first to the Cape Verde Islands, and thence to Brazil. Standing offshore, they then sailed southward along the east coast of South America; the estuary of the Río de la Plata was explored in the vain hope that it might prove to be a strait leading to the Pacific. Magellan's ships then sailed south along the coast of Patagonia. The Gulf of St. George, and doubtless many more small embayments, raised hopes that a strait had been found, only to dash them; at last at Port Julian, at 49°15' S, winter quarters were established. In September 1520, a southward course was set once more, until, finally, on October 21, Magellan found a strait leading westward. It proved to be an extremely difficult one: it was long, deep, torturous, and rock-walled; bedevilled by icy squalls and dense fogs, it was a miracle that three of the five ships got through its 325-mile length. After 38 days, they sailed out into the open ocean. Once away from land, the ocean seemed calm enough; Magellan consequently named it the Pacific. The Pacific, however, proved to be of vast extent, and for 14 weeks the little ships sailed on a northwesterly course without encountering land. Short of food and water, the sailors ate sawdust mixed with ship's biscuits and chewed the leather parts of their gear to keep them-

Contarini's map

Magellan's voyages

selves alive. At last, on March 6, 1521, exhausted and scurvy-ridden, they landed at the island of Guam. Ten days later they reached the Philippines, where Magellan was killed in a local quarrel. The survivors, in two ships, sailed on to the Moluccas; thus, sailing westward, they arrived at last in territory already known to the Portuguese sailing eastward. One ship attempted, but failed, to return across the Pacific. The remaining ship, the "Vittoria," laden with spices, under the command of the Spanish navigator Juan Sebastián del Cano, sailed alone across the Indian Ocean, rounded the Cape of Good Hope, and arrived at Seville on September 9, 1522, with only 18 survivors of the 239 men who had set sail with the expedition three years earlier. Del Cano, not having allowed for the fact that his circumnavigation had caused him to gain a day, was greatly puzzled to find that his carefully kept log was one day out; he was, however, delighted to discover that the cargo that he had brought back more than paid for the expenses of the voyage.

It is fitting to consider this first circumnavigation as marking the close of the Age of Discovery. Magellan and his men had demonstrated that Columbus had discovered a New World and not the route to China and that Columbus' "Indies"—the West Indies—were separated from the East Indies by a vast ocean.

Not all the major problems of world geography were, however, now solved. Two great questions still remained unanswered. Were there "northern passages" between the Atlantic and Pacific oceans more easily navigable than the dangerous Strait of Magellan to the south? Was there a great landmass somewhere in the vastness of the southern oceans—a Terra Australis ("southern land") that would balance the northern continents?

#### THE EMERGENCE OF THE MODERN WORLD

The centuries that have elapsed since the Age of Discovery have seen the end of dreams of easy routes to the East by the north, the discovery of Australasia and Antarctica in place of Terra Australis Incognita, and the identification of the major features of the continental interiors.

While, as in earlier centuries, traders and missionaries often proved themselves also to be intrepid explorers, in this most recent period of geographical discovery the seeker after knowledge for its own sake played a greater part than ever before.

**The northern passages.** Roger Barlow, in his *Briefve Summe of Geographie*, written in 1540–41, asserted that "the shortest route, the northern, has been reserved by Divine Providence for England."

The concept of a Northeast Passage was at first favoured by the English: it was thought that, although its entry was in high latitudes, it "turning itself, trendeth towards the southeast . . . and stretcheth directly to Cathay." It was also argued that the cold lands bordering this route would provide a much needed market for English cloth. In 1553 a trading company, later known as the Muscovy Company, was formed with Sebastian Cabot as its governor. Under its auspices numerous expeditions were sent out. In 1553 an expedition set sail under the command of Sir Hugh Willoughby; Willoughby's ship was lost, but the exploration continued under the leadership of its pilot general, Richard Chancellor. Chancellor and his men wintered in the White Sea, and next spring "after much adoe at last came to Mosco." Between 1557 and 1560, another English voyager, Anthony Jenkinson, following up this opening, travelled from the White Sea to Moscow, then to the Caspian, and so on to Bukhara, thus reaching the old east-west trade routes by a new way. Soon, attempts to find a passage to Cathay were replaced by efforts to divert the trade of the ancient silk routes from their traditional outlets on the Black Sea to new northern outlets on the White Sea.

The Dutch next took up the search for the passage. The Dutch navigator William Barents made three expeditions between 1594 and 1597 (when he died in Novaya Zemlya). The English navigator Henry Hudson, in the employ of the Dutch, discovered between 1605 and 1607 that ice blocked the way both east and west of Svalbard (Spitsbergen). Between 1725 and 1729, and from 1734 to

1743, a series of expeditions inspired by the Danish-Russian explorer Vitus Bering attempted the passage from the eastern end, but it was not until 1878–79 that Baron Erik Nordenskiöld, the Finnish-Swedish scientist and explorer, sailed through it.

The Northwest Passage, on the other hand, also had its strong supporters. In 1576 Humphrey Gilbert, the English soldier and navigator, argued that "Mangia [South China], Quinzay [Hangchow] and the Moluccas are nearer to us by the North West than by the North East," while John Dee in 1577 set out the view that the Strait of Anian, separating America from Asia, led southwest "along the backside of Newfoundland." In 1534 Jacques Cartier, the French navigator, explored the St. Lawrence estuary. In 1576 the English explorer Sir Martin Frobisher found the bay named after him. Between 1585 and 1587, the English navigator John Davis explored Cumberland Sound and the western shore of Greenland to 73° N; although he met "a mighty block of ice," he reported that "the passage is most probable and the execution easy." In 1610 Henry Hudson sailed through Hudson Strait to Hudson Bay, confident, before he was set adrift by a mutinous crew, that success was at hand. Between 1612 and 1615, three English voyagers—Robert Bylot, Sir Thomas Button, and William Baffin—thoroughly explored the bay, returning convinced that there was no strait out of it leading westward. As in the quest for a Northeast Passage, interest turned from the search for a route leading to the riches of the East to the exploitation of local resources. Englishmen of the Hudson's Bay Company, founded in 1670 to trade in furs, explored the wide hinterlands of the St. Lawrence estuary and Hudson Bay. Further search for the passage itself did not take place until the 19th century: Sir William Parry (1819–25), Sir John Franklin (1819–45) and more than 40 expeditions sent out to search for Franklin and his party failed to find it. It was left to the Norwegian explorer Roald Amundsen to be the first to sail through the passage, which he did in 1903–05.

**Eastward voyages to the Pacific.** By the end of the 16th century, Portugal in the East held only the ports of Goa and Diu, in India, and Macau, in China. The English dominated the trade of India, and the Dutch that of the East Indies. It was the Dutch, trading on the fringes of the known world, who were the explorers. Victualing their ships at the Cape, they soon learned that, by sailing east for some 3,000 miles (5,000 kilometres) before turning north, they would encounter favourable winds in setting a course toward the Spice Islands (now the Moluccas). Before long, reports were received of landfalls made on an unknown coast; as early as 1618, a Dutch skipper suggested that "this land is a fit point to be made by ships . . . in order to get a fixed course for Java." Thereafter, the west coast of Australia was gradually charted: it was identified by some as the coast of the great southern continent shown on Mercator's map and, by others, as the continent of Loach or Beach mentioned by Marco Polo, interpreted as lying to the south of Malacca; Polo, however, was probably describing the Malay Peninsula.

In 1642, a farsighted governor general of the Dutch East India Company, Anthony van Diemen, sent out the Dutch navigator Abel Tasman for the immediate purpose of making an exploratory voyage, but with the ultimate aim of developing trade. Sailing first south then east from Mauritius, Tasman landed on the coast of Tasmania, after which he coasted round the island to the south and, sailing east, discovered the South Island of New Zealand; "we trust that this is the mainland coast of the unknown South land," he wrote. He sailed north without finding Cook Strait, and, making a sweeping arc on his voyage back to the Dutch port of Batavia (today Djakarta, capital of Indonesia), he discovered the Tonga and the Fiji islands. In 1644, on a second voyage, he traced the north coast of Australia from Cape York (which he thought to be a part of New Guinea) to the North West Cape.

**Westward voyages to the Pacific.** The earlier European explorers in the Pacific were primarily in search of trade or booty; the later ones were primarily in search of information.

The search  
for a  
Northeast  
Passage

The  
discovery  
of  
Australia

The traders, for the most part Spaniards, established land portages from harbours on the Caribbean to harbours on the west coast of Central and South America; from the Pacific coast ports of the Americas, they then set a course westward to the Philippines. Many of their ships crossed and recrossed the Pacific without making a landfall; many islands were found, named, and lost, only to be found again without recognition, renamed, and perhaps lost yet again. In the days before longitude could be accurately fixed, such uncertainty was not surprising.

Some voyages—for example, those of Álvaro de Mendaña de Neira, the Spanish explorer, in 1567 and 1568; Mendaña and the Portuguese navigator Pedro Fernández de Quirós in 1595; Quirós and another Portuguese explorer, Luis de Torres, in 1606—had, among other motives, the purpose of finding the great southern continent. Quirós was sure that in Espiritu Santo in the New Hebrides he had found his goal; he “took possession of the site on which is to be founded the New Jerusalem.” Torres sailed from there to New Guinea and thence to Manila, in the Philippines. In doing so, he coasted the south shore of New Guinea, sailing through Torres Strait, unaware that another continent lay on his left hand.

The English were rivals of the Spaniards in the search for wealth in unknown lands in the Pacific. Two English seamen, Sir Francis Drake and Thomas Cavendish, circumnavigated the world from west to east in 1577 to 1580 and 1586 to 1588, respectively. One of Drake’s avowed objects was the search for Terra Australis. Once through Magellan’s straits, however, strong winds made him turn north—perhaps not reluctantly; he then sailed along the coast of Peru with great financial profit, and continuing northward, perhaps in search of the Strait of Anian, he explored the west coast of North America to 48° N. He returned south to winter in New Albion (California); the next summer he sailed on the Spanish route to Manila, then returning home by the Cape.

Despite the fact that he participated in several buccaneering voyages, the English seaman William Dampier, who was active in the late 17th and early 18th centuries, may be regarded as the first to travel mainly to satisfy scientific curiosity. He wrote: “I was well satisfied enough knowing that, the further we went, the more knowledge and experience I should get, which was the main thing I regarded.” His book *A New Voyage Round the World*, published in 1697, further popularized the idea of a great southern continent.

In the late 18th century, the final phase of Pacific exploration occurred. The French sent the explorer Louis-Antoine de Bougainville to the Pacific in 1768. He appears to have been more of a skeptic than many of his contemporaries, for, while he agreed “that it is difficult to conceive such a number of low islands and almost drowned lands without a continent near them,” at the same time he maintained that “if any considerable land existed hereabouts we could not fail meeting with it.” The British, for their part, commissioned John Byron in 1764 and Samuel Wallis and Phillip Carteret in 1766 “to discover unknown lands and to explore the coast of New Albion.” For all the navigational skill and personal endurance shown by captains and crews, the rewards of these voyages in increasing geographical knowledge were not great. The courses sailed were in the familiar waters of the southern tropics, none was through the dangerous waters of higher latitudes.

Capt. James Cook, the English navigator, in three magnificent voyages at long last succeeded in demolishing the fables about Pacific geography. He was given command of an expedition to observe the transit of the planet Venus at Tahiti on June 3, 1769; with the observation completed, he carried out his instructions to search the area between 40° and 35° S “until you discover it [Terra Australis] or fall in with the eastern side of the land discovered by Tasman and now called New Zealand.” He reached New Zealand, circumnavigated both islands, sailed westward, and on April 19, 1770, made landfall on the eastern coast of Australia. He then turned northward, charting carefully, being well aware of the dangers of the Great Barrier Reef. At Cape York, Cook took possession

of the whole eastern coast, to which he gave the name New South Wales. He sailed through Torres Strait, recognizing as he did so that New Guinea was an island. When Cook sailed back to England by Batavia and the Cape, the coastline of the fifth continent was almost complete; only in the south did it still remain unknown. In 1798 to 1799, two British navigators, George Bass and Matthew Flinders, circumnavigated Tasmania, and in 1801–03 Flinders charted the coast of the Great Australian Bight and circumnavigated the continent, thereby proving that there was no strait from the bight to the Gulf of Carpentaria.

In a second voyage, from 1772 to 1775, which in many ways was the greatest of the three, Cook searched systematically for the elusive continent that many still believed might exist. The first summer he examined the area to the south of the Indian Ocean; in the second, he searched the ocean between New Zealand and Cape Horn; and, in the third, the ocean between Cape Horn and the Cape of Good Hope. He sailed home convinced that the great southern continent of the map makers (*i.e.*, a continent in the South Pacific east of New Zealand) was a fable.

With the exploration of the Pacific completed, interest in a Northwest Passage revived. In 1778 Cook proceeded to latitude 65° N, but he found no way through the ice barrier either to east or to west. He then sailed south to Hawaii, where he was killed in a dispute with the islanders.

Terra Australis Incognita had disappeared: there was now no unknown landmass in the southern oceans. It was Matthew Flinders who suggested that the fifth continent should be named Australia—a name that had long associations with the South Seas and that accorded well with the names of the other continents.

**The continental interiors.** At the opening of the 19th century, the major features of Europe, Asia, and North and South America were known; in Africa some classical misconceptions still persisted; inland Australia was still almost blank; and Antarctica was not on the map at all.

The river systems were the key to African geography. The existence of a great river in the interior of West Africa was known to the Greeks, but in which direction it flowed and whether it found an outlet in the Sénégal, the Gambia, the Congo, or even the Nile were in dispute. A young Scottish surgeon, Mungo Park, was asked to explore it by the African Association of London. In 1796 Park, who had travelled inland from the Gambia, saw “the long sought for majestic Niger flowing slowly eastwards.” On a second expedition, attempting to follow its course to the mouth, he was drowned near Bussa, in what is now Nigeria. In 1830 an English explorer, Richard Lander, travelled from the Bight of Benin, on the West African coast, to Bussa, and he then navigated the river down to its mouth, which was revealed as being one of the delta distributaries that, because of the trade in palm oil, were known to traders as “the oil rivers” on the Gulf of Guinea.

The Zambezi, in south central Africa, was not known at all until, in the mid-19th century, the Scottish missionary-explorer David Livingstone crossed the Kalahari from the south, found Lake Ngami, and, hearing of populous areas farther north, came upon the river in midcourse. On a great exploratory journey from 1852 to 1856, the main purpose of which was to expose the slave trade, he first travelled upstream, crossed the watershed between the tributaries of the upper Zambezi and those of the lower Congo, and reached the west coast at Luanda, Angola. From there a year’s march brought him back to his starting point near the falls that the Africans called “smoke does sound” but that Livingstone prosaically renamed the Victoria Falls; from here he followed the Zambezi downstream, reaching the east coast at Quelimane, in Portuguese East Africa (Mozambique). On his second journey, sent out by the British government to test the navigability of the lower Zambezi, he explored the Shire (Chire) and Rovuma rivers and reached Lake Nyasa. His last journey, from 1865 to 1871, was undertaken at the behest of the president of Britain’s Royal Geographical Society (suc-

sor to the African Association) "to solve a question of intense geographical interest . . . namely the watershed or watersheds of southern Africa." On this journey Livingstone investigated the complex drainage system between Lake Nyasa and Lake Tanganyika and explored the headwaters of the Congo. He refused to return to England with the Welsh explorer Henry Morton Stanley, who was sent to his rescue in 1871, as he was still uncertain of the position of the watershed between the Nile and the Congo; he wondered if the Lualaba was perhaps a headstream of the Nile. He struggled back to the maze of waterways around Lake Bangweulu and died there in 1873.

The source of the Nile

The whereabouts of the source of the Nile had intrigued men since the days of the pharaohs. A Scottish explorer, James Bruce, travelling in Ethiopia in 1770, visited the two fountains in Lake Tana, the source of the Blue Nile, first discovered by the Portuguese priest Paez in 1618. The English explorers Richard Burton and John Speke discovered Lake Tanganyika in 1857. Speke then travelled north alone and reached the southern creek of a lake, which he named Victoria Nyanza. Without exploring farther, he returned to England, sure that he had found the source of the Nile. He was right—but he had not seen the outlet, and Burton did not believe him. In 1862 Speke, travelling with the Scottish explorer James Grant, found the Ripon Falls, in Uganda (now submerged following the construction of a dam for Owen Falls hydroelectric station), and "saw without any doubt that Old Father Nile rises in Victoria Nyanza." Stanley completed the puzzle in 1875; he circumnavigated Vic-

toria Nyanza, crossed to the Lualaba, followed that river to the Congo, and then followed the Congo to its mouth. The pattern made by the river systems of Africa was elucidated at last.

The interior of Australia also posed a problem: was its heart an inland sea or a desert? This question did not arouse anything approaching the same degree of public interest that was taken in the geography of Africa. Exploration was slow; the early settlers on the eastern coast found that the valleys led to impassable walls at the valley heads. In 1813 the Australian explorer Gregory Blaxland successfully crossed the Blue Mountains by following a ridge instead of taking a valley route. Rivers were found beyond the mountains, but they did not behave as expected. Another explorer, the Australian John Oxley, in 1818 observed: "on every hill a spring, in every valley a rivulet, but the river itself disappears." He guessed that the great fan of rivers that drained the western slopes of the Great Dividing Range of eastern Australia fell into an inland sea. The Australian Charles Sturt resolved the problem by an imaginative journey made in 1829–30. He embarked on the Murrumbidgee River and was "hurried into a great and noble river [the Murray]." A week later he encountered another big river flowing into the Murray from the north, which he rightly concluded was the Darling, the middle course of which he had explored the year before. The voyage ended when he found that the Murray drained into Encounter Bay on the south coast. The heart of Australia was not an inland sea but a desert. Many more expeditions were needed to map the continent's ma-

## Exploring the polar regions

major features, but two revealed its great extent. In 1840–41 the Australian Edward John Eyre travelled along the south coast from Adelaide to Albany, a distance of more than 1,300 miles (2,100 kilometres); the Australians Robert Burke and William John Wills travelled from Melbourne in the southeast to the Gulf of Carpentaria in the north.

The exploration of the polar regions was the work of the first half of the 20th century. Scientific curiosity mainly inspired the various enterprises, although political rivalry also played some part.

In the North Polar regions, the scientific age began with the voyaging of William Scoresby, an English whaler and scientist, who in 1806 reached  $81^{\circ}21'N$ . In 1828 an English explorer, Sir William Parry, travelling over drift ice from Svalbard, reached  $82^{\circ}N$ . The Norwegian explorer Fridtjof Nansen in 1893 attempted to reach the Pole by allowing his ship, the "Fram," to be frozen into the ice in the East Siberian Sea in the hope that a current would carry her over the Pole to east Greenland. At  $84^{\circ}N$   $102^{\circ}E$ , Nansen with a companion left the ship and travelled by sled to  $86^{\circ}13'N$ : the ship eventually emerged from the pack ice north of Svalbard. In 1909 an American explorer, Robert Peary, reached the North Pole by journeying by sled with 50 Eskimos from Ellesmere Island, northwest of Greenland. Soundings of 9,000 feet (2,700 metres) were made within five miles (eight kilometres) of the Pole; it seemed, therefore, that there was no continent here. In 1958 the United States submarines "Skate" and "Nautilus" travelled across the Arctic under the ice cap.

The great southern continent, having been located within the Antarctic Circle by Captain Cook, lay there neglected for some 50 years. From 1839 to 1843, the English rear admiral James Ross, in command of the ships "Erebus" and "Terror," explored the coast of Victoria Land. In 1894 Leonard Christensen, captain of a Norwegian whaler, landed a party at Cape Adare, the first to set foot on Antarctica. In the first decade of the 20th century, various explorers, including Britons such as William Bruce, Robert Falcon Scott, and Sir Ernest Henry Shackleton, the German Erich von Drygalski, and the Frenchman Jean-Baptiste Charcot, confirmed the existence of an ice cap of continental dimensions. In 1908–09 Shackleton led a brilliant expedition, during which he examined the Great Barrier, climbed to 11,000 feet (3,400 metres), and reached  $88^{\circ}23'S$ . Scott and his party reached the Pole on January 17, 1912, but only to find that the Norwegian explorer Roald Amundsen had already been there on December 11, 1911; Scott's party, caught in a blizzard, died on their return journey. In 1928 Sir Hubert Wilkins, the British explorer and aviator, flew over Grahamland, using Deception Island as a base. In 1957 and 1958 the British explorer Vivian Fuchs and Sir Edmund Hillary, the New Zealand mountaineer, travelled across the continent. (J.B.Mi.)

## The modern discipline of geography

As indicated in the brief survey introducing this article, academic geography is primarily concerned with areal differentiation; that is, with the distribution, or spatial variation, of phenomena on the Earth's surface and within its atmospheric envelope. The contemporary discipline—the concepts and structure of which are examined in detail in the remainder of this article—deals with the differences as well as with the similarities between places, with the distribution of the environmental features (both physical and man-made) of the Earth, and with the associations between these features. Thus, although the adjective geographic is popularly applied to relief features only, in reality it possesses a much wider connotation.

The development and distinctiveness of geography as an academic discipline stem from man's curiosity about spatial variations in his environment. The Earth is composed not of uniform areas but of an intricate series of overlapping zones of different characteristics. Geography seeks to provide a coherent and organized understanding of this subject matter, whose variations originate from the social, economic, and political processes of a varied

human race and from the basic physical and biotic processes that produce differences in climate, relief, and vegetation. Animate human processes, however, are mediated through decision-making structures of various kinds, and these add still another level of complexity to any attempt at explanation, and there is an ever present danger of repeating 19th-century deterministic explanations whereby man's actions were popularly considered to be controlled by his environment. Controlled observation and experimentation are much more likely to provide the causal relationships involved in inanimate geographical processes.

Geography is concerned not so much with the uniqueness of spatial distributions as with their regularities. It is also accepted that the subject matter of geography is one of common concern among many disciplines, each of which approaches and structures the phenomena under study in a different way. With geography the special perspective is the spatial one, and it is this that provides the basis for the individual organizational method of the geographer and the corpus of spatial concepts and generalizations that constitutes the discipline.

Despite the enormous success of the analytical method in science, whereby subject matter has been broken down into increasingly specialized parts for academic study, scientists often feel that many problems are capable of solution only by interdisciplinary effort and by methods—notably systems analysis—that stress the connection between processes. Geography is well placed to benefit from these approaches, for the subject has an interdisciplinary perspective simply because it looks at a series of processes from one particular viewpoint. Since the early 1960s, geography has seen significant changes in its methodology, changes that have placed the discipline in the mainstream of modern scientific inquiry. These changes, together with advances resulting from the application of quantitative techniques, have enabled geographers to cope more precisely with a greater number of facts. The scope of the subject nevertheless remains enormous, and this makes the organization of the spatial approach a particularly important aspect of the training of a geographer. Yet geographers are still interested only in the regional scale, the study of the Earth as the home of man.

## CHARACTERISTICS OF GEOGRAPHICAL INQUIRY

The restriction of geographical studies to a spatial perspective and a regional level of resolution has, in turn, produced an extensive overlap between geography and the everyday interests and experience of the layman, as well as with other academic fields. Geography has also frequently lost part of its academic territory because individual aspects of geographical knowledge have been subjected to specialist scrutiny and, through an ever present tendency to "fission," have crystallized out as separate sciences.

**The problem of overlap.** The problem of overlap has increased in recent years, notably as the result of the development of virtually instantaneous global communication and the increased social mobility in advanced nations, which have afforded an opportunity to great numbers of people to experience and describe regional environmental differences. Geographers thus no longer hold (as they did in the medieval period) a monopoly on this type of information. Most laymen nevertheless satisfy their curiosity about different places in the world by communicating individual descriptions, and only rarely does lay description bear the traditional characteristics of systematic inquiry—the careful measurement, integration, and accurate presentation of material.

The breadth of the subject matter of geography also means that there is considerable overlap between the work of geographers and other academics—an overlap that occasionally makes it difficult to distinguish the essential geographic contribution. This problem has been partially resolved by the development of specialized inquiries designed to focus upon specific clusters of phenomena or processes within geography. These specialisms—"systematics"—have close links with other academic

Animate and inanimate geographical processes

The limitations of the spatial approach

The role  
of  
"sys-  
tematics"

fields; thus, political geography investigates the interrelationships between geography and political science, and biogeography applies geographical principles to biology (see below *The branches of geographical inquiry*). Geography has also studied some areas of knowledge—notably those that do not form the basis of a separate academic discipline, as in the case of the study of landforms (geomorphology) or of settlements—from a viewpoint over and above that of purely spatial interest. Geomorphology has been of marginal interest to geologists in Europe, and geographers have thus been to the fore in this field. In North America, however, the interest of geologists in contemporary landforms has been stronger, and the field is an area of genuine interdisciplinary effort. The study of human settlements has only recently become the subject of major professional inquiry; many aspects, especially of urban settlement, have thus been studied by geographers.

Conversely, many aspects of scientific study that traditionally are primarily geographic in method have been embedded in other disciplines: distributional studies of individual phenomena as diverse as plants or diseases have been undertaken by botanists or medical research workers. Other fields, as in the case of the study of international trade flows or of territorial behaviour in housing estates, have been developed, respectively, by economists and sociologists. Most geographers interested in such movement patterns have concentrated on the regional scale, studying such features as the spheres of influence of towns, the migration of people, or the definition of metropolitan regions.

In addition, other, more practical studies have hitherto been carried out by market analysts, economists, engineers, and others responsible for the location of new industries or shopping centres, despite the basically geographical nature of the problem. Geography as a distinct academic discipline is also intimately connected with four other fields: regional science, ecology, planning, and ekistics, all with a common interest in responding to spatial problems in the environment. There are, however, some differences in objective and scope: regional scientists are interested primarily in theoretical and statistical approaches to human, especially economic, distributions; ecologists study the biosphere with particular reference to the interrelationships between plants and animals and their environment; planners collect information on a spatial basis but are more interested in the applications of this knowledge; and ekistics, a recent addition to the academic ranks, seeks to provide a science of human settlements.

**The problem of fission.** Modern geographers regard their subject as a "following" rather than a "leading" discipline; most major breakthroughs in scientific understanding, they recognize, tend to be made in other fields. This is a reversal of the subject's role in past centuries, during which geography was often called the "mother" of the natural and social sciences, as in the case of academic disciplines as diverse as pedology (the study of soils) or social anthropology. This type of fission was also seen in more technical areas; for example, surveys of regional land use and agriculture of the kind pioneered by British geographers in the 1930s have since been adopted on a worldwide basis. The greater infusion of capital and the concentration of research effort implicit in these changes have inevitably stimulated major developments in this field of study, and the application of Earth satellite photography and mapping is likely to provide even greater breakthroughs.

The classic example of such academic fission away from geography lies in the realm of geodesy and cartography. Although geographers still teach the rudiments of these subjects, they have become specialized disciplines in their own right. The beginning of this separation can be traced back to the dual heritage of the classical Greek geographers—the regional descriptions of Strabo and Ptolemy's linear representation of the Earth's features by symbols and lines. Between the Renaissance and the 19th century, the Ptolemaic tradition became associated with the need for precise—and increasingly mathematical—

navigational aids and survey and map-projection techniques and also with the military sponsorships of map production. Geodesy thus moved toward applied problems and away from the main geographic consensus. Cartography specialists are found in most university geography departments, but they are now something of an anachronism.

**The "new geography."** For geography the decade of the 1960s was characterized by a fundamental re-examination of the subject's approach to spatial analysis. The impact of these methodological changes has been so considerable that it has given rise to the appellation "the new geography," a reference not to any basic change in the aims of geography but rather to the remarkable technical and methodological innovations that have provided geographers with a new set of descriptive and analytical procedures.

These changes are as fundamental in nature as those introduced by the German scholars Alexander von Humboldt and Carl Ritter, the founders of modern geography, in the mid-19th century. Humboldt and Ritter replaced the gazetteer descriptions and the often-quiet armchair speculation about foreign lands of their predecessors with a formalized, systematic approach. Both men emphasized the role of direct and personal observation and the general need for an empirical approach in any geographical inquiry. Although these methods were an essential component of progress in a formal 19th-century discipline, they seem to have encouraged a later generation of geographers to overemphasize direct observation through fieldwork and to underestimate the part played by speculation in the initial stages of any study. The fieldwork tradition is still an important aspect of geography, but the introduction of more rigorous methods of data collection in society as a whole (at least in the developed nations of the Northern Hemisphere) has rendered individual fieldwork unnecessary in much geographical study.

There were, however, some geographers who did not accept the empirical, inductive approaches favoured by the majority of their colleagues. Thus, in studying the central-place systems, or urban networks, of south Germany in the 1930s, Walter Christaller carefully distinguished among all the possible sources of variation that could affect the pattern of agricultural service centres, put forward a theoretical explanation, and only then tested the empirical evidence. Although Christaller's central-place theory has been found to have a number of limitations, his methodological approach ensures him a major place in any consideration of contemporary geography. During the late 1950s, recognition of the work of Christaller and of other geographers pursuing his line of thought provided the impetus for a number of methodological advances; the result was a complete overthrow of the established consensus. The assimilation of statistical techniques into geography was the most visible of these changes, which were sometimes also known as the "quantitative revolution." A less visible but perhaps more significant change was the deliberate placing of spatial associations in hypothesis-testing frameworks amenable to the application of exact statistical testing techniques. Finally, the application of advanced statistical procedures (notably multivariate analysis) and of computer technology has, together with the accumulation of data from remote sensor devices, enabled geographers to accommodate a larger number of variables in any analysis with greater speed and objectivity.

These technical changes are not unique to geography, for, since the 1950s, they have had similar impact on most of the other natural and social sciences. In the case of geography, the conceptual changes that accompanied such quantitative developments—changes that involve the application of most of the methods of modern science—have been of greater long-term relevance: geographers have begun to create a series of stringent spatial concepts in which the development of laws and theories is a major goal. Mathematical models and methods, using probabilistic concepts and advanced simulation techniques, provide a new armoury of techniques and descriptions, while

The

of modern  
geography

Geography  
as the  
"mother"  
of the  
sciences

Practical  
applications of  
geography

the more informal layman's approach has fallen by the wayside.

All of these advances have resulted in a shift in emphasis away from the descriptive side of the discipline and toward practical applications. This is especially true of the study of animate processes, in which, as has been noted, the presence of consciousness has prompted the study of decision making in a spatial context, particularly in the economic field. In this area—obviously of major importance in the developing regions of the globe and in the centrally planned economies—the empirical tradition of the geographer has served to correct the rather abstract thinking (often expressed in models of optimal, rather than realistic, conditions) of the professional economist. Locational analysis of this kind is now in the forefront of geographical endeavour, a trend that fits in well with increasing public concern for effective control of the natural and, particularly, the man-made environment.

#### THE BRANCHES OF GEOGRAPHICAL INQUIRY

Geography's major contribution to knowledge thus consists of extending and disseminating information about the spatial variation and problems of the Earth's physical and social environment. In ancient and medieval times, geography progressed from describing the characteristic features of different countries to plotting the location of such features with greater accuracy. During the 20th century, more attention has been paid to systematic studies of geographical data, while at the same time a strong tradition of field observation and of interest in the natural and human aspects of geographic phenomena have combined to make geography one of the first disciplines to fulfill a bridging function between the natural and social sciences. As a result, the branches of geographical inquiry fall into three major areas: studies associated with the regional concept, the major systematic branches of human geography, and the major systematic branches of physical geography.

**The regional concept.** *Regions and regional classifications.* In both social and natural sciences, there are many words used in everyday language that also have a specific professional meaning: "region" is one such word. The term derives from the subjective awareness of differences among places on the Earth's surface, and professional regional description is one of the ways geographers introduce order into their description of the spatial variations that create these differences. Although it could be argued that no two places on the Earth's surface are completely identical, there is no need to assume, conversely, that these places can therefore be described only as unique entities. All places share some features in common, and these can be identified and described. The differences can then be analyzed. Acceptance of this important generalization leads directly to a realization of the need to place it in an organizational framework. For the modern geographer, the region is just such an intellectual concept, for it provides a logical way of reducing the complexity of the real world to a smaller and more comprehensible number of elements.

Although the region represents an organization of a set of characteristics possessed by part of terrestrial space, it must be distinguished clearly from mathematical space, which has no real-world relevance. In order to comprise a region, a set of areas must have some common characteristic that differentiates it from other areas, and the areas must be contiguous. For example, a set of areas each experiencing over 50 inches of rainfall or each containing households with an average per capita income of over \$1,000 (or 1,000 rupees or 1,000 yen) per year, if contiguous, provide an example of a homogeneous region (sometimes also called a uniform or a formal region), as they are defined on the basis of the homogeneity of some formal named characteristic. At this stage, it does not matter whether these areas are in excess (moderately or wildly) of the rainfall or income limits: these values are merely the operational definitions of this particular type of homogeneity. Subsequently, other, additional regions may indeed be described—perhaps com-

prised of areas experiencing over 100 inches of rainfall or of areas where per capita income is over \$1,500, and so on.

These examples deal only with one geographical feature at a time, but the basic idea has been extended to define regions characterized by two or more features; these are known professionally as multiple-feature homogeneous regions. Using the examples described above, this type of region could be found by identifying an area with over 50 inches of rainfall in which income is over \$1,000 per capita. When all the distributional characteristics of areas are used to define homogeneity, the term *compages* has been applied. For example, an area with a distinctive combination of climate, relief, and vegetation, as well as cultural and economic patterns (such as the Mekong Delta in Viet Nam), could be described as a *compages* on a world scale.

Two other types of region widely known to the professional geographer are the "polarized" (or "functional") region and the "programming" region. In the former case, homogeneity is defined not by the material description of some structural geographic characteristic but by reference to the similarity of relationships or functions among the constituent parts of the area. A simple example of a functional region is the trading area of a town, which may have a core (an area that represents the heart of the organization or function, perhaps the number of customers patronizing a shopping centre) and a periphery, which is characterized by a decline in the influence of this function outward from the centre. The edges of the region (zones of transition) are represented by the points at which the functional relationships are dissipated and disappear, perhaps to be replaced by influences emanating from other centres: in the example, there would be a fringe area in which potential customers would have the choice of patronizing another shopping centre.

In the case of the programming region, an active rather than a descriptive entity, the region is designed to serve a particular objective within the designated space. The best examples are afforded by political areas or planning regions. The Tennessee Valley Authority was created in the 1930s to improve the ecological balance in an impoverished area of the United States and to raise the standard of living of people within the area. Similar projects were initiated under the first Soviet five-year plans, and since that time most countries of the world, developed and developing, have defined special development areas in which tax or other financial incentives are used alongside direct government assistance to prevent future decay or to promote future growth in the economy of the area. All such projects represent, to the geographer, examples of programming regions.

All these regions are defined on different bases, so there is no reason why they should coincide fully with any particular area; yet, programming regions are often defined on the basis of some other regional type. For example, one urgent contemporary issue of concern to the geographer stems from the multiplicity of municipalities and the conflicting jurisdictions within large urban areas; many people have proposed one simple territorial unit for the government of each of the large cities of the world. If such regions were defined on the basis of homogeneity of land use, the units would be restricted to the contiguous built-up areas of the cities, but, if they were defined on the basis of functional homogeneity, the suburbs and satellites beyond the immediate built-up areas could be included, as well as smaller towns within the metropolitan spheres of influence. A major task of urban geographers—working in a context of accelerating world urbanism—has been to resolve these problems in order to achieve an effective definition of various metropolitan areas.

The application of modern scientific methods to geographical problems has clarified much of the previous thinking about regions. Most contemporary geographers consider that regionalization is not an intuitive art but is a process of classification with basic similarities to other classifications. The utility of any single approach

Program-  
ming  
regions

Homoge-  
neous  
regions

to the professional definition of a region depends on the purpose of the classification, and this, it is felt, should be stated clearly at the beginning of the exercise. Such attitudes are of comparatively recent origin and cannot be considered an absolute consensus. Older opinions still survive, in particular, the belief among more traditional geographers that there is some "natural" system of regions that represents the best classification for many purposes, and that it is the task of the profession to search for this system. Most geographers believe that these "natural" regions are as elusive as the natural classifications sought for in other disciplines, but this view must be qualified in two important respects. First of all, a sizable group of geographers accepts the multiplicity of regional classifications but believes that in any particular case there is some scale of regionalization that is more appropriate than others. The idea may be compared to the resolution level of a microscope—a variety of magnifications is possible but the understanding of the characteristics of any object may be clarified by the use of one particular resolution level. The second qualification is more important, as it rests upon a major difference of opinion between Western (mostly European and North American) and Marxist geographers. Most Soviet geographers extend their Marxist-Leninist view of society to the belief that there is one natural system of economic regions that will best integrate the social and environmental variations of society and act as a foundation for building Socialism and Communism. These regions should, they feel, be isolated and translated into programming regions. Yet, in spite of these theoretical problems, the differences on the practical side of regional classification are minimal. Indeed, much of the credit for early work on the application of quantitative methods to regional classification must go to such Polish geographers as K. Dziewonski. The ideas were extended by Brian J.L. Berry and others in the United States by the early 1960s, as a whole, witnessed a tremendous expansion of worldwide interest in this line of inquiry. Geographers have begun to test the utility of a whole range of statistical grouping and clustering methods for regional classification. These re-orientations have, nevertheless, only clarified the objectivity of regional analysis. They have not changed the fundamental purposes of regionalization, which is to give names to particular areas, to make it easier to transmit and store information about places, to provide inductive generalizations, and to provide data for planning purposes.

**Regional geography.** The formal study of regions and the creation of regional generalizations is the primary responsibility of regional geography, although the recent development of regional science has made significant theoretical contributions to the study of human distributions. The scope of regional geography is potentially enormous because it attempts to involve all the significant locational features known about any area, primarily by using multifeature homogeneous and polarized regions of the type described above. Since this information is increasing at an accelerating rate, regional studies are in constant danger of fragmentation, not least because of a factual overload. There is a danger of a return to the gazetteer approach to description, in which facts are listed by location and little attempt is made to integrate them. These problems are especially relevant to human distributions, in which the rapidity of changes means that the generalizations established are time dependent, and in constant need of updating. The result is that it is difficult for the regional geographer to construct the type of concise and immutable generalization that seems to be possible in many of the physical sciences.

Although the problem of information overload, as it is called, has increased in severity, integration of the geographical facts within the confines of one single study or even the production of a concise generalization has always been difficult. Out of the wide variety of regional studies produced by geographers, the most successful has probably been a series of monographs—known as *Géographie universelle*—emanating (1927–48) from the French school of geographers. The series was initially

planned by Paul Vidal de la Blache, but most of the direction was carried out after his death by Lucien Gallois, with Emmanuel de Martonne and Albert Demangeon among the principal contributors. This series depended heavily on the identification of *pays*, a French term describing areas with a distinctively integrated assemblage of physical and human features. These monographs became classics of modern geography not only because they were prepared by scholars with rigorous, incisive minds but also because they were written in a clear, concise, literary style.

Despite the overall success of the French school of geography, a comparison of the individual regional monographs demonstrates that the interpretation of industrial areas was not as good as that of other regions, primarily because of the absence in such areas of the intimate man-land associations so characteristic of pre-industrial rural societies. The subjectivity of the regional definitions also made it hard to test the utility of the regional classifications and interpretations offered. Overall, however, the studies did lead to the emergence of a school of thought that regarded regional geography as the core of the entire discipline. Many geographers still seem to accept this view, but they are becoming a minority and are particularly vulnerable to criticism when they describe regions from a subjective standpoint.

The difficulty of encompassing all the geographical facts of an area in one regional study contributed to a variation of the *pays* approach. Instead of attempting to use all the salient facts, the "theme" approach searches for some feature or key to the understanding of the area. The development of the theme is similar to the approach used by historians who regarded the "frontier" concept as the primary motive force in U.S. history. In essence, this development takes the distribution of some key criterion (for example, language), considers its relationship to other features (e.g., a distinctive cultural assemblage), and attempts to provide an explanation for the spatial variation in this distribution. Although the theme approach has been used with great effect in many areas, it suffers from the obvious defect of overdependence on one characteristic or set of characteristics. Recognition of the persistence of social and economic discrepancies between the regions of a country has nevertheless led, in many nations, to a series of developmental programs designed to eradicate these differences. Geographers have thus been employed in identifying and monitoring these trends or have produced regional studies that have drawn attention to some developing aspects of society in such a way that they become the springboard for popular concern. Two of the recent examples are a study of urbanization on the northeast seaboard of the United States by a leading French geographer, Jean Gottmann, which created public awareness of "megalopolis"; and "Paris et le désert français" by his compatriot J.F. Gravier, which was especially influential in demonstrating the extent of regional imbalance within France and the dominating position of Paris—a matter of no small concern to a series of French administrations.

**Regionalism.** Other scholars have also been interested in the regional concept and have applied the idea to their own disciplines. Usually the term regionalism is used in a broad descriptive way: a good example is the phenomenon known as political regionalism (or sectionalism), which refers to the localized persistence of a set of voting patterns or other manifestations of political behaviour. Although the identification of such areas is clearly another application of the regional concept of the geographer, it is usually carried out in a subjective and descriptive way. For example, the work of regional novelists and artists, who by persistently setting their stories or paintings within the framework of a particular landscape have created an artistic appreciation of the essential features of the area, has achieved great popularity. Most countries have examples of this type of description: one of the best known in the English language is contained in the writings of Thomas Hardy, who combined elements of the southern English landscape to produce a fictitious area that he referred to as Wessex. Elsewhere the classic

The classic French monographs

The "theme" approach

The role of regional novelists

descriptions of the interior of Brazil by Euclides da Cunha in *Os Sertões* brilliantly capture the feeling as well as the nature and history of the landscape.

This type of writing has heightened the overall public appreciation of the differences between places. In addition, a revival of interest in political regionalism has occurred in most countries in recent years. The reasons for this are complex but may perhaps be attributed to two basic causes. The first cause is political and economic in aspect: modern governments have become more interventionist in all aspects of society, and the growth of an administrative bureaucracy has led to the centralization of power in many areas. Structural changes in economic life have also resulted in the persistence of social and economic variations within most countries, creating an expanding metropolitan or industrial "core" area and a visibly different declining or stagnating periphery. The second cause is largely cultural in nature: most countries retain areas in which a separate culture, or subculture, is significant. Linguistic or religious differences are particularly important in such cases. When combined with a resentment of economic progress in, say, the metropolitan core of the nation state, these cultural differences may encourage a regional feeling of political inferiority, and have indeed created major problems for many contemporary states. In some cases, regionalism survives in part in distinctive voting patterns that persist through generations, as was the case of the traditional allegiance to the Democratic Party in the Southern states of the United States. Elsewhere, the feeling of distinctiveness is translated into a resurgent tribalism, as in much of Africa, or a resurgent nationalism, as in Quebec, Scotland, Wales, Brittany, or Croatia. The modern geographer—hopefully in a position to supply objective data underlying regional trends—can play an important role in such cases.

**Human geography.** Human geography, as a branch of the modern discipline, deals with the changing distribution and spatial organization of a variety of human characteristics, ranging from great urban centres built by man to the geographical diffusion of specific technical innovations in agriculture. By applying geographical methods and techniques of analysis to such features, the knowledge accumulated in other social studies—history, politics, economics, and sociology—may be seen in a new light and often extended considerably.

Three changes have occurred in this branch of geography in recent years: the first was the application of the new conceptual methods and quantitative techniques to human distributions, which produced greater precision in all aspects of the field. The recent adoption of model building and simulation techniques has provided human geographers with some of the benefits of experimentation, allowing them to vary the inputs, or functional relationships, used with any model to produce alternative results. For example, the effect of building a new town within the trade area of existing towns could be calculated in this way. A set of attractiveness indices based on potential sales volume could be used alongside existing travel behaviour to predict future "shopping flows" to various sizes of centres. The second change was in the explicit study of the role of perception and images in mediating between man's actions and his social and physical environment. These variables are being measured precisely and incorporated into analytical frameworks, instead of being used in a descriptive fashion. These behavioral and decision-making approaches have isolated the differences between cultural preferences for various types of environment and produced a greater appreciation of the reasons lying behind any individual use of the environment. A classic illustration of this type of approach frequently has been produced by the responses of Eskimo and American children to photographs of Arctic shorelines and mixed woodland and grass landscapes. To most Americans, the Arctic is inhospitable, to the Eskimo it is "home," an area containing a known set of potential food resources, not the unexplored and unknown environment represented by temperate woodlands. The third change is related to the organization of the individual systematic branches of human geography;

the new methods resulted in a greater cooperation between geographers working in the five major traditional areas: social and cultural geography, political geography, economic geography, urban geography, and historical geography. These subdivisions, nevertheless, remain important in their own right.

**Social and cultural geography.** Social and cultural geography developed out of an interest in mapping such distributions as age-sex differences in human populations, the ethnic background of rural groups, or with tracing the changing distributions of such cultural features as language and religion. These traditional interests are still important and have been improved by the application of more sophisticated cartographic and quantitative methods. Influenced by the contributions of T. Hägerstrand and other Swedish geographers, contemporary research is now often devoted to a complicated analysis of the stages and rules by which social and cultural phenomena are diffused over time and space. Less attention is paid to the individuality of a particular process or phenomena—an artifact, a cultural trait, a population movement, or a disease distribution—and more emphasis is given to formalizing the decision-making structures and patterns of territorial behaviour to which these specific distributions can be related.

**Political geography.** All political systems, when seen from the viewpoint of the geographer, have two basic characteristics: the process by which they function and—more significantly—the territory to which they are bound. This intimate association provides the basis for the field of political geography, which deals with the spatial analysis of political phenomena, either through the study of a political area or through the study of the impact of political decisions upon man's environment. This branch of the discipline obviously calls for a close working relationship with both political scientists and historians. During the late 19th and the early 20th centuries, this field was one of the most influential in human geography. Scholars such as Friedrich Ratzel in Germany and Sir Halford John Mackinder in England contributed substantially to theories of global strategy and to the development of what became known as geopolitics. The subsequent misapplication and distortion of these views, particularly their use as a justification for the territorial expansion of Nazi Germany in the 1930s, resulted in a marked avoidance of the field by later generations of geographers.

Most contemporary effort in political geography has been applied to the study of political areas, whether at the international, national, regional, city, or even very local scale. The analysis of political boundaries and their reorganization has attracted considerable interest, as has the evolution, structure, and functioning of political areas. The use of modern techniques of analysis has led to attempts to measure the efficiency and effectiveness of all types of political areas. In recent years there has been some revival of interest in the study of the geographical aspects of political and territorial behaviour and of the geographical impact of political decisions. For example, there have been studies, by political geographers, of the distribution of voting patterns and of the decision-making structures lying behind the creation of such political entities as capital cities, national parks, metropolitan areas, or even such specific territorial legislation as that concerning fishing rights or offshore limits. There is a marked emphasis on the development of conceptual models, rather than on the presentation of relevant information in the form of empirical case studies.

**Economic geography.** Economic geography seeks to explain the location of the production and consumption of economic commodities, services, and transactions. Most early studies were empirically orientated and concerned with the worldwide distribution of such individual types of production as wheat, cotton, gold, and power generation. Special attention was paid to the association of these enterprises with the physical environment and the delimitation of economic regions. Today, as much attention is paid to the impact of government regulation or the distributional effects of differential freight rates. The

and  
geopolitics

The three  
basic  
innovations in  
recent  
years

experience obtained from a series of case studies of such occurrences has been used to formulate a much more abstract approach to the field, in which the principles of economic location are developed on a theoretical basis: the early contributions of three German location theorists—Johann von Thünen in agriculture and Alfred Weber and August Lösch in industrial production—were of great significance. Modern economic trends have involved greater attention—at least in developed Western countries—to the market as the major locational factor behind the siting of many industries and also to the interaction and linkages between individual productive and consumptive units. As a result, the analysis of the urban-industrial complex has become one of the most important aspects of contemporary economic geography; it is associated closely with the formulation of regional government policy.

**Urban geography.** Unlike the other fields mentioned above, urban geography does not focus upon an individual set of processes but studies the geography of a particular type of area, namely, those defined as urban regions. This branch of the discipline began with the analysis of the location of towns, but most contemporary research concentrates upon four separate areas of interest. The first, the spatial study of the role of the city in society, forms an essential backcloth for all the other groups, since it deals with the growth of urbanization, the extent and problems of world urbanization, and the definition of urban and metropolitan units. The second area of interest lies in the classification of city types, the identification of the unique social and economic character of one city compared with all other cities. Closely connected with this interest is the study of the influence of cities, an approach that has been dominated by studies of trade areas and the consequences of urban sprawl into the countryside. The fourth field of interest is the study of the city as area. In many countries the European and Japanese tradition of studies of the morphology (that is, of the layout and buildings) of cities has been recently superseded by a North American tradition that pays more attention to changing spatial variations in the social, commercial, and industrial patterns of towns. Typologies of commercial structures and urban social systems, the processes seen to lie behind the formation of ghettos, and also the migration of groups and individuals within the city have been popular areas of study in this connection. Many of the new quantitative techniques that have transformed modern geography were first applied to studies in urban geography, and urban geographers have also been leaders in the application of mathematical models to geographical studies. They also have close ties with urban planning agencies, although this link is perhaps more developed in those nations that place great emphasis on central-planning systems.

**Historical geography.** The strong association of many European geographers with the disciplines of history and archaeology led to the early separation of historical geography as a distinct branch of the discipline. Historical geographers were concerned with either a series of reconstructions of past landscapes or the study of spatial change in one or more characteristics of an area through time, perhaps over several centuries. Most of the historical geography written in recent years has used this approach, although distinctive contemporary trends place an emphasis on the application of precise quantitative measurements to such historical changes and also on attempts to analyze rigorously the decision-making structures that are envisaged as having contributed to these changes. The reconstruction of past landscapes is easier to define and bears close analogies to regional geography, although few recent studies have been as successful as the classic monographs produced by H.C. Darby (an interpretation of the Domesday Book, the great survey of 11th-century England originally compiled at the request of William the Conqueror) or Carl Ortwin Sauer (with respect to sequential occupations of Southern California).

**Other branches of human geography.** A wide variety of other systematic branches can be postulated, since

there are potentially as many fields as there are clusters of human phenomena. Thus, population geography has close links with the discipline of demography and deals with the distribution of specific population characteristics. Significant modern trends in this area include the application of sophisticated mapping and analytical techniques to demographic data. There are also developing interests in concepts of optimum population density and population pressure in relation to regional land resources. Transportation geography has been developed primarily by economic geographers interested in transactions and flows across space. Much of the research has been devoted to the refinement of transportation models for the city, and geographers working in this field have a close association with transport engineers. Agricultural geography developed out of cultural and economic geography and studies the geography of agricultural systems. This focus leads to studies of the distribution of crop types, as well as the physical and economic relationships involved. Important emphasis is placed upon land-tenure systems and the effect of varying cropping practices on the management of resources.

**Physical geography.** Until recent years, analytical studies in physical geography progressed at a rate faster than those in human geography. This may reflect the earlier adoption by physical geographers of that accurate instrumentation that provided precise quantified data for analysis. The greater stability of most—though not all—physical processes and the fact that they were not mediated through conscious decision-making structures also provided obvious advantages in this respect.

Three major trends can be differentiated within the systematic branches of contemporary physical geography. First, more sophisticated data-collecting and technical-processing systems have been applied to physical distributions. For example, infrared photography has added another dimension to the traditional dependence on black and white air photography for studying large-scale vegetation systems and pollution hazards. Second, process-orientated approaches have tended to replace distributional studies of the pattern or form of physical features. This has generated a much greater degree of rapport between geographers and other scientists, notably geophysicists. Third, the interrelationship between human and physical processes has also been reactivated as a major area of study, and there have been attempts to measure the varying human response to changes in the physical environment, and, in particular, their effect on man's evaluation and perception of his environment. This has led to greater interest in the need for conservation of natural resources or for the designation and preservation of areas of special scientific value. Other studies include the analysis of flood hazard (especially concerning the human settlement of river floodplains); of climate modification by man, especially in urban and industrial areas; of drought or hail damage to crop systems; and even of the effect of cultural traditions upon land use.

**Geomorphology.** A major subbranch of physical geography, geomorphology is the science of landforms and has been jointly cultivated by geographers and geologists. It is often regarded as a separate discipline. Several individual specializations within geomorphology have become associated with the study of single processes—thus, volcanology studies volcanoes and seismology studies earthquakes.

The earliest geomorphological studies concentrated on the origin and distribution of the Earth's landforms, a process involving the description, identification, and classification of each landform according to its origin—whether the feature was an erosional or depositional product of, for example, river-system, glacial, or wind action. As many landforms were relict features, the product of some long-extinct physical process (as in the case of features resulting from Ice Age glaciation), geomorphologists tended to view the landscape in terms of chronological development. In the case of river systems, this led to an overdependence on the theory of the cycle of erosion, originally formulated by a U.S. geologist William Morris Davis but derived from the biological cycle

The four  
areas of  
urban  
interest

Modern  
techniques  
of data  
collection

of youth, maturity, and old age that was popular in the late 19th century.

These interests remain important, especially for British geomorphologists, but more emphasis is now being placed on the physical processes of change, particularly as more accurate dating techniques can now be applied. Studies of the movement of silt and pebbles in rivers, glaciers, and oceans and also of alterations in river beds or in what is termed shoreline geometry are becoming more frequent. The result is often a greater involvement with engineering principles.

**Climatology.** Climatology is concerned with the seasonal characteristics of weather patterns experienced over various parts of the Earth and with the processes that contribute to these features. Although the subject is dependent on the fundamentals of meteorology, which is itself closely linked to the basic laws of physics and hydrodynamics, the geographical perspective leads to an emphasis on the spatial results of these weather processes. Once the development of standardized recording equipment had produced comparable data on the basic climatic variables of temperature, rainfall, and windflow, geographers were able to formulate systems for a classification of the major climatic zones of the Earth. Today, there is less emphasis on classification and more on the processes themselves. This has encouraged research on the energy and water balance of the atmosphere and the simulation of climatic systems. Many geographers also seem to prefer to study microclimates (the climates of small regions). Since the microclimate of any area is significantly modified by the surface characteristics of the Earth, a considerable literature on the modifications of climate by surface texture and topography is developing, with emphasis upon the heat-island effects of large cities and the influence of local conditions on the distribution of air pollution.

The study  
of  
micro-  
climates

**Biogeography.** Biogeography is the study of the geographical distribution of plants and animals. Its particular approach is shared with ecologists, although they tend to focus on the environmental relationships of plants and animals rather than on trying to produce regional descriptions and explanations of variations in the biosphere. Modern biogeographers have concentrated on the study of plants, have been responsible for mapping large-scale vegetation zones, and for relating the characteristics of such zones to variations in relief, climate, and soils. Recent trends also involve the application of concepts of the ecosystem to geographical distributions in order to produce quantified descriptions of the biological input and output within any area. These methods include the study of the inflow of energy, productivity, transformation, and decomposition of matter. This approach has more than an academic value, as it enables a much more accurate measurement of the effect of man or animals on any specific regional association. Indeed, this applied aspect, especially in the field of conservation and the reconciliation of conflicting uses of land, has become a major interest of most biogeographers.

**Other branches of physical geography.** Physical geography, like human geography, has a number of other subbranches. Geographical studies in the science of soils (pedology) have been most closely associated with mapping the distribution of soil types and relating these characteristics to other environmental features. In particular, the impact of soil variations on crop yields, vegetation type, and the effect of cultural and agricultural cropping practices on soil erosion have been investigated. Hence, the analysis of soil characteristics in isolation has been left to the soil chemist, and geographers use the results of such specialists' work in their own studies.

Similar remarks can be made about geographical interest in the science of water and water flow (hydrology). It is not the hydraulic or chemical properties of water flow that are of major interest to the modern geographer but the effect of water distribution on the rest of the environment. Flood and drought studies, together with water-resource evaluation, bring the hydrologist in close contact with the climatologist. In addition, the impact of floods, droughts, or even normal water runoff on the hu-

man occupancy of an area or the relationship of these processes to landforms or vegetation are also of geographical concern.

Medical geography spans the human and physical branches of the subject and may be traced back to the interest of Greek geographers in the influence of climate on health, death rates, and diseases. During the 19th century the relationships discovered were often expressed in a deterministic manner, thus giving undue emphasis to the effects of climate and other physical features. Today, geographers still cooperate with physicians in using modern techniques for mapping the distribution of deaths from various diseases (often an interesting indicator of the economic development of regions), and the information thus gained may also provide clues indicating some of the causal processes behind distributional variations. Given the amount of specialized medical knowledge required, work in this field is usually undertaken in medical-research institutes, although some geographers produced a series of valuable studies of the impact of climate on human physiology during World War II.

tribution  
of diseases

#### METHODOLOGICAL PROBLEMS AND PROSPECTS

The tendency to fission and overlap so characteristic of geographical inquiry, when combined with a geographic methodology that has not created any technological mystique, has often produced predictions of the disintegration of geography as a specialized discipline. Since the 1960s, however, there has been a remarkable renewal of interest in man's social and physical environment and in the future organization of global society. As a result, greater attention has been paid to regional and distributional studies and to the interrelationship between man and his environment. Geography has contributed substantially to the discussion of these issues. This is particularly true where the subject is developed in a formal, educational way within existing high school systems, a situation that is perhaps more applicable to Europe (including the Soviet Union) than to the United States or to the countries of the developing world. Geography is not, however, the sole focus of efforts to organize coherent environmental studies: an interdisciplinary effort is required for a complete understanding in this area, and geographers can only contribute an individual set of perspectives and skills. Yet, it is still true that the impact of this specifically geographical contribution is impeded by a set of basic problems that continually re-assert themselves.

**The problem of numbers.** The formal contribution of geography to environmental knowledge is diminished by the limited numbers of practicing professional geographers, a situation that is exacerbated by the fact that the majority of geographers are engaged in teaching rather than in research. This ensures that geographers cannot generate their own body of data accumulated through empirical studies but are forced to use information from a wide variety of other sources. As the geographical field is shared with other people, it seems that geographers will continue to make the most of their limited resources by paying more attention to the formalization of concepts and techniques, some of which may have general application.

**The problem of the analytical method.** The analytical standards employed by other scientists have not always been as rigorously employed in geography, primarily because of the difficulty of isolating the problems in a controlled laboratory environment. In addition, replication (the name technically given to the series of repetitive experiments needed to verify general relationships) can rarely be employed. Temporal and spatial variations ensure that the relationships to be studied in any environment may alter at another time period and will certainly have a different value in another area. More rigorous research designs and the use of model-building and simulation techniques may mitigate these problems but are unlikely to eradicate them completely.

**The problem of scale.** The perennial geographical problem seems to be that of scale. Generalizations and relationships established at one scale of geographical

The lack  
of a  
controlled  
laboratory  
environ-  
ment

inquiry may not be useful at another scale. This makes it difficult for the contemporary geographer to present an integrated account of an area in which local generalizations fit neatly into continental size comments. Other scientists—for example, physicists—have the same problem when they are dealing with issues at the fundamental particle, electron, or atomic scale, but they rarely try to treat these relationships simultaneously. The geographer's problem is that the everyday experience of man is at a local level, and he must attempt to build up generalizations from this "particle" level, with all its distortions and individuality.

**The problem of correlations.** Another constant geographical issue concerns the nature of spatial correlations. Not only is it true that correlations formulated at one scale do not always apply at another, but an association between two variables in any area may be of a casual rather than a causal nature. Although this is a well-established feature of statistical analysis, it has produced confusion in the past and led to the assumption that, since the characteristics of people in one type of environment are similar to those in another, there must be a causal environmental connection or else contact between the two peoples. Parallel processes of development frequently represent a more viable alternative explanation.

**The problem of individual objects.** Unlike most disciplines, geography did not emerge by defining a set of discrete individual entities that could be dissected or classified academically, as in the case of the rocks of the geologist or the plants of the botanist. The result is partially a problem of "identity" and perhaps underlies the assumption of methodological uniqueness that has been associated with the philosophy of geography since it was first formulated in its modern form by the German philosopher Immanuel Kant. Although this issue has now been resolved by the realization that all disciplines define, operationally, the object of their study, it means that geographers must be constantly wary about the way in which they derive information. Thus, geographical distortions in the size of census-collection units make it difficult to produce comparable generalizations at the same scale for different sets of data. Fortunately, many planning agencies and census bureaus are investigating the possibility of adopting grid-coordinate reference systems for their geographical basis. As remote sensor devices operate on the same principle, information retrieval, integration, and processing in the future may be eased considerably.

**The problem of measurement and techniques.** Despite undoubted advances in geographical understanding gained by the enthusiastic use of more precise quantitative techniques, some doubts have been raised as to the appropriateness of some of the measures. Many of the standard statistical tests, such as the concept of mean and standard deviation, were not formulated with respect to spatial distributions, and they may need adjustments or even replacement when used in the study of geographical data. Perhaps of greater relevance is the growing realization that geometries other than the Euclidean may be more usefully used in geography, a factor that would have enormous methodological impact on our future understanding of man and his geographic environment. Be that as it may, the modern geographer, in spite of his vast and often bewildering array of mathematical techniques and in spite of being closeted in a laboratory-like atmosphere, still retains much of the curiosity about man and his differing ways of life on our planet that moved his Classical and medieval predecessors to push out the boundaries of the known world. (W.K.D.D.)

**Sources and institutions:** The major English-language bibliographical sources are *Geographical Abstracts*, *Current Geographical Publications*, and *New Geographical Literature and Maps*. Two comprehensive dictionaries of geographical terms are L. DUDLEY STAMP (ed.), *A Glossary of Geographical Terms* (1961); and F.J. MONKHOUSE, *A Dictionary of Geography* (1965). A guide to an international list of geographical journals and series of research papers is provided by C.D. HARRIS and J.D. FELLMANN, in the *International List of Geographical*

*Serials*, 2nd ed. rev. (1971). The International Geographical Union is the world organization of geographers and meets every four years, although representatives of commissions on various geographical topics meet with much greater frequency. It issues the *I.G.U. Bulletin*. The most comprehensive list of geographical societies, institutions, and academic geographers is contained in EMIL MEYNEN (ed.), *Orbis geographicus: World Directory of Geography* (1964); see also G.R. CRONE, *Modern Geographers: An Outline of Progress in Geography Since 1800 A.D.* (1951), a short, well-balanced survey; R.A. SKELTON, *Explorers' Maps* (1958), which deals with the role of the geographer as map-maker and contains excellent illustrations; R.E. DICKINSON and O.J.R. HOWARTH, *The Making of Geography* (1933), still a very useful summary; and R.E. DICKINSON, *The Makers of Modern Geography* (1969), a more detailed study of the German and French geographers.

**General works:** The basic sources for information on the contemporary methodology of geography are the NATIONAL ACADEMY OF SCIENCES, *The Science of Geography* (1965); WILLIAM BUNGE, *Theoretical Geography* (1962); DAVID HARVEY, *Explanation in Geography* (1969); and E.A. ACKERMAN, *Geography As a Fundamental Research Discipline* (1958). These approaches may be contrasted with the older consensus, represented by RICHARD HARTSHORNE, *The Nature of Geography* (1939); or his more recent statement, *Perspective on the Nature of Geography* (1959). More substantive reviews of the literature in specific fields of geography are provided by RICHARD J. CHORLEY and PETER HAGGETT (eds.), *Models in Geography* (1967), and can be compared with P.E. JAMES and C.F. JONES (eds.), *American Geography: Inventory and Prospect* (1954). Two collections of essays provide articles that chart the progress of the recent methodological and technical developments, namely, W.K.D. DAVIES (ed.), *The Conceptual Revolution in Geography* (1972); and B.J.L. BERRY and DUANE MARBLE (comps.), *Spatial Analysis* (1968). The reawakening of interest in the interrelationship between man and his environment may also be traced in W.L. THOMAS (ed.), *Man's Role in Changing the Face of the Earth* (1956); and RICHARD J. CHORLEY (ed.), *Water, Earth and Man* (1969). More specific studies include T.F. SAARINEN, *Perception of the Drought Hazard on the Great Plains* (1966); and JAN BURTON and R.W. KATES (eds.), *Readings in Resource Management and Conservation* (1965).

**Human geography:** Valuable summaries of the impact of modern geographical methodology on the study of human distributions are provided by PETER HAGGETT, *Locational Analysis in Human Geography* (1965); and RONALD ABLER, JOHN S. ADAMS, and PETER GOULD, *Spatial Organization: The Geographer's View of the World* (1971). More specific contributions dealing with the behavioral approach may be found in ALLAN R. PRED, *Behavior and Location*, pt. 1 (1967); and KEVIN R. COX and R.G. GOLLEDGE (eds.), *Behavioral Problems in Geography* (1969). Studies of spatial perception are still in their infancy, but a useful collection of introductory studies is provided by DAVID LOWENTHAL (ed.), *Environmental Perception and Behavior* (1967).

**Social and cultural geography:** Influential in the development of a quantitative and theoretical approach to movements is TORSTEN HAGERSTRAND, *Innovation Diffusion As a Spatial Process* (1967). More traditional approaches are provided by the collection of essays in P.L. WAGNER and M.W. MIKESELL, *Readings in Cultural Geography* (1962); and F.E. DOHRS and L.M. SOMMERS (comps.), *Cultural Geography: Selected Readings* (1967).

**Political geography:** A basic collection of essays surveying the field is contained in R.E. KASPERSON and J.V. MINGHI (eds.), *The Structure of Political Geography* (1969). HAROLD and MARGARET SPROUT, *The Ecological Perspective on Human Affairs* (1965), provides a concise overview of the relationships between human society and the geographical environment.

**Economic geography:** Two traditional, empirically based textbooks in the field are GUNNAR ALEXANDERSSON, *Geography of Manufacturing* (1967); and J.W. ALEXANDER, *Economic Geography* (1963), and with H.H. MCCARTY and JAMES B. LINDBERG, *A Preface to Economic Geography* (1966), providing a more rigorous introduction to concepts and principles. A basic, theoretical survey is found in AUGUST LOSCH, *Die räumliche Ordnung der Wirtschaft*, 2nd ed. (1944; Eng. trans., *The Economics of Location*, 1954). WALTER CHRISTALLER, *Die zentralen Orte in Süddeutschland* (1933; Eng. trans., *Central Places in Southern Germany*, 1966), is one of the first attempts to produce a major theoretical study in geography. The limitation of this central-place theory and more recent empirical evidence in the field is shown in B.J.L. BERRY, *Geography of Market Centers and Retail Distribution* (1967). A joint venture by economists and geographers led to the production of a multivolume survey of world agricul-

ture, entitled *World Agricultural Atlas* (Istituto Geografico de Agostini, 1969). Two comprehensive, introductory, systematic studies of world agricultural patterns are PETER LAUT, *Agricultural Geography*, 2 vol. (1968); and HOWARD F. GREGOR, *The Geography of Agriculture* (1970).

**Urban geography:** A classic study of the urbanization of an area is provided by JEAN GOTTMANN, *Megalopolis: The Urbanized Northeastern Seaboard of the United States* (1961). More specific examples of the functional approach to urban geography may be found in B.J.L. BERRY and FRANK E. HORTON (eds.), *Geographic Perspectives on the Urban Systems* (1970). This may be compared with the more traditional world surveys found in JACQUELINE BEAUJEU-GARNIER and GEORGES CHABOT, *Traité de géographie urbaine* (1963; Eng. trans., *Urban Geography*, 1967); or the historical-morphological emphasis of R.E. DICKINSON, *The West European City*, 2nd ed. rev. (1962).

**Historical geography:** The alternative approaches to historical geography can be seen by comparing H.C. DARBY (ed.), *An Historical Geography of England Before 1800* (1936); and A.R.H. BAKER, JOHN D. HAMSHIRE, and JOHN LANGTON (comps.), *Geographical Interpretations of Historical Sources* (1970); and with CLIFFORD T. SMITH, *An Historical Geography of Western Europe Before 1800* (1967).

**Physical geography (Climate):** Introductory works on climate are represented by R.G. BARRY and RICHARD J. CHORLEY, *Atmosphere, Weather and Climate* (1968); and J.A. DAY and G.L. STERNES, *Climate and Weather* (1970). A comprehensive bibliography on urban climates may be found in T.J. CHANDLER, *Selected Bibliography on Urban Climate* (1970). See also T.J. CHANDLER, *The Climate of London* (1965). Although an interest of physicians rather than of geographers, SIDNEY H. LICHT (ed.), *Medical Climatology* (1964), demonstrates the degree of medical specialism required in geographical studies of human physiology. (**Geomorphology**): Traditional approaches to the study of landforms are represented by W.D. THORNBURY, *Principles of Geomorphology*, 2nd ed. (1968); and ARTHUR HOLMES, *Principles of Physical Geology* (1965). More specific examples of modern trends in specific branches may be seen in MARIE MORISAWA, *Streams: Their Dynamics and Morphology* (1968); CLIFFORD EMBLETON and C.A. KING, *Glacial and Periglacial Geomorphology* (1968). A survey of world landscape morphology has been attempted by LESTER C. KING, *Morphology of the Earth*, 2nd ed. (1967). (**Biogeography**): One of the classics of the field, M.I. NEWBIGIN, *Plant and Animal Geography* (1936, reprinted 1968), has only recently been superseded by DAVID WATTS, *Principles of Biogeography* (1971), although the close relationships with ecology ensure that many geographers use standard ecological sources. Useful examples of the geographical approach are provided by S.R. EYRE, *Vegetation and Soils*, 2nd ed. (1968) and *World Vegetation Types* (1971).

**Exploration:** HERODOTUS, *History*, trans. by J. ENOCH POWELL, 2 vol. (1949); STRABO, *Geography*, trans. by H.L. JONES, 8 vol. (1917–32); M.P. CHARLESWORTH, *Trade-Routes and Commerce of the Roman Empire*, 2nd ed. rev. (1970); PETER G. FOOTE and DAVID M. WILSON, *The Viking Achievement* (1970); GEORGE KIMBLE, *Geography in the Middle Ages* (1938, reprinted 1968); E.G.R. TAYLOR, *Tudor Geography, 1485–1583* (1930, reprinted 1968) and *Late Tudor and Early Stuart Geography, 1583–1650* (1934, reprinted 1968); EDWARD HEAWOOD, *A History of Geographical Discovery in the Seventeenth and Eighteenth Centuries* (1912, reprinted 1965); J.N.L. BAKER, *A History of Geographical Discovery and Exploration*, rev. ed. (1937), still perhaps the best single volume on the whole field; SIR PERCY M. SYKES, *A History of Exploration from the Earliest Times to the Present Day*, 2nd ed. (1936), a very readable account. (*On the classical period*): E.H. BUNBURY, *A History of Ancient Geography Among the Greeks and Romans*, 2nd ed., 2 vol. (1883), a standard work; J.O. THOMSON, *A History of Ancient Geography* (1948), well-documented review of geographical knowledge of the period and a discussion of the geographical theories; MAX CARY and E.H. WARMINGTON, *The Ancient Explorers* (1929), a readable account of recorded exploratory journeys. (*On the medieval period*): C.R. BEAZLEY, *The Dawn of Modern Geography*, 3 vol. (1897–1906), a standard work on geographical ideas and knowledge AD 300–1420; ARTHUR P. NEWTON (ed.), *Travel and Travellers of the Middle Ages* (1926, reprinted 1968); JOHN K. WRIGHT, *Geographical Lore of the Time of the Crusades* (1925, reprinted 1965); *The Travels of Marco Polo the Venetian*—SIR HENRY YULE edited the standard edition, but the Everyman edition is the most readily available. (*On the Age of Discovery*): A.P. NEWTON (ed.), *The Great Age of Discovery* (1932, reprinted 1969); CECIL JANE (ed.), *Select Documents Illustrating the Four Voyages of Columbus*, 2 vol. (1930–33); J.A. WILLIAMSON, *The Voyages of the Cabots . . .* (1929) and *The Cabot Voyages and Bristol Discovery*

*Under Henry VII* (1962); F.H.H. GUILLEMARD, *Life of Ferdinand Magellan* (1890, reprinted 1971). (*On the modern period*): RICHARD HAKLUYT, *The Principall Navigations, Voiages and Discoveries of the English Nation*, 3 vol. (1598–1600)—a useful and accessible edition has been edited by JOHN MASEFIELD (1927–28); J.C. BEAGLEHOLE, *The Exploration of the Pacific*, 3rd ed. (1966); *The Journals of Captain James Cook on His Voyages of Discovery*, 3 vol. (1955–67); MARGERY PERHAM and JACK SIMMONS (eds.), *African Discovery*, 2nd ed. (1957); ERNEST SCOTT (ed.), *Australian Discovery*, 2 vol. (1929, reprinted 1966), a wide selection of passages from the journals of African and Australian explorers, with comment; CLEMENTS MARKHAM, *The Lands of Silence* (1921); ROBERT HUXLEY (ed.), *Scott's Last Expedition*, 2nd enl. ed. (1964).

(J.B.Mi./W.K.D.D.)

## Geological Sciences

The geological sciences deal with the study of the Earth. Their major divisions include physical and historical geology, paleontology (the study of fossils), sedimentology (the study of sediments and their conversion to rock), geomorphology (the study of landforms and surface processes), stratigraphy (the study of strata, or layered rocks), geophysics, geodesy (the study of the form of the Earth), geochemistry, mineralogy and crystallography, petrology (the study of rocks), structural geology (the study of rock geometry and deformation), engineering geology, the various branches of economic geology, including mining geology and petroleum geology, and certain aspects of hydrology, oceanography, meteorology, and the planetary sciences. These divisions are so intimately interrelated that no sharp boundaries truly exist. Furthermore, they intergrade with physics, chemistry, biology, and some branches of engineering, including civil engineering, mining engineering, and petroleum engineering. The term geology, meaning literally the study of the Earth, is broadly inclusive and can be regarded as embracing all of the geological sciences. The purpose of this article is to treat the nature, scope, and methods of the geological sciences rather than the substantive knowledge garnered by the many divisions and aspects of the geological sciences, which is taken up in detail in other articles. For treatment of the relation of the geological sciences to the hydrologic and atmospheric sciences, and to science and technology in general, see EARTH SCIENCES.

This article is divided into the following sections:

- I. Study of the composition of the Earth
  - Mineralogy
  - Petrology
    - Igneous petrology
    - Sedimentary petrology
    - Metamorphic petrology
  - Economic geology
  - Geochemistry
    - Chemistry of the Earth
    - Isotopic geochemistry
- II. Study of the structure of the Earth
  - Geodesy and geophysics
    - Figure of the Earth
    - Scope and techniques of geophysics
  - Structural geology
    - Small-scale features
    - Large-scale features
  - Volcanology
- III. Study of surface features and processes
  - Geomorphology and glacial geology
  - Engineering, environmental, and urban geology
- IV. Study of Earth history
  - Historical geology
  - Paleontology
  - Stratigraphy and sedimentology
  - Astrogeology

Generally speaking, geology is concerned with the rocks that form the outer part of the solid Earth. An understanding of these rocks and of changes in their composition and arrangement that have occurred and are now going on involves principles and techniques of physics and chemistry. Geophysics and geochemistry are logical outgrowths of this overlap in interest that extends beyond the visible rocky shell to deeper zones of the Earth. Biology also plays an essential role in the study of rocks

Purpose  
of the  
geological  
sciences

because many rocks show the effects of biologic processes and contain records of animals and plants that lived in past ages. Paleontology, the study of fossils, is an essential part of geology; the aid of organic chemistry is required for study of the interactions among rock materials and many biological substances. Nearly all geological study seeks to determine an order of events, and a main objective of the science is to work out the full history of the Earth and its animal and plant inhabitants.

The intergradational nature of the divisions of the geological sciences requires that geological scientists be versatile in their approach to problems. There has been a progressive shift, particularly notable in the past several decades, for geologists to employ a variety of disciplines and subdisciplines. Modern practice in petrology involves extensive use of chemistry and physics and, to a lesser extent, various mathematical tools, including statistics and differential equations. Paleontology also may involve at times the use of statistics, organic chemistry, physical chemistry, and many physical aspects of geology. Mathematical models and the statistical analysis of data are important facets of geomorphology, stratigraphy and sedimentology, and other divisions previously cited. Hence, an important element in the training of geologists is an appreciation of the role of other disciplines, both within the geological sciences and in disciplines outside geology. Some of the problems of geology are so strongly dependent upon allied sciences that chemists, physicists, and mathematicians have been attracted to them.

The geological sciences serve man in a variety of ways. As in all sciences, one of the strong motivating forces is man's curiosity about nature. Many of the great problems of geology, such as the origin and development of mountains and the evolution of the Earth's crust and ocean basins, are replete with unanswered questions. Yet, the excitement of geology and its essence as a science or group of sciences lie in the search for answers. The goals of geology are not solely to yield answers to problems of nature, however. Geological applications that are useful to man in a practical and commercial sense are also sought. Exploration for deposits of metallic ores, such as those of iron, copper, lead, zinc, gold, and silver, for example, are broadly guided by geology, often coupled with applied aspects of geophysics and geochemistry. The search for petroleum also is strongly influenced by those aspects of geology dealing with the deposition and deformation of sedimentary rocks and with the flow of underground fluids, including water, oil, and natural gas. Also notable is the rise in the use of engineering geology in land-use planning, particularly in urban areas, where geological considerations generally should have great influence on the location of buildings, bridges, roads, nuclear reactors, and other structures, with respect to the ability of soil and underlying rocks to provide support and with regard to avoidance of landslides and potential earthquake hazards in many parts of the world.

## I. Study of the composition of the Earth

### MINERALOGY

Mineralogy is the scientific study of minerals, the basic units of composition of most rocks. By generally accepted definition, a mineral is a naturally occurring solid material of more or less specific chemical composition that generally occurs in crystalline form and is usually inorganic in nature. Although oil and coal are commonly referred to as minerals (or more specifically as mineral fuels), neither oil nor coal is a mineral as defined in geology because neither is crystalline and both have an organic origin. It is difficult, however, to define the term mineral simply and precisely because there are numerous exceptions to those qualities that generally define a mineral.

Mineralogy as a discipline has had very close historical ties with geology as a whole. Minerals as basic constituents of rocks and ore deposits are quite obviously an integral aspect of geology. The problems and techniques of mineralogy, however, are distinct in many respects from those of the rest of geology, with the result that

mineralogy has grown to be a large and complex discipline in itself. Its ties to other disciplines, notably chemistry and physics, are almost as strong as its ties with geology.

Approximately 3,000 distinct mineral species are recognized, but comparatively few are important in the kinds of rocks that are abundant in the outer part of the Earth. Thus a few related minerals known as the feldspars, together with quartz and mica, are the essential ingredients in granite and its near relatives. Limestones, which are widely distributed on all continents, consist largely of only two minerals, calcite and dolomite. Many rocks have a more complex mineralogy, and in some the mineral particles are so minute that they can be identified only through highly specialized techniques. Several clay minerals important in rocks known as shales or clay stones, for example, cannot be resolved by the most powerful optical microscopes and must be studied by methods mentioned below.

Under favourable conditions mineral substances have grown into nearly perfect crystals that have distinctive external forms. Silicon dioxide forms clear crystals of quartz that are hexagonal prisms with terminations shaped as pyramids; iron sulfide forms perfect cubes of pyrite, the faces marked with parallel lines. But when a substance crystallizes in bulk, crowding of grains growing from neighbouring centres prevents formation of recognizable crystals, though each mineral is formed with its peculiar internal atomic structure. Modern laboratories have varied and highly effective devices for working out the mineral content of rock materials. Standard equipment is the petrographic microscope, constructed for viewing thin sections of rock that are ground uniformly to a thickness of about 0.025 millimetre (0.001 inch) in light that is polarized by polarizing prisms incorporated in the microscope. If the rock is crystalline, its essential minerals can be determined by their peculiar optical properties as revealed in transmitted light under magnification, provided that the individual crystal grains can be distinguished. Opaque minerals, such as those with a high content of metallic elements, require a technique employing reflected light from polished surfaces. This kind of microscopic analysis has particular application to metallic ore minerals. Another device exposes mineral grains to X-rays, which pass through a specimen and outline on photographic film a pattern that represents its atomic structure, peculiar to a given mineral species. Substances such as clay minerals are made up of particles that are submicroscopic to ordinary petrographic microscopes. Such particles become clearly visible under the electron microscope, however, which gives images with diameters enlarged tens of thousands of times. The several clay minerals also can be identified by a technique known as differential thermal analysis, which takes advantage of pronounced differences in thermal properties. The instrument used in the analysis automatically draws graphs that are recognized as peculiar to given mineral compositions.

The science of crystallography is concerned with the geometrical properties and internal structure of crystals. Because minerals are generally crystalline, crystallography is an essential aspect of mineralogy. The domain of crystallography has grown well beyond mineralogy, however, and is also closely tied with metallurgy, ceramics, and other aspects of materials science, and with physics, chemistry, and biochemistry, all of which are concerned to some degree with the properties of crystalline materials, including those of both inorganic and organic origin. The instruments of crystallography include those listed above, notably the polarizing or petrographic microscope and X-ray-diffraction equipment. In addition, an instrument known as a goniometer, which determines angles between crystal faces, is in common use.

Analytical chemistry plays a major role in the study of minerals and rocks. An exact quantitative analysis is a valuable supplement to other techniques, and for many specimens the chemical examination plays a major role. Rocks with glassy texture have no clear atomic organization and therefore are not generally responsive to mi-

analysis  
and  
mineral  
synthesis

Importance  
to man

croscopic study. Natural glasses are common in rocks of volcanic origin. In many such specimens, however, small mineral grains scattered through a glassy groundmass can be recognized under a microscope, giving information to supplement the chemical study; but the quantitative analysis is of first importance.

Although a major concern of mineralogy is to describe and classify the geometrical, chemical, and physical properties of minerals, it is also concerned with their origin. Physical chemistry and thermodynamics are basic scientific tools for understanding mineral origin. Some of the observational data of mineralogy consist of the behaviour of solutions in precipitating crystalline materials under controlled conditions in the laboratory. Certain minerals can be created synthetically under conditions in which temperature and concentration of solutions are carefully monitored. Other experimental methods include study of the transformation of solids at relatively high temperatures and pressures to yield specific minerals or assemblages of minerals. Experimental data obtained in the laboratory, coupled with chemical and physical theory, enable the conditions of origin of many naturally occurring minerals to be inferred. For information on the substantive aspects of mineralogy, see MINERALS; CRYSTALLOGRAPHY; the several articles on specific mineral groups, such as FELDSPARS; or CLAY MINERALS; and the article GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES, particularly for basic information on mineral synthesis.

#### PETROLOGY

Petrology is the study of rocks, and, because most rocks are composed of minerals, petrology is strongly dependent on mineralogy. In many respects mineralogy and petrology share the same problems; for example, the physical conditions that prevail (pressure, temperature, time, and presence or absence of water) when particular minerals or mineral assemblages are formed. Although petrology is in principle concerned with rocks throughout the crust, as well as those of the inner depths of the Earth, in practice the discipline is mainly concerned with those that are accessible in the outer part of the Earth's crust. Rock specimens obtained from the surface of the Moon and those that ultimately will be obtained from other planets are also proper considerations of petrology.

The rocks of the Earth's crust are exposed to view only on continents and islands, which form almost 30 percent of the earth's surface. The known rocks are divisible into three main groups: igneous rocks, which have solidified from molten silicate material called magma; sedimentary rocks, which are composed of fragments derived from pre-existing rocks, or from materials precipitated from solution, or from organic products; and metamorphic rocks, which have been derived from either igneous or sedimentary rocks under conditions that caused changes in composition, texture, and internal structure.

**Igneous petrology.** The igneous rocks are formed as either extrusive or intrusive masses. Extrusive rocks are products of volcanic action; they appear at the surface as molten lavas that spread in sheets and harden, or they are made up of fragments, large and small, blown from vents by violent gaseous explosions. Intrusive rocks have formed by slow cooling of molten masses below the Earth's surface; many such bodies are now exposed to view because long-continued erosion has removed the cover of older rocks. Some of these bodies may have been magma reservoirs that supplied volcanoes in the past.

The grain size or texture of igneous rocks is closely related to the mode of origin. Lavas generally are fine-grained, even glassy, because rapid loss of heat and resulting solidification allowed little or no opportunity for mineral grains to grow. But the same kind of magma, under a cover of solid rock thousands of feet thick, will lose heat very slowly; accordingly, the grains will have a much longer time period for growth, and the resultant rock will be coarse-grained. Examples are ordinary granites in which all grains of the essential minerals can be distinguished with the unaided eye. A rock with similar

chemical composition that formed in a lava flow may have a uniform appearance, with no distinguishable grains; magnification up to 50 or 100 times under a petrographic microscope may reveal a texture and mineral composition strikingly like that of the granite, however. Such a rock, known as rhyolite, is said to have aphanitic (*i.e.*, invisible) texture.

In a general way the textures of igneous rocks vary according to the depth at which the bodies were formed. Deep-seated (abyssal or plutonic) bodies are coarse-grained; intrusive bodies that cooled at shallower depths (hypabyssal masses) generally have medium to fine grains; and extrusive rocks are fine-grained to glassy. There are, however, some complexities in this general rule. Many sheets of rhyolite lava have large and well-formed crystals of feldspar and quartz isolated in an aphanitic groundmass; such rock is called rhyolite porphyry, and its crystals are called phenocrysts. Presumably these formed in a quiescent magma body underground, part of which was erupted in a volcanic outbreak, whereupon the magma enclosing the crystals cooled quickly to form rock with fine grain size. Such porphyritic texture is common also in bodies of both the shallow- and deep-zone intrusive rock types. In such rocks the groundmass has visible grains that are much smaller than the enclosed phenocrysts. The contrasting grain size in all porphyries suggests an abrupt change in physical-chemical conditions while the parent bodies were forming.

Knowledge of intrusive igneous bodies has been built up slowly by comparative studies, some in regions in which erosion has brought to light only the masses that developed at shallow depths, others in profoundly eroded belts in which what might be called the bones of extinct mountains can be seen. Beneath growing mountain chains around the Pacific Ocean, igneous intrusive action is doubtless now in progress, though beyond the range of direct observation. Study of extrusive activity and the resulting rocks is more favourable because of opportunities for direct observation. Active volcanic centres are widely distributed, and some of these are under continuous observation. The behaviour of Vesuvius and other Mediterranean volcanoes has been watched through many centuries, and well-equipped scientific stations have been in operation for some decades at a number of active centres. Study of active volcanoes is supplemented by observations made on great volumes of older volcanic products, which, because they accumulated on the Earth's surface, are much more accessible than the intrusive bodies that have come into view only through chance exposure by erosion.

Igneous petrology has several main concerns. An older, but still important aspect, is the classification of igneous rocks according to those properties that may be studied and observed more or less directly (descriptive classification) or their classification according to inferred conditions of origin (genetic classification). The principal problems of igneous petrology concern the source of materials in rock, the mode of emplacement of igneous bodies, and the physical and chemical conditions of origin. Many of these problems are approached through traditional methods that involve microscopic study of thin sections and field mapping at various levels of detail of rocks exposed at the surface. When mine workings or core holes permit underground observation, large-scale geometrical relationships may be observed and interpreted in three dimensions. Of particular note is the rise in the past two decades of experimental methods in which high pressures and elevated temperatures are obtained under simulated rock-forming conditions in the laboratory. The experimentalist can create synthetic igneous rocks, such as granites, from materials placed in small cylinders under carefully observed conditions. The small, artificially produced specimens of igneous rock may be compared with actual specimens of igneous rock, and, in turn, the range of physical conditions under which actual igneous rocks have formed can be deduced. The Geophysical Laboratory of the Carnegie Institution of Washington, D.C., established in 1904, has been a leader in experimental ig-

and  
origin

neous petrology. For further information on the substantive aspects of igneous petrology, see IGNEOUS ROCKS; IGNEOUS ROCKS, EXTRUSIVE; IGNEOUS ROCKS, INTRUSIVE; and IGNEOUS ROCKS, PYROCLASTIC. See also VOLCANOES; and GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES, particularly for basic information on rock synthesis.

**Sedimentary petrology.** Rock materials exposed to air and moisture are subject to continual change, both physical and chemical. Bedrock is broken into pieces, large and small, which are moved by running water and other agents to lower elevations and spread in sheets over lake bottoms, floodplains, and sea floors. Dissolved matter is carried to seas and other water bodies, and some of it is precipitated either chemically or by the action of organisms. The deposited material becomes compacted, and in time much of it is cemented into firm rock. Generally, the process of deposition is not continuous but sporadic, and sheets of material representing separate episodes come to form distinct layers of rock. As a result the sedimentary rocks are stratified; the individual layers form beds or strata.

Large parts of every continental mass are covered with sedimentary rocks that represent deposits formed during many periods of the Earth's history. In part these bedded rocks are nearly horizontal, as they were originally; but in large areas, particularly in mountain belts, they show various degrees of tilting and deformation. The principal kinds of sedimentary rocks include conglomerate, sandstone, mudstone, siltstone, shale, limestone, dolomite, and gypsum.

Sedimentary petrology is concerned with the description and classification of sedimentary rocks, interpretation of the processes of transportation and deposition of the sedimentary materials forming the rocks, the environment that prevailed at the time the sediments were deposited, and the alteration (compaction, cementation, and chemical and mineralogical modification) of the sedimentary material after deposition.

There are two main branches of sedimentary petrology. One branch deals with carbonate rocks, namely limestones and dolomites, composed principally of calcium carbonate (calcite) and calcium magnesium carbonate (dolomite). A major concern of carbonate petrology is to devise classification systems that are capable of describing the large numbers of types of limestones and dolomites. Much of the complexity in classifying carbonate rocks stems partly from the fact that many limestones and dolomites have been formed, directly or indirectly, through the influence of organisms, including bacteria, lime-secreting algae, various shelled organisms including mollusks and brachiopods, and by corals. In limestones and dolomites that were deposited under marine conditions, commonly in shallow warm seas, much of the material initially forming the rock consists of skeletons or fragments of skeletons of lime-secreting organisms. In many examples, this skeletal material is preserved as fossils; alternatively, the original material may have been dissolved and recrystallized. Some of the major problems of carbonate petrology concern the physical and biological conditions of the environments in which carbonate material has been deposited, including water depth, temperature, degree of illumination by sunlight, motion by waves and currents, and the salinity and other chemical aspects of the water in which deposition occurred. The problems of carbonate petrology are strongly interdisciplinary and involve biology, physical chemistry, and biochemistry.

The other principal branch of sedimentary petrology is concerned with the sediments and sedimentary rocks that are essentially noncalcareous. These include sands and sandstones, clays and claystones or mudstones, siltstones, conglomerates, glacial till, and the varieties of sandstones, siltstones, and conglomerates; for example, the graywacke-type sandstones and siltstones. These rocks are broadly known as clastic rocks because they consist of distinct particles or clasts. Like the other branches of petrology, clastic petrology is concerned with classification, particularly with respect to the mineral composition

of fragments or particles, as well as the shapes of particles (angular versus rounded), and the degree of homogeneity of particle sizes. Other main concerns of clastic petrology are the mode of transportation of sedimentary materials, including the transportation of clay, silt, and fine sand by wind, and the transportation of these and coarser materials through suspension in water, through traction by waves and currents in rivers, lakes, and seas, and sediment transport by ice.

Sedimentary petrology is also concerned with the small-scale structural features of sediments and sedimentary rocks. There is no sharp division between large-scale structural and sedimentary features, which are also the domain of structural geology and stratigraphy, and the small-scale features. Structural features that can be conveniently seen in a specimen that can be held in the hand are within the domain of sedimentary petrology. These features include the geometrical attitude of mineral grains with respect to each other, small-scale cross stratification, the shapes and interconnections of pore spaces, and the presence of fractures and veinlets that fill fractures. Collectively, small-scale structural features may be described as the fabric of the rock, although the term fabric is also commonly applied to the arrangement of mineral grains. The attribute of fabric is also an important aspect of igneous rocks and metamorphic rocks.

For further information on the substantive aspects of sedimentary petrology, see SEDIMENTARY ROCKS; CONGLOMERATES AND BRECCIAS; SANDSTONES; GRAYWACKES; SHALES; LIMESTONES AND DOLOMITES; SILICEOUS ROCKS; and EVAPORITES. See also MARINE SEDIMENTS; and GEOCHEMICAL EQUILIBRIA AT LOW TEMPERATURES AND PRESSURES, particularly for basic information on the conditions of formation of certain sedimentary mineral deposits.

**Metamorphic petrology.** Metamorphism means, literally, transformation in form, and logically the term might be applied to any profound change. In geology the meaning is restricted; generally it does not include the decay of rock materials exposed to the weather or the fusion of rocks by igneous processes, although both these classes of changes have been considered to be aspects of metamorphism by some geologists. Metamorphic rocks have been developed from earlier formed igneous and sedimentary rocks by heat and pressure at some depth, most effectively in mountainous regions. Resultant changes occur in the texture, mineral composition, and structural features of the rock. Survival of some characteristics of the original rock indicates that fusion has not played an essential part in the change, nor has recrystallization at temperatures below that of fusion been so extreme as to obliterate all aspects of the original rock, save its chemical composition.

Two general kinds of metamorphic effects are recognized: (1) dynamic metamorphism, resulting from strong forces and perhaps aided by an increase in temperature from friction; and (2) thermal metamorphism, which is caused by high temperature in rocks adjacent to intrusive igneous bodies. Effects are accentuated by the introduction of elements by fluids that move from a molten mass into the surrounding rock. Susceptibility of different rocks to either types of metamorphism varies greatly. In part of the Appalachian Mountain belt in Pennsylvania, for example, coal in strongly crumpled beds has been changed to anthracite, which is a type of coal from which nearly all volatile matter has been expelled; but the shale beds adjacent to this coal are unchanged except for the crumpling. By contrast, in a more strongly deformed belt in Rhode Island, coal has been changed into graphite, and, in the enclosing shale beds, shearing has developed thin cleavage planes lined with flakes of mica. Temperature alone, however, is capable of altering rocks. Near intrusive igneous masses, shale is commonly altered to hornfels, a hard metamorphic rock studded with crystals of minerals that grew as a result of temporarily elevated temperatures as the igneous body was intruded. Beds of sandstone alongside altered shale, however, are generally unchanged except for cementation of quartz grains.

Dynamic and thermal metamorphism

Carbonate sedimentology and clastic sedimentology

Extreme metamorphism in some mountain zones has resulted from combined dynamic and thermal effects. Fluids rising from deep-seated igneous bodies or plutons have combined with rock material in deformed sedimentary rocks, and the resultant product is indistinguishable from granite that has crystallized from magma. To some extent, therefore, granite rocks may be a product of metamorphic as well as igneous processes.

Many of the metamorphic rocks consist of flaky minerals, such as mica and chlorite, set in a parallel arrangement. These minerals cause the rock to split into thin sheets, and the rocks are said to be foliated. The commonest kinds of foliated metamorphic rock are slate, phyllite, schist, and gneiss. Marble and quartzite are non-foliated metamorphic rocks.

Problems of metamorphic petrology

The problems of metamorphic petrology are similar to those of igneous petrology in that they are generally concerned with the conditions of pressure, temperature, and gross chemical environment that prevailed when particular suites of minerals formed in various types of metamorphic rocks. Other problems include the nature and attitude of the deforming forces, as manifested in the fabric of dynamically metamorphosed rocks. Evidence derived from the study of metamorphic rocks has an important bearing on many fundamental questions in geology, such as the depth to which former sedimentary rocks that have been metamorphosed were buried. The presence of minerals that form at high pressures and that occur as replacements in rocks that have been metamorphosed form one basis for estimating the former maximum depth of burial. Other metamorphic minerals that are known to form within certain temperature ranges are forms of geologic thermometers that yield evidence about the temperatures that prevailed close to the margins of igneous bodies when they were intruded. For further information on the substantive aspects of metamorphic petrology, see METAMORPHIC ROCKS; ROCK METAMORPHISM, PRINCIPLES OF; and ROCKS, PHYSICAL PROPERTIES OF.

#### ECONOMIC GEOLOGY

The mineral commodities on which our civilization is heavily dependent are obtained from the Earth's crust and therefore have a prominent place in the study and practice of that branch of geology termed economic geology. In turn, economic geology consists of several principal subbranches that include the study of ore deposits, petroleum geology, and the geology of nonmetallic deposits (excluding petroleum), such as coal, stone, salt, gypsum, clay and sand, and other commercially valuable materials. The study of water in the ground, or hydrogeology, may also be classed as a branch of economic geology (see further GROUNDWATER).

Branches and objectives of economic geology

None of these branches of economic geology are sharply defined subdisciplines. Instead, they involve application in some degree of most, if not all, of the other disciplines within the geological sciences. The practice of economic geology is distinguished, however, by the fact that its objectives are to aid in the exploration for and extraction of mineral resources. The objectives are, therefore, economic. In petroleum geology, for example, a common goal is to guide oil-well-drilling programs so that the most profitable prospects are drilled, and those that are likely to be of marginal economic value, or barren, are avoided. A similar philosophy influences the other branches of economic geology. In this sense, economic geology can be considered as an aspect of business that is devoted to economic decision making. Many deposits of economic interest, particularly deposits of metallic ores, are of extreme scientific interest in themselves, however, and they have warranted intensive study that has been somewhat apart from economic considerations.

The practice of economic geology provides employment for many of the world's geologists. On a world basis, probably more than two-thirds of those persons employed in the geological sciences are engaged in work that touches on the economic aspects of geology. These include geologists whose main interests lie in many fields

within the geological sciences. The oil industry collectively is the largest employer of economic geologists. Geologists with principal interests that include stratigraphy, sedimentary petrology, structural geology, paleontology, and geophysics are widely employed in the petroleum industry.

Economic geology is faced with exceptional challenges at this point in time. The world's steadily expanding population, coupled with the rise in standard of living in many countries, has caused consumption of virtually all mineral commodities to rise sharply. The consumption of oil and natural gas has grown steadily, as has that of most metals, including iron, copper, lead, zinc, and silver. Even sand and gravel, which are of relatively small unit value, are in increasing demand and are in short supply in some urban areas. The task facing economic geologists is to guide the exploration for and exploitation of these commodities and, at the same time, ensure that man's environment be as little damaged as possible. These demands are in conflict; oil cannot be produced nor iron ore mined without some degradation of the natural environment.

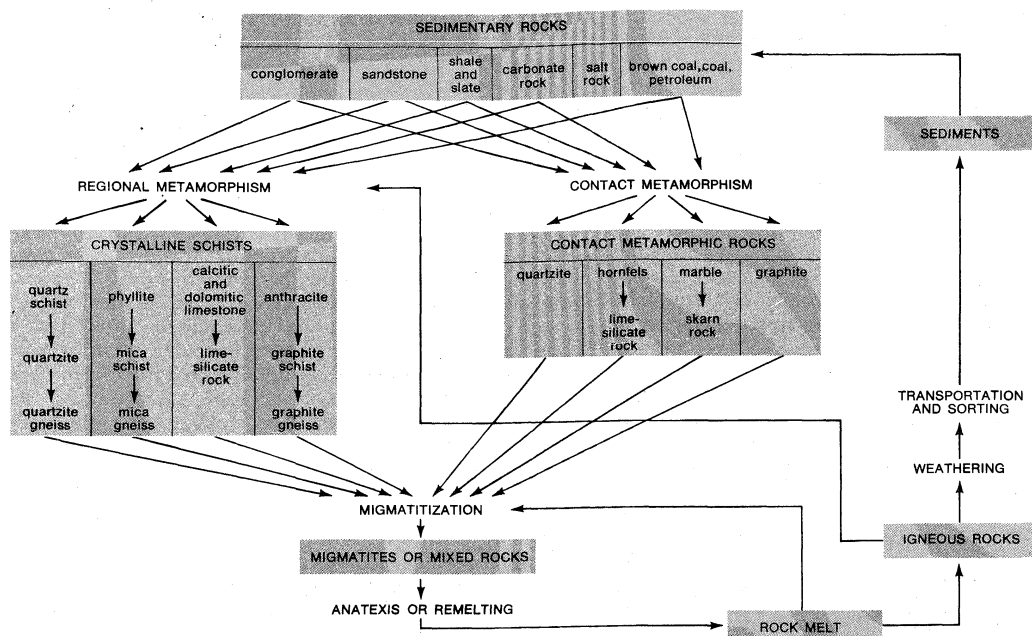

For further information on the substantive aspects of economic geology, see ORE DEPOSITS; PETROLEUM; NATURAL GAS; COALS; OIL SHALES; and PHOSPHORITES. See also OCEANS AND SEAS: *Economic aspects of oceans and seas.*

#### GEOCHEMISTRY

**Chemistry of the Earth.** Geochemistry is broadly concerned with the application of chemistry to virtually all aspects of geology. Inasmuch as the Earth is composed of the chemical elements, all geological materials and most geological processes can be regarded from a chemical point of view. Most problems of geochemistry are so inextricably linked with other aspects of geology that it is difficult to isolate them as purely geochemical problems. Some of the major classes of problems that broadly belong to geochemistry are as follows: (1) origin and abundance of the elements in the solar system, Galaxy, and universe (cosmochemistry); (2) abundance of elements in the major divisions of the Earth, including the core, mantle, crust, hydrosphere, and atmosphere; (3) behaviour of ions in the structure of crystals; (4) chemical reactions in cooling magmas and the origin and evolution of deeply buried intrusive igneous rocks; (5) chemistry of volcanic (extrusive) igneous rocks and of phenomena closely related to volcanic activity, including hot-spring activity, emanation of volcanic gases, and origin of ore deposits formed by hot waters derived during the late stages of cooling of igneous magmas; (6) chemical reactions involved in weathering of rocks in which earlier formed minerals decay and new minerals are created; (7) the transportation of weathering products in solution by natural waters in the ground and in streams, lakes, and the sea; (8) chemical changes that accompany compaction and cementation of unconsolidated sediments to form sedimentary rocks; and (9) the progressive chemical and mineralogical changes that take place as rocks undergo metamorphism.

One of the great, general concerns of geochemistry is the continued recycling of the materials of the Earth's crust, largely through agencies of the hydrosphere (earth's waters) and atmosphere, coupled with mountain building and other forms of deformation of the Earth's crust. Questions pertaining to the locally changing balances of the Earth's chemical elements as they undergo separation and segregation during transportation and subsequent recombination in the Earth's rock or crustal cycle are central to geochemistry. The behaviour of dissolved materials in natural waters, under the relatively low temperatures that prevail at or near the surface of the Earth, is an integral aspect of the crustal cycle. Weathering processes supply dissolved material, including silica, calcium carbonate, and other salts, to streams. These materials then enter the oceans, where some remain in solution (such as sodium chloride), whereas others are progressively removed to form certain sedimentary rocks, including limestone and dolomite, and, where conditions are conducive for the origin of deposits formed

Kinds of geochemical problems

The major cycle of matter.

From K. Rankama and T.G. Sahama, *Geochemistry* (copyright 1950); University of Chicago Press

by means of evaporation, gypsum (hydrous calcium sulfate), rock salt (halite), and potash deposits may be formed.

The behaviour of biological materials and their subsequent disposition are important aspects of geochemistry, generally termed organic geochemistry or biogeochemistry. Organic geochemistry is closely allied with many aspects of biology and, of course, owes major allegiance to organic chemistry. Major problems of organic geochemistry include the question of the chemical environment on earth in which life originated; the modification of the hydrosphere, and particularly the atmosphere, through the effects of life; and the incorporation of organic materials in rocks, including carbonaceous material in sedimentary rocks. The origin and chemical transformations of biological material to form deposits of coal, petroleum, and natural gas are included in the last category. Organic chemical reactions influence many geochemical processes, including rock weathering and production of soil, the solution, precipitation, and secretion of such dissolved materials as calcium carbonate, and the alteration of sediments to form sedimentary rocks.

Geochemistry has applications to other subdisciplines within geology, as well as to disciplines relatively far removed from geology. At one extreme, geochemistry is linked with cosmology in a number of ways. These include the study of the chemical composition of meteorites, the relative abundance of elements in the Earth, Moon, and other planets, and the ages of meteorites and of rocks of the crust of the Earth and Moon as established by radiometric means. At another extreme, the geochemistry of traces of metals in rocks and soils and, ultimately, in the food chain has important consequences for man and for the vast body of lesser organisms on which he is dependent and with whom he coexists. Deficiencies in traces of copper and cobalt in forage plants, for example, lead to diseases in certain grazing animals and may locally influence man's health. These deficiencies are in turn related to their concentrations in rocks and the manner in which they are chemically combined within soils and rocks.

**Isotopic geochemistry.** One aspect of geochemistry deals with the geological role of isotopes. Some chemical elements consist of several isotopes, as do the three naturally occurring isotopes of oxygen, oxygen-16, oxygen-17, and oxygen-18. Each isotope is characterized by a particular configuration in its nucleus; all isotopes of oxygen have eight protons in their nuclei, but the number of neutrons differs. Oxygen-16 has eight neutrons

(eight neutrons plus eight protons yield a mass number of 16), oxygen-17 has nine neutrons, and oxygen-18 has ten neutrons. The mass numbers of isotopes of other elements are defined similarly, as the sum of the number of neutrons and the number of protons.

Isotopic geochemistry has several principal roles in geology. One role is concerned with the enrichment or impoverishment of various particular isotopic species that results from the influence of differences in mass of molecules that contain different isotopes. An individual water molecule that contains an oxygen-18 atom is about 11 percent heavier than a water molecule that contains an oxygen-16 atom. The difference affects the rate at which water molecules pass from one phase to another—that is, when water evaporates or passes from the liquid phase to the vapour phase or is transformed to or from the solid state. As a result, such natural processes as evaporation, condensation, and crystallization, tend to progressively fractionate or segregate isotopic species. Evaporation of water brings about a small but measurable enrichment in the proportion of oxygen-18 in the liquid phase and a corresponding impoverishment in the vapour phase. These isotopic-fractionation processes are affected by variations in temperature. As a consequence, measurements of the proportions of various isotopic species can be used as a form of geologic thermometer. The ratio of oxygen-16 to oxygen-18 in calcium carbonate secreted by various marine organisms from calcium carbonate in solution in seawater is influenced by the temperature of the seawater. Precise measurement of the proportions of oxygen-16 with respect to oxygen-18 in calcareous shells of various fossil marine organisms provides a means of estimating the temperatures of the seas in which they lived.

The varying temperatures of the oceans during and between the major advances of glaciers during the ice ages have been inferred by analyzing the isotopic composition of the skeletons of floating organisms recovered as fossils in sediment on the sea floor. Other uses of isotopic analyses that involve temperature-dependent-rate processes include the progressive removal of crystals from cooling igneous magmas.

Another major role of isotopic geochemistry that is of enormous importance in geology is radiometric age dating. The ability to quantify the geological time scale, that is, to date the events of the geological past in terms of numbers of years, is largely a result of coupling radiometric-dating techniques with older, classical methods of establishing relative geologic ages. Radiometric-dating

Oxygen isotopes and their utilization

Radiometric dating

methods are based on the general principle that a particular radioactive isotope (radioactive parent or source material) incorporated in geological material decays at a uniform rate, producing a decay product, or daughter isotope. Some radiometric "clocks" are based on the ratio of the proportion of parent to daughter isotopes, others are based on the proportion of parent remaining, and still others are based on the proportion of daughter isotopes with respect to each other. For example, uranium-238 decays ultimately to lead-206, which is one of the four naturally occurring isotopic species of lead. Minerals that contain uranium-238 when initially formed may be dated by measuring the proportions of lead-206 and uranium-238; the older the specimen, the greater will be the proportion of lead-206 with respect to uranium-238. The decay of potassium-40 to form argon-40 (calcium-40 is also produced in this decay process) is also a widely used radiometric-dating tool, although there are several other parent-daughter pairs that are used in radiometric dating, including another isotope of uranium (uranium-235), which decays ultimately to form lead-207, and thorium-232, which decays ultimately to lead-208.

Uranium-238 and uranium-235 both decay very slowly, although uranium-235 decays more rapidly than uranium-238. The rate of decay may be expressed in several ways. One way is by the radioactive isotope's half-life, which is that interval of time in which half of any given initial amount will have decayed. The half-life of uranium-238 is about 4,510,000,000 years, whereas the half-life of uranium-235 is about 713,000,000 years. Other radioactive isotopes decay at greatly differing rates, with half-lives ranging from a small fraction of a second to quadrillions of years.

Carbon-14 is a radioactive isotope of carbon (carbon-12 and carbon-13 are stable isotopes) with a half-life of slightly more than 5,700 years. Carbon-14 is incorporated in all living material, for it is derived either directly or indirectly from its presence in atmospheric carbon dioxide. The moderately short half-life of carbon-14 makes it useful for dating biological materials that are more than a few hundred years old and less than roughly 40,000 or 50,000 years old. It has been used to provide correlation of events within this time span, particularly those of the Pleistocene Epoch involving the Earth's most recent ice ages.

For further information on the substantive aspects of geochemistry, see *ELEMENTS, GEOCHEMICAL DISTRIBUTION OF; DATING, RELATIVE AND ABSOLUTE*; and articles treating the geochemistry of the atmosphere and hydrosphere, namely *ATMOSPHERE; FRESHWATER, GEOCHEMICAL PROPERTIES OF; and OCEANS AND SEAS*. ## II. Study of the structure of the Earth

### GEODESY AND GEOPHYSICS

The purely scientific objective of geodesy is to determine the size and shape of the Earth and, in cooperation with other geological sciences, to study the internal structure of the Earth. The practical role of geodesy is to provide a network of accurately surveyed points on the Earth's surface the vertical elevations and geographic position of which are precisely known and, in turn, may be incorporated in maps. When two geographic coordinates of a control point on the Earth's surface, its latitude and longitude, are known, as well as its elevation above sea level, the location of that point is known with an accuracy within the limits of error involved in the surveying processes. In mapping large areas, such as a whole state or country, the irregularities in the curvature of the Earth must be considered. A network of precisely surveyed control points provides a skeleton to which other surveys may be tied to provide progressively finer networks of more closely spaced points. The filling-in process also belongs to the domain of geodesy. The resulting networks

of points have many uses, including anchor points or bench marks for surveys of highways and railroads and other civil features. A major use of control points is to provide reference points to which the contour lines and other features of topographic maps are tied. Most topographic maps are made through the use of photogrammetric techniques and aerial photographs.

Geophysics pertains to studies of the Earth that involve the methods and principles of physics. The scope of geophysics touches on virtually all aspects of geology, ranging from considerations of the conditions in the Earth's deep interior, where temperatures of several thousands of degrees Celsius and pressures of millions of atmospheres prevail, to the Earth's exterior, including its atmosphere and hydrosphere. In fact, geophysics properly extends to the solar system as a whole, including the other planets and the radiation that permeates space within and beyond the solar system. Thus geophysics merges with astronomy, meteorology, and physical oceanography, as well as touching upon virtually all of the geological sciences. Many of the problems of geophysics are analogous to those of astronomy because the subject studied is seldom under direct observation, and conclusions must be drawn largely on the basis of physical and mathematical interpretation of physical measurements. The study of the Earth's interior provides a good example of the geophysicist's approach to problems. Direct observation is obviously impossible. Extensive knowledge of the Earth's interior has been derived from a variety of measurements, however, including seismic waves produced by quakes that travel through the earth, measurements of the flow of heat from the earth's interior in the Earth's outer crust, and by astronomical and other geological considerations.

**Figure of the Earth.** The Earth's figure is that of a surface called the geoid, which over the Earth is the average sea level at each location; under the continents the geoid is an imaginary continuation of sea level. The geoid is not a uniform spheroid, however, because of the existence of irregularities in the attraction of gravity from place to place on the Earth's surface. This results from differences in the density of rocks in the Earth's crust and major variations in the thickness of the crust. These irregularities of the geoid would bring about serious errors in the surveyed location of control points if astronomical methods, which involve use of the local horizon, were used solely in determining locations. Because of these irregularities, the reference surface used in geodesy is that of a regular mathematical surface, an ellipsoid of revolution that fits the geoid as closely as possible. This reference ellipsoid is below the geoid in some places and above it in others.

Mathematically speaking, the geoid is an equipotential, or level, surface, which may be defined as a surface over which the potential function is constant, or uniform. This potential function is the result of the effect of the gravitational attraction of the Earth, coupled with the effect caused by rotation of the Earth about its axis. Over the oceans, mean sea level defines the geoid surface, but over the land areas, the geoid is an imaginary sea-level surface. If a series of canals of sufficient depth were dug over the land areas of the world and connected with the sea, the level of water in these canals would define the geoid.

Modern studies of the figure of the Earth have made use of satellite data in recent years, which have refined the established values of the earth's dimensions.

**Scope and techniques of geophysics.** Geophysics may be divided into a number of overlapping branches, including geodesy in many accounts, in the following way: (1) study of the variations in the Earth's gravity field; (2) seismology, the study of the Earth's crust and interior by analysis of the transmission of elastic waves that are reflected or refracted; (3) the physics of the outer parts of the atmosphere, with particular attention to the radiation bombardment from the sun and from outer space, including the influence of the Earth's magnetic field on radiation intercepted by the Earth (see further *ATMOSPHERIC SCIENCES*); (4) terrestrial electricity, which is the study of

The geoid and the spheroid

Establishing latitude and longitude

the storage and flow of electricity in the atmosphere and Earth; (5) geomagnetism, the study of the source, configuration, and changes in the Earth's magnetic field and the study and interpretation of the remnant magnetism in rocks induced by the Earth's magnetic field when the rocks were formed (paleomagnetism); (6) the study of the Earth's thermal properties, including the temperature distribution of the Earth's interior and the variation in the transmission of heat from the interior to the surface of the Earth; and (7) considerations relating to the deformation of the solid Earth that involve flowage of the mantle and its influence on the crust of the Earth, including broad-scale warping of the crust, mountain building, the development of large-scale rifts in the crust, and the drifting, or horizontal displacement, of continents.

Measurement of the Earth's properties

The techniques of geophysics include measurement of the Earth's gravitative field (using gravimeters and torsion balances), measurement of the magnetic field with magnetometers at the surface of the Earth or towed behind airplanes, measurement by recording seismographs of elastic waves that have been produced naturally by earthquakes or by minor movements in the Earth's crust, or artificially, through explosions, dropping of large weights on the ground, or abrupt electrical discharges. Other tools and techniques of geophysics are diverse. Some involve laboratory studies of rocks and other earth materials under high pressures and elevated temperatures. The transmission of elastic waves through the crust and interior of the Earth is strongly influenced by the behaviour of materials under the extreme conditions at depth; consequently, there is strong motive to attempt to simulate those conditions of elevated temperatures and pressures in the laboratory. At another extreme, data gathered by rockets and space satellites yield much information concerning radiation flux in space and the magnetic effects of the Earth and other planetary bodies in space, as well as providing a large improvement in precision in establishing locations in geodetic surveying, particularly over the oceans. Finally, it should be emphasized that the tools of geophysics are essentially mathematical and that most geophysical concepts are necessarily expounded mathematically.

Geophysics has major influence both as an aspect of pure science, in which the objective is pursuit of knowledge for the sake of knowledge alone, and as an applied science in which the objectives involve solution of problems of practical or commercial interest. Its principal commercial applications lie in the exploration for petroleum and, to a lesser extent, in the search for metallic ore deposits. Geophysical methods also are used in certain geological-engineering applications, as in determining the depth of alluvial fill that overlies bedrock, which is an important factor in the construction of highways and large buildings. Study of hydrology and groundwater geology also involves applied aspects of geophysics.

For further information on the substantive aspects of geodesy and geophysics, see EARTH, FIGURE OF; EARTH, STRUCTURE AND COMPOSITION OF; EARTH, GRAVITATIONAL FIELD OF; EARTH, HEAT FLOW IN; EARTH, MAGNETIC FIELD OF; EARTH, MECHANICAL PROPERTIES OF; EARTHQUAKES; and ROCKS, PHYSICAL PROPERTIES OF.

#### STRUCTURAL GEOLOGY

Structural geology deals with the geometrical relationships of rocks and geologic features in general. The scope of structural geology is vast, extending over a scale of sizes ranging from microscopic to the configuration of the Earth as a whole. Furthermore, most geologic features have an aspect that pertains to their geometrical or spatial relationships and therefore are properly included in the domain of structural geology.

**Small-scale features.** Structural features may be divided into two broad classes: the primary structures that were acquired in the genesis of a rock mass and the secondary structures that result from later deformation of the primary structures. Most layered rocks (sedimentary rocks, some lava flows, and pyroclastic deposits) were deposited initially as nearly horizontal layers. Horizontal layering is, thus, one of the aspects of rock structure.

Rocks that were initially horizontal may be deformed later by folding or by fracturing and may be displaced along fractures. If displacement has occurred and the rocks on the two sides of the fracture have moved in opposite directions from each other, the fracture is termed a fault; if displacement has not occurred (except for a minor amount of pulling apart of the rock on the two sides of the fracture), the fracture is called a joint. It is clear that faults and joints are generally secondary structures; that is, their relative age is younger than the rocks that they intersect, but their age may be only very slightly younger. Many joints in igneous rocks, for example, were produced by contraction when the rocks cooled. On the other hand, some fractures in rocks, including igneous rocks, are related to weathering processes and expansion related to removal of overlying load. These will have been produced long after the rocks were formed.

Structural geology intergrades with petrology when the small-scale geometrical relationships in rocks are considered. The geometrical attitude of individual mineral grains within a rock is an aspect of that rock's structure. In sedimentary rocks, grains that are elongate commonly tend to be oriented so that their long directions are more or less parallel to the gross layering of the rock. On the other hand, in some sedimentary rocks, particularly sandstones and in some limestones composed principally of fragments, there is a lesser scale layering, termed cross-bedding, or cross stratification, in which the layers are oriented at a distinct angle to the larger scale bedding or layering. These aspects of sedimentary structure are primary, having been acquired when the sediments were deposited. The attitudes of particles forming sedimentary rocks also constitute aspects of petrology, which is concerned not only with the mineral composition of rocks but also with the sizes and shapes of the mineral grains and the way in which they have been aggregated together. The geometrical relationship of mineral grains in igneous and metamorphic rocks is also an aspect common to both structural geology and to petrology. The orientation of mineral grains in some igneous rocks, for example, reflects the influence of flowage of the rock while in a molten or softened state and is, therefore, a primary structural feature. On the other hand, the orientation of grains in metamorphic rocks commonly is a result of deformation that occurred during the metamorphic processes and is, therefore, of secondary origin.

**Large-scale features.** Toward the other size extreme are large-scale structural features that include mountain ranges and gently warped strata that extend over large areas. They encompass the major features of the Earth itself, namely the continents, oceanic basins, mid-ocean ridges; the major faults of the crust that intersect or bound the immense plates into which the crust appears to be segmented; and the major divisions of the Earth's interior—its crust, mantle, and core.

The methods of structural geology are nearly as diverse as those of the geological sciences as a whole. Small-scale structural features may be studied either in hand specimen, or examined microscopically, using the same general techniques used in petrology, in which sections of rock mounted on glass slides are ground very thin and are then examined by transmitted light with polarizing microscopes. On larger scale, the techniques of field geology are employed. These include the preparation of geologic maps that show the areal distribution of geologic units selected for representation on the map. They also include the plotting of the orientation of such structural features as faults, joints, cleavage, small folds, and the attitude of beds with respect to three-dimensional space. A common objective is to interpret the structure at some depth below the surface. It is possible to infer with some degree of accuracy the structure beneath the surface by using information available at the surface. If geological information from drill holes or mine openings is available, however, the configuration of rocks in the subsurface commonly may be interpreted with much greater assurance as compared with interpretations involving projection to depth based largely on information obtained at the surface. Vertical graphic sections are

Faults, joints, and mineral orientation

Field geology and the mapping of structural features

widely used to show the configuration of rocks beneath the surface. In addition, contour maps that portray the elevation of particular layers with respect to sea level or some other datum are widely used, as are contour maps that represent thickness variations. The methods of stratigraphy, the study of strata, merge with those of structural geology, particularly in dealing with sedimentary rocks.

Where large-scale features are involved, such as mountains, continents, and oceanic basins, the methods of structural geology are principally those of geophysics and include the use of seismological, magnetic, and gravitational methods. Most of the inferences concerning the depth to the base of the crust beneath chains of mountains are based on interpretation of gravitational and seismological data. It is to be emphasized, however, that a large number of aspects of geology must be brought to bear on such major questions as the depth to the roots of mountain chains. The variation in the density of rocks, which is in itself an aspect of petrology, has major influence on the ability of the Earth's crust to support chains of mountains. There is strong evidence that many major chains of mountains are literally buoyed up by roots that are of lower density than that of surrounding rocks (isostasy). These variations in density, which locally affect the gravitational field of the earth, are of major importance in geodesy and provide evidence through the form of gravity measurements that permit the configuration of the mountain roots to be interpreted. The study of the major structural features of the Earth's crust is termed tectonics or, sometimes, tectonophysics.

The processes that affect geologic structures, including those that cause deformation of rocks, rarely can be observed directly. The nature of the deforming forces and the manner in which the Earth's materials deform under stress can be studied experimentally and theoretically, however, thus providing insight into the forces of nature. One form of laboratory experimentation involves the deformation of small, cylindrical specimens of rocks under very high pressures. Other experimental methods include the use of scale models of folds and faults consisting of soft, layered materials, in which the objective is to simulate the behaviour of real strata that have undergone deformation on a larger scale over much longer time.

Theoretical studies of structural deformations employ mathematical tools derived from physics and engineering. The behaviour of layers of rock undergoing gentle folding may be likened to a series of parallel beams that undergo bending. The forces involved in the folding and bending may be represented algebraically and geometrically. Attempts to apply the tools of physical mechanics to structural geology are difficult, however, because of the irregular nature of most rock units and because of uncertainty as to the forces that cause rocks to deform, particularly over the long span of time involved in nature compared with the short-term behaviour of materials deformed experimentally in the laboratory.

For further information on the substantive aspects of structural geology, see ROCK DEFORMATION; and ROCKS, PHYSICAL PROPERTIES OF.

#### VOLCANOLOGY

Volcanology is the science of volcanoes and deals with their structure, petrology, and origin. It is also concerned with the contribution of volcanoes to the rock structure of the Earth's crust, with their role as contributors to the atmosphere and hydrosphere and to the balance of chemical elements in the Earth's crust, and to the relationships of volcanoes to certain forms of metallic ore deposits. In addition, the study of volcanoes is closely linked with the study of large-scale crustal phenomena, including earthquakes and mountain building.

Volcanoes result from material emerging in molten form from the depths of the Earth's crust. Volcanic rocks include lavas that have solidified upon cooling after emerging in liquid form, as well as pyroclastic deposits—fragments ejected from volcanoes and spread over the slopes of volcanic mountains or blown over larger areas before deposition. The size of volcanic ejecta ranges from

blocks as large as a house to fine grains of pumice and microscopic particles of volcanic ash.

Many of the problems of volcanology are closely related with those of the origin of mountains and continents. An important question concerns the origin of molten lava. Geophysical evidence indicates that the crust of the Earth behaves essentially as a rigid solid, and yet the lava emerging at the surface is liquid. It can be argued that liquefaction of lava is related to reduction of pressure as the volcanic material is transported to the surface. Understanding of the geological controls of liquefaction and the routes by which material emerges from the depths of the crust is among the major objectives of volcanology.

One of the principal motives for studying volcanoes and volcanic products is that volcanism involves processes that were important in the origin and early evolution of the Earth. Of course, virtually all present-day geologic processes have influenced the history of the earth for much of geologic time. Volcanism, however, appears to represent a class of processes that was probably much more intense in the Earth's early stages. Volcanic products include water (commonly emitted as steam or water vapour) and various gases including ammonia and carbon dioxide. The atmosphere and hydrosphere are believed to be largely derived from volcanic emanations, modified by biological processes. Much of the water present at the Earth's surface, which has aggregated mostly in the oceans but to a lesser extent in glaciers, streams, lakes, and groundwater, probably has gradually emerged from the Earth's interior by means of volcanoes, beginning very early in the earth's history. The principal components of air, nitrogen and oxygen, probably have been derived through modification of ammonia and carbon dioxide emitted by volcanoes. Emissions of vapours and gases from volcanoes are an aspect of the degassing of the Earth's interior. Although the degassing processes that affect the Earth were probably much more vigorous when it was newly formed more than 4,000,000,000 years ago, it is interesting to consider that the degassing processes are still at work; but their scale is vastly reduced compared with their former intensity.

The study of volcanoes is dependent on petrology, which involves the examination of rocks in thin section with the polarizing microscope. Volcanic rocks that are glassy contain mineral grains too small to be distinguished with the microscope. These may require chemical analysis for adequate identification and classification. Analyses of volcanic gases and of hot springs in volcanic regions provide information about the late stages of volcanic activity, which are characterized by emission of volatile materials, including sulfurous gases. Many commercially valuable deposits of ores, particularly those that consist of metallic sulfides, are believed to have formed through the influence of hot, aqueous solutions of ultimate igneous origin and are termed hydrothermal ore deposits. Although many ore deposits have been formed at substantial depths under elevated temperatures and pressures, some ore deposits, particularly those yielding sulfides of mercury and antimony, are closely related to present-day hot springs in volcanic regions.

Volcanoes are serious hazards to property and human life. The catastrophic destruction of Pompeii in AD 79 by the eruption of Mt. Vesuvius is, no doubt, the best-known disaster caused by volcanic eruption. Yet, there have been many other recorded volcanic disasters, including a number in the 20th century. Considering the potential for destruction wrought by renewed future activity of volcanoes that are presently dormant or only slightly active, there is large incentive to develop methods of predicting volcanic eruptions. Studies of active volcanoes in Hawaii indicate that subtle but measurable changes in the shape of volcanoes sometimes occur immediately prior to specific eruptions. On the other hand, the most important need is to predict the times of eruption of volcanoes that are now essentially dormant and that stand close to cities. Unfortunately, the intervals of quiescence and eruption of volcanoes that have been intermittently active in the past are not very useful in predicting the

Prediction  
of  
eruptions

Volcanic  
processes  
and  
problems

times of future eruptions. Obviously it would be desirable to forecast eruptions with a precision of days or weeks, but this cannot be done at present and may ultimately prove to be impossible. Nevertheless, there is continued need for research on means of predicting eruptions. The substantive aspects of volcanology are covered in the article VOLCANOES.

### III. Study of surface features and processes

#### GEOMORPHOLOGY AND GLACIAL GEOLOGY

Geomorphology is literally the study of the form or shape of the Earth. In contrast to geodesy, however, geomorphology deals principally with the topographic features of the Earth rather than with the overall shape of the Earth. Geomorphology is concerned with the classification, description, and origin of landforms and is interdependent with many other branches of the geological sciences, particularly those dealing with processes that act on the landscape. These include glacial geology (the study of glaciers and their geological effects), hydrology (particularly fluvial processes), pedology (the study of soils), structural geology, volcanology, sedimentology, marine geology, meteorology, climatology, and aspects of biology, including plant ecology.

The events that influence the shape of landforms include most geologic processes, either directly or indirectly. The configuration of the Earth's surface reflects to some degree virtually all of the processes that take place at or close to the surface, as well as those that take place deep in the crust. The intricate details of the shape of a mountain range, for example, result more or less directly from the processes of erosion that are at work progressively removing material from the range. The spectrum of erosive processes includes weathering and soil-forming processes, and transportation of materials by running water, wind action, and mass movement. Glacial processes have been particularly influential in many mountainous regions. These processes are destructional in the sense that they are modifying and gradually destroying the previous form of the range. Also important in governing the external shape of the range are the constructional processes that are responsible for uplift of the mass of rock from which the range has been sculptured. A volcanic cone, for example, may be created by successive outpouring of lava, perhaps coupled with intermittent ejection of volcanic ash and tuff. If the cone has been built up rapidly, so that there has been relatively little time for erosive processes to modify its form, its shape is governed principally by the constructional processes involved in outpouring of volcanic material. But the forces of erosion begin to modify the shape of a volcanic landform almost immediately and continue indefinitely. Thus, at no time can its shape be regarded as purely constructional or purely destructional, for its shape is necessarily a consequence of the mutual interplay of these two great classes of processes.

Study of the processes that influence landforms is an important aspect of geomorphology. These include the study of activity of streams and lakes, which merges with hydrology and limnology, the transport and deposition of dust and sand by wind, the study of mass movement of material through downhill creep of soil and rock and by landslides and mudflows, and study of beach and shoreline processes that involve the mechanics and effects of waves and currents. Study of these different classes of processes forms subdisciplines that exist more or less in their own right. Yet, understanding the development of landforms and establishing a genetic classification that considers their origin are largely dependent on an understanding of processes.

Classification of landforms is a major aspect of geomorphology. A variety of classification systems have been devised in the past century in which a general objective has been to describe and group landforms according to the processes that shaped or influenced them. In addition, some classification systems incorporate the stage of development of landforms as an aspect of their evolutionary development through geologic time and take into consideration such influences as lithology of

the rocks, the attitudes of strata and the presence of faults and joints, and factors of broad influence, including regional uplift and climatic changes.

In considering the origin of a particular landscape, for example, an intricately dissected high-plateau region such as the Grand Canyon region of the Colorado Plateau in northern Arizona, the influence of the structure of the rocks on the landscape is at once apparent. The Colorado Plateau is carved from flat-lying or gently dipping sedimentary rocks that include sandstones, limestones, and shales. The intricate steplike topography of much of the region is strongly influenced by the erosional behaviour of these rocks, particularly as a result of the alternation of resistant and relatively nonresistant rock units. If the rocks had been intricately folded instead of being only slightly deformed, the topographic configuration of the region would be vastly different. Furthermore, the climate of the region has had a large influence. The arid or semi-arid climate of the Colorado Plateau profoundly affects the vegetative cover, and this in turn influences erosion by running water. The configuration of the plateau probably would be measurably different if it had continuously evolved in a humid climate of high rainfall. Finally, the Colorado Plateau has a complex geologic history. Generally speaking, its history involves uplift of the Earth's crust over broad areas, coupled with sculpture of the land by running water, including the carving of deep canyons and their tributaries, such as the Grand Canyon, by streams. The uplift of the crust, however, did not take place as a single uniform rise but, rather, occurred intermittently, with erosion of large volumes of rock coupled with pulses of renewed uplift. The present landscape thus represents the combined effects of processes, rock materials and structures, and the region's geologic history. The scope of geomorphology embraces all these aspects.

Glacial geology can be regarded as a branch of geomorphology, although glacial geology is such a large area of research that it stands as a distinct subdiscipline within the geological sciences. Glacial geology is concerned with the properties of glaciers themselves, as well as with the effects of glaciers as agents of both erosion and deposition. Glaciers are accumulations of snow transformed into solid ice. Important questions of glacial geology concern the climatic controls that influence the occurrence of glaciers, the processes by which snow is transformed into ice, and the mechanism of the flow of ice within glaciers. Other important questions involve the manner in which glaciers serve as erosive agents, not only in mountainous regions but also over large regions where great continental glaciers now extend or once existed. Much of the topography of the northern part of North America and Eurasia, for example, has been strongly influenced by glaciers. In places, bedrock has been scoured clean of most surficial debris. Elsewhere, deposits of glacial till mantle much of the area. Other extensive deposits include unconsolidated sediments deposited in former lakes that existed temporarily as a result of dams created by glacial ice or by glacial deposits. Many presently existing lakes are of glacial origin. The Great Lakes, for example, owe their origin to the erosive effects of large lobes of glacial ice, as well as to deposits left behind by the ice sheets.

Other branches of the geological sciences are closely linked with glacial geology. In glaciated regions, the problems of hydrology and hydrogeology are strongly influenced by the presence of glacial deposits. Furthermore, the suitability of glacial deposits as sites for buildings, roads, and other man-made features is influenced by the mechanical properties of the deposits and by soils formed on them.

For further information on the substantive aspects of geomorphology and glacial geology, see LANDFORM EVOLUTION; GLACIATION, LANDFORMS PRODUCED BY; ICE SHEETS AND GLACIERS; and articles on the several important processes, namely WIND ACTION; FLUVIAL PROCESSES; WATER WAVES; EARTH MOVEMENTS ON SLOPES; and HILLSLOPES. #### ENGINEERING, ENVIRONMENTAL, AND URBAN GEOLOGY

These disciplines are broadly concerned with the application of geology to construction engineering and to problems of land use. The location of a bridge, for example, involves geological considerations in selecting sites for the supporting piers. The strength of such geological materials as rock or compacted clay that occur at the sites of the piers should be adequate to support the load placed on them. Engineering geology is concerned with the engineering properties of geological materials, including their strength, permeability, and compactability, and with the influence of these properties on the selection of locations for large buildings, roads and railroads, bridges, dams and reservoirs, and other major civil features, including airfields, river and ocean piers, and harbour breakwaters. In this context, engineering geology merges with various branches of both civil engineering and soil mechanics.

Environmental geology and urban geology are closely related to engineering geology. Urban geology can be considered an aspect of environmental geology and is concerned with the application of engineering geology and other branches of geology to environmental problems in urban areas. Environmental geology is not sharply defined but is generally concerned with those aspects of geology that touch on man's environment. Broadly speaking, all aspects of geology influence man's environment, but, more specifically, environmental and urban geology deal in large measure with those aspects of geology that directly influence man's use of land. These include the stability of sites for buildings and other civil features, sources of water supply, contamination of waters by sewage and chemical pollutants, and selection of sites for burial of refuse so as to minimize pollution by seepage. Questions of geologic hazards, including earthquakes, tsunamis (water waves of seismic origin), and floods, are also broadly relevant to environmental and urban geology. The source of geological building materials, including sand, gravel, and crushed rock, is also relevant. Finally, the distribution of naturally occurring toxic or hazardous materials, such as compounds of mercury and certain radioactive materials, has an influence on man's health and therefore is properly within the sphere of environmental geology.

Pedology  
or soil  
science

Soil science, or pedology, also can be mentioned in the environmental context. It is an interdisciplinary science that owes strong allegiance to mineralogy, glacial geology, climatology, hydrology, physical chemistry, biochemistry, geochemistry, and to aspects of biology, including plant ecology, bacteriology, and mycology (the study of fungi). In agriculture, pedology is linked with agronomy and forestry. In civil engineering and in engineering geology, the physical properties of soils, including plasticity and compactability, are important considerations in the location of civil structures. The soil is the principal bridge between the inanimate physical world and the biological world. Soil is not only of both physical and biological origin but it is also a major component of the environment, affecting directly or indirectly all forms of life. Soil is not sharply distinguished from weathered rock, although a convenient definition of soil is that it is that part of the mantle of weathered material that can support rooted plants.

For information on some of the substantive aspects of the disciplines cited or alluded to here, see EARTH MOVEMENTS ON SLOPES; SOILS; WEATHERING; RIVERS AND RIVER SYSTEMS; SEDIMENT YIELD OF DRAINAGE SYSTEMS; URBAN CLIMATES; and PHYSIOGRAPHIC EFFECTS OF MAN.

#### IV. Study of Earth history

##### HISTORICAL GEOLOGY

One of the major objectives of geology is to establish the history of the Earth from its inception to the present moment in time. This is an extraordinarily difficult objective, demanding use of most of the scientific tools that the geologist has at his command. In contrast to the

written records of much of human history, geological history must be inferred largely from evidence obtained from the Earth and other planets. There are many forms of evidence. The most important is provided by the geometrical relationships of rocks with respect to each other, particularly layered rocks, or strata, the relative ages of which may be determined by applying simple principles. One of the major principles of stratigraphy, the science of strata, is that within a sequence of layers of sedimentary rock, the oldest layer is necessarily at the base of a sequence of strata and that the layers are progressively younger with ascending order in the sequence. This is termed the law of superposition and is one of the great general principles of geology. There are, of course, exceptions to the law of superposition, as for example when a sequence of beds or layers has been overturned by structural deformation. These exceptions do not invalidate the law, however, for it implies that the succession of ages in a sequence of sedimentary strata is from oldest to youngest in ascending stratigraphic order. Ordinarily, beds of sedimentary rocks are deposited more or less horizontally (the law of initial horizontality). In some regions, sedimentary strata have remained more or less horizontal long after they were deposited. Some of these sedimentary rocks were deposited in shallow seas that once extended over large areas of the present continents. In many places, sedimentary rocks lie much above sea level, reflecting vertical shift of the crust relative to sea level. In regions where the rocks have been strongly deformed through folding or faulting, the original attitudes of strata may be greatly altered, and sequences of strata that were once essentially horizontal may now be steeply inclined or overturned.

Prior to the development of radiometric methods of dating rocks, the ages of rocks and other geologic features could not be expressed quantitatively or as numbers of years but instead were necessarily expressed solely in terms of relative ages, in which the age of a particular geologic feature could be expressed as relatively younger or older than other geologic features. The ages of different sequences of strata, for example, can be compared with each other in this manner, and their relative ages with respect to faults, igneous intrusions, and other features that exhibit crosscutting relationships can be established. Given such a network of relative ages, a chronology of events has been gradually established in which the relative time of origin of various geologic features is known. This is the main thread of historical geology—an ordered sequence of geological events whose occurrence and relative ages have been inferred from evidence preserved in the rocks. In turn, the development of radiometric dating methods has permitted numerical estimates of age to be incorporated in the scale of geological time.

The geological time scale, with its geological eras, periods, and epochs, has evolved over the course of several centuries, with many of the divisions of time in present use having been initially defined in the 19th century. Although absolute-age estimates have been assigned to the divisions of geological time, it should be emphasized that the geological time scale is based on relative ages established through use of classical principles of stratigraphy and that it is not generally dependent on the presence of numerical estimates of age. The availability of quantitative methods of establishing ages has, however, added much precision to the geological time scale.

The divisions of geological time have been defined in terms of the time required for deposition of certain sequences of strata. The Cambrian Period, for example, is defined as the time during which the sedimentary rocks were deposited that form the Cambrian System of strata, as known in Wales (between 570,000,000 and 500,000,000 years ago). The definition of the Cambrian System of strata is more or less arbitrary. Strata termed Cambrian in Wales form a thick and complex sequence of strata the conditions of deposition of which are not well understood and that have been extensively structurally deformed since they were deposited. In spite of these complications and shortcomings, the Cambrian System

Divisions  
of  
geological  
time

in Wales, in effect, defines that interval of geological time that is called the Cambrian Period. Although the Cambrian Period spans a particular sequence of years, the definition of the Cambrian Period is necessarily in terms of the rocks that form the Cambrian System and is not defined in terms of a particular time span.

In spite of the seemingly precise compartmentation of geological time into the eras, periods, and epochs of the present time scale, there are many uncertainties that stem from the subjective, arbitrarily chosen boundaries between systems of strata. A major problem concerns "missing" intervals of strata that define systems. Although geological time is continuous, it cannot be assumed that the sequences of strata chosen to define intervals of geological time are necessarily continuous, and, in fact, many sequences used to define the systems of rocks are known to be incomplete. This is indicated by intervals of erosion evidenced by unconformities or breaks in continuity of deposits within the sequences.

For information on the substantive aspects of historical geology as discussed above, see GEOLOGICAL TIME SCALE; STRATIGRAPHIC BOUNDARIES; and the several articles covering the geological record—e.g., CAMBRIAN PERIOD; MESOZOIC ERA; HOLOCENE EPOCH.

#### PALEONTOLOGY

The geological time scale is based principally upon the relative ages of sequences of sedimentary strata. Establishing the ages of strata within a region, as well as the ages of strata in other regions and on different continents, involves stratigraphic correlation from place to place. Although correlation of strata over modest distances often can be accomplished by tracing out particular beds from place to place, correlation over long distances and over the oceans almost invariably involves comparison of fossils. With rare exceptions, fossils occur only in sedimentary strata. Paleontology, which is the science of ancient life and deals with fossils, is mutually interdependent with stratigraphy and with historical geology. Paleontology also may be considered to be a branch of biology.

*Invertebrate paleontology.* Organic evolution is the essential principle involved in the use of fossils for stratigraphic correlation. Organic evolution incorporates progressive irreversible changes in the succession of organisms through time. A small proportion of types of organisms has undergone little or no apparent change over long intervals of geologic time, but most organisms have progressively changed, and earlier forms have become extinct and, in turn, have been succeeded by more modern forms, ad infinitum. Organisms preserved as fossils that lived over a relatively short span of geological time and that were geographically widespread are particularly useful for stratigraphic correlation. These fossils are indices of relative geologic age and may be termed index fossils. The various subdivisions of the Cambrian System, for example, have been correlated in various parts of the world on the basis of trilobites and other invertebrate fossils preserved in Cambrian strata. Certain types of trilobites occur only in the lower part of the Cambrian System, and their presence is an indication of Early Cambrian age; this permits correlation of Lower Cambrian strata between continents. Trilobites are generally good index fossils because they were widespread occupants of shallow seas that extended over continents. The trilobites evolved steadily, and older forms progressively became extinct and were succeeded by newer forms. Trilobites as a whole, however, had an extremely long reign before their extinction at the close of the Permian Period (225,000,000 years ago).

Fossils play another major role in geology because they serve as indicators of ancient environments. Trilobites are marine organisms and occur in association with other fossil organisms that lived in the sea. Therefore, the presence of trilobites preserved in sedimentary strata generally can be regarded as reliable evidence that the strata were deposited in the sea, and not in lakes or bogs.

The forms of fossils that are of use and interest to geology and paleontology are almost as vast as the organisms

that presently populate the world. One of the major branches of paleontology is invertebrate paleontology, which is principally concerned with fossil marine invertebrate animals large enough to be seen with little or no magnification. The number of invertebrate fossil forms is large and includes brachiopods, pelecypods, cephalopods, gastropods, corals and other coelenterates (e.g., jellyfish), bryozoans, sponges, various arthropods (invertebrates with limbs—e.g., insects), including trilobites, echinoderms, and many other forms, some of which have no living counterparts. The invertebrates that are used as index fossils generally possess hard parts, a characteristic that has fostered their preservation as fossils. The hard parts preserved include the calcareous or chitinous shells of the brachiopods, cephalopods, pelecypods, and gastropods, the jointed exoskeletons of arthropods such as the trilobites, and the calcareous skeletons of frame-building corals and bryozoans. The vast variety of organisms lacking hard parts are poorly represented in the geological record; however, they have sometimes been found to occur as impressions or carbonized films in finely laminated sediments.

*Vertebrate paleontology.* Vertebrate paleontology is concerned with fossils of the vertebrates: fish, amphibians, reptiles, birds, and mammals. Although vertebrate paleontology has close ties with stratigraphy, vertebrate fossils generally have not been extensively used as index fossils for stratigraphic correlation, vertebrates generally being much larger than invertebrate fossils, and consequently more rare. Fossil mammals, however, have been widely used as index fossils for correlating certain non-marine strata deposited during the Tertiary Period (from 65,000,000 to 2,500,000 years ago).

*Micropaleontology.* Micropaleontology, as its name implies, involves the study of organisms so small that they can be observed readily only under magnification. The size range of microscopic fossils, however, is immense. The term micropaleontology often connotes that aspect of paleontology devoted to the Foraminifera, which are protozoans, each consisting of a single cell and possessing a hard skeleton. Foraminifera range in size from those that are readily viewable in hand specimens, down to those that must be magnified several tens of times for easy viewing. Micropaleontology, viewed in total, however, involves successive ranges of sizes of microscopic fossils down to organisms that must be magnified hundreds of times or more for viewing. In fact, the most minute organisms under investigation in the mid-1970s were observed with electron microscopes under thousands of magnifications. The study of ultrasmall fossils is perhaps the fastest growing segment of contemporary paleontology and is dependent upon modern laboratory instruments, including electron microscopes and advanced light microscopes, as well as highly specialized methods of specimen preparation, in which the ultrasmall fossils are segregated from the rock material where they occur or where they are etched into relief, so that they may be viewed on surfaces under high magnification.

*Paleobotany.* Paleobotany is the study of fossil plants. The oldest widely occurring fossils are various forms of calcareous algae that apparently lived in shallow seas, although some may have lived in freshwater. Their variety is so profuse that their study forms an important branch of paleobotany. Other forms of fossil plants consist of land plants or of plants that lived in swamp forests, standing in water that was fresh or may have been brackish. The coal-forming swamps of the Pennsylvanian Period (from 325,000,000 to 280,000,000 years ago) are particularly well-known as a source of spectacularly preserved ancient plants, many of large size, although coals also have formed in swamp environments during other geological periods.

*Palynology.* Palynology deals with plant spores and pollen that are both ancient and modern and is a branch of paleobotany. It plays an important role in studies of ancient climates, particularly through studies of deposits formed during glacial and interglacial stages. Study of a sequence of spore- or pollen-bearing beds may reveal suc-

Sizes of  
micro-  
fossils

Organic  
evolution  
and index  
fossils

Taxo-  
nomic  
classifica-  
tion of  
fossils

cessive climatic changes, as indicated by changes in types of spores and pollen derived from different vegetative complexes. Spores and pollen, being minute, are borne by the wind and spread over large areas. Furthermore, spores and pollen tend to be resistant to decay and may thus be preserved in sediments under adverse conditions.

The methods of classifying fossils have been subjected to increased scrutiny in recent years. The establishment of the taxonomic categories into which fossil organisms are classed is to a major extent a matter of individual judgment and tends to be highly subjective. Controversy reigns between the "lumpers" and "splitters," representing extremes of views among paleontologists who classify and define fossils according to species, genera, and higher taxonomic categories. At one extreme, there are those (the splitters) who tend to give relatively strong weight to small differences in form between different specimens, establishing relatively large numbers of different species and genera. At the other extreme, the lumpers tend to be conservative in the number of taxonomic categories, minimizing lesser variations by lumping specimens into a smaller number of taxonomic categories. Rigid rules for taxonomic classification are difficult or impossible to devise. Continuous evolution resulting in progressive changes in form makes compartmentation into rigid categories an artifice of convenience (see POLLEN STRATIGRAPHY).

**Biometric methods.** In the past decade, the methods of biometry and numerical taxonomy have risen to prominence, both in paleontology and in the classification of living organisms. The objectives of biometrical and numerical taxonomic methods include description of the shape or form of organisms statistically and the expression of taxonomic relationships quantitatively. The similarity of a given species to another species in the same genera can be expressed as a numerical coefficient. In turn, a hierarchy of relationships in a grouping of related taxonomic forms can be expressed as a matrix of coefficients. Statistical methods, particularly those of multivariate statistics, generally are needed to seek out relationships if numerical data are employed. Furthermore, the application of statistical methods has given impetus to the use of assemblages of organisms to define a taxonomic species instead of employing a single type specimen. In spite of the seeming merits of numerical taxonomy, the subject is fraught with controversy and is far from universal acceptance.

For information on the substantive aspects of paleontology, see FOSSIL RECORD, which covers invertebrate and vertebrate fossils, microfossils, and fossil plants.

**STRATIGRAPHY AND SEDIMENTOLOGY**

Inasmuch as stratigraphy deals principally with sedimentary rocks, it is closely allied with sedimentology, the study of sediments. Sedimentology deals with the processes of sedimentation and with the subsequent modification of sediments as they are transformed into rocks. Toward one extreme, sedimentology merges with sedimentary petrology and with mineralogy. Toward the other extreme, it merges with stratigraphy. The extremes may be viewed according to scale of size, stratigraphy dealing with the large-scale aspects, ranging from details of bedding to aspects involving variation on a regional or continental scale. Sedimentary petrology, on the other hand, deals generally with the small-scale aspects, at the hand-specimen, microscopic, and chemical levels. Sedimentology is a bridge between these extremes.

Stratigraphy, sedimentology, sedimentary petrology, and the mineralogy and geochemistry of sediments are currently the subject of intensive, coordinated research. Important questions concerned the deposition and subsequent alteration of ancient carbonate deposits (limestones and dolomites), many of which have large areal extent and which in some places pass laterally into evaporite deposits containing gypsum, anhydrite, halite, and other salts. Study of carbonate deposits now forming in modern seas is an essential aspect of this research. Other research is focussed on the deposition of alternating shales and sandstones through the influence of deltaic

and near-shore distributary systems. Comparison of modern deltas forming on continental shelves with ancient deposits of deltaic origin has sharpened insight into origin of the ancient deposits.

For information on some of the substantive aspects of stratigraphy and sedimentology, see STRATIGRAPHIC BOUNDARIES; and SEDIMENTARY ROCKS. See also RIVER DELTAS for coverage of modern work on these features.

**ASTROGEOLOGY**

Astrogeology is concerned with the geology of the solid bodies in the solar system, the planets and asteroids (minor planets). Questions of origin of the planets and asteroids are germane to both geology and astronomy; astrogeology is a bridge between the two groups of sciences. Except for studies of the Earth, astrogeology largely has been concerned with the geology of the Moon. Prior to the advent of manned landings on the Moon in 1969, most of the knowledge of the Moon was derived from study of photographs, made first with telescopes and later through television images telemetered to Earth from spacecraft. An intensive study of photographs has provided a basis for detailed mapping of the Moon's side that faces the Earth. By employing basic geologic principles for determining relative ages, including superposition of features and crosscutting relationships among them, it has been possible to establish a chronology of relative ages of events revealed in the surficial features of the Moon on photographs.

Some of the basic geological problems of the Moon are similar to those of the Earth. An important question concerns the age, lithologic nature, and thickness of the Moon's crust. Another is whether the Moon is internally active or is geologically dead. The Earth, of course, is active internally in both its mantle and deep crust. The craters of the Moon, which have been studied for centuries, have evoked much speculation. A key question is whether they were formed principally by impact of large meteorites, are volcanic in origin, or a combination of both. There can be little doubt, however, that meteorite impact has been of appreciable importance. Exploration of the Moon has given strong impetus to the study of impact craters on Earth. The Earth's known or suspected impact craters are geologically young, whereas most of the Moon's impact craters are undoubtedly much older, some perhaps having been formed early in the Moon's history. The lack of relatively ancient impact craters on the Earth is explained simply by the fact that early impact craters, which very probably existed in abundance, have long since been destroyed by the continuous erosional and depositional processes that occur on the Earth. On the other hand, the lack of an atmosphere and hydrosphere decrees that comparable processes have not occurred on the Moon (see further METEORITE CRATERS).

**BIBLIOGRAPHY.** C.R. LONGWELL, R.F. FLINT, and J.E. SANDERS, *Physical Geology* (1969), an authoritative, thorough, general coverage of the physical aspects of the geological sciences, with emphasis on the role of geologic processes as in rock cycle; J. GILLULY, A.C. WATERS, and A.O. WOODFORD, *Principles of Geology*, 4th ed. (1971), a broad treatment of physical geology; A. HOLMES, *Principles of Physical Geology* (1965), an extremely thorough, detailed coverage of physical geology; R.H. DOTT, JR., and R.L. BATTEN, *Evolution of the Earth* (1971), a readable, thorough treatment of the principles of historical geology, accompanied by a survey of the evolution of the continents; A.O. WOODFORD, *Historical Geology* (1965), a detailed treatment of the principles of interpretation of geologic history, coupled with a survey of the geologic history of North America.

(J.W.Ha.)

**Geological Time Scale**

The geological time scale is the calendar for events in Earth history. It is based on stratigraphy, which is the study of sedimentary rocks and their historical significance. Sedimentary rocks have accumulated through geological time in ancient marine and terrestrial environments, and they contain fossils, the remains of once-living organisms. Because living things have constantly changed by evolution through geological time, particular kinds of

Types of units

organisms are characteristic of particular parts of the geologic column. For this reason, the fossils that occur in sedimentary rocks provide the chief means of correlating rock units and establishing a standard geological time scale. Since the 1950s radiometric dating has provided absolute age data to supplement the relative dates obtained from the fossil record.

There are two conceptually different kinds of units in the geological record: rock-stratigraphic units and time-stratigraphic units. Rock-stratigraphic units describe particular kinds of rocks that constitute a mappable formation. The formations in a given area generally are arranged in chronological order (younger rocks overlies older). Time-stratigraphic units, by contrast, contain rocks formed during a particular segment of geologic time without regard to the rock types involved. The boundaries of time-stratigraphic units must be inferred from fossil or other evidence. Correlation of the strata according to their age is a vital process in working out the geological history of a region.

The fundamental time-stratigraphic units are the geological systems that are defined on the basis of selected sedimentary sequences in type areas. The systems are grouped for convenience into larger units (erathems), and they are subdivided into progressively smaller units, namely, series, stages, and zones. Geological time units are simply abstractions of the time-stratigraphic units, and they are given the same names. For example, the Cambrian System, defined by a sequence of sedimentary rocks in Wales, is the basis for a pure time term, the Cambrian Period, that surely existed everywhere, although in many areas it is unrepresented or only partly represented by a rock record. Corresponding time-stratigraphic and geological time terms are as follows:

time-stratigraphic units	geologic time units
Erathem	Era
System	Period
Series	Epoch
Stage	Age
Zone	Phase

The fundamental geologic time units, the periods, are grouped into larger units called eras. From names proposed by Adam Sedgwick in 1838 and by John Phillips in 1841, the periods are placed in the Paleozoic, Mesozoic, and Cenozoic eras. These names derive from "ancient life," "middle life," and "modern life," reflecting the profound changes that occurred in living organisms at the outset of each. The eras and periods (and Cenozoic epochs) of the geological time scale are shown below.

The old rocks below the Paleozoic have always been known simply as the Precambrian. These rocks contain no diagnostic fossils and their subdivision never has been possible. Younger rocks of the Paleozoic, Mesozoic, and Cenozoic can be grouped under the complementary term Phanerozoic, which means "evident life."

Initial efforts directed toward formulating a time scale based on sedimentary rock strata were made in the late 18th century. Stratigraphers added much refinement during the 19th century, but it was not until the advent of radiometric dating in the early decades of the 20th century that they realized that the fossiliferous Phanerozoic rocks, to which their previous efforts had been almost exclusively devoted, constituted only a minor portion of geologic time. It is now known that Precambrian time represents the first 85 percent of earth history.

This article treats the historical development of the geological time scale and its calibration. On methods of dating, see DATING, RELATIVE AND ABSOLUTE; for relevant information on stratigraphy and sedimentation, see EARTH, GEOLOGICAL HISTORY OF; STRATIGRAPHIC BOUNDARIES; and SEDIMENTARY ROCKS; see also FOSSIL RECORD; PRECAMBRIAN TIME; and the several articles on the geological periods and eras (e.g., ORDOVICIAN PERIOD).

HISTORICAL DEVELOPMENT OF THE TIME SCALE

Nicolaus Steno perceived the guiding principle of superposition of strata in 1669 and was the first to express the idea that they were initially deposited in a horizontal

relative duration of eras	era	period	epoch	duration in millions of years (approx.)	millions of years ago (approx.)

position. In 1760 Giovanni Arduino placed the rocks of the same region into three main categories: (1) Primary: crystalline rocks with metallic ores; (2) Secondary: hard stratified rocks with fossils; (3) Tertiary: weakly consolidated stratified rocks, usually with marine shells. Almost simultaneously Johann Gottlob Lehmann (1756) recognized in Thuringia a threefold grouping of rocks, which can be characterized as (1) crystalline, (2) stratified, and (3) alluvial; and within a few years similar threefold groupings of rocks were recognized elsewhere in Europe and as far away as the Urals. Recognition of threefold groupings of rocks based on the principle of superposition thus provided an early framework of thought, but rock types incorrectly were equated to geological ages. The stratified series of Lehmann, for example, generally was believed to be the result of the universal Noachian Deluge. In their search for principles of rock classification, the early workers assumed that their major rock groupings, and even the smaller rock units that composed them, each represented a discrete episode in geological time. This school of thought was codified into a rigid scheme by Abraham Gottlob Werner of Freiberg, Saxony, so that by the late 18th century, Werner's version became the reigning doctrine of the time.

Werner thought that all rocks were deposits of a primeval ocean that once covered the entire Earth. These deposits were divided into four distinct series. The Primitive Series, deposited from the cloudy primeval ocean, included granite, gneisses, schists, and other crystalline rocks. The Transition Series included slates, graywackes, and some limestone. Both of these series consisted of "universal formations" and were considered to have enveloped the entire global surface at one time. The overlying Stratified Series, consisting of sandstone, limestone, salt, gypsum, coal, and basalt, and the Alluvial Series, consisting chiefly of sand, clay, and gravel, were deposited as the ocean water supposedly subsided below the level of the highest mountain tops.

Werner's erroneous ideas ultimately gave way to the views of James Hutton, a Scot, who in 1795 maintained that present rates of geologic processes, such as erosion of rocks and deposition of sediment, were sufficient to account for all the Earth's features provided that there had been vastly more time than the 6,000 years generally interpreted from the Scriptures. Chiefly because it

Early theories

The  
discoveries  
of Smith  
and Cuvier

required a great amount of time, Hutton's philosophy did not gain immediate favour, but it became accepted after the writings of Charles Lyell beginning in 1830.

The old idea that ages of rocks may be ascertained by their composition failed to stand up under field observations, and in the early decades of the 19th century it was replaced by the much more fruitful concept of faunal succession that was discovered by William Smith. Between the years 1793 and 1815 Smith examined rock strata throughout much of Great Britain, and he found that each sedimentary rock unit contained its own distinguishing assemblage of fossils. This was commonly the only way that different units of similar rock type could be distinguished. Smith was thus able to recognize specific rock units in areas where rock type alone was inconclusive. Utilizing his new principle, Smith produced the first geologic map of England and Wales in 1815, and this represented a landmark in the knowledge and understanding of rocks. The discovery that strata may be identified by their contained fossils made time correlation between distant localities possible.

Using Smith's methods, Georges Cuvier, a French zoologist, worked out the detailed stratigraphic sequence of vertebrates and marine invertebrates in the Tertiary strata of the Paris Basin. In 1812 he showed conclusively that many fossil invertebrates had no known counterparts living today. The reality that many once-living species had become extinct was at last clear.

The discoveries of Smith and the refinements added by Cuvier made possible the recognition of rocks of the same age in widely separated areas irrespective of rock types. It thus became feasible to define major units of sedimentary rock and, using their distinctive fossils, to distinguish their time counterparts in remote regions. Thus the stage was set for realization of a geologic time scale, and in the three decades following these discoveries most of the geologic systems in use today were defined. The geologic time scale continued to evolve slowly until the turn of the 20th century. Although it has been quite stable since then, it is still subject to future refinements. The following chronological outline traces the origin of the names currently in use.

**Geological systems.** *Tertiary.* Coined as a descriptive term in 1760 by Arduino, Tertiary units were traced widely. Tertiary strata were the object of Cuvier's landmark faunal studies in the Paris Basin, and following analysis of invertebrate faunas by Charles Lyell and Gerard Deshayes in the late 1820s and early 1830s, the Tertiary attained the status of a time-stratigraphic system. Today it is widely considered a system of the Cenozoic Era. Its constituent series were named in France. The Eocene, Miocene, and Pliocene were defined by Charles Lyell in 1833 on the basis of the relative proportions of living and extinct fossils in each. August von Beyrich added the Oligocene in 1854; Wilhelm Schimper the Paleocene in 1874.

*Jurassic.* In 1795 Alexander von Humboldt, a pioneer German geologist, recognized the strata of the Jura Mountains in northern Switzerland as a separate unit. Initially it was only a descriptive unit, but later (1839), C.L. von Buch redefined the Jurassic into a time-stratigraphic context and noted three divisions that he suggested might be further divided in accord with fossil content, a course followed by later workers.

*Cretaceous.* A Belgian geologist, Omalius d'Halloy, in 1822 proposed this term for strata of the Paris Basin. The term derives from the Latin word for chalk and is entirely descriptive. From the outset, the Cretaceous included more than just chalk beds, even in its type area where the lower portion consists of sandstone and shale. In 1906 T.C. Chamberlin and R.D. Salisbury proposed dividing the Cretaceous of the United States into two systems, the Comanchean below and a restricted Cretaceous above. Their proposal, however, never met with acceptance.

*Carboniferous.* Two British geologists, William Conybeare and William Phillips, proposed this name in 1822 for strata in central England that contained coal beds.

Although the term Carboniferous is wholly descriptive, Conybeare and Phillips anticipated that their system might later be widely recognizable by its distinctive fossils.

*Quaternary.* In 1829 Jules Desnoyers proposed this term in the Paris Basin for a sequence of diverse sedimentary and volcanic materials that he thought to be younger than the Tertiary rocks. Today Quaternary includes the Pleistocene Series (proposed by Lyell in 1839), which constitutes deposits formed during the glacial ages, and the Holocene or Recent Series (proposed by Lyell in 1833), which dates from the last retreat of the continental glaciers from North America and Europe.

*Triassic.* Friedrich von Alberti, a German geologist, introduced this essentially descriptive name in 1834 to a sequence of rocks with a striking threefold division. In the type area of southern Germany, the strata are widely traceable but poorly fossiliferous. In the Alps to the south, a complete sequence of marine faunas provides the standard of reference for worldwide correlation.

*Cambrian and Silurian.* After intensive study of the Paleozoic sequence in Wales, two British geologists, Adam Sedgwick and Roderick Impey Murchison, named the Cambrian and Silurian, respectively, for ancient Welsh tribes in 1835. Each worker attempted to recognize physical breaks in the stratigraphic record as boundaries for his system. Murchison carefully documented the abundant fossils of his Silurian strata, but Sedgwick's strata were less fossiliferous, and his breakdown of the Cambrian was essentially lithologic. Murchison had begun with the top of the Lower Paleozoic sequence in the southeast, and Sedgwick had begun at the base in the northwest and they worked toward one another. Later, when it became clear that their systems overlapped, a quarrel ensued. The controversy that followed was resolved 44 years later when Charles Lapworth named the Ordovician System for the disputed interval.

*Devonian.* In 1840 Murchison and Sedgwick jointly named the Devonian for the rocks of Devonshire in southern England, prior to their misunderstanding over the contact between the Cambrian and Silurian. Devonshire is a poor type area because the rocks are intensely deformed and the basal contact is not exposed. Nevertheless, the rocks are fossiliferous and can be distinguished from the Silurian below and the Carboniferous above; this led to their distinction of the Devonian. Murchison and Sedgwick showed that fossils could be used to recognize the Devonian System in the Rhineland where it is more fossiliferous and better exposed. This later came to be the worldwide standard of reference.

*Permian.* Murchison named his system in 1841 for the province of Perm, in Russia, where a great thickness of limestones overlies the Carboniferous. Murchison recognized that the fossils differ from those found in older and younger strata, and he ascertained that Permian strata could be identified in widespread areas by their distinctive fossils before he formally named this system.

*Mississippian.* Alexander Winchell introduced this term into American stratigraphic terminology in 1870 for the well-exposed Lower Carboniferous strata of the Mississippi Valley. T.C. Chamberlin and R.D. Salisbury elevated it, along with the Pennsylvanian, to system status in their influential textbook of 1906, and they justified this division largely on the basis of the supposed widespread unconformity that separated the two. The U.S. Geological Survey has recognized it officially since 1953, but it has not found use outside North America.

*Ordovician.* In 1879 Charles Lapworth proposed this system to include the disputed interval between the Cambrian and Silurian and to express the apparent threefold paleontologic division in Early Paleozoic strata of Europe. Boundaries of Lapworth's Ordovician were solely paleontological, based chiefly on graptolites.

*Pennsylvanian.* In 1891 Henry Shaler Williams coined this name from the state of Pennsylvania for Upper Carboniferous strata as a counterpart to Winchell's Lower Carboniferous Mississippian strata. Chamberlin and Salisbury elevated it, with the Mississippian, to full system

The  
work of  
Sedgwick  
and  
Murchison

status in their 1906 text. Since its introduction it has been used extensively in North America, but not elsewhere. Like the Mississippian, it has been formally recognized by the U.S. Geological Survey since 1953.

**Other systems.** Other system names have achieved regional recognition. For example, geologists in northern Europe use Gotlandian in place of "Silurian" in its modern sense. The Eocene and Neogene are commonly used as systems of the Cenozoic Era, especially in Europe. The top of the Oligocene divides the two of them.

**Stages and zones.** In publications between 1840 and 1852 the French paleontologist Alcide d'Orbigny divided the Cretaceous of France into small units that he termed stages. Each stage was based on a fossil aggregate that was unique to it and that permitted its widespread recognition, unlike the much more local variations based solely on rock types. The German paleontologist Albert Oppel, in 1856-1859, refined paleontologic correlation still further. He determined the stratigraphic ranges of many species with precision in numerous localities and introduced the concept of the paleontologic zone as a subdivision of the stage. The early recognition of stages and zones based on stratigraphic ranges of fossils was strictly empirical. In 1859 the widely used practice of correlation by fossils was at last placed on a firm theoretical basis by Charles Darwin's proofs of organic evolution.

**Recognition of systems in practice.** The Ordovician, Devonian, and Permian systems and the epochs of the Tertiary System were proposed initially as interpretive units, on the basis of the chronologic value of their contained fossils and on their inferred significance as discrete chapters in earth history. The Cambrian, Carboniferous, Jurassic, Cretaceous, and Tertiary were proposed largely as descriptive units and were defined initially on rock type without emphasis on the potential time value of their fossils. These units, however, later yielded fossils that proved to be diagnostic of their particular position in geologic time, and these systems took their places in the time scale. Thus, regardless of just how it was conceived originally, each system has been subsequently recognized in widely separated areas entirely on the basis of distinctive fossils. The systems currently in use have proven to be remarkably convenient units, and they have been successfully discriminated in virtually all parts of the world.

Many system boundaries today are problematical because they were not clearly stipulated or because type areas of adjacent systems are widely separated geographically. Those who initially defined the systems usually searched for the "natural" boundaries as interpreted from physical or biologic criteria. In many cases, however, the level of the apparently natural boundary in one area differed from that in another area. In other cases, the "natural" boundaries were in fact unconformities, namely, surfaces representing a considerable gap in geologic time between younger strata above and older rocks below. As world geologic knowledge developed, it became clear that many unconformities in type areas were represented elsewhere by continuous successions of strata that fell between defined systems. Faunas of these previously unstudied portions of the record were typically transitional between those of the overlying and underlying systems. Assignments of the problematical strata to one system or the other were somewhat arbitrary. Controversies soon arose over placement of boundaries of nearly all the systems, and many of these continue to the present day.

It appears that agreement on the placement of boundaries can be resolved only by international agreement. To this end, the International Union of Geological Sciences established an International Geological Correlation Program in 1967, which gave initial priority to the fixing of system boundaries.

**RADIOMETRIC CALIBRATION OF THE TIME SCALE**

Although Precambrian rocks lack useful fossils for time-stratigraphic purposes, development of the techniques of radiometric dating has provided a method for correlating

them and a potential tool for recognizing Precambrian time-stratigraphic units. In Phanerozoic rocks radiometric dates have greatly enhanced the understanding of the magnitude of geologic time and of rates of geologic processes. Although the radiometric calibration of the time scale is still in its formative stages, existing knowledge already permits the placing of a newly dated rock, whether igneous, metamorphic, or sedimentary, in the proper Phanerozoic series almost as confidently as if it contained diagnostic fossils.

**Radiometric theory and methods.** Radiometric dating depends on the presence in certain minerals of radioactive nuclides, which decay continuously to radiogenic daughter nuclides. Rates of radioactive decay are commonly expressed in terms of half-life, the time required for half of any given quantity of parent radioactive atoms to decay. The half-life of a radioactive nuclide is a constant and is unaffected by physical or chemical conditions or by the length of time the parent atoms have been in existence.

Most methods of radiometric dating are based on the accumulated quantity of atoms produced by radioactive decay. When a mineral containing the radioactive atoms crystallized, it contained no atoms of the decay product. With time, radioactive decay produces radiogenic daughter atoms in place of the radioactive parent atoms in the mineral's crystal lattice. At any stage of the process, the age of the mineral in years may be calculated from the ratio of daughter and parent atoms. In order for the accumulation method to yield significant results, two conditions must be satisfied: first, that the system has remained closed and there has been no addition or escape of undetected atoms during the existence of the mineral; and second, that no undetected atoms of the daughter nuclide were present in the mineral when it formed.

Dozens of radioactive nuclides occur in nature, but many are extremely rare, and others decay either too slowly or too rapidly to be of value for dating the geologic time scale. Just four nuclides (uranium-238, uranium-235, rubidium-87, and potassium-40) have provided nearly all of the radiometric ages for ancient rocks. The main methods used for age determinations of significance to the geological time scale are shown in the Table.

**Chief Methods of Determining Radiometric Ages for the Geological Time Scale**

parent nuclide	half-life (in 000,000 years)	daughter nuclide	minerals and rocks commonly dated
Uranium-238	4,510	lead-206	zircon uraninite pitchblende
Uranium-235	713	lead-207	zircon uraninite pitchblende
Rubidium-87	47,000	strontium-87	muscovite biotite lepidolite microcline whole metamorphic rock
Potassium-40	1,300	argon-40	biotite hornblende glauconite sanadine whole volcanic rock

Uranium-238 and uranium-235 always occur together in nature, and an advantage of the uranium-lead method is that the separate isotopes provide a cross-check in determining ages. Uranium is a rare element, and suitably datable minerals in which it occurs as a primary constituent are rare. Uranium, however, occurs in trace amounts in the common igneous mineral zircon, grains of which are isolated from their host rocks for dating. Zircons usually provide reliable radiometric dates.

The potassium-argon method is widely useful because potassium occurs abundantly in many common minerals, and laboratory techniques for measuring minute quantities of the daughter argon-40 are extremely refined. Basalts are rich in potassium-bearing minerals, but

Potassium-argon dating

individual mineral grains are so small that they cannot be isolated from the rock mass. In order to date these fine-grained rocks, a sample of the rock itself is subjected to analysis without separating mineral components, and this is termed the "whole-rock method." The whole-rock method has been applied successfully to basalts as young as 100,000 years. In addition to igneous minerals, the sedimentary mineral glauconite, which forms in certain environments, is datable by the potassium-argon method. A drawback to the potassium-argon method is that argon, being a gas, escapes easily from the host mineral grains upon heating or stress. Consequently burial to even moderate depths tends to promote argon loss and to lower the apparent age of the rock.

The rubidium-strontium method has been widely applied to igneous and metamorphic rocks, but it is especially valuable for the latter. In dating metamorphic rocks, the whole-rock method is commonly used. A weakness of the rubidium-strontium method is that the half-life of rubidium-87 is so long that it introduces a substantial measurement error in laboratory determinations, particularly in younger portions of the geologic column.

**Dating sedimentary rocks.** All of the methods discussed above depend very largely upon igneous and metamorphic minerals and, hence, igneous and metamorphic events can be dated with good accuracy. It has proved to be difficult, however, to tie igneous and metamorphic radiometric ages into fossil-bearing sedimentary rocks on which the geologic time scale is based. Radiometric ages have been correlated with the geologic time scale in three different ways: bracketed igneous intrusives, interbedded volcanic rocks, or authigenic minerals (those formed *in situ*) in the sedimentary strata themselves.

A dated igneous intrusive provides a minimum age for a sedimentary rock that it intrudes and a maximum age for a sedimentary rock deposited on top of it. Stratigraphic age of the intrusive may thus be bracketed between groups of strata whose geologic ages are known. Unfortunately, most intrusives are bracketed widely in time. A few, however, are bracketed within a small interval and their ages have provided key dates for the radiometric time scale.

Volcanic ash or lava flows can be introduced suddenly into sedimentary environments without interrupting sedimentation. Igneous material datable radiometrically may thus become interbedded with fossiliferous sedimentary rocks datable according to the geologic time scale. Interbedded sediments and volcanic rocks have provided some of the most valuable reference points in the radiometric time scale.

Direct radiometric dating of sedimentary rocks depends on minerals that crystallize during their deposition. The minerals cannot be detrital grains, for these simply reflect the age of the pre-existing source rock. Most direct radiometric dates of sedimentary rocks have been provided by the mineral glauconite, which sometimes crystallizes on the sea floor while marine sediments accumulate. Glauconite is a complex silicate containing potassium and hence it is datable by the potassium-argon method. Unfortunately, glauconite loses argon even if buried to moderate depths, and glauconite dates commonly err in being too young. They do, however, provide reliable minimum ages.

Radiometric calibration of the geologic time scale has only begun, but already ages of most of the important boundaries within the Phanerozoic portion of the time scale are known within fairly narrow limits, and some systems are quite well dated throughout. In some parts of the Phanerozoic scale, however, large gaps still remain for which virtually no reliable radiometric determinations have been made. Ages of the system boundaries as presently known are shown adjacent to the geologic time scale previously shown.

**Subdivision of Precambrian time.** Before the advent of radiometric dating, the Precambrian was never divisible into time-stratigraphic units because, unlike the Phanerozoic, Precambrian rocks contain no distinctive fos-

sils. The problem for the Precambrian, therefore, is not to determine ages of previously defined time-stratigraphic boundaries. Instead it is to establish, on the basis of the radiometric ages themselves, a usable scheme of time-stratigraphic classification.

In the Precambrian, as in the Phanerozoic, igneous and metamorphic rocks provide the vast majority of reliable dates, and orogenic episodes, which produced widespread igneous and metamorphic activity, have provided the framework for Precambrian time-stratigraphic classifications that have been attempted thus far. Many problems exist in unravelling the Precambrian radiometric record. Commonly the last orogeny that affected an area obliterates the radiometric record of all previous events. It is not clear whether or not some orogenies have been worldwide in their effect. Time-stratigraphic classifications for the Precambrian thus far have been proposed only for individual regions or continents. The Canadian Shield, for example, a region that has been extensively studied, is divisible into several large provinces that have distinctive structures and characteristic radiometric ages that cluster around 2,390, 1,640, and  $880 \times 10^6$  years, indicating three main orogenic episodes. These provide the framework for the regional Precambrian time-stratigraphic classification. The Kenoran orogeny marks the boundary between two large time divisions, the Archaean and Proterozoic. The Hudsonian and Grenville orogenies subdivide the Proterozoic into three eras, the Aphebian, Helikian, and Hadrynian. Precambrian shields of other continents likewise contain discrete provinces in which radiometric dates cluster together, but orogenic episodes were not all synchronous with those determined for the Canadian Shield, and each region appears to have its own characteristic breakdown of Precambrian chronology. It is still highly questionable whether a single formal time-stratigraphic scheme based on radiometric methods will be found very useful for relating Precambrian rocks worldwide.

**Ages of meteorites and of the Earth.** Much evidence has been accumulated in recent years concerning the age of meteorites (*q.v.*), which have been studied by various radiometric dating methods. Most of them appear to have had a common time of origin at about  $4,600 \times 10^6$  years. About 7 percent of the known meteorites consist mostly of iron, and the remainder consist chiefly of silicate minerals. Iron meteorites contain practically no uranium but considerable amounts of lead, and this lead is thought to represent primordial lead whose isotopic composition has never been altered by radiogenic additions. Assuming that the isotopic composition of primordial earth lead was the same as meteorite lead, the Earth can be treated as a closed system just like any radioactive mineral sample and dated by the uranium-lead method. First it is necessary to determine the amounts of uranium-238, uranium-235, lead-206, and lead-207 that are present in the Earth's crust today. Then, subtracting the amount of lead-206 and lead-207 inferred to have been present at the time of its origin, application of the uranium-lead method gives an age for the Earth of about  $4,600 \times 10^6$  years. Numerous samples of Moon rocks collected by the Apollo missions likewise have ages of about  $4,600 \times 10^6$  years, and this is now believed to be the approximate time of origin of the solar system and of formation of the Earth.

In both North America and Europe the most ancient rocks dated have indicated ages of about  $3,500 \times 10^6$  years. The most ancient rocks known from Africa and from Australia are only slightly younger. Although the data are sparse, the similarity in ages of the oldest rocks from several continents is probably a significant coincidence. The Earth may have undergone a thermal episode at about the time that served to melt and homogenize the crust. Whether or not this speculation is valid, rocks of the Earth's crust provide no direct evidence concerning the first  $1,000 \times 10^6$  years of earth history.

**Future of the time scale.** The geologic time scale is still being shaped and refined, and the potential for the greatest increase in knowledge is certainly in the Pre-

Time  
divisions  
of the  
Canadian  
Shield

cambrian. Whether or not a single worldwide framework of time-stratigraphic classification proves workable, the chronology of Precambrian events is expected to contribute significantly to the understanding of evolution of the earth's crust, atmosphere, and ocean and to the long development of life prior to the Paleozoic.

Progress in improving the Phanerozoic time scale will come about chiefly through adding of historical detail. Critical boundaries must be better defined and stabilized by international agreement in standard sections. This will require continued refinement of paleontologic zones, particularly using groups of microfossils, many of which have thus far received only cursory study. Progress in the Phanerozoic, however, like that in the Precambrian, will not be measured by the extent to which formalized classification schemes find common acceptance, but by the increase in the actual understanding and appreciation of the processes that, through geologic time, have shaped the earth.

## Geometry, Algebraic

Algebraic geometry is a branch of mathematics in which the properties of a geometrical structure are described by means of algebraic expressions. Historically, the subject developed from the study of loci (collections of all points the location of which is determined by stated conditions) in projective space, again by algebraic means. A projective space of  $n$  dimensions is denoted by  $P_n$  and is a set of elements, called points, endowed with certain allowable coordinate systems. In an allowable coordinate system  $x$  each point  $A$  of  $P_n$  is determined by a set of  $n+1$  numbers  $(x_0, \dots, x_n)$  that are not all zero. Two such sets,  $(x_0, \dots, x_n)$  and  $(x'_0, \dots, x'_n)$ , determine the same point if, and only if, there is a number  $\rho$  such that  $x_i = \rho x'_i$  ( $i = 0, \dots, n$ ). Any set  $(x_0, \dots, x_n)$  corresponding to  $A$  are the homogeneous coordinates of  $A$  in the coordinate system  $x$ . If  $y$  is any other coordinate system, the relation between the  $x$  and  $y$  coordinates  $(x_0, \dots, x_n)$ ,  $(y_0, \dots, y_n)$  of  $A$  is given by equations that are linear (see Box, equations 1), in which coefficients  $a_{ij}$ ,  $b_{ij}$  are numbers independent of  $A$ , and  $\rho$  and  $\sigma$  are factors of proportionality.

### BASIC CONCEPTS AND SOME PRELIMINARY REMARKS

To define an algebraic locus in  $P_n$ , an allowable coordinate system  $x$  is selected, and a set of homogeneous polynomial equations expressed through functions  $f_i$  (see 2) are derived in which the coefficients are constants. If  $a_0, \dots, a_n$  are numbers (not all zero) such that  $f_i(a_0, \dots, a_n) = 0$  ( $i = 1, 2, \dots$ ), then  $f_i(\rho a_0, \dots, \rho a_n) = 0$  ( $i = 1, 2, \dots$ ) for any constant  $\rho$ . The point  $(a_0, \dots, a_n)$  of  $P_n$  then satisfies the polynomial equations (see 2). The aggregate of such points form what is known as an algebraic variety  $U$ , in  $P_n$ . This definition does not depend on the coordinate system chosen. If  $y$  is another coordinate system in  $P_n$ , related to the system  $x$  by the first equations (see 1), a suitable modification of the equations (see 3) in the  $y$  coordinates define the same variety  $U$  in  $P_n$ .

To complete the definition of algebraic geometry as

the study of algebraic varieties in  $P_n$ , it is necessary to be more precise about the numbers that constitute the coordinates of points or the coefficients of equations. In classical geometry, these are taken to be complex numbers; i.e., numbers involving the factor  $\sqrt{-1}$ . In the operations involved in algebraic geometry, only a limited number of properties of complex numbers are used.

The operations of addition and multiplication have the following properties, in which  $a$ ,  $b$ , and  $c$  represent complex numbers:

A. Addition has the properties of associativity (see 4) and commutativity (see 5).

There is a unique number, 0 (zero), for which  $0 + a = a$  for all  $a$ .

Corresponding to any  $a$  there is a unique number  $-a$  such that  $a + (-a) = 0$ . This means that numbers form a commutative group under addition.

B. Multiplication has the properties that:

It is associative; i.e.,  $a(bc) = (ab)c$ .

It is commutative; i.e.,  $ab = ba$ .

There is a unique number 1 (unity) such that  $a \cdot 1 = a$ , for all  $a$ .

For any nonzero number,  $a$ , there is a unique number  $a^{-1}$  such that  $a \cdot a^{-1} = 1$ . This means that the nonzero numbers form a commutative group under multiplication.

C.  $a(b + c) = ab + ac$ ; i.e., multiplication is distributive over addition.

A set of elements (e.g.,  $a$ ,  $b$ , and  $c$ ) with two laws of composition, addition and multiplication, that obey the rules A, B, and C is called a field. Other examples of fields are the rational numbers (integers as well as all numbers obtainable as ratios of integers that are not zero, together with field properties, constituting the field  $Q$ ), and the integers modulo a prime number  $p$  (the integers from 0 to  $p - 1$ , inclusive, together with field properties, constituting the field  $Z_p$ ). Instead of taking the numbers used in the definition of algebraic geometry to be complex numbers, it is more usual to choose them from any selected field  $k$ . Projective  $n$ -space over the field  $k$  is usually denoted by  $P_n(k)$ .

Definition  
of a field

Given a field  $k_1$ , there may exist a subset of elements of  $k_1$ , which form a field  $k_2$ , with the same addition and multiplication;  $k_2$  is a subfield of  $k_1$  and  $k_1$  an extension of  $k_2$ . If any coordinate system  $x$  is chosen in  $P_n(k_1)$ , those points having  $x$  coordinates that lie in  $k_2$  form a space  $P_n(k_2)$ . The space  $P_n(k_1)$  is then an extension of  $P_n(k_2)$ . An algebraic variety in  $P_n(k_2)$  is defined by equations with coefficients in  $k_2 \subseteq k_1$  (the symbol  $\subseteq$  denotes that  $k_2$  is identical with  $k_1$  or is contained in  $k_1$ ) and hence uniquely defines a variety of  $P_n(k_1)$ ; but a variety of  $P_n(k_1)$  need not define one in  $P_n(k_2)$ . If  $U$  is defined over  $k_2$ , there may be points on  $U$ , regarded as a variety in  $P_n(k_1)$ , that are not points of  $P_n(k_2)$ . The usual practice is to speak of  $k_2$  as the field of definition of  $U$ , and points on it, when it is considered as a locus over an extension of  $k_2$ , as belonging to  $U$  in a suitable extension of  $k_2$ .

Any field  $k$  and an algebraic variety  $U$  defined over  $k$  may be considered. If  $\alpha$  is an element of an extension of  $k$  that satisfies an algebraic equation with coefficients  $a_i$  (see 6) in which  $a_i$  is in  $k$ ,  $\alpha$  is said to be algebraic over  $k$  (rational over  $k$  if  $m = 1$ ). There exists a field  $\bar{k}$ , uniquely determined to within isomorphism, such that (1) every element of  $\bar{k}$  is algebraic over  $k$ ; (2) every element of any extension of  $\bar{k}$  that is algebraic over  $\bar{k}$  belongs to  $\bar{k}$ . The field  $\bar{k}$  is called the algebraic closure of  $k$ . The space  $P_n(k)$  can be embedded in  $P_n(\bar{k})$ . If  $U$  is defined over  $k$ , any point of  $P_n(k)$  that lies on  $U$  is an algebraic point of  $U$  [a rational point if it lies in  $P_n(k)$ ].

The elementary theory of systems of polynomials with coefficients in  $k$  leads to some basic properties of algebraic varieties. First, if  $U$  is defined in  $P_n(k)$  by the set of polynomial equations (2), there exists a finite number  $r$  such that  $U$  is given by  $r$  equations expressed with functions  $f_i$  (see 7). Second, if  $\theta(x_0, \dots, x_n)$  is a homogeneous polynomial with coefficients in  $k$  such that  $\theta(a_0, \dots, a_n) = 0$  for every algebraic point  $(a_0, \dots, a_n)$  on  $U$ , then, for some integer  $s$ , the  $s$  power of the homogeneous polynomial is related to the  $r$  functions through equations (see 8) in which  $b_i(x_0, \dots, x_n)$  is a homogeneous polynomial of suitable degree, with coefficient in

The zero  
position  
principle

$k$ . This is the *Nullstellensatz* (zero position principle) of the 19th-20th-century German mathematician David Hilbert.

If  $V$  is a second algebraic variety in  $P_n(k)$ , defined by  $s$  equations expressed in terms of functions  $g_j$  (see 9), then the equations (2) and (3) can be taken together to define a third algebraic variety  $W$ , which consists of all the points (in any extension of  $k$ ) that lie both on  $U$  and on  $V$ . The intersection of  $U$  and  $V$  may be written  $W = U \cap V$  or  $V \cap U$ . The union  $W$  of  $U$  and  $V$  is defined to be the variety defined by the equations composed of products of the  $f_i$  and  $g_j$  (see 10). Every point on  $U$  or on  $V$  lies on  $W$ , and every point of  $W$  not on  $U$  is such that  $f_i(a_0, \dots, a_n) \neq 0$  for some  $i$ , and it follows from (10) that the  $g_j$  are zero (see 11). Here the point lies on  $V$ , so  $W$  is the variety formed by points on  $U$  or on  $V$  (see 12). It is also noted that a distributive relation holds (see 13).

A variety  $W$  in  $P_n(k)$  is said to be irreducible if the equation  $W = U \cup V$ , when  $U, V$  are defined over  $k$  necessarily implies  $W = U$  or  $W = V$ . An equivalent condition is the following:  $W$  is irreducible if, and only if, it has the property that if  $f(x_0, \dots, x_n), g(x_0, \dots, x_n)$  are polynomials over  $k$  such that  $f(x_0, \dots, x_n)g(x_0, \dots, x_n) = 0$  on  $W$ , then  $f(x_0, \dots, x_n)$  or  $g(x_0, \dots, x_n)$  vanishes at every point of  $W$ . It is to be noted that a variety  $W$  may be irreducible in  $P_n(k)$ , but reducible over an extension of  $k$ . If it is irreducible over every extension of  $k$  it is absolutely irreducible: if  $k$  is algebraically closed, every irreducible variety is absolutely irreducible.

from ap-  
plications  
of the  
theory of  
poly-  
nomials

Further applications of the theory of polynomials lead to the following theorems: (I) Any algebraic variety  $W$  defined over  $k$  can be written in an essentially unique way as the union of a finite number of irreducible varieties; and (II) any chain  $U_0 \subset U_1 \subset U_2, \dots$  of irreducible varieties in  $P_n(k)$ , each of which is a proper subvariety of its successor, is of finite length. The maximum length of such a chain terminating in an irreducible variety  $W$  is  $d + 1$ , in which  $d$  is the dimension of  $W$ . It is to be noted that the dimension of  $P_n(k)$ , which is denoted  $\dim P_n(k)$ , is equal to  $n$ . The considerations that are given above form the basis on which algebraic geometry of varieties in a projective space  $P_n(k)$  is constructed. It may be noted, however, that in the case in which  $k$  is the field  $\mathbb{C}$  of complex numbers, other nonalgebraic techniques are available. This is true because of the existence in  $P_n(\mathbb{C})$  of a Hausdorff topology (named for Felix Hausdorff), namely, the complex topology. A coordinate system  $x$  in  $P_n(\mathbb{C})$  is chosen and  $A, B$  are taken to be two points of which the  $x$ -coordinates are  $(a_0, \dots, a_n), (b_0, \dots, b_n)$ . The distance  $d(A, B)$  between  $A$  and  $B$  is defined to be the positive square root of a certain function of the  $a_i, b_i$  and their conjugates (see 14). The sets  $d(A, X)$  less than the bound  $\epsilon$ , for all  $A, \epsilon$ , are taken as the basic open sets, all other open sets being the unions of basic open sets; the topology of  $P_n(\mathbb{C})$  is defined by its open sets. The definition of distance in  $P_n(\mathbb{C})$  depends on the choice of the allowable coordinate system, but not the derived topology.

The complex topology in  $P_n(\mathbb{C})$  can be used to define a topology of any algebraic variety  $U$  in  $P_n(\mathbb{C})$ , the open sets in  $U$  being the intersection of  $U$  with the open sets of  $P_n(\mathbb{C})$ . This is of prime importance in the case in which  $U$  is irreducible, and nonsingular; that is, when every point  $P$  of  $U$  has a neighbourhood that can be put in one-to-one correspondence with the points of the complex space  $(u_1, \dots, u_d)$  by means of equations which define coordinates  $x_i$  (see 15). The space  $U$  is then a complex manifold, the study of which is a separate branch of mathematics but which can be used to develop the algebraic geometry of varieties defined over the complex field.

Another topology, the Zariski topology (after Oscar Zariski, a 20th-century Russian-born U.S. mathematician), will be introduced below into the study of varieties over any field  $k$ . Even when  $k$  is the field  $\mathbb{C}$  of complex numbers, it is quite different from the complex topology, and is not a Hausdorff topology. (That is, two different points cannot be distinguished by respective inclusion in two non-intersecting open sets.)

- (1)  $\rho y_i = \sum_{j=0}^n a_{ij} x_j, \quad \sigma x_i = \sum_{j=0}^n b_{ij} y_j$
- (2)  $f_i(x_0, \dots, x_n) = 0, \quad i = 1, 2, \dots$

- (12)  $W = U \cup V = V \cup U$
- (13)  $V \cap (U_1 \cup U_2) = V \cap U_1 \cup V \cap U_2$
- (14)  $\begin{cases} \left( \sum_k a_k \bar{b}_k \right) \left( \sum_k \bar{a}_k b_k \right) \\ 1 - \frac{\left( \sum_k a_k \bar{a}_k \right) \left( \sum_k b_k \bar{b}_k \right)}{\left( \sum_k a_k \bar{a}_k \right) \left( \sum_k b_k \bar{b}_k \right)} \end{cases}$   
in which  $\bar{b}_k$  is the complex conjugate of  $b_k$ , and  $\bar{a}_k$  is the complex conjugate of  $a_k$ .
- (15)  $\begin{cases} x_i = \psi_i(u_1, \dots, u_d), & i = 0, \dots, d \\ \text{when the } \psi_i(u_1, \dots, u_d) \text{ are analytic functions,} \\ \text{and } d \text{ is the dimension of } U. \end{cases}$
- (16)  $(y_1^\alpha, \dots, y_n^\alpha) = (x_0/x_\alpha, \dots, x_j/x_\alpha, \dots, x_n/x_\alpha), \quad j \neq \alpha$

#### PROJECTIVE AND ABSTRACT VARIETIES

Modern algebraic geometry is mainly concerned with properties of varieties that are independent of the projective spaces in which the varieties are embedded. It is therefore necessary to find a set of intrinsic properties of an algebraic variety that will lead to an abstract definition of a variety; this, in turn, leads to a generalization of the notion of a variety.

Although there are good reasons for considering algebraic varieties in a projective space  $P_n(k)$ , in practice there are advantages in regarding  $P_n(k)$  as a union of affine spaces. The points of  $P_n(k)$  that are not in the subspace such that  $x_\alpha = 0$  form what is called an affine space  $A_n^\alpha(k)$ , with affine coordinates (see 16). If  $U$  is an algebraic variety in  $P_n(k)$ , the points of  $U$  in  $A_n^\alpha(k)$  form an affine variety  $U^\alpha$ . From a study of affine varieties in  $A_n^\alpha(k)$ , consideration can be made how to fit them together to form an algebraic variety in projective space  $P_n(k)$  (briefly, a projective variety).

If  $A_n(k)$  is an affine space with coordinate system  $(y_1, \dots, y_n)$ , the polynomials in  $(y_1, \dots, y_n)$ , with coefficients in  $k$ , form a set with two laws of composition, addition and multiplication. Under addition the polynomials form a commutative group, and multiplication is associative, commutative, and distributive over addition; further, the unity 1 of  $k$  has the property that  $1 \cdot f(y_1, \dots, y_n)$

$= f(y_1, \dots, y_n)$  for all polynomials  $f(y_1, \dots, y_n)$ . A set with two laws of composition satisfying these properties is called a ring with unity 1. The ring of polynomials is denoted by  $k[y_1, \dots, y_n]$ , and, if the product of two of its elements  $\alpha$  and  $\beta$  is 0, then either  $\alpha$  or  $\beta$  is 0. It is then called an integral domain.

An affine variety  $V$  is defined as the set of points satisfying a number of polynomial equations  $f_i(y_1, \dots, y_n) = 0$  ( $i = 1, 2, \dots$ ). The polynomials that vanish on  $V$  have properties (see 18) that imply, in brief, that the polynomials that vanish on  $V$  form a so-called ideal  $\mathfrak{i}$ . Given any ideal  $\mathfrak{i}$  in  $k[y_1, \dots, y_n]$ , there exists a finite number of polynomials in  $\mathfrak{i}$ , say  $f_i(y_1, \dots, y_n)$  ( $i = 1, \dots, r$ ), such that any polynomial in  $\mathfrak{i}$  can be written in the form of a sum of products of  $f_i$  and  $a_i$  (see 19) for suitable polynomials  $a_i(y_1, \dots, y_n)$ . The polynomials  $f_i(y_1, \dots, y_n)$  are referred to as forming a basis for  $\mathfrak{i}$ . If  $V$  is the affine variety defined by the polynomials of  $\mathfrak{i}$ , the set of all polynomials that vanish on  $V$  form an ideal  $\mathfrak{j}$ ; thus,  $\mathfrak{i} \subseteq \mathfrak{j}$ , and  $\mathfrak{j}$  is called the radical of  $\mathfrak{i}$ .

An affine variety  $V$  is said to be irreducible if it has the property that if  $f(y_1, \dots, y_n)g(y_1, \dots, y_n) \in \mathfrak{j}$ , the maximal ideal defining  $V$  necessarily implies that either  $f(y_1, \dots, y_n)$  or  $g(y_1, \dots, y_n)$  is in  $\mathfrak{j}$ ; in other words,  $V$  is irreducible if, and only if, the radical  $\mathfrak{j}$  is a prime ideal.

If  $V$  is an irreducible variety in  $A_n(k)$ , and  $\mathfrak{p}$  the associated prime ideal of  $k[y_1, \dots, y_n]$ , then two elements  $\alpha, \beta$  of  $k[y_1, \dots, y_n]$  are said to be equivalent modulo  $\mathfrak{p}$  if  $\alpha - \beta \in \mathfrak{p}$ ;  $\mathfrak{p}$  divides the elements of the ring into equivalence classes. If  $\eta_i$  denotes the equivalence class containing  $y_i$ , any element  $f(y_1, \dots, y_n)$  of  $k[y_1, \dots, y_n]$  belongs to an equivalence class that can be represented by  $f(\eta_1, \dots, \eta_n)$ . It is clear that the equivalence classes can be added and multiplied to form a ring (with unity). This ring is denoted by  $k[y_1, \dots, y_n]/\mathfrak{p}$ .

This process of forming the remainder-class ring does not depend on the fact that  $\mathfrak{p}$  is prime. If  $\mathfrak{p}$  is prime, the ring is an integral domain (see 20). This integral domain is here denoted by  $R(V, k)$ ; the intrinsic algebraic geometry on  $V$  is developed in terms of this ring, just as the geometry of varieties in  $A_n(k)$  is developed in terms of  $k[y_1, \dots, y_n]$ .

If  $W$  is any subvariety of  $A_n(k)$  contained in  $V$ , and if  $\mathfrak{j}$  is the ideal of  $k[y_1, \dots, y_n]$  formed by all the polyno-

mials that vanish on  $W$ , because  $W \subseteq V$ ,  $\mathfrak{p} \subseteq \mathfrak{j}$ , it is readily verified that the image of  $\mathfrak{j}$  in  $k[y_1, \dots, y_n]/\mathfrak{p}$  is an ideal  $\mathfrak{j}/\mathfrak{p}$  of  $R(V, k)$ , prime if, and only if,  $\mathfrak{j}$  is prime. Conversely, if  $\mathfrak{q}$  is an ideal of  $R(V, k)$ , it is the image of an ideal of  $k[y_1, \dots, y_n]$  containing  $\mathfrak{p}$ , which is prime if, and only if,  $\mathfrak{q}$  is prime. Thus the varieties on  $V$  correspond to the ideals in  $R(V, k)$ , just as the varieties in  $A_n(k)$  correspond to ideals in  $k[y_1, \dots, y_n]$ . The union and intersection of varieties on  $V$  are defined as above; also the dimension of  $W$  (irreducible) on  $V$  is the maximum length (minus one) of a chain of irreducible varieties in  $V$ ,  $W_0 \subset W_1 \subset \dots \subset W_r = W$ , and coincides with the dimension of  $W$  as a variety of  $A_n(k)$ .

If  $W$  is an irreducible subvariety of  $V$ , and  $\mathfrak{q}$  the prime ideal of  $R(V, k)$  that defines it, then the local ring of  $W$  on  $V$  can be defined and denoted by  $R_W(V, k)$  as follows. All pairs  $(\alpha, \beta)$  of elements of  $R(V, k)$  in which  $\beta \notin \mathfrak{q}$  are considered. Addition and multiplication of pairs is defined in terms of addition and multiplication of components (see 21); this is allowable because  $\beta \notin \mathfrak{q}$ ,  $\beta' \notin \mathfrak{q}$  implies  $\beta\beta' \notin \mathfrak{q}$ ,  $\mathfrak{q}$  being prime. The pairs thus form a ring, with unity  $(1, 1)$ . The pairs of the form  $(0, \beta)$  form a prime ideal of this ring, and the classes of equivalent pairs modulo this ideal form the local ring  $R_W(V, k)$ , which is, in fact, an integral domain. The elements of  $R_W(V, k)$  are usually denoted by  $\alpha/\beta$ , in which  $(\alpha, \beta)$  is any pair of the equivalence class represented by the element.

It will be clear that if  $W, W'$  are irreducible varieties on  $V$ , and  $W$  is contained in  $W'$ , then the same relationship holds between corresponding local rings, two cases being of special importance (see 22). When  $k$  is algebraically closed,  $W$  is a single point; more generally it consists of a finite set of points algebraically conjugate over  $k$ . An important theorem states that the intersection of the local rings of all the zero-dimensional varieties on  $V$  is the ring  $R(V, k)$ .

In the case of a projective algebraic variety  $U$  in  $P_n(k)$ , the affine varieties  $U^\alpha$  in  $A_n^\alpha(k)$  ( $\alpha = 0, \dots, n$ ) have to be considered. The rings  $R(U^\alpha, k)$  are all different. If  $W$  is any irreducible variety in  $U$ , however, and  $W^\alpha = U^\alpha \cap W$ , the local ring of  $W^\alpha$  consists of fractions that can be represented by ratios  $a/b$ , when  $a$  and  $b$  are homogeneous polynomials in  $(x^0, \dots, x^n)$  of the same degree, each reduced modulo the equations of  $U$ . It follows that the local rings of  $W^\alpha$  and  $W^\beta$  can be identified (see 23) for all  $\alpha, \beta$ . In particular, the function field of  $U^\alpha$  can be identified with that of  $U^\beta$ ; it also defines the function field of  $U$ .

The field  $U$  can be regarded as the union of the affine varieties  $U^\alpha$ , joined together, just as coordinate neighbourhoods are joined together to give a differentiable manifold. To be more precise, what is known as Zariski topology can be introduced into an affine variety  $V$  by defining the closed sets to be the subvarieties of  $V$ . The variety  $V$  is itself an open set. The points of  $U$  that lie in  $U^\alpha$  and in  $U^\beta$  form an open set  $U^{\alpha\beta}$  of  $U^\alpha$  and an open set  $U^{\beta\alpha}$  of  $U^\beta$ . There is a one-to-one correspondence between the points of  $U^{\alpha\beta}$  and those of  $U^{\beta\alpha}$ , which is continuous in each direction, because open sets correspond to open sets, and the local rings of corresponding irreducible subvarieties can be identified.

This leads to the generalization of the French-born U.S. mathematician André Weil of a projective variety. If  $V^\alpha$  ( $\alpha = 1, 2, \dots, r$ ) denotes  $r$  affine algebraic varieties, consideration can be given to the case in which for each pair  $\alpha, \beta$  there exist open sets  $V^{\alpha\beta}$  on  $V^\alpha$ ,  $V^{\beta\alpha}$  on  $V^\beta$ , in one-to-one continuous correspondence (continuity being defined in terms of the Zariski topology); so that the local rings of corresponding subvarieties of  $V^{\alpha\beta}$  and  $V^{\beta\alpha}$  are isomorphic (i.e., in one-to-one correspondence with ring operations preserved). Then  $V^\alpha$  and  $V^\beta$  can be joined by identifying corresponding points and corresponding local rings. The affine varieties  $V^\alpha$  ( $\alpha = 1, \dots, r$ ) can thus be joined together to give what is referred to as abstract variety  $V$ . Any point  $P$  of  $V$  lies in at least one  $V^\alpha$  (see 24).

It may be noted that the process of constructing an abstract variety, when applied to a subset of the affine vari-

Weil's generalization of a projective variety

eties  $U^\alpha$  that cover a projective variety  $U$ , defines an abstract variety that may form a proper open subset of  $U$ ; in this case, the abstract variety is not complete. It is also possible to construct abstract varieties that cannot be embedded in a projective space.

If  $U$  or  $V$  are two abstract varieties, consideration can be given to a mapping of an open set  $U'$  of  $U$  into  $V$  that can be given locally in terms of local coordinate systems by equations (see 25). These equations (25) define the image of any algebraic point  $P$  of the domain of  $(\xi_1, \dots, \xi_n)$ , provided that  $Y_i(\xi_1, \dots, \xi_n)$  is contained in the local ring of the irreducible zero-dimensional variety  $U_0$  containing  $P$ . In this case the image of  $U_0$  is a well-defined zero-dimensional variety  $V_0$  of  $V$  and from the equations (25) a homomorphism (or operation preserving mapping)  $R_{V_0}(V, k)$  to  $R_{U_0}(U, k)$  is deduced. The equations (25) are then referred to as defining a mapping  $U' \rightarrow V$  that is regular at  $U_0$ . It may be possible to use the equation to define the mapping  $U \rightarrow V$  at all points of  $U'$  by giving special interpretation to the images of places on  $U$  at which the mapping is not regular. This mapping is then called a rational mapping. It is a regular mapping if it is regular at all places of  $U$ : it can be denoted by special symbolism (see 26).

Two algebraic varieties are referred to as equivalent if there is a one-to-one correspondence between them that is regular in each direction. Two varieties  $U$  and  $V$  are referred to as birationally equivalent if they contain open sets  $U'$  and  $V'$  that are in bi-regular correspondence. Much of classical algebraic geometry is devoted to the study of properties of varieties invariant under birational transformations. One of the advantages of using birational correspondences rather than bi-regular ones is that difficulties are avoided that arise as a result of the presence of singularities (multiple curves or other subvarieties). The main problem in this field is that of finding a nonsingular algebraic variety,  $U$ , that is birationally equivalent to an irreducible algebraic variety  $V$ , such that the mapping  $\pi: U \rightarrow V$  is regular (but not bi-regular). The most general solution of this problem was obtained by the Japanese-born U.S. mathematician Heisuke Hironaka in 1964.

Birational correspondences can also be used to give a convenient definition of a complete variety. If  $U$  is any abstract variety and  $V$  any algebraic variety such that there is a birational correspondence between  $U$  and an open subset of  $V$ , the product  $U \times V$  can be constructed with  $\Delta$  denoting a set of points  $x, y$  such that  $x$  and  $y$  are corresponding points of  $U$  and  $V$ . The set of points  $\Delta$  is an algebraic subvariety of  $U \times V$ . The abstract variety  $U$  is referred to as complete if the projection of  $\Delta$  (proj  $\Delta$ ) on  $V$  is  $V$ , for all  $V$ . To see the significance of this definition, consideration may be given to  $U'$  being any affine open set on  $U$ ; it is bi-regularly equivalent to a variety  $U''$  in affine space  $A_n(k)$ . By  $V$  there may be denoted the variety in  $P_n(k)$  such the  $U''$  is an intersection of affine space and  $V$  (see 27). It readily follows that if  $U$  is not complete, proj  $\Delta$  on  $V$  is an open set of  $V$ , which is a proper subset of  $V$ .

Much of the geometry on an algebraic variety  $U$  of dimension  $e$  is concerned with the subvarieties, and systems of subvarieties, on  $U$ .

The free group  $G_e(U)$ , generated by the irreducible subvarieties of  $U$  of dimension  $e$ , can be considered. Any element of  $G_e(U)$  is of the form  $\sum \rho_i D_i$ , summation being on  $i$ , in which  $\rho_i$  is an integer (only different from zero for a finite number of  $i$ ), and  $D_1, D_2$  are irreducible varieties of  $U$  of dimension  $e$ . This element is referred to as an  $e$ -cycle. In general, two irreducible subvarieties  $P, Q$  of dimensions  $r, s$ , respectively, intersect in a variety consisting of a finite number of subvarieties of dimension  $q = r + s - d$ . Each of these subvarieties has a well-defined multiplicity, and with these multiplicities the intersection  $P \cdot Q = Q \cdot P$  is a well-defined  $q$ -cycle. The intersection of an  $r$ -cycle and an  $s$ -cycle may possibly also be defined (see 28).

Two  $e$ -cycles  $D$  and  $D'$  on  $U$  are rationally equivalent if on the product variety  $U \times L$ , in which  $L$  is the straight line parameterized by (that is, described alge-

(24)  $\left\{ \begin{array}{l} \text{Any point } P \text{ of } V \text{ lies in at least one } V^\alpha: \text{ If } \xi_1^\alpha, \dots, \xi_n^\alpha \\ \text{generate the ring } R(V^\alpha, k) \text{ and } U' \text{ is any open set of } V^\alpha \\ \text{containing } P, U' \text{ is called an affine neighbourhood of} \\ P \text{ and } (\xi_1^\alpha, \dots, \xi_n^\alpha) \text{ are local coordinates in } U'. \end{array} \right.$

(25)  $\left\{ \begin{array}{l} (\xi_1, \dots, \xi_n) \text{ and } (\eta_1, \dots, \eta_m) \text{ on } U' \text{ and } V, \text{ by the} \\ \text{equations } \eta_i = Y_i(\xi_1, \dots, \xi_n), i = 1, \dots, m, \\ \text{when } Y_i(\xi_1, \dots, \xi_n) \text{ is in the function field of } U, \\ i = 1, \dots, m. \end{array} \right.$

(26)  $\left\{ \begin{array}{l} (\pi, \pi^*): \pi: U' \rightarrow V; \pi^*: R_{\pi U_0}(V, k) \rightarrow R_{U_0}(U, k), \\ \text{for all zero-dimensional varieties } U_0 \text{ on } U. \end{array} \right.$

(27)  $U'' = A_n(k) \cap V$

(28)  $\left\{ \begin{array}{l} \text{The intersection of an } r\text{-cycle } P = \sum \rho_j P_j \text{ and an} \\ s\text{-cycle } Q = \sum \sigma_i Q_i \text{ is then defined to be} \\ \sum \rho_i \sigma_j P_i Q_j \text{ (if it is defined at all).} \end{array} \right.$

(29)  $\alpha \in A_r(U), \quad \beta \in A_s(U)$

(30)  $A(U) = \sum_{i=0}^d A_i(U)$

braically with the aid of) the elements of  $k$ , there exists an  $(e+1)$ -cycle  $C$  such that  $C$  meets  $U \times 0$  in  $D \times 0$ , and  $U \times 1$  in  $D' \times 1$ . The  $e$ -cycles that are equivalent to zero form a subgroup  $g_e(U)$  of  $G_e(U)$ . The remainder-class ring is denoted by  $A_e(U)$ . If  $\alpha$  and  $\beta$  belong to class rings corresponding to  $r$ - and  $s$ -cycles, respectively (see 29), then representative cycles  $a, b$  can be found in  $G_r(U), G_s(U)$  such that  $a \cdot b$  is well defined in  $G_q(U)$ . If  $a', b'$  are any other representative cycles of  $\alpha, \beta$  such that  $a' \cdot b'$  is well defined, it readily follows that  $a \cdot b$  is equivalent to  $a' \cdot b'$ , and hence that  $\alpha, \beta$  determine a well-defined element  $\alpha \cdot \beta$  of  $A_q(U)$ . With this definition of multiplication, the graded group (see 30) has the structure of a ring. This ring is the Chow ring of  $U$ .

An important property of the Chow ring is that if  $f: U \rightarrow V$  is a regular map of  $U$  on  $V$ , every irreducible subvariety on  $U$  maps to an irreducible subvariety of  $V$ , and there is a homomorphism  $f_*: A(U) \rightarrow A(V)$  with  $A(U), A(V)$  regarded as additive groups. This homomorphism, however, does not imply a homomorphism of the rings  $A(U), A(V)$ . On the other hand, if  $D$  is any subvariety of  $V, f^{-1}D$  is a subvariety of  $U$ , and a mapping  $f^*: A(V) \rightarrow A(U)$  can be deduced that is a ring homomorphism. The structure of  $A(U)$  throws great light on the geometry of  $U$ . A case of special interest is that in which  $d$ , the dimension of  $U$ , is 1. The class of equivalent 0-cycles of order zero form a subgroup  $G$  of  $A_0(U)$ . The subgroup  $G$  can be represented by the points of a complete nonsingular projective variety of  $J$  over  $k$ , of dimension  $g$ , in which  $g$  is the genus of  $U$  (see below). The operations of the group  $G$  are represented by a regular map  $J \times J \rightarrow J$ . The group  $A_0(U)/G$  is isomorphic to the additive group of integers.

#### SHEAVES AND SCHEMA

In studying algebraic varieties by means of local rings it is seldom necessary to consider individual points: the irreducible subvarieties of dimension zero are the smallest sets that must be considered. If these sets are renamed points, a variety  $U$  is then a space  $X$  consisting of points endowed with a topology (the Zariski topology) with a ring associated with each point. The set of rings is said to form a sheaf over  $X$ .

For a topological space denoted by  $X$  it is supposed that there is a ring  $O(U)$  associated with each open set,  $U$ , of

- (31)  $\{r_{U'U}: O(U) \rightarrow O(U')$   
If  $U'' \subseteq U' \subseteq U$ , then  $r_{U''U} = r_{U''U'} \circ r_{U'U}$
- (32)  $r_{PU}: O(U) \rightarrow O_P$
- (33)  $\left\{ \begin{array}{l} \text{(i) There is a projection } \pi: S \rightarrow X \text{ (if } \sigma \in O_P, \pi\sigma = P); \\ \text{(ii) } \pi \text{ is locally a homeomorphism (i.e., one-to-one and} \\ \text{continuous in both directions);} \\ \text{(iii) } \pi^{-1}P \text{ has a ring structure that is continuous.} \end{array} \right.$
- (34)  $r'_{U'U}: \Gamma(U, S) \rightarrow \Gamma(U', S)$ ; if  $\gamma: U \rightarrow S$  is in  $\Gamma(U, S)$ , then  $r'_{U'U}(\gamma) = \gamma|_{U'}$  (restriction of  $\gamma$  to  $U'$ ).
- (35)  $\left\{ \begin{array}{l} \text{If } (X, O_X) \text{ is a ringed space, a pre-sheaf of modules} \\ (M(U), k_{U'U}) \text{ can be considered, in which } M(U) \text{ is an} \\ O(U)\text{-module and } (O(U), r_{U'U}) \text{ is the canonical pre-sheaf} \\ \text{of } O_X. \text{ Suppose that the homomorphism} \\ k_{U'U}: M(U) \rightarrow M(U') \text{ is such that if } a \in M(U), \alpha \in O(U), \\ \text{then } k_{U'U}(\alpha a) = r_{U'U}\alpha \circ k_{U'U}a. \text{ The resulting sheaf of} \\ \text{modules is called an } O_X\text{-module.} \end{array} \right.$
- (36)  $\phi(U): \Gamma(U, O_Y) \rightarrow \Gamma(\theta^{-1}U, O_X)$
- (37)  $(\theta, \phi): (x, O_X) \rightarrow (y, O_Y)$
- (38)  $\rightarrow F_1 \rightarrow F_2 \rightarrow F_3 \rightarrow F_4 \rightarrow \dots$
- (39)  $\{C_{\alpha_0 \dots \alpha_p}\}$ , in which  $C_{\alpha_0 \dots \alpha_p} \in \Gamma(U_{\alpha_0} \cap \dots \cap U_{\alpha_p}, F)$ .
- (40)  $\left\{ \begin{array}{l} \text{The coboundary operator } \partial_p \text{ is a homomorphism} \\ \mathbb{G}_p \rightarrow \mathbb{G}_{p+1}, \text{ in which } \partial\{C_{\alpha_0 \dots \alpha_p}\} = \{C_{\alpha_0 \dots \alpha_{p+1}}\}, \\ \text{in which } C_{\alpha_0 \dots \alpha_p} = \sum_{r=0}^{p+1} (-1)^r C'_{\alpha_0 \dots \alpha_r \dots \alpha_{p+1}}, C'_{\beta_0 \dots \beta_p} \\ \text{being the restriction of } C_{\beta_0 \dots \beta_r} \text{ to } U_{\alpha_0} \dots U_{\alpha_{p+1}}, \\ \beta_0 \dots \beta_p \text{ being a subset of } \alpha_0 \dots \alpha_{p+1}. \end{array} \right.$
- (41)  $\phi_{VU}: H^p(U, F) \rightarrow H^p(V, F)$

$X$ . If, further,  $U'$  is an open set contained in  $U$ , then there is a well-defined homomorphism defined in terms of a set of rings and satisfying certain conditions (see 31). Such a set of rings  $O(U)$  and homomorphisms  $r_{U'U}$  define a pre-sheaf over  $X$ . By considering a sequence  $U_1 \supset U_2 \supset \dots$  of open sets converging to a point  $P$ , the direct limit of the  $O(U_\alpha)$  is defined, as is a ring  $O_P$  associated with  $P$ , and a homomorphism  $r_{PU}$  that maps from a set of rings to a ring (see 32). The set  $S$  of elements of  $O_P$  for all  $P$  in  $X$  may be considered; the set  $S$  can be endowed with a topology by defining open neighbourhoods of each element. If  $\sigma$  denotes an element of  $O_P$ , then there exists a neighbourhood  $U$  of  $P$  and an element  $S_U$  of  $O(U)$  such that  $r_{PU}S_U = \sigma$ . If  $Q$  is any point of  $U$ , then the direct limit process defines a unique element  $r_{QU}S_U$  of  $O_Q$  corresponding to  $S_U$  for every point  $Q$  of  $U$ . As  $Q$  describes  $U$ ,  $r_{QU}S_U$  defines a set of  $S$  (containing  $\sigma$ ): this may define an open neighbourhood of  $\sigma$ . The set  $S$  is then a space with three properties (see 33);  $\pi^{-1}P$  is called the stalk of  $S$  at  $P$ , and  $S$  is a sheaf of rings over  $X$ . The situation now is that  $X$  is a topological space with a privileged sheaf  $O_X = S$  of rings over it. The entity  $(X, O_X)$  is called a ringed space. An algebraic variety can thus be represented as a ringed space.

A section of the sheaf  $S$  over an open set  $U$  of  $X$  is a continuous mapping  $\alpha: U \rightarrow S$  such that  $\pi\alpha$  maps  $U$  into itself identically. It can be verified that the section over  $U$  will have the structure of a ring, which is denoted by  $\Gamma(U, S)$ , and if  $U' \subseteq U$  there is a homomorphism of inclusion (see 34) in terms of which a set of rings and homomorphisms can be used to form a pre-sheaf. It can be shown that the sheaf  $S'$  defined by this pre-sheaf is equal to  $S$ . The pre-sheaf  $(\Gamma[U, S], r'_{U'U})$  is the canonical pre-sheaf of  $S$ .

The definition of sheaves can clearly be extended to define sheaves of groups or other sets with an algebraic structure (see 35). The resulting sheaf of modules is then called an  $O_X$ -module; its stalk at any point  $x$  is an  $O_x$ -module.

Consideration may be given to  $(X, O_X)$ ,  $(Y, O_Y)$  denoting two ringed spaces, with a continuous mapping  $\theta: X \rightarrow Y$ . If  $U$  is any open set of  $Y$  and there is a corresponding homomorphism (see 36), then if the homomorphisms  $\phi(U)$  are compatible with the restriction homomorphisms on  $X, Y$ , there is obtained a homomorphism  $\theta: O_Y \rightarrow O_X$  that induces a homomorphism of the stalk  $O_{y\theta}$  of  $O_Y$  into  $O_x$ , for all  $x$  in  $X$ . The pair  $(\theta, \phi)$ , suitably defined (see 37), is called a morphism. When  $(X, O_X)$  and  $(Y, O_Y)$  are the ringed spaces defined by algebraic varieties  $V_1, V_2$ , the morphism is just a regular mapping  $V_1 \rightarrow V_2$ .

To regard an algebraic variety as a ringed space and study the properties of sheaves over it has proved so powerful a method in algebraic geometry that Alexandre Grothendieck, a German-born French mathematician, has been led to a further generalization of an algebraic variety. Consideration may be given first to an affine variety. As a ringed space it is defined by an integral domain  $R(V, k)$ , and the points (zero-dimensional subvarieties) are defined by the maximal prime ideals of  $R(V, k)$ . In Grothendieck's treatment this is generalized by considering any commutative ring  $R$ . The points may no longer be defined by the maximal prime ideals of  $R$ , because if  $R$  is not a Noetherian ring (after Emmy Noether, a German mathematician) there may be no maximal ideals. Therefore all the prime ideals of  $R$  have to be considered as points. The closed sets of this aggregate are the points corresponding to prime ideals that contain an ideal  $\mathfrak{I}$  of  $R$ . The points, with this topology, form a space that is called an affine schema. A pre-schema is then defined as a ringed space that is covered by a system of open sets each of which is an affine schema. A schema is a pre-schema that satisfies a further condition somewhat analogous to the completeness condition for abstract varieties. The techniques employed to study algebraic varieties by using the theory of sheaves can then be applied to schemas. Some difficulties, however, occurring in the general case, do not arise in the case when the ringed space is an algebraic variety.

In all that follows it will be assumed that  $(X, O_X)$  is the ringed space of a nonsingular irreducible projective algebraic variety  $X$ .

If  $F$  and  $G$  are taken to be two sheaves over  $X$ , then a homomorphism  $\alpha: F \rightarrow G$  is a continuous mapping of  $F$  into  $G$  (when each is regarded as a topological space) that induces a homomorphism  $\alpha_x: F_x \rightarrow G_x$  of the stalks at each point  $x$ . It is clear that the image  $F'$  of  $F$  in  $G$  has the structure of a sheaf, and the kernel of  $\alpha$ ; that is, the elements of  $F_x$  that map to zero in  $G_x$  for all  $x$  form a sub-sheaf of  $F$ . The quotients  $G_x/F'_x$  further form a sheaf  $G/F'$ . A sequence (see 38) of sheaves and homomorphisms is referred to as exact if the image of each homomorphism is the kernel of the following one.

For each integer  $p$  ( $p \geq 0$ ) a cohomology group,  $H^p(X, F)$ , can be defined for any sheaf  $F$ . If  $U = \{U_\alpha\}$  is any covering of  $X$  by open sets, then a  $p$ -cochain of  $U$  is a specific system of sections (see 39). The  $p$ -cochains form a group  $b_p$  under addition. The co-boundary operator  $\partial_p$  can be defined (see 40).

The elements of the kernel of  $\partial_p$  are  $p$ -cocycles and form a group  $\gamma_p$ ;  $\partial_{p-1}b_{p-1}$  is a subgroup of  $b_p$ , and because  $\partial_p\partial_{p-1} = 0$ , it is a subgroup  $\beta_p$  of  $\gamma_p$ . The quotient group  $\gamma_p/\beta_p$  is denoted by  $H^p(U, F)$ . If  $V$  is another covering of  $X$  by open sets,  $H^p(V, F)$  can be defined similarly; and if  $V$  is a refinement of  $U$ , so that each  $V_\lambda$  is contained in at least one  $U_\alpha$ , a corresponding homomorphism can also be defined (see 41). These groups and homomorphisms define in the usual way a direct limit, denoted by  $H^p(X, F)$ , which is called the  $p$ th cohomology group of  $F$ . If  $U$  is any open set of  $X$  the cohomology group  $H^p(U, F)$  can be defined similarly. It may be noted that if  $F$  is an  $O_X$ -module,  $H^p(U, F)$  can be given the structure of an  $O(U)$ -module. For complete algebraic varieties over  $k$ ,  $\Gamma(X, O_X) = k$ , and  $H^p(X, F)$  is a vector

Grothendieck's generalization

space (that is, a collection of vectors satisfying certain algebraic properties) over  $k$ .

If there is (see 42) an exact sequence of sheaves and homomorphisms, there can be defined homomorphisms

$$H^p(X, F) \xrightarrow{\alpha_p} H^p(X, G), \text{ and } H^p(X, G) \xrightarrow{\beta_p} H^p(X, H).$$

There can also be determined  $H^p(X, H) \xrightarrow{\delta_p} H^{p+1}(X, F)$ , thus a sequence, called a cohomology sequence, can be obtained (see 43). For the ringed spaces  $(X, O_X)$  derived from a complete algebraic variety  $X$ , this sequence is exact. For more general ringed spaces it may not be exact. For schemas, Grothendieck defines cohomology in a different way, and the Grothendieck cohomology sequence corresponding to (42) is exact. For the spaces under consideration here the Čech cohomology (named for Eduard Čech, a Czech mathematician) coincides with the Grothendieck cohomology.

Consideration may be given to the ringed space  $(X, O_X)$  corresponding to an algebraic variety  $X$ . A coherent sheaf on it can be defined as follows:  $O_X^n$  denotes the sheaf that is the direct sum of  $n$  copies of  $O_X$ . An  $O_X$ -module  $F$  is referred to as coherent if there can be found integers  $n, m$  and homomorphisms  $\alpha, \beta$  so that a certain sequence (see 44) is exact. (On more general ringed spaces coherent sheaves have to be defined differently.) Coherent sheaves have certain properties that make them easier to deal with than more general sheaves. Their main properties are: (A) If in the exact sequence of sheaves (see 42) any two of the sheaves  $F, G, H$  are coherent, so is the third; (B) If  $F$  is a coherent sheaf,  $H^p(X, F)$  is a vector space of finite dimension over  $k$ , and  $H^p(X, F) = 0$  for  $p$  sufficiently large.

Consideration may be given to the free group  $\kappa$  generated by addition of the coherent sheaves over  $X$ . If  $\kappa'$  denotes the subgroup generated by elements of  $\kappa$  of the form  $G - F - H$ , for all sheaves,  $F, G, H$ , such that the sequence (42) is exact and the quotient group  $\kappa/\kappa'$  is denoted by  $K(X)$ , then  $K(X)$  is a group having many connections with the Chow ring of the algebraic variety  $X$  that defines the ringed space  $(X, O_X)$ .

Letting  $(X, O_X)$  and  $(Y, O_Y)$  be ringed spaces, assumed to be algebraic varieties, and  $(\theta, \phi)$  a morphism between them (see 45), then the effects of this morphism on sheaves on  $X$  and on  $Y$  may be considered.

A. If  $F$  is a coherent sheaf over  $Y$ , there can be defined a module  $M(U)$  associated with an open set  $U$  of  $X$  by  $M(U) = \Gamma(\theta U, F)$ . It is then possible to define a homomorphism (see 46) so that there is a pre-sheaf over  $X$ . The derived sheaf may be denoted by  $\phi^!F$ ; it can be shown to be a coherent sheaf over  $X$ . Moreover, if a sequence involving  $F, G, H$  is an exact sequence of homomorphisms of coherent sheaves over  $Y$ , then a corresponding sequence of derived sheaves (see 47) is exact over  $X$ . Thus  $\phi^!$  defines a homomorphism  $K(Y) \rightarrow K(X)$ .

B. If  $F$  is an  $O_X$ -module over  $X$ , there can be defined a pre-sheaf over  $Y$  by associating with each open set  $U$  of  $Y$  the module  $\Gamma(\theta^{-1}U, F)$ , and defining suitable homomorphisms between modules (see 48), in which  $U' \subseteq U$ . The induced sheaf over  $Y$  is denoted by  $\phi_*F$ . If  $F, G, H$  are  $O_X$ -modules such that the sequence (42) is exact, a sequence of homomorphisms (see 49), however, can be deduced. In general this is not exact. Thus  $\phi_*$  does not define a homomorphism  $K(X) \rightarrow K(Y)$ . The image  $\phi_*F$  of  $F$  in  $K(Y)$  can, however, be defined as follows:

If  $U$  is any open set of  $Y$ , by associating with  $U$  the  $O(\theta^{-1}U)$ -module  $H^p(\theta^{-1}U, F)$ , a pre-sheaf over  $Y$  can be defined by the usual process. Hence, a sheaf can also be defined. This is denoted by  $R^p\phi_*F$ . It is a coherent sheaf. The element of  $K(Y)$ ,  $\phi_*F$ , is given by  $\sum_{p \geq 0} (-1)^p R^p\phi_*F$ ,

a finite sum because  $H^p(\theta^{-1}U, F)$  is always zero for sufficiently large  $p$ . If the sequence (42) is an exact sequence of sheaves, the exactness of the cohomology sequence (43) leads to an equality in  $K_0(Y)$  (see 50). Thus  $\phi_*$  defines a homomorphism  $\phi_*: K(X) \rightarrow K(Y)$ .

#### APPLICATIONS TO ALGEBRAIC GEOMETRY

If  $X$  is a complete irreducible algebraic variety of dimension  $d$ , and  $(X, O_X)$  is the associated ringed space, then

$$(42) \quad 0 \rightarrow F \xrightarrow{\alpha} G \xrightarrow{\beta} H \rightarrow 0$$

$$(43) \quad 0 \rightarrow H^0(X, F) \xrightarrow{\alpha_0} H^0(X, G) \xrightarrow{\beta_0} H^0(X, H) \xrightarrow{\delta_0} H^1(X, F) \rightarrow \dots \rightarrow H^{p-1}(X, H) \xrightarrow{\delta_{p-1}} H^p(X, F) \xrightarrow{\alpha_p} \dots$$

$$(44) \quad O_X^n \xrightarrow{\alpha} O_X^m \xrightarrow{\beta} F \rightarrow 0$$

$$(45) \quad \begin{cases} \theta: X \rightarrow Y \\ \phi_x: O_{\theta x} \rightarrow O_x \end{cases}$$

$$(46) \quad h_{U'U}: M(U) \rightarrow M(U') \text{ for } U' \subseteq U$$

$$(47) \quad \begin{cases} 0 \rightarrow F \rightarrow G \rightarrow H \rightarrow 0 \\ 0 \rightarrow \phi^!F \rightarrow \phi^!G \rightarrow \phi^!H \rightarrow 0 \end{cases}$$

$$(48) \quad \Gamma(\theta^{-1}U, F) \rightarrow \Gamma(\theta^{-1}U', F)$$

$$(49) \quad 0 \rightarrow \phi_*F \rightarrow \phi_*G \rightarrow \phi_*H \rightarrow 0$$

$$(50) \quad 0 \rightarrow \phi_*F \rightarrow \phi_*G \rightarrow \phi_*H \rightarrow 0$$

$$(51) \quad h_{UU_\alpha}: M(U_\alpha) \rightarrow M(U)$$

$$(52) \quad F_D = H^0(X, F_D)$$

there are two groups on  $X$ : the group  $K(X)$  defined above, and the Chow ring  $A(X)$ , regarded as an additive group. Many problems of algebraic geometry are concerned with relations between  $K(X)$  and  $A(X)$ . Sometimes it is convenient to extend  $A(X)$  so that it is the group generated by the equivalence classes of cycles with rational numbers as coefficients; the extended group is then denoted by  $A(X) \times Q$ , in which  $Q$  is the field of rational numbers.

If  $D$  is a divisor of  $X$ —that is, a cycle of dimension  $d - 1$ —there exists a covering  $U = (U_\alpha)$  of  $X$  so fine that in  $U_\alpha$  there is an element  $\phi_\alpha$  of the function field  $\Sigma$  of  $X$  such that  $D \cap U_\alpha = D_\alpha$  is the divisor consisting of the zero of  $\phi_\alpha$  minus the poles of  $\phi_\alpha$ , each counted with proper multiplicity.  $\phi_\alpha$  is determined in  $U_\alpha$  except for a factor that has no poles or zeros in  $U_\alpha$ . In  $U_\alpha \cap U_\beta$ ,  $\phi_\alpha/\phi_\beta$  has no poles or zeros. The elements  $\Psi$  of  $\Sigma$  such that  $\Psi\phi_\alpha$  is contained in  $O(U_\alpha) = \Gamma(U_\alpha, O_X)$  form a  $O(U_\alpha)$ -module of  $M(U_\alpha)$ . If  $U \subseteq U_\alpha$ , the  $M(U)$  can be defined in the same way together with a natural homomorphism (see 51).

The modules  $M(U_\alpha)$ , and homomorphisms  $h_{UU_\alpha}$  form a pre-sheaf. The sheaf obtained from it is coherent: it is denoted by  $F_D$ . Any section  $\Psi$  of  $F_D$  is an element  $\Psi$  of  $\Sigma$ . In the open set  $U_\alpha$ ,  $\Psi$  defines a local divisor  $E_\alpha$  such that  $F_\alpha = E_\alpha + D_\alpha$  is a positive divisor. Globally, divisors  $E, F$  of  $X$  exist such that  $E = F - D$  is the divisor of the function  $\Psi$ . Hence  $E$  is rationally equivalent to zero and  $F$  is a positive divisor rationally equivalent to  $D$ . It may readily be shown that  $F_D = F_{D'}$ , in which  $D'$  is any divisor equivalent to  $D$ . Hence  $F_D$  only depends on the divisor class of  $D$ . It can be shown also that the system of all positive divisors equivalent to  $D$  is identical with the system of divisors defined by sections of  $F_D$  (see 52).  $H^0(X, F_D)$  is a vector space (over  $k$ ) of finite dimension whose one-dimensional vector subspaces correspond to positive divisors equivalent to  $D$ .

Thus a situation exists in which a certain class of coherent modules correspond to elements of  $A(X)$ . By itself, this is not very informative: what is needed is a defined homomorphism  $K(X) \rightarrow A(X) \times Q$ . There are two ways of special importance for establishing such a homomorphism.

Mappings  
using  
Chern  
classes

A. Extending an idea (the Chern classes, denoted  $ch$ , after Shiing-Shen Chern, a Chinese-born U.S. mathematician) borrowed from differential geometry, there can be defined a mapping (see 53). In a sense it generalizes the mapping of  $F_D$  to the divisor class of  $D$  given above. For  $F_D$ ,  $ch F_D$  is the element of  $A(X) \times Q$  defined by a sum (see 54) involving  $D^i$ , in which  $D^i$  is the equivalence class defined by the product of  $i$  divisor classes equivalent to  $D$ . The mapping  $ch F$  of any coherent sheaf is then constructed by a geometrical argument from the mappings  $ch F_D$ .

$$(53) \quad ch: K(X) \rightarrow A(X) \times Q$$

$$(54) \quad 1 + D + \frac{1}{2!} D^2 + \cdots + \frac{1}{r!} D^r + \cdots$$

$$(55) \quad (\theta, \phi)(X, O_X) \rightarrow (Y, O_Y)$$

$$(56) \quad \begin{cases} K(X) \xrightarrow{ch} A(X) \times Q \\ \phi_! \uparrow \quad \uparrow \phi^* \\ K(Y) \xrightarrow{ch} A(Y) \times Q \end{cases}$$

$$(57) \quad gr: K(X) \rightarrow A(X) \times Q$$

$$(58) \quad \begin{cases} (\theta, \phi): (X, O_X) \rightarrow (Y, O_Y) \text{ defines} \\ \phi_!: K(X) \rightarrow K(Y), \text{ and } \phi_*: A(X) \times Q \rightarrow A(Y) \times Q \end{cases}$$

$$(59) \quad \begin{cases} K(X) \xrightarrow{gr} A(X) \times Q \\ \phi! \downarrow \quad \downarrow \phi_* \\ K(Y) \xrightarrow{gr} A(Y) \times Q \end{cases}$$

$$(60) \quad \phi_! F = H^0(X, F) - H^1(X, F) + H^2(X, F) - \cdots$$

$$(61) \quad \phi_! F = \chi(F) = \dim H^0(X, F) - \dim H^1(X, F) + \dim H^2(X, F) - \cdots$$

$$(62) \quad \begin{cases} 0 \rightarrow F_{-Q} \rightarrow F_D \rightarrow A_P \rightarrow 0 \\ 0 \rightarrow F_{-Q} \rightarrow O_X \rightarrow A_Q \rightarrow 0 \end{cases}$$

$$(63) \quad \begin{cases} \chi(F_D) = \chi(F_{-Q}) + \chi(A_P) \\ \quad = \chi(O_X) + N \end{cases}$$

$$(64) \quad \begin{cases} \chi(F_D) = \dim H^0(X, F_D) - \dim H^1(X, F_D) \\ \dim H^0(X, F_D) = d \end{cases}$$

$$(65) \quad H^1(X, F_D) = \dim H^0(X, F_{K-D})$$

$$(66) \quad d = N - g + 1 + i_D$$

If  $(\theta, \phi)$  denotes a regular mapping  $X \rightarrow Y$  (see 55), then the mappings necessary for a specific diagram (see 56) have all been defined. A fundamental property of the homomorphism  $ch$  is that this is a commutative diagram of homomorphisms.

B. A second homomorphism (denoted  $gr$  for Grothendieck) can be defined (see 57). Corresponding to a morphism, other homomorphisms (see 58) also have been defined. Grothendieck's form of the Riemann-Roch theorem states that a certain diagram (see 59) is commutative.

All the usual forms of the Riemann-Roch theorem can be deduced from Grothendieck's formula by taking  $Y$  to be a single point:  $(Y, O_Y) = (P, k)$ . A coherent sheaf over  $P$  is just a finite-dimensional vector space, over  $k$ , and if  $F$  is any coherent sheaf,  $\phi_! F$  is then given (see 60).  $A(P)$  is the group  $mP$  ( $m$  an integer) and  $A(P)$  is thus

isomorphic with the additive group of integers  $Z$ . Identifying  $A(P)$  with  $Z$ , a final statement can be expressed (see 61).

Consideration may be given to the case in which  $X$  is an irreducible complete curve. Any divisor  $D$  is given by  $D = P - Q$ , in which  $P$  and  $Q$  are positive divisors. The construction of  $F_{-Q}$ ,  $F_D$  and  $F_0 = O_X$  can be effected and exact sequences established (see 62) that involve  $A_P$ . Here  $A_P$  is a sheaf of which the stalk is zero except in the points of  $P$  in which it is a vector space the dimension of which is the multiplicity of the point.  $\chi(A_P) = \text{ord } P$  (the number of points of  $P$  each counted with the proper multiplicity).  $\chi(A_Q)$  is similarly defined. Since  $\phi_!$  is a homomorphism of  $K(X) \rightarrow K(P)$ , a conclusion can be drawn (see 63) that involves  $N$ , in which  $N$  is the order of  $D$ ;  $\chi(O_X)$  is a numerical character of  $X$ , equal to  $1 - g$ , in which  $g = \dim H^1(X, O_X)$  is the genus of  $X$ . It is possible to express (see 64) the dimension of the vector space representing the positive divisors equivalent to  $D$ ;  $\dim H^1(X, F_D)$  is equal to  $i_D$ , the index of speciality of  $D$ , and has the following interpretation. There is, on  $X$ , a well-defined equivalence class of divisors  $K$ , which can be defined in terms of the Chern classes of the tangent bundle of  $X$ . An equality can also be used (see 65). The combination of these results leads to a final result for  $d$  (see 66).

The same process can be applied to calculate  $\chi(F_D)$  for the sheaf corresponding to any divisor class  $D$  on an irreducible variety  $X$  of dimension  $p$  in terms of characters of  $D, D^2, \dots, D^p$ . The term  $\dim H^0(X, F_D)$  of  $\chi(D)$  gives the dimension of the linear system of positive divisors equivalent to  $D$ . The other terms  $\dim H^p(X, F_D)$  are invariants of this system, which can be given interpretations in terms of classical algebraic geometry.

**BIBLIOGRAPHY.** BARTEL L. VAN DER WAERDEN, *Einführung in die algebraische Geometrie* (1939), contains a fuller introductory account of the geometry of varieties in projective space. The birational geometry of algebraic varieties over the field of complex numbers is dealt with in many works by Italian geometers. OSCAR ZARISKI, *Algebraic Surfaces* (1935), contains a comprehensive account of this, with a full bibliography. The notion of an abstract variety is due to ANDRÉ WEIL, *Foundations of Algebraic Geometry*, rev. ed. (1962); SERGE LANG, *Introduction to Algebraic Geometry* (1958), contains an elementary account. For the theory of sheaves, see ROGER GODEMONT, *Topologie algébrique et théorie des faisceaux* (1958). For information about schema, see ALEXANDRE GROTHENDIECK, *Éléments de géométrie algébrique*, 4 pt. (1960-66).

## Geometry, Analytic and Trigonometric

Geometry is the branch of mathematics originally thought to be concerned solely with the properties of space and objects—points, lines, angles, planes, surfaces, and solids—in space. After the work of the modern German mathematician David Hilbert, at the turn of the 20th century, the foundations of geometry were generalized and the classical concepts of space and objects in space, which derived from intuition, were replaced with abstract ideas. A step toward the generalization of classical geometry was taken when the branch of geometry known as analytical geometry was created and first used in 1637 by an outstanding French mathematician and philosopher, René Descartes. Descartes applied algebra to geometry not just in the use of algebra to manipulate the dimensions of geometric figures but also in the representation of a point by a pair of numbers and the representation of lines and curves by equations. It was a powerful general method of solving certain geometric problems and one that could be applied to certain types of curves more readily than the geometry of the Greeks that was based on axioms.

The basis of analytic geometry is the idea that a point in space can be specified by numbers giving its position. The notion that any point, for example, can be indicated by its latitude, longitude, and height above the Earth goes back to Archimedes of Syracuse and to Apollonius of Perga, who lived in the 3rd century bc. It was Des-

cartes and another 17th-century Frenchman, Pierre de Fermat, however, who developed that notion systematically. The idea of using negative distances is due to Sir Isaac Newton in 17th-century England and the German mathematician and philosopher Gottfried Wilhelm Leibniz, in the 18th century.

An outline of the present article is as follows.

 Special curves

#### PLANE ANALYTIC GEOMETRY

**Cartesian coordinates.** In two dimensions the position of a point in a plane can be specified by its distance from two intersecting lines, called axes. For instance, in Figure 1 two lines at right angles to each other intersect at the point  $O$ , called the origin. One axis is the line  $OX$ , the other  $OY$ , and any point in the plane can be denoted by two numbers giving its perpendicular distances from  $OY$  and from  $OX$ .

A general point  $(x, y)$  can be reached by travelling a distance  $x$  along  $OX$  and then a distance  $y$  along a line parallel to  $OY$ .  $OX$  is called the  $x$ -axis,  $OY$  the  $y$ -axis, and the point is said to have coordinates  $(x, y)$ . In the coordinate system shown, as is indicated in the diagram, the  $x$ -coordinate is positive for points to the right of the  $y$ -axis and negative for points to the left of this axis. The  $y$ -coordinate is positive for points above the  $x$ -axis and negative for points below it. The coordinates of the origin are  $(0, 0)$ . All of these coordinates are called Cartesian coordinates (which are named after Descartes). If oblique axes are used, the position of a point is defined in the same way: by its distance along lines parallel to the  $x$  and  $y$  axes.

Figure 1: Cartesian coordinates, rectangular (left) and oblique (right). (See text.)

**Straight lines.** In a coordinate system a line can be represented by an equation. For example, all the points  $(0, y)$  lie on the  $y$ -axis and have an  $x$ -coordinate that is zero. Thus the  $y$ -axis has the equation  $x = 0$ . Similarly, the  $x$ -axis has the equation  $y = 0$ . If any other line is taken through the origin, the ratio of  $x$  to  $y$  is always constant and may be expressed by the equation  $y = mx$ ,  $m$  being a constant, or the ratio of  $x$  to  $y$  may also be expressed by an arbitrary linear combination that is restricted to equal 0 and that contains two coefficients (see Box, equation 1).

Any line can be represented by an equation obtained in

the following way. A point  $(x_1, y_1)$  is taken in the line and a new pair of axes drawn parallel to the original pair and with  $(x_1, y_1)$  as origin. If the coordinates with respect to these axes are  $(x', y')$ , the equation of the line must be of the form already given but this time containing the new variables in place of the old (see 2). Because  $x' = x - x_1$  and  $y' = y - y_1$ , the equation of the line, in terms of the original coordinates, is a general linear expression set equal to 0 and including a constant term (see 3) in which  $c$  is a constant.

Thus every straight line has an equation of this form and every equation of this form represents a straight line. Such equations, in which the powers of  $x$  and  $y$  are unity (or one), are called linear equations.

$$(1) \quad ay + bx = 0$$

$$(2) \quad ax' + by' = 0$$

$$(3) \quad a(x - x_1) + b(y - y_1) = 0, \quad \text{or} \quad ax + by + c = 0$$

$$(4) \quad \begin{cases} ax + by + c = 0 \\ y = -\frac{ax}{b} - \frac{c}{b} \end{cases}$$

$$(5) \quad y = mx + d$$

$$(6) \quad \frac{x}{x_0} + \frac{y}{y_0} = 1$$

$$(7) \quad \frac{y - y_1}{y_2 - y_1} = \frac{x - x_1}{x_2 - x_1}$$

$$(8) \quad \begin{vmatrix} x & y & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix} = 0$$

$$(9) \quad \begin{vmatrix} x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \end{vmatrix} = 0$$

The equation with linear and constant terms  $a, b, c$  (see 4) rearranges to an expression (see 5) with  $y$  on the left and a form including slope  $m$  as coefficient of  $x$  and including  $y$ -intercept  $d$ . When Cartesian coordinates are used,  $m$  is the slope of the line and  $d$  is the intercept on the  $y$ -axis, because it is the point on the  $y$ -axis intercepted by the line. This form of the equation is particularly convenient. For instance, the line  $y = x$  goes through the origin ( $d = 0$ ) and has a gradient of 1 (see Figure 2). The line  $y = -1x + 4$  intercepts the  $y$ -axis at  $y = 4$  and has a gradient of  $-1$ ; that is, it slopes in the opposite direction to  $y = x$ . If two lines have the same value of  $m$ , they are parallel; thus  $y = 3x + 4$  is parallel to  $y = 3x + 7$ . A line with a gradient  $m$  is perpendicular to a line with a gradient  $-1/m$ . Thus  $y = 3x + 4$  is perpendicular to  $-3y = x + 6$ .

Another form of the equation for a straight line is the intercept form in which the sum of the ratio of the variables to  $x_0$  and  $y_0$  is restricted to equal 1 (see 6). In this case,  $x_0$  and  $y_0$  are the intercepts on the  $x$  and  $y$  axes, respectively.

A straight line going through two points  $(x_1, y_1)$  and  $(x_2, y_2)$  has an equation that is given by a ratio of differences (see 7).

This equation is often stated in the form of a determinant, which is restricted to equal 0 (see 8). The condition for three points  $(x_1, y_1)$ ,  $(x_2, y_2)$ , and  $(x_3, y_3)$  to be on the same line is also expressible in terms of a determinant (see 9).

**Intersection of two lines.** The point of intersection of two lines is found by solving their equations simultaneously. For instance, the lines with equations of specific type (see 10) may be found to meet at the point  $(-2, 1)$ .

**Parametric equations.** In some cases parametric equations are used to express a line; i.e., equations giving  $x$  and  $y$  in terms of a single variable (parameter)  $t$ . For example, any line through the point  $(x_1, y_1)$  can be described by parametric equations with parameters  $l$  and  $n$  (see 11) in which  $l$  and  $n$  depend on the direction of the line. Sometimes the single parameter  $t$  is replaced by two parameters  $t_1$  and  $t_2$ , which are related by an auxiliary equation. For example, the general point  $(x, y)$  on a line through  $(x_1, y_1)$  and  $(x_2, y_2)$  has equations that are supplemented by the condition that the sum of the two parameters should equal one (see 12).

**Distances.** When Cartesian coordinates are used, the distances between points can easily be found using Pythagoras' theorem. A point  $(x, y)$  at a distance from the origin  $(0, 0)$  is expressed in terms of a square root (see 13). The distance between two points  $(x_1, y_1)$  and  $(x_2, y_2)$  is expressed in terms of a square root of squares of differences (see 14).

The distance from a point  $(x_1, y_1)$  to a line  $ax + by + c = 0$  can also be found. The line along which the dis-

Figure 2: Straight lines (see text).

- (10)  $y = x + 3$  and  $2y = x + 4$
- (11)  $x = x_1 + lt$  and  $y = y_1 + nt$
- (12)  $x = t_1x_1 + t_2x_2$ ,  $y = t_1y_1 + t_2y_2$ , and  $t_1 + t_2 = 1$
- (13)  $\sqrt{x^2 + y^2}$
- (14)  $\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$
- (15)  $\frac{ax_1 + by_1 + c}{\sqrt{a^2 + b^2}}$
- (16)  $\begin{cases} a_1x + b_1y + c_1 = 0 \\ a_1x + b_1y + c_2 = 0 \end{cases}$
- (17)  $\frac{c_1 - c_2}{\sqrt{a_1^2 + b_1^2}}$
- (18)  $x^2 + y^2 = r^2$
- (19)  $(x - h)^2 + (y - k)^2 = r^2$
- (20)  $x^2 + y^2 - 6x - 4y - 3 = 0$
- (21)  $(x - 3)^2 + (y - 2)^2 = 4^2$
- (22)  $x^2 + y^2 + 2ax + 2by + c = 0$
- (23)  $(x + a)^2 + (y + b)^2 = a^2 + b^2 - c$
- (24)  $h = -a$ ,  $k = -b$ , and  $r^2 = a^2 + b^2 - c$
- (25)  $\sqrt{a^2 + b^2 - c}$
- (26)  $x^2 + y^2 + 2ax + 2by + c = 0$
- (27)  $x^2 + y^2 + 2a'x + 2b'y + c' = 0$
- (28)  $\begin{cases} x^2 + y^2 + 2ax + 2by + c = x^2 + y^2 + 2a'x + 2b'y + c' \\ \text{i.e., } 2(a - a')x + 2(b - b')y + (c - c') = 0 \end{cases}$
- (29)  $x^2 + y^2 + 2kx + c = 0$

tance is measured intersects  $ax + by + c = 0$  at right angles, and thus its gradient is known. This, and the fact that it passes through  $(x_1, y_1)$ , leads to its equation. Thus the point of intersection of this perpendicular with the original line can be found, and the distance follows (see 15). Similarly, the distance between two parallel lines (see 16) can be shown to be calculable (see 17).

**The circle.** A circle is a curve consisting of all those points of a plane that lie at a fixed distance from a particular point in the plane, this point being the centre. When rectangular axes are used, a point  $(x, y)$  is at a distance  $\sqrt{x^2 + y^2}$  from the origin, by Pythagoras' theorem. The distance between two points  $(x_1, y_1)$  and  $(x_2, y_2)$  is the square root of  $(x_1 - x_2)^2 + (y_1 - y_2)^2$ . If  $r$  is the radius of the circle, and it has its centre at the origin of a Cartesian coordinate system, then points on the circle have coordinates  $(x, y)$  given by the equation that again is a restricted sum of squares (see 18).

More generally, if the centre of the circle is  $(h, k)$ , the equation is one that involves a sum of squares in which  $h$  and  $k$  are subtracted from the variables (see 19). For example, the equation of quadratic form with specific values of the coefficients (see 20) represents a circle of radius 4 and centre  $(3, 2)$ , because it can be put in the form that makes clear where the centre of the circle is and what the radius of the circle is taken to be (see 21).

Any equation of the form of a general quadratic (see 22) may be written in a form (see 23) that is equivalent to the equation of the circle if algebraic conditions are satisfied (see 24). The last of these conditions is not possible for any real value of  $r$  if  $a^2 + b^2 - c$  is negative; but, if  $a^2 + b^2 - c$  is positive, the equation is seen to represent a circle the centre of which is  $(-a, -b)$  and radius expressed in terms of a square root (see 25). The constants  $a$ ,  $b$ , and  $c$  may be determined to satisfy specified conditions, and the circle becomes then definitely fixed. For instance, if the circle is to pass through three given points, the coordinates of these must satisfy the equation, and, on substituting them for  $x$  and  $y$ , three equations are obtained giving  $a$ ,  $b$ , and  $c$ .

A point  $(x, y)$  from which the tangent to the first circle expressed with parameters  $a, b, c$  (see 26) is equal to the tangent to another circle expressed with parameters that are primed (see 27) satisfies the equation that identifies two quadratic forms (see 28). This equation, if the circles have not the same centre, is of the first degree, so that the point  $(x, y)$  lies on a fixed straight line, called the radical axis of the circles. If the circles have two points in common, the radical axis is the line joining these points. The equation of a circular form with parameter  $c$  (see 29) represents, for different values of  $c$ , different circles of which any two have the  $y$ -axis as their radical axis. These circles are said to form a coaxial system. If  $c$  is

Circles of a coaxial system

negative, all the circles pass through the same two points on the  $y$ -axis. If  $c$  is positive, none of the circles intersect. In either case one circle of the system may be found to pass through any given point that is not on the  $y$ -axis.

The equation of the tangent at a point  $(x_1, y_1)$  on a circle may be shown to be calculated from the condition that the tangent at that point has a specific slope and point of contact (see 30). If, however,  $(x_1, y_1)$  is not on but outside the circle, the equation represents the polar of  $(x_1, y_1)$ ; that is, the straight line joining the points of contact of tangents from  $(x_1, y_1)$ .

**Conic sections.** A circle is a special case of a group of curves known as conic sections, or conics. They were first studied in the 4th century BC by Menaechmus of Greece, who described them as curves obtained by the intersection of a right circular cone and a plane, hence their name. According to the angle of intersection the conic is a parabola, ellipse, circle, or hyperbola. This construction is shown in Figure 3, for a double right-circular cone. A cone can be generated by fixing a central point on a straight line segment and moving the end of the line segment around a circle. Each half of the cone thus generated is called a nappe.

An ellipse results from a section that completely cuts one nappe. A circle is a special case of an ellipse produced by a section perpendicular to the axis. A parabola is produced by a cutting plane parallel to a generating line. A section parallel to the axis cuts both nappes and produces a hyperbola.

Figure 3: Conic sections (see text).

The work of the Greek mathematicians on conic sections

Menaechmus, a pupil of both the philosopher Plato and the scientist Eudoxus of Cnidus, was led to the study of conics by his efforts to solve the problem of constructing a cube twice as large by volume as a given cube, the so-called Delian problem.

The 4th-century-BC geometer Euclid wrote four books on conic sections, but his work is completely lost. Archimedes succeeded in finding the area of the ellipse and of

$$(30) \quad x_1x + y_1y + a(x + x_1) + b(y + y_1) + c = 0$$

$$(31) \quad ax + by + c = 0$$

$$(32) \quad \sqrt{(x_1 - p)^2 + (y_1 - q)^2}$$

$$(33) \quad \frac{ax_1 + by_1 + c}{\sqrt{a^2 + b^2}}$$

$$(34) \quad \sqrt{(x_1 - p)^2 + (y_1 - q)^2} = \frac{e(ax_1 + by_1 + c)}{\sqrt{a^2 + b^2}}$$

$$(35) \quad (a^2 + b^2)\{(x_1 - p)^2 + (y_1 - q)^2\} = e^2(ax_1 + by_1 + c)^2$$

$$(36) \quad Ax^2 + Bx^2y + Cxy^2 + Dx + Ey + F = 0$$

$$(37) \quad \frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$$

a sector of the parabola by a method closely akin to that of integral calculus, although calculus was not developed until the 17th century.

The pinnacle of Greek geometry, and perhaps of Greek mathematics in general, was reached by Apollonius of Perga in his eight books on conic sections, only the first seven of which have survived, but they contain the elementary theory of conics in a complete form. Apollonius was the first to show that all conics are sections of any circular cone, right or oblique. In studying these curves Apollonius treated them as plane curves, however, without regard to their spatial origin. The terms ellipse, hyperbola, and parabola were introduced by Apollonius.

Succeeding generations of Greek mathematicians added but little to the admirable treatise of the "Great Geometer," as Apollonius was called. An important contribution by Pappus of Alexandria in the 4th century AD, however, should be mentioned. He showed that the ratio of the distances of any point on any conic from a fixed point (the focus) and a fixed line (the directrix) is a constant. The constant ratio is called the eccentricity and is denoted by  $e$ . This is the definition used here to obtain the equation of a conic in Cartesian coordinates. The general equation of a straight line (see 31) is taken for the directrix and a fixed point  $(p, q)$  is taken for the focus. If  $x_1, y_1$  is a point on the conic, its distance from the focus is easily obtained. It is obtained as a square root of squares of differences between the parameters involved (see 32). The perpendicular distance from  $(x_1, y_1)$  to the directrix can also be obtained (see 33). Thus, because  $x_1, y_1$  is on a conic a condition holds that involves  $e$  (see 34),  $e$  being the eccentricity. Thus the operations of cross-multiplication and squaring are used (see 35). If the  $x_1$  and  $y_1$  are replaced by  $x$  and  $y$ , this gives a general equation for all points on a conic. It can be rearranged to an equation of the form of a quadratic (see 36) in which  $A, B, C, D, E$ , and  $F$  are constants for a particular conic and depend on the eccentricity and the position of the focus and directrix. This general equation of a conic shows that a conic is completely determined if five points on it are known. It gives equations for an ellipse, parabola, or hyperbola depending on whether  $e$  is less than, equal to, or exceeds unity.

**The ellipse.** An ellipse is a conic with an eccentricity less than unity. It is convenient to choose the focus of the ellipse on the  $x$ -axis and the directrix perpendicular to this axis. If this is done the ellipse has its centre at the origin and an equation with a sum of squares restricted to equal one (see 37). This is the standard form of the ellipse and is shown in Figure 4. It cuts the  $x$ -axis at  $(a, 0)$  and  $(-a, 0)$ , these being the vertices. It also cuts the  $y$ -axis at  $(0, b)$  and  $(0, -b)$ . The line  $AA'$  of length  $2a$  is called the major axis, and  $BB'$ , with a length  $2b$ , is the minor axis. The area of an ellipse is  $\pi ab$  (the Greek

Figure 4: The standard form of the ellipse (see text).

The foci  
of an  
ellipse

letter pi,  $\pi$ , representing the ratio of the circumference to the diameter of the circle). The ellipse has in fact two foci,  $F$  and  $F'$ , and two directrices,  $R_1R_2$  and  $R_1'R_2'$ .

The foci are points  $(ae, 0)$  and  $(-ae, 0)$ , and the directrices cut the  $x$ -axis at the points  $(a/e, 0)$  and  $(-a/e, 0)$ . A circle of radius  $a$  with  $B$  as its centre cuts the  $x$ -axis at  $F$  and  $F'$ . As a consequence an algebraic expression relates  $e$ ,  $a$ , and  $b$  (see 38).

If  $P$ , a point on the ellipse, has coordinates  $(x, y)$ , its distance from the directrix  $R_1R_2$  is  $(a/e) - x$ .

Thus from the definition the distance from the focus to the point  $P$  is determined (see 39) and the same can be calculated with respect to the focus  $F'$ . Thus the sum of these distances should add to twice the value of  $a$  (see 40). This leads to an alternative definition of the ellipse as the locus of a point that moves so that the sum of its distances from two fixed points is a constant. This property is the basis of a simple method of drawing an ellipse. Two pins are fixed at the foci and a loop of string placed over them. A pencil point is used to pull the string taut, forming a triangle, and the pencil is moved over the paper around the pins.

A circle around the ellipse with  $O$  as its centre and a radius  $a$  is called the major circle or auxiliary circle.

Figure 5: Ellipse and the major (or auxiliary) circle. The two foci of the ellipse are  $F$  and  $F'$ . A line that is drawn perpendicular to the  $x$ -axis at  $S$  cuts the ellipse and the circle at  $P$  and  $P'$ , respectively.

Similarly, the circle with radius  $b$  and lying inside the ellipse is the minor circle. These two circles are called the eccentric circles of the ellipse.

If a line is drawn perpendicular to the  $x$ -axis from a point  $S$ , it cuts the ellipse at  $P$  and the major circle at  $P'$ . The angle  $SOP'$  is called the eccentric angle of the ellipse (Figure 5). The points  $P$  and  $P'$  are called corresponding points, and it can be shown that  $P'S/PS = a/b$ .

One useful property of an ellipse is known as the

$$(38) \quad ae = \sqrt{a^2 - b^2}, \quad \text{thus} \quad e^2 = 1 - \frac{b^2}{a^2}$$

$$(39) \quad \begin{cases} FP = e\left(\frac{a}{e} - x\right) = a - ex \\ FP' = a + ex \end{cases}$$

$$(40) \quad FP + FP' = 2a$$

$$(41) \quad x^2 + y^2 = a^2$$

$$(42) \quad \frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$$

$$(43) \quad \frac{x^2}{a^2} - \frac{m^2 x^2}{b^2} = 1; \quad \text{i.e.,} \quad x^2(b^2 - a^2 m^2) = a^2 b^2$$

$$(44) \quad x = \frac{\pm ab}{\sqrt{b^2 - a^2 m^2}}$$

$$(45) \quad b^2 - a^2 m^2 = 0$$

$$(46) \quad b^2 = a^2 m^2 \quad \text{or} \quad m = \pm \frac{b}{a}$$

$$(47) \quad \begin{cases} y = \frac{b}{a}x \\ y = -\frac{b}{a}x \end{cases}$$

$$(48) \quad \frac{y^2}{b^2} - \frac{x^2}{a^2} = 1$$

optical property: that the lines  $FP$  and  $F'P$  make equal angles with a tangent to the curve at the point  $P$ . If a source of radiation or sound is placed at the focus of a concave reflector with elliptical section, the radiation is converged onto the other focus. This property is used in certain practical applications.

The smaller the eccentricity of an ellipse the nearer its foci are together and the more it resembles a circle. If  $b = a$  the eccentricity is zero, the foci coincide, and the ellipse becomes a circle with equation in the familiar form for radius  $a$  (see 41) and area  $\pi a^2$ .

**The hyperbola.** A hyperbola is a conic with an eccentricity greater than unity. It has the standard form shown in Figure 6, in which  $F$  and  $F'$  are the foci. Its equation is one that involves a difference of squares (see 42) and it cuts the  $x$ -axis at  $A$  and  $A'$ , which have respective coordinates  $(a, 0)$  and  $(-a, 0)$ . The segment  $AA'$ , of length  $2a$ , is called the transverse axis, and the segment of the  $y$ -axis,  $BB'$ , with length  $2b$ , is called the conjugate axis. The coordinates of the foci are  $(ae, 0)$  and  $(-ae, 0)$ , and the directrices are the lines  $x = a/e$  and  $x = -a/e$ .

It is not possible to draw tangents to the hyperbola through the origin; the lines either intersect the curve or miss it altogether. A line  $y = mx$ —that is, a straight line through the origin—cuts the hyperbola at points with  $x$ -coordinates given by the formula for the hyperbola with  $y$  replaced by  $mx$  (see 43, 44). These meeting points coincide for the value of  $m$  for which  $y = mx$  is a tangent. This occurs when a simple algebraic condition is met (see 45) and  $x$  is infinity. Thus the tangent touches the curve at infinity and is called an asymptote. It has a value of  $m$  given by an algebraic solution showing two values (see 46). Thus there are two asymptotes with equations whose slopes differ by  $-1$  (see 47).

The equation in which the roles of  $a$  and  $b$  are interchanged (see 48) is that of the conjugate hyperbola of

The  
asymptote

the one above. Conjugate hyperbolas have the same asymptotes, and the conjugate axis of one is the transverse axis of the other and vice versa.

A hyperbola for which  $b = a$  is called a rectangular hyperbola and has the equation in which the constant  $a^2$  is equal to the difference of the variables squared (see 49). The transverse and conjugate axes are then equal, and the asymptotes have equations  $y = x$  and  $y = -x$ . Clearly the asymptotes are perpendicular to each other and bisect the coordinate axes. If the asymptotes are used as the coordinate axes, a rectangular hyperbola has the simple equation  $xy = c$ , in which  $c$  is a constant. Thus the rectangular hyperbola is a graph of two inversely proportional variable quantities related by the equation  $y = c/x$ .

Figure 6: The hyperbola (see text).

**The parabola.** The parabola is a conic with an eccentricity of unity and may be thought of as a limiting case between an ellipse ( $e < 1$ ) and a hyperbola ( $e > 1$ ). It is the path of a point that moves in a plane so as to be equidistant from a fixed point and a fixed line. The standard form of a parabola has the equation  $y^2 = 2px$  and is shown in Figure 7. The vertex is at the origin, the focus is a distance  $p/2$  from the origin (its coordinates are  $(p/2, 0)$ ), and the directrix is parallel to the  $y$ -axis a distance  $p/2$  on the other side of the origin (its equation is  $x = -p/2$ ). The chord  $PP'$  through the focus perpendicular to the  $x$ -axis is called the *latus rectum* of the parabola (the *latera recta* of an ellipse and hyperbola are similarly defined).

One important property of the parabola is that the angle made by a line  $FM$  from the focus to any point  $M$  with the tangent at  $M$  is equal to the angle between the tangent and a line from  $M$  parallel to the axis of symmetry. This is the basis of many practical applications because radiation or sound emitted from a source

Figure 7: Parabola (see text).

$$(49) \quad x^2 - y^2 = a^2$$

$$(50) \quad y = ax^2 + bx + c$$

$$(51) \quad \begin{cases} \frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \\ 2x + \frac{2y}{b^2} \frac{dy}{dx} = 0 \end{cases}$$

$$(52) \quad \text{gradient at } (x_1, y_1) \text{ is } \frac{-b^2 x_1}{a^2 y_1}$$

$$(53) \quad y - y_1 = m(x - x_1)$$

$$(54) \quad y - y_1 = \frac{-b^2 x_1}{a^2 y_1} (x - x_1)$$

$$(55) \quad \frac{y_1 y}{b^2} + \frac{x_1 x}{a^2} = \left( \frac{y_1^2}{b^2} + \frac{x_1^2}{a^2} \right)$$

$$(56) \quad \frac{y_1^2}{b^2} + \frac{x_1^2}{a^2} = 1$$

$$(57) \quad \frac{yy_1}{b^2} + \frac{xx_1}{a^2} = 1$$

$$(58) \quad \begin{cases} \frac{a^2 y_1}{b^2 x_1} \\ \frac{a^2 x}{b^2 y} = a^2 - b^2 \end{cases}$$

at the focus of a reflector with a parabolic section is reflected in a parallel beam. Similarly, a parallel beam hitting the reflector is converged onto the focus. Thus parabolic reflectors are used in car headlights, searchlights, electric heaters, and many other devices.

The parabola may be thought of as an elongated ellipse with its centre and one focus and vertex all coinciding at infinity. Its optical property is thus a special case of that of an ellipse, namely the reflection of light emitted from one focus onto the other. The parabola is the trajectory of a projectile moving under the influence of gravity with no air resistance. The graph of a quadratic polynomial (see 50) is also a parabola.

**Tangents and normals to curves.** The equation of the tangents to a curve can be found at any point on the curve  $(x_1, y_1)$  by obtaining the gradient of the curve at that point. This is done by taking its derivative (see ANALYSIS, REAL) at the point. For example, an ellipse has an equation both sides of which can be differentiated (see 51). It follows that the gradient at the point  $(x_1, y_1)$  can be calculated (see 52) and this is the gradient  $m$  of the tangent, which, because it goes through  $(x_1, y_1)$ , has an equation with  $m$  as parameter (see 53). Thus the equation of the tangent is determined (see 54). This rearranges to an equality between a linear expression and a sum of squares (see 55). Because  $(x_1, y_1)$  lies on the ellipse and involves the same sum of squares (see 56), the tangent has the equation that results by setting the linear term equal to a constant, namely the constant 1 (see 57). The normal on any point on a curve is the line perpendicular to the tangent at that point. At  $(x_1, y_1)$  it has a gradient that is easily determined, as is its equation (see 58). The tangents and normals to other curves are found in a similar way.

#### TRIGONOMETRY

Trigonometry is the branch of mathematics concerned with specific functions of angles and their application to

Practical applications of the parabola

calculations in geometry. For example, if a right-angled triangle contains an angle, symbolized here by the Greek letter alpha,  $\alpha$ , the ratio of the side of the triangle opposite to  $\alpha$  to the side opposite the right angle (the hypotenuse) is called the sine of  $\alpha$ . The ratio of the side adjacent to  $\alpha$  to the hypotenuse is the cosine of  $\alpha$ . These functions are properties of the angle  $\alpha$ , and calculated values have been tabulated for many angles. They are used in obtaining unknown angles and distances from known or measured angles in geometric figures. The subject developed from a need to compute angles and distances in such fields as astronomy, map making, surveying, and artillery range finding. Problems involving angles and distances in one plane are covered in plane trigonometry. Applications to similar problems in more than one plane of three-dimensional space are considered in spherical trigonometry.

**History.** Trigonometry among the early mathematicians was essentially a computational science based on geometrical theorems. What is now embodied in a formula earlier had to be described by words as a succession of computational steps, each justified by the citation of an appropriate geometrical theorem. The absence of negative numbers made necessary the discussion of many more cases in the solution of triangles. One or more steps in a solution was the passage from the length of an arc to the length of its chord (Greek) or the length of half the chord of the double arc (Hindu) or vice versa, a feat accomplished by means of a table. In the 12th century the Arabic word for the half chord of the double arc was confused with another word and translated "sinus" (sine). The difficulty of making tables with irrational entries (not expressible in ratios of integers) without decimals (first systematically introduced into arithmetic late in the 16th century) was met by selecting a circle so large that when the chords used were computed to the nearest integer the desired accuracy was attained. This unfortunately introduced into the discussions supporting the solutions the added complexity of proportionality between similar figures.

Trigonometry, uniting as it did aspects of the three disciplines of arithmetic, algebra, and geometry, progressed more slowly than did geometry. Astronomy, however, of great interest to the early Hindus and Arabs, required as a tool the solution of spherical triangles, a fact that drove them to master this art. It is, accordingly, not surprising that the development of spherical trigonometry preceded that of plane trigonometry. Not until about the 13th century did trigonometry divorce itself from astronomy and become an independent subject matter.

In the extant mathematical literature of the civilizations preceding the Greeks occur a few calculations suggestive of trigonometric calculations but no further evidence of the science. The early Greek writers appear to have advanced a step further by making calculations based on the proportionality of similar triangles. In the determination of a height by comparison of its shadow with the shadow of a known height can be seen the germ of the tangent function. Greek writers of the 4th century AD called Hipparchus, who lived in the 2nd century BC, the originator of the science of trigonometry. He was reputed to have calculated a table of chords in 12 books. To what extent he may have developed the uses of the table is unknown because the complete work is lost.

Menelaus, about the end of the 1st century, is also reputed to have produced a treatment of the trigonometry of chords in six books, but this work is also lost. An extant work contains the important theorem of Menelaus and the corresponding theorem for the sphere upon which later writers based their work on trigonometry.

The first extant work on trigonometry is contained in the *Almagest*, a work on astronomy in 13 books, produced by Ptolemy of Alexandria around the middle of the 2nd century. In one section is a table of chords at intervals of 30' (minutes), accurate to at least five places, and the method of computing the tables is explained. Another section is devoted to the solution of triangles,

particularly spherical. Theorems are verified concerning chords that involve implicitly the equivalence of the addition formulas, the half-angle formulas, and the law of sines.

No Hindu work is extant, but it is known that Hindu mathematicians made tables of sines, the half chord of the double arc, at intervals of  $3^\circ 45'$  using only the equivalent of  $\sin^2 a + \cos^2 a = 1$ ;  $\cos a = \sin(90 - a)$ ; and  $1 - \cos 2a = 2 \sin^2 a$ . These tables were used to solve right triangles, plane and spherical. This work was translated into Arabic about the last quarter of the 8th century.

In the late 9th century the Arab al-Battānī added the law of cosines for oblique spherical triangles and introduced the sine for the chord into the work of Ptolemy and also into his tables. He brought into use the tangent and cotangent functions and constructed a table for them at intervals of  $1^\circ$ .

Abū al-Wafā' in the last half of the 10th century gave a more accurate method for computing sines and established the complete generality of the sine law for spherical triangles. He introduced the secant and cosecant (both definable in terms of the more familiar sine and cosine) and studied the interrelations of the six trigonometric lines associated with an arc. Credit for establishing the general sine law for plane triangles is given to the Persian al-Bīrūnī (973–1048).

Jabir of Seville, in the second half of the 11th century, added to the four formulas of Ptolemy the equivalent of the fifth formula for right spherical triangles. The systematization of plane and spherical trigonometry as a discipline independent of astronomy was finally achieved by the great Persian mathematician Nasir ad-din at-Tusi in the second half of the 13th century. Essentially, the same work was done for the Western world independently by the Prussian astronomer Johann Müller (1436–76), known as Regiomontanus, the notions of the Arabic world having filtered into Europe over several centuries, that via the East coming much later than that via Spain. The development of arithmetic and algebra allowed the successors of Regiomontanus in Europe to unify and simplify the trigonometry of the triangle by substituting the angle for arc and the ratio for the trigonometric line, and by abstracting from the cumbersome treatment of Regiomontanus the essential formulas convenient for calculations. The cosine law for plane triangles appears for the first time in the work of a 16th-century French mathematician, François Viète.

The invention of logarithms (or powers of a fixed number such that a desired numerical result is obtained as the power of the given fixed number or "base") by Napier stimulated the development of formulas suitable to their use. The law of tangents appears in the writings of Viète and the half-angle formulas in the works of an Austrian mathematician, Rhäticus, in 1568 and an English mathematician, William Oughtred, in 1657. Napier's formulas called "analogies" appeared in 1619, while the Gauss-Delambre and Mollweide relations (trigonometric in nature) came later, in 1807–09. Abraham de Moivre and Leonhard Euler were among the first to open the field of analytic trigonometry. The work of Fourier on trigonometric series appeared in 1807.

**Trigonometric functions.** For the purpose of trigonometry, a somewhat more general concept of angle is required than that used in geometry. An angle  $A$  with vertex at  $V$ , the initial side of which is  $VP$  and the terminal side of which is  $VQ$ , is indicated in Figure 8 by the solid circular arc. This angle is said to be generated by the continuous counterclockwise rotation of a line segment about the point  $V$  from the position  $VP$  to the position  $VQ$ . A second angle  $A'$  with the same initial

Figure 8: General angle (see text).

Arab contributions

Early Greek trigonometry

Figure 9: Addition of angles (see text).

Positive and negative angles

and terminal sides, indicated in Figure 8 by the broken circular arc, is generated by the clockwise rotation of the line segment about the point  $V$  from the position  $VP$  to the position  $VQ$ . Angles are considered positive when generated by counterclockwise rotations, negative when generated by clockwise rotations. The positive angle  $A$  and the negative angle  $A'$  in Figure 8 are generated by less than one complete rotation of the line segment about the point  $V$ . All other positive and negative angles with the same initial and terminal sides are obtained by rotating the line segment counterclockwise or clockwise, respectively, about the point  $V$  one or more complete turns before coming to rest at  $VQ$ .

Numerical values can be assigned to angles by selecting a unit of measure for angles. Besides the complete revolution and the right angle, the units commonly used are the degree and the radian. The degree is  $1/90$  of a right angle. There are  $60'$  (minutes) in a degree and  $60''$  (seconds) in a minute. In theoretical work, the radian is the most convenient unit. It is the angle at the centre of a circle that intercepts an arc equal in length to the radius. From these definitions, it follows that 1 revolution  $= 4$  right angles  $= 360^\circ = 2\pi$  radians.

Equal angles are angles with the same measure; i.e., they have the same sign and the same number of degrees. Any angle  $-A$  has the same number of degrees as  $A$  but is of opposite sign. Its measure, therefore, is the negative of the measure of  $A$ . If the angles  $A$  and  $B$  have the initial sides  $VP$  and  $VQ$  and the terminal sides  $VQ$  and  $VR$ , respectively, then the angle  $A + B$  has the initial and terminal sides  $VP$  and  $VR$ , respectively (see Figure 9). The angle  $A + B$  is called the sum of the angles  $A$  and  $B$ , and its relation to  $A$  and  $B$  when  $A$  is positive and  $B$  is positive or negative is illustrated in Figure 9. The sum  $A + B$  is the angle the measure of which is the algebraic sum of the measures of  $A$  and  $B$ . The difference  $A - B$  is the sum of  $A$  and  $-B$ . Thus all angles coterminal with angle  $A$  (i.e., with the same initial and terminal sides as angle  $A$ ) are given by  $A \pm 360n$ , in which  $360n$  is an angle of  $n$  complete revolutions. The angles  $(180 - A)$  and  $(90 - A)$  are the supplement and complement of angle  $A$ , respectively.

**Trigonometric functions of an angle.** There are six functions of an angle commonly used in trigonometry. Their names and abbreviations are sine (sin), cosine (cos), tangent (tan), cotangent (cot), secant (sec), and cosecant (csc). To define these functions for any angle  $A$ , the angle is placed in position (Figure 10, left) on a rectangular coordinate system with the vertex of  $A$  at the origin and the initial side of  $A$  along the positive  $x$ -axis;  $r$  (positive) is the distance from  $V$  to any point  $Q$  on the terminal side of  $A$ , and  $(x, y)$  are the rectangular coordinates of  $Q$ . The six functions of  $A$  are then defined by six ratios (see 59). Because division by zero is not allowed, the tangent and secant are not defined for angles the terminal side of which falls on the  $y$ -axis, and the cotangent and cosecant are undefined for angles the terminal side of which falls on the  $x$ -axis. From these definitions follow three reciprocal relations for cotangent, secant, and cosecant (see 60) and the quotient identities for the tangent and cotangent (see 61). When the Pythagorean equality  $x^2 + y^2 = r^2$  is divided in turn by  $r^2$ ,  $x^2$ , and  $y^2$ , the three squared relations relating cosine and sine, tangent and secant, cotangent and cosecant (see 62) are obtained.

If the point  $Q$  on the terminal side of angle  $A$  in standard position has coordinates  $(x, y)$ , this point will have coordinates  $(x, -y)$  when on the terminal side of  $-A$  in

$$(59) \quad \begin{cases} \sin A = y/r & \cot A = x/y \\ \cos A = x/r & \sec A = r/x \\ \tan A = y/x & \csc A = r/y \end{cases}$$

$$(60) \quad \begin{cases} \cot A = 1/\tan A & \sec A = 1/\cos A \\ \csc A = 1/\sin A \end{cases}$$

$$(61) \quad \tan A = \sin A/\cos A \quad \cot A = \cos A/\sin A$$

$$(62) \quad \begin{cases} \cos^2 A + \sin^2 A = 1; & 1 + \tan^2 A = \sec^2 A \\ \cot^2 A + 1 = \csc^2 A \end{cases}$$

$$(63) \quad \begin{cases} \sin(-A) = -\sin A & \cot(-A) = -\cot A \\ \cos(-A) = \cos A & \sec(-A) = \sec A \\ \tan(-A) = -\tan A & \csc(-A) = -\csc A \end{cases}$$

$$(64) \quad \begin{cases} \sin(A \pm 90) = \pm \cos A & \cot(A \pm 90) = -\tan A \\ \cos(A \pm 90) = \mp \sin A & \sec(A \pm 90) = \mp \csc A \\ \tan(A \pm 90) = -\cot A & \csc(A \pm 90) = \pm \sec A \end{cases}$$

$$(65) \quad \begin{cases} \cos(A \pm B) = \cos A \cos B \mp \sin A \sin B \\ \sin(A \pm B) = \sin A \cos B \pm \cos A \sin B \end{cases}$$

$$(66) \quad \begin{cases} x = x' \cos B - y' \sin B \\ y = x' \sin B + y' \cos B \end{cases}$$

$$(67) \quad \begin{cases} \sin(2A) = 2 \sin A \cos A \\ \cos(2A) = \cos^2 A - \sin^2 A = 2 \cos^2 A - 1 \\ \quad \quad \quad = 1 - 2 \sin^2 A \\ \sin^2(A/2) = (1 - \cos A)/2 \\ \cos^2(A/2) = (1 + \cos A)/2 \end{cases}$$

standard position. From this fact and the definitions are obtained further identities for negative angles (see 63). These relations may also be stated briefly by saying that cosine and secant are even functions, while the other four are odd functions.

It is evident that a trigonometric function has the same value for all coterminal angles. When  $n$  is an integer, therefore,  $\sin(A \pm 360n) = \sin A$ ; there are similar relations for the other five functions. These results may be expressed by saying that the trigonometric functions are periodic and have a period of  $360^\circ$  or  $180^\circ$ .

When  $Q$  on the terminal side of  $A$  in standard position has coordinates  $(x, y)$ , it has coordinates  $(-y, x)$  and  $(y, -x)$  on the terminal side of  $A + 90$  and  $A - 90$  in standard position, respectively. Consequently six formulas follow (see 64). The formulas display the fact that a function of the complement of  $A$  is equal to the corresponding cofunction of  $A$ .

Of fundamental importance for the study of trigonometry are the addition formulas, or the functions of the sum or difference of two angles (see 65). These relations may be derived from formulas (see 66) for the rotation of the coordinate axes through the angle  $B$  about the origin, and these formulas are evident from Figure 10 (right), because  $x = ON = OP + LM = OL \cos B + LQ \cos(B + 90)$ , which is the relation already expressed (see 66). Similarly,  $y = NQ = PL + MQ = OL \sin B + LQ \sin(B + 90)$ , which is also an earlier expression (66). To obtain the addition formulas (65) it is only necessary to divide each equation in the given formulas (66) by  $r = OQ$ , and use the definitions of sine and cosine.

From the addition formulas are derived the double-angle and half-angle formulas (see 67). Numerous identities of lesser importance can be derived from the above basic identities.

Figure 10: (Left) Angle in standard position. (Right) Rotation of axes (see text).

**Tables of natural functions.** To be of practical use, the values of the functions must be readily available for any given angle. The identities  $\sin(A \pm 360n) = \sin A$  as well as other identities (see 64) show that the values of the functions for all angles can readily be found from the values for angles from  $0^\circ$  to  $45^\circ$ . For this reason, it is sufficient to list in a table the values of sine, cosine, tangent, and cotangent of all angles from  $0^\circ$  to  $45^\circ$  that are integral multiples of some convenient unit (commonly  $1'$ ). Such tables are called tables of natural trigonometric functions.

For angles that are not integral multiples of the unit, the values of the functions may be interpolated. Because the values of the functions are in general irrational numbers, they are entered in the table as decimals, rounded off at some convenient place. For most purposes, four or five decimal places are sufficient, and tables of this accuracy appear in most texts. Simple geometrical facts alone, however, suffice to determine the values of the trigonometric functions for the angles  $0^\circ$ ,  $30^\circ$ ,  $45^\circ$ ,  $60^\circ$ , and  $90^\circ$ . These values are listed in a table, which also illustrates the arrangement used in larger tables (see 68). The names at the head of such a table are used for angles less than  $45^\circ$ , listed in the left-hand column; the names at the foot of the table are used for the complementary angles, larger than  $45^\circ$ , listed in the right-hand column. For example, from the table  $\cos 30^\circ = \frac{1}{2}\sqrt{3}$ , and  $\cot 60^\circ = \frac{1}{3}\sqrt{3}$ .

**Plane trigonometry.** In many applications of trigonometry the essential problem is the solution of triangles. If enough sides and angles are known, the remaining sides and angles as well as the area can be calculated, and the triangle is then said to be solved. Triangles can be solved by the law of sines and the law of cosines. To secure symmetry in the writing of these laws, the angles of the triangle are lettered  $A$ ,  $B$ , and  $C$  and the lengths of the sides opposite the angles are lettered  $a$ ,  $b$ , and  $c$ , respectively. An example of this standardization is shown in Figure 11.

The law of sines or sine theorem is expressed as an equality involving three sine functions (see 69) while a law of cosines or cosine theorem is an identification of the cosine with an algebraic expression formed from the lengths of sides opposite the corresponding angle (see 70) with similar expressions for  $\cos B$  and  $\cos C$  obtained by cyclic permutation of the three letters. In Figure 11,  $b \sin A = h = a \sin B$ , from which the first equality follows (see 69). The second is shown by drawing a perpendicular from  $A$  to the opposite side of the triangle. Also  $c = b \cos A + a \cos B$  and likewise  $b = a \cos C + c \cos A$ ,  $a = c \cos B + b \cos C$ . When these three equations are multiplied by  $c$ ,  $b$ ,  $-a$ , respectively, and added, the result is  $c^2 + b^2 - a^2 = 2bc \cos A$ , which when divided by  $2bc$  becomes an expression for  $\cos A$  (see 70). To solve a triangle, all the known values are substituted into equations expressing the laws of sines and cosines (see 69, 70) and the equations are solved for the unknown

Figure 11: Standard lettering of a triangle (see text).

values. The law of sines is employed when two angles and a side are known or when two sides and an angle opposite one are known. The law of cosines is appropriate when two sides and an included angle are known or three sides are known. The area of the triangle (see 71) may be found from a formula derived from the relations concerning area of a triangle and the sine of an angle.

Texts on trigonometry derive other formulas for solving triangles and for checking the solution, especially those suited to logarithmic calculation. With the advent of calculators and electronic computers, however, computation by logarithms has lost some of its advantage, and it is no longer so necessary to adapt formulas to logarithmic computation when machines are available.

**Spherical trigonometry.** The fundamental configuration of space to which the formulas of spherical trigonometry apply is the trihedral angle formed by three rays—half lines—radiating from a point. The point is the vertex, the rays are the three edges, the planes and angles determined by the rays taken in pairs are the three faces, and the three face angles, symbolized by the Greek letters alpha, beta, and gamma,  $\alpha$ ,  $\beta$ , and  $\gamma$ , of the trihedral angle. The faces in pairs form three dihedral angles  $A$ ,  $B$ , and  $C$  opposite, respectively, to the face angles. The formulas of spherical trigonometry relate the trigonometric functions of these six angles.

For the trihedral angle, there is the law of sines (see 72) that may be derived from Figure 12 (left) in which the planes  $PQS$  and  $PRS$  are perpendicular to the edges  $VQ$  and  $VR$ , respectively. The first equality is a result of the relations  $PS = QP \sin B = VP \sin \alpha \sin B = RP \sin A = VP \sin \beta \sin A$ . The second equality may be verified in like manner.

There is a first law of cosines for the trihedral (see 73) with similar expressions for  $\cos \beta$  and  $\cos \gamma$  obtained by cyclic permutation of the letters. In Figure 12 (right), the plane  $PQR$  is perpendicular to the edge  $VP$ . The law of cosines applied to the plane triangles  $PQR$  and  $VQR$  gives  $QR^2 = PQ^2 + PR^2 - 2PQ \cdot PR \cos A = VQ^2 + VR^2 - 2VQ \cdot VR \cos \alpha$ . After transposing and using the Pythagorean theorem,  $2VQ \cdot VR \cos \alpha = 2VP^2 + 2PQ \cdot PR \cos A$ . When this relationship is divided by the value  $(VQ)(VR)$ , it becomes the first law of cosines for the trihedral (see 73) equation using the definitions of the trigonometric functions.

The first law of cosines

The law of sines

Figure 12: Trihedral angles for derivation of the laws of (left) sines and (right) cosines.

If at the vertex of a trihedral three rays are drawn perpendicular to the three inner faces of the trihedral, a second trihedral is obtained called the polar trihedral of the first. The first is also the polar of the second. The face angles  $\alpha'$ ,  $\beta'$ , and  $\gamma'$  of the polar trihedral are the supplements of the dihedral angles  $A$ ,  $B$ , and  $C$  of the given trihedral, and hence the face angles  $\alpha$ ,  $\beta$ , and  $\gamma$  of the given trihedral are the supplements of the dihedral angles  $A'$ ,  $B'$ , and  $C'$  of the polar trihedral.

The first law of cosines when applied to the polar trihedral and then simplified by the relations  $\cos \alpha' = \cos(180 - A) = -\cos A$ , and so on, yields the second law of cosines for the given trihedral (see 74) and two additional relations for  $\cos B$  and  $\cos C$ , obtained by cyclic permutation of the letters.

When the vertices of a spherical triangle are joined to the centre of the sphere, there is formed a trihedral angle with vertex at the centre (Figure 13). The sides  $a$ ,  $b$ , and  $c$  of the spherical triangle are the great circle arcs intercepted by the face angles  $\alpha$ ,  $\beta$ , and  $\gamma$ , and the angles

Figure 13: Spherical triangle and trihedral angle.

of the spherical triangle are the dihedral angles  $A$ ,  $B$ , and  $C$  of the trihedral. The faces of the polar trihedral intersect the sphere in the polar triangle of the given spherical triangle. Because a trigonometric function of a central angle and of the intercepted arc have the same value, the law of sines (see 72) yields a law of sines for spherical triangles expressed in ratios of sine functions (see 75). Similarly, the first law of cosines (see 73) gives a law of cosines for the sides of the spherical triangle (see 76), and the second law of cosines (see 74) furnishes a law of cosines for the angles of a spherical triangle (see 77).

Solving the spherical triangle

To solve a spherical triangle, the known values are substituted in formulas, the laws of sines and cosines for the spherical triangle (see 75, 76, 77), and the resulting equations are solved for the unknowns. When three sides or two sides and the included angle are given, the law of cosines for the sides (see 76) is appropriate, and the law of cosines for the angles (see 77) is used when three angles or two angles and an included side are given. If two sides and an angle opposite one side or two angles and a side opposite one angle are given, the law of sines (see 75) is applied first, and the solution is completed by the use of a pair of equations (see 76, 77).

The area of the spherical triangle is given by the product of  $E$  and the square of  $r$  (see 78) in which  $r$  is the radius of the sphere, and  $E$  is the excess of  $A + B + C$  over two

right angles measured in radians. It should also be noted that a solution of a spherical triangle yields a solution of the polar triangle.

Other relations between the sides and angles of a spherical triangle are derived in texts on spherical trigonometry. In particular, John Napier's analogies are formulas relating the half angles and half sides. Each formula contains five of the six parts and is well suited to logarithmic solutions of a spherical triangle. Other formulas of a similar character include the half-angle formulas, the half-side formulas, and the so-called analogies of Gauss-Delambre.

When angle  $C$  is  $90^\circ$ , the triangle is a right spherical triangle. Because  $\sin C = 1$  and  $\cos C = 0$ , the relations in the spherical triangle (see 75, 76, 77) yield formulas (see 79) for the right spherical triangle.

**Analytic trigonometry.** Trigonometric functions of a real variable  $x$  are defined by means of the trigonometric functions of an angle. For example,  $\sin x$  in which  $x$  is real is defined to have the value of the sine of the angle containing  $x$  radians. Similar definitions are made for the other five trigonometric functions of the real variable  $x$ . These functions satisfy the previously noted trigonometric relations (see 60–65 and 67) with  $A$ ,  $B$ ,  $90$ , and  $360$  replaced by  $x$ ,  $y$ ,  $\pi/2$ , and  $2\pi$ , respectively. The minimum period of  $\tan x$  and  $\cot x$  is  $\pi$ , and of the other four functions it is  $2\pi$ .

In the calculus it is shown that  $\sin x$  and  $\cos x$  are sums of power series (see 80). These series may be used to compute the sine and cosine of any angle. For example, to compute the sine of  $10^\circ$ , it is necessary to find the value of  $\sin \pi/18$  because  $10^\circ$  is the angle containing  $\pi/18$  radians. When  $\pi/18$  is substituted in the series for  $\sin x$ , it is found that the first two terms give 0.17365, which is correct to five decimals for the sine of  $10^\circ$ . By taking enough terms of the series, any number of decimal places can be correctly obtained.

Tables of the functions may be used to sketch the graphs of the functions, shown in Figure 14. The diagrams give the graph of each function for one period. To obtain the complete graph in each figure it is only necessary to extend the curve indefinitely in both directions by repetitions of the piece of graph shown in the figure.

$$(74) \quad \cos A = -\cos B \cos C + \sin B \sin C \cos \alpha$$

$$(75) \quad \frac{\sin a}{\sin A} = \frac{\sin b}{\sin B} = \frac{\sin c}{\sin C}$$

$$(76) \quad \begin{cases} \cos a = \cos b \cos c + \sin b \sin c \cos A \\ \cos b = \cos c \cos a + \sin c \sin a \cos B \\ \cos c = \cos a \cos b + \sin a \sin b \cos C \end{cases}$$

$$(77) \quad \begin{cases} \cos A = -\cos B \cos C + \sin B \sin C \cos a \\ \cos B = -\cos C \cos A + \sin C \sin A \cos b \\ \cos C = -\cos A \cos B + \sin A \sin B \cos c \end{cases}$$

$$(78) \quad \text{area} = Er^2$$

$$(79) \quad \begin{cases} \sin a = \sin c \sin A = \tan b \cot B \\ \sin b = \sin c \sin B = \tan a \cot A \\ \cos c = \cos a \cos b = \cot A \cot B \\ \cos A = \cos a \sin B = \tan b \cot c \\ \cos B = \cos b \sin A = \tan a \cot c \end{cases}$$

$$(80) \quad \begin{cases} \sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots \\ \cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots \end{cases}$$

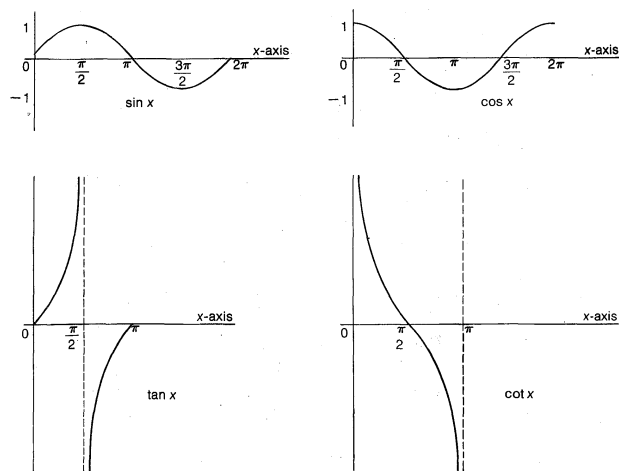

Figure 14: Graphs of some trigonometric functions.

Each of the trigonometric functions has an inverse. For instance, the inverse sine of  $x$  is the angle the sine of which is  $x$ . It is written  $\sin^{-1} x$  or  $\arcsin x$ . The other trigonometric functions also have inverses:  $\arctan x$ ,  $\arccos x$ , etc.

#### COORDINATES AND TRANSFORMATION OF COORDINATES

**Polar coordinates.** For problems involving directions from a fixed origin (or pole)  $O$ , it is often convenient to specify a point  $P$  by its polar coordinates  $(r, \theta)$ , in which  $r$  is the distance  $OP$  and  $\theta$  is the angle that the direction of  $r$  makes with a given initial line, which may be identified with the  $x$ -axis of rectangular Cartesian coordinates as shown in Figure 15. The point  $(r, \theta)$  is the same as  $(r, \theta + 2n\pi)$  for any integer  $n$ . It is sometimes desirable to allow  $r$  to be negative, so that  $(r, \theta)$  is the same as  $(-r, \theta + \pi)$ .

Given the Cartesian equation for a curve, the polar equation for the same curve can be obtained by substituting the forms for  $x$  and  $y$  in terms of radius and angle as expressed throughout the trigonometric functions (see 81). For instance, the circle  $x^2 + y^2 = a^2$  has the polar equation  $(r \cos \theta)^2 + (r \sin \theta)^2 = a^2$ , which reduces to  $r = a$ . (The positive value of  $r$  is sufficient, if  $\theta$  takes all values from  $-\pi$  to  $\pi$  or from  $0$  to  $2\pi$ ). Thus the polar equation of a circle simply expresses the fact that the curve is independent of  $\theta$  and has constant radius. In a similar manner, the line  $y = x \tan \alpha$  has the polar equation  $\sin \theta = \cos \theta \tan \alpha$ , which reduces to  $\theta = \alpha$ . (The other solution,  $\theta = \alpha + \pi$ , can be discarded if  $r$  is allowed to take negative values.) Some examples of curves in polar coordinate systems are given below in the section *Special curves*.

**Transformation of coordinates.** A transformation of coordinates in a plane is a change from one coordinate system to another. A point in the plane will have two sets of coordinates giving its position with respect to the two coordinate systems used. The transformation expresses the relationship between a point or locus in one system and that in another.

One type of transformation is that just discussed: the transformation between polar and Cartesian coordinates with the same origin as in Figure 16. The equations giving the transformation are  $x = r \cos \phi$  and  $y = r \sin \phi$ . Similarly, it is possible to accomplish transformation between rectangular and oblique coordinates.

Figure 15: Cartesian and polar coordinates.

In a translation of Cartesian coordinate axes, a transformation is made between two sets of axes that are parallel to each other but have their origins at different positions. If a point has coordinates  $(x, y)$  in one system and  $(x', y')$  in a second, then the transformation equations are linear including the constants  $h$  and  $k$  (see 82). Here  $(h, k)$  is the origin of the second system in terms of the first coordinate system. These transformation equations were used earlier to derive the general equation of a straight line. The common use of translations of axes is to simplify the equations of curves. For example, an equation that is quadratic with linear and constant terms (see 83) can be simplified with translations to an equation involving only squares of  $x$  and  $y$  and a constant term. In other words, the curve represents an ellipse with its centre at the point  $(3, 1)$  in the  $(x-y)$  coordinate system. The equation reduces to the standard form when the coordinates are translated to this point.

A rotation of coordinate axes is one in which a pair of axes giving the coordinates of a point  $(x, y)$  are rotated through an angle  $\phi$  to give a new pair of axes in which the point has coordinates  $(x', y')$ . This is shown in Figure 16, from which it is apparent that the transformation equations are trigonometric in form (see 84). The application of these formulas to the rectangular hyperbola involving the difference of squares (see 85), with  $\phi = 45^\circ$ , leads to the equation  $xy = c$ , giving the form of the rectangular hyperbola when its asymptotes are used as the coordinate axes.

Rotation  
of  
coordinate  
axes

$$(81) \quad x = r \cos \theta, \quad y = r \sin \theta$$

$$(82) \quad \begin{cases} x = x' + h \\ y = y' + k \end{cases}$$

$$(83) \quad \begin{cases} 2x^2 + y^2 - 12x - 2y + 17 = 0 \\ x = x' + 3 \\ y = y' + 1 \\ x^2 + y^2/2 = 1 \end{cases}$$

$$(84) \quad \begin{cases} x = x' \cos \phi - y' \sin \phi \\ y = x' \sin \phi + y' \cos \phi \end{cases}$$

$$(85) \quad x^2 - y^2 = a^2$$

$$(86) \quad Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$$

$$(87) \quad \Delta = \frac{1}{2} \begin{vmatrix} 2A & B & D \\ B & 2C & E \\ D & E & 2F \end{vmatrix}$$

$$(88) \quad \begin{cases} B^2 - 4AC = 0, & B^2 - 4AC > 0 \\ B^2 - 4AC < 0 \end{cases}$$

**Discriminant of a conic.** A conic is represented by a general equation of the second degree with the form that includes squared terms, cross product terms, and linear terms, as well as a constant (see 86). The discriminant is denoted by  $\Delta$  (Greek delta) and is defined by a determinant in which constants of the general equation appear (see 87).

The discriminant and the expression  $(B^2 - 4AC)$  are invariants for rotational and translational transformations. They are used as criteria for the form of the curve represented by the general equation.

Three cases occur that are expressed in terms of numerical values for the above expression (see 88). In the first case the curve is a parabola if  $\Delta$  is not zero, and if  $\Delta$  is zero the curve is two parallel or coincident straight lines or there is no (real) curve. In the second case the curve is a hyperbola if it is not the case that  $\Delta = 0$  and two

Figure 16: Rotation of axes.

intersecting lines if  $\Delta = 0$ . In the third case the curve is an ellipse if it is not the case that  $\Delta = 0$  and becomes a single point if  $\Delta = 0$ .

The cases in which  $\Delta = 0$  are limiting. A point is the limiting case of an ellipse in which the section of the cone is taken through its vertex. Similarly, an axial section of cones through the vertex gives two intersecting lines, a limiting case of the hyperbola. The parabola becomes a single line if the section plane is tangential to the cone and a pair of parallel lines when the vertex of the cone is at infinity (the "cone" is then a cylinder). These limiting cases are called degenerate conics. The general equation of a conic can be put in a form involving the discriminant (see 89).

**Barycentric and areal coordinates.** If two masses of magnitude  $t_1$  and  $t_2$  are placed at points  $P_1$  and  $P_2$ , their total mass appears to act at point  $P$  on the line  $P_1P_2$ .  $P$  divides the distance  $P_1P_2$  in the ratio  $t_2:t_1$  and is known as the centroid or centre of mass. Its coordinates are rational functions of the  $\{x_k\}$  and  $\{t_k\}$  (see 90). For three masses in a plane at points  $P_1, P_2, P_3$ , the centroid has coordinates also rational functions of the  $\{x_k\}$  and  $\{t_k\}$  (see 91). Suitable values of  $t_1, t_2, t_3$  will place the centroid  $P$  anywhere in the plane, and they are called the barycentric coordinates of the point (the centroid) with respect to the triangle of reference,  $P_1P_2P_3$ . They are homogeneous coordinates, because for any  $k \neq 0$  masses  $kt_1, kt_2$ , and  $kt_3$  have the same centroid as  $t_1, t_2$ , and  $t_3$ . The barycentric coordinates of  $P$  are proportional to the areas of the three triangles  $PP_2P_3, PP_3P_1, PP_1P_2$ . Accordingly, when normalized so that the sum of the  $\{t_k\}$  equals 1 (see 92) they are called areal coordinates.

#### PROJECTIVE AND SOLID ANALYTIC GEOMETRY

**Analytic projective geometry.** The 16th–17th-century German astronomer Johannes Kepler conceived the idea of extending the Euclidean (or affine) plane by postulating a line at infinity the points of which lie on collections of parallel lines called "pencils." The plane so extended is called the projective plane. In terms of barycentric coordinates, the line at infinity has the equation restricting the  $\{t_k\}$  to equal 0 (see 93). General projective coordinates  $(x_1, x_2, x_3)$  are derived by the substitution  $t_i = k_i x_i$ , in which the coefficients  $k_i$  are three constants. The line at infinity is now expressed in terms of a linear combination of coordinates (see 94) and any other homogeneous linear equation represents an ordinary line. The transition to projective geometry is completed by waiving the distinction, so that a point at infinity is treated just like any other point. This vital step was taken by another 19th-century German mathematician, Karl G.C. von Staudt. It enables the points of the projective plane to be defined as the ordered triads of numbers  $(x_1, x_2, x_3)$ , not all zero, with the convention that  $(kx_1, kx_2, kx_3)$  is the same point for all nonzero values of  $k$ .

Given two points  $(x_1, x_2, x_3)$  and  $(y_1, y_2, y_3)$ , or more

concisely,  $(x)$  and  $(y)$ , an arbitrary point collinear with them may be expressed in the form  $(x + ty)$  (see 95). In this notation, two triangles in perspective from  $(u)$  may be expressed in the concise notation (see 96). Corresponding sides of the triangles meet in three collinear points (see 97) in agreement with the two-triangle theorem of the 17th-century French mathematician Girard Desargues.

The general homogeneous linear transformation  $x'_i = \sum c_{ij}x_j$  (summed over  $j$ ), in which  $\det(c_{ij}) \neq 0$ , transforms collinear points into collinear points; i.e., it is a collineation. For instance, the collineation that leaves unchanged the first two coordinates and modifies the third with multiplication by a constant (see 98) is a homology that leaves invariant every line through the point  $(0, 0, 1)$  and every point on the line  $x_3 = 0$ .

**Solid analytic geometry.** Much of analytic geometry may be extended from two dimensions to three or more. In ordinary space a point has three Cartesian coordinates  $(x, y, z)$ , a plane has a linear equation (see 99), and a line may be specified in various ways; for example, as the intersection of two planes or as the join of two points or as proceeding from a given point in a given direction.

The last aspect yields parametric equations that are linear in the parameter and in the coordinates (see 100). Polar coordinates have two spatial counterparts: cylindrical coordinates  $(r, \theta, z)$ , in which  $r$  and  $\theta$  are related to  $x$  and  $y$  in the usual way; and spherical polar coordinates, which consist of distance from the origin, latitude (or colatitude), and longitude. Barycentric (and also other projective) coordinates are referred to a tetrahedron  $P_1P_2P_3P_4$ .

#### SPECIAL CURVES

Partly due to the study of the Greeks in pure geometry, but largely due to the influence of analytic geometry and the calculus, there have been developed a large number of special curves that have received names more or less generally accepted by mathematicians. For the purposes of the present article, it seems best to arrange the curves roughly in this order: plane algebraic curves according to degree, followed by plane transcendental curves, gen-

$$(89) \quad Ax^2 + Bxy + Cy^2 - \frac{\Delta}{B^2 - 4AC} = 0$$

$$(90) \quad \frac{x_1 t_1 + x_2 t_2}{(t_1 + t_2)}, \quad \frac{y_1 t_1 + y_2 t_2}{(t_1 + t_2)}$$

$$(91) \quad \begin{cases} \frac{x_1 t_1 + x_2 t_2 + x_3 t_3}{t_1 + t_2 + t_3}, & \frac{y_1 t_1 + y_2 t_2 + y_3 t_3}{t_1 + t_2 + t_3} \\ \frac{z_1 t_1 + z_2 t_2 + z_3 t_3}{t_1 + t_2 + t_3} \end{cases}$$

$$(92) \quad t_1 + t_2 + t_3 = 1$$

$$(93) \quad t_1 + t_2 + t_3 = 0$$

of mass

Figure 17: Cubical parabola.

eral classes of curves, and curves of double curvature. The standard equations of the curves are referred to when appropriate, and the general shapes of the most important plane curves considered are shown by accompanying figures.

Cubical parabola (see 101) is one of the canonical forms of cubics studied by Sir Isaac Newton. The special case (see 102) shown in Figure 17 was used by the German philosopher-mathematician Gottfried Wilhelm Leibniz in 1675 and (for  $a = 1$ ) by the French mathematician Gaspard Monge in 1815.

Figure 18: Semicubical parabola.

Semicubical, or Neil's, parabola (see 103) is the curve that in 1687 Leibniz proposed to find along which a particle may descend under the action of gravity so as to describe equal vertical spaces in equal times. The Dutch astronomer and physicist Christiaan Huygens found that the semicubical parabola met this requirement. The curve is called an isochronous curve (see Figure 18).

Cissoid of Diocles (see 104) is a curve invented by Diocles (c. 180 BC) in connection with the duplication of the cube (Figure 19).

Strophoid (see 105) was first considered by the English mathematician Isaac Barrow in 1670. When  $\alpha = 90^\circ$  the strophoid (see 106) is right (see Figure 20).

Figure 19: Cissoid of Diocles.

Folium of Descartes (see 107) is a curve with an asymptote (see 108) first discussed by Descartes in 1638 (see Figure 21A).

Trisectrix of Maclaurin (see 109) was first studied by the Scottish mathematician Colin Maclaurin in 1742 in relation to the problem of trisecting an angle.

Witch of Agnesi, or versiera (see 110), was discussed and named *versiera* (Italian for "she-devil" or "witch") by Maria Agnesi in 1748, but the curve had been studied earlier by Fermat and Guido Grandi in 1703.

Serpentine (see 111) was studied and named by Newton in 1701 and earlier in 1692 by G.-F.-A. L'Hospital and Huygens.

Trident of Newton, or parabola of Descartes (see 112), is shown in one form in Figure 21B.

Cartesian curve is the name given to the curve that is formed by the locus of a point  $P$  whose distances  $r_1$  and  $r_2$  from two points (foci)  $F_1$  and  $F_2$  are connected by a linear relation (see 113). The equation of the curve can be expressed in rectangular coordinates (see 114). It is also called a Cartesian oval, although it consists of two ovals (Figure 21C). When  $m = \pm 1$  the locus is a central conic. The distance between the foci is  $c$ , and when  $m = a/c$ , a limaçon of Pascal results. The curve originated with Descartes in 1637 and was studied by Newton, and others.

Cassinian curve, or Cassinian ovals, or Cassinian ellipse (see 115), was first conceived by the Italian-born French astronomer Giovanni Domenico Cassini in 1680 in the study of the relative motions of the Earth and the Sun. The shape of the curve depends upon the ratio  $c:a$ . The curve may be defined as the locus of a point that moves so that the product of its distances from two fixed points (foci)  $A$  and  $B$  (Figure 22) is a constant,  $c^2$ . When  $c > a$  the curve consists of two loops; when  $c = a$  the Cassinian becomes the lemniscate of Bernoulli. The number of foci may be greater than two. By varying their number and their disposition, curves of odd shapes may be produced.

$$(101) \quad y = ax^3 + bx^2 + cx + d \quad \text{or} \quad y = ax^2(x - e)$$

$$(102) \quad y = ax^3$$

$$(103) \quad x^3 = ay^2$$

$$(104) \quad y^2 = x^3/(2a - x) \quad \text{or} \quad r = 2a \tan \theta \sin \theta$$

$$(105) \quad r = a \sin(\alpha - 2\theta)/\sin(\alpha - \theta)$$

$$(106) \quad r = a \cos 2\theta/\cos \theta \quad \text{or} \quad y^2 = x^2(a - x)/(a + x)$$

$$(107) \quad x^3 + y^3 = 3axy$$

$$(108) \quad x + y + a = 0$$

$$(109) \quad \begin{cases} x(x^2 + y^2) = a(y^2 - 3x^2) \\ \text{or } y^2 = x^2(3a + x)/(a - x) \\ \text{or } r = a \sec \theta - 4a \cos \theta = 2a \sin 3\theta/\sin 2\theta \end{cases}$$

$$(110) \quad y(x^2 + a^2) = a^3$$

$$(111) \quad x^2y + aby - a^2x = 0 \quad (ab > 0)$$

$$(112) \quad xy = cx^3 + dx^2 + ex + f$$

$$(113) \quad r_1 + mr_2 = a$$

$$(114) \quad [(x^2 + y^2)(1 - m^2) + 2m^2cx + a^2 - m^2c^2]^2 = 4a^2(x^2 + y^2)$$

$$(115) \quad (x^2 + y^2)^2 - 2a^2(x^2 - y^2) + a^4 - c^4 = 0$$

Figure 20: Strophoid.

Lemniscate of Bernoulli (see 116) was first conceived by the Swiss mathematician Jakob Bernoulli in 1694.

Conchoid, or shell form (see 117), was devised by the Greek mathematician Nicomedes (c. 200 BC) in relation to the problem of the duplication of the cube. Nicomedes apparently recognized the three types of the curve shown in Figure 23.

Limaçon of Pascal (see 118) was discovered by Étienne Pascal (father of Blaise) and named by another French mathematician, Gilles-Personne Roberval, in 1650. The three forms of the curve (see 119) shown in Figure 24 correspond to various values of  $b$ .

Figure 21: Three classic curves. (A) Folium of Descartes. (B) Trident of Newton. (C) Cartesian ovals.

Cardioid (see 120) is a curve (see curve 2 in Figure 24) that is the locus of a point on the circumference of a circle rolling upon the circumference of another circle of equal size.

Tricuspid, or deltoid (see 121), was first conceived by Euler (1745); see Figure 25.

Simple folium, double folium, and trifolium are curves such that

$$(x^2 + y^2) [y^2 + x(x + b)] = 4axy^2 \text{ or } r = -b \cos \theta + 4a \cos \theta \sin^2 \theta.$$

The simple folium, double folium, and trifolium correspond to  $b = 4a$ ,  $b = 0$ ,  $b = a$ .

Figure 22: Cassinian ovals.

Bicorn, or cocked hat, are terms that have been applied to two different quartics (see Figure 26A). One form was named "bicorn" and discussed by the British-born U.S. mathematician James Joseph Sylvester in 1864 and by the British mathematician Arthur Cayley three years later (see 122). Another form has been referred to as a "cocked hat" (see 123).

Bullet-nose curve was discussed by P.H. Schoute in 1885. This curve and the cross curve have similar equations (see 124).

Devil's curve, or devil on two sticks (see 125), shown in Figure 26B, was first studied by the Swiss physicist Gabriel Cramer in 1750.

Eight curve (see 126) is also known as the lemniscate of Gerono.

$$(116) \quad (x^2 + y^2)^2 = a^2(x^2 - y^2) \quad \text{or} \quad r^2 = a^2 \cos 2\theta$$

$$(117) \quad (x - b)^2(x^2 + y^2) - a^2x^2 = 0 \quad \text{or} \quad r = a + b \sec \theta$$

$$(118) \quad (x^2 + y^2 - 2ax)^2 = b^2(x^2 + y^2) \quad \text{or} \quad r = b + 2a \cos \theta$$

$$(119) \quad b > 2a, \quad b = 2a, \quad b = a$$

$$(120) \quad \begin{cases} (x^2 + y^2 - 2ax)^2 = 4a^2(x^2 + y^2) \\ r = 2a(1 + \cos \theta) \\ x = a(2 \cos \theta - \cos 2\theta), \quad y = a(2 \sin \theta - \sin 2\theta) \end{cases}$$

$$(121) \quad \begin{cases} x = a(2 \cos \theta + \cos 2\theta), \quad y = a(2 \sin \theta + \sin 2\theta) \\ \text{or } (x^2 + y^2 + 12ax + 9a^2)^2 - 4a(2x + 3a)^3 = 0 \end{cases}$$

$$(122) \quad 2y^4 - 9y^3 - 17y^2 + 125y - xy^3 - 29xy^2 + 205xy + 72x^2y - 27x^3 - 25x^2 = 0$$

$$(123) \quad y^2(a^2 - x^2) = x^2 + a(2y - a)^2$$

$$(124) \quad \begin{cases} \frac{a^2}{x^2} - \frac{b^2}{y^2} = 1 \\ \frac{a^2}{x^2} + \frac{b^2}{y^2} = 1 \end{cases}$$

$$(125) \quad y^4 + my^2 - x^4 + nx^2 = 0$$

$$(126) \quad x^4 = a(x^2 - y^2) \quad \text{or} \quad r^2 = a^2 \cos 2\theta \cos^4 \theta$$

$$(127) \quad a^2x^4 = b^4(x^2 + y^2) \quad \text{or} \quad r = b^2/(a \cos^2 \theta)$$

$$(128) \quad y^2(x^2 + y^2) = a^2x^2 \quad \text{or} \quad r = a \cot \theta$$

$$(129) \quad b^2y^2 = x^3(a - x)$$

$$(130) \quad \begin{cases} (x^2 + y^2 - 4a^2)^3 = 108a^4y^2 \quad \text{or} \\ (r/2a)^{2/3} = (\sin \frac{1}{2}\theta)^{2/3} + (\cos \frac{1}{2}\theta)^{2/3} \end{cases}$$

$$(131) \quad (x^2 + y^2 - a^2)^3 + 27a^2x^2y^2 = 0 \quad \text{or} \quad x^{2/3} + y^{2/3} = a^{2/3}$$

Kampyle of Eudoxus (see 127) was used in connection with the problem of the duplication of the cube (Figure 26C).

Kappa curve, or Gutschoven's curve (see 128), was conceived by G. van Gutschoven (c. 1662) and studied by Newton and Johann Bernoulli.

Pear-shaped quartic (see 129) was studied by G. de Longchamps in 1886.

Nephroid (see 130) was discovered by Huygens and Ehrenfried Walther Tschirnhausen between 1678 and 1690; it was studied by Jakob Bernoulli in 1692.

Astroid, or tetracuspid (see 131), was first discussed by Johann Bernoulli in 1691-92 (Figure 26D).

Figure 23: Conchoid.

Cayley's sextic (see 132) was discovered by Maclaurin in 1718 and studied in detail by Cayley.

Watt's curve (see 133) is the sextic curve generated by a point  $P$  of the side  $BC$  of a three-bar linkage  $AB, BC, CD$ , the points  $A$  and  $B$  remaining fixed while the others vary (see Figure 27).  $O$  is the midpoint of  $AD$ ;  $AO = a$ ,  $AB = CD = b$ ,  $BP = PC = c$ ; and  $\theta$  varies from 0 to  $\pi$ .

Pearls of Sluze (see 134) was studied by Baron René Française de Sluze between 1657 and 1698 and named by Blaise Pascal.

Lamé curves (see 135) are a family of curves discussed in 1818 by the French geometer and engineer Gabriel Lamé. The curves are algebraic or transcendental depending on whether  $n$  is rational or irrational.

Rhodonea curves (see 136) were so named by the

Figure 24: Limaçon of Pascal.

Italian mathematician Guido Grandi, between 1723 and 1728, because of their fancied resemblance to roses. When  $k$  is an integer there are  $k$  or  $2k$  petals of the rose curves depending on whether  $k$  is odd or even, respectively. The number of petals is finite or infinite depending on whether  $k$  is rational or irrational, respectively. Several curves corresponding to particular values of  $k$  have attracted special attention.

Curve of pursuit, or pursuit curve: If a point  $A$  describes a known curve ( $A$ ), the curve ( $P$ ) described by a point  $P$  is a curve of pursuit if the motion of  $P$  is always directed toward  $A$  and if both  $A$  and  $P$  move with uniform velocities. The problem of the pursuit curve was first formulated and solved by the French scientist Pierre Bouguer in 1732. If ( $A$ ) is a straight line, the equation of ( $P$ ) has two possible forms (see 137). A study of this curve was made by Arthur Bernhart.

The epicycloid and hypocycloid are the curves traced out by points on the circumferences of circles of radius  $b$

Figure 25: Tricuspid.

that roll without slipping on the exterior and interior, respectively, of a fixed circle of radius  $a$ . The parametric equations of the epicycloid and the hypocycloid can be given (see 138). When the point lies in the plane of the rolling circle but not on the circumference, it generates epitrochoids and hypotrochoids. These four kinds of curves attracted the attention of the French physicist Philippe de la Hire, Girard Desargues, Leibniz, Newton, and others. They admit as special cases many well-known curves such as the cardioid and the deltoid.

Bowditch curves, or Lissajous curves (see 139), are shown in Figure 28. These curves were first considered by Nathaniel Bowditch in 1815 and studied in detail and independently by the French physicist Jules-Antoine Lissajous in 1857. They find applications in astronomy, physics, and other sciences.

$$(132) \quad \begin{cases} 4(x^2 + y^2 - ax)^3 = 27a^2(x^2 + y^2)^2 & \text{or} \\ r = 4a \cos^3(\theta/3) \end{cases}$$

$$(133) \quad r^2 = b^2 - [a \sin \theta \pm (c^2 - a^2 \cos^2 \theta)^{1/2}]^2$$

$$(134) \quad y^n = k(a-x)^p x^m \quad (m, n, p \text{ are positive integers})$$

$$(135) \quad (x/a)^n + (y/b)^n = 1$$

$$(136) \quad r = a \cos k\theta \quad \text{or} \quad r = a \sin k\theta$$

$$(137) \quad \begin{cases} y = cx^{m+1}/(m+1) + 1/cx^{m-1}/(m-1) \\ y = cx^2 - \log x \end{cases}$$

$$(138) \quad \begin{cases} x = (a+b) \cos \phi - h \cos[(a+b)\phi/b] \\ y = (a+b) \sin \phi - h \sin[(a+b)\phi/b] \\ x = (a-b) \cos \phi + h \cos[(a-b)\phi/b] \\ y = (a-b) \sin \phi - h \sin[(a-b)\phi/b] \end{cases}$$

$$(139) \quad \begin{cases} x = a \sin(m_1 u + n_1), & y = b \sin(m_2 u + n_2) \\ \text{or } x = a \sin(nt + c), & y = b \sin t \end{cases}$$

$$(140) \quad r^n = a^n \cos n\theta$$

$$(141) \quad x = a(\phi - \sin \phi), \quad y = a(1 - \cos \phi)$$

$$(142) \quad x = a\theta - h \sin \theta, \quad y = a - h \cos \theta$$

$$(143) \quad x = \frac{a}{2^{1/2}} \int_0^v \frac{\sin v \, dv}{v^{1/2}}, \quad y = \frac{a}{2^{1/2}} \int_0^v \frac{\cos v \, dv}{v^{1/2}}$$

Sinusoidal spirals (see 140) were first studied by Maclaurin; in the general equation  $n$  is a rational number, positive or negative. For  $n = -1, +1, +1/2, -1/2, -2$ , and  $+2$ , the curve is, respectively, a line, a circle, a cardioid, a parabola, an equilateral hyperbola, and a lemniscate of Bernoulli.

Cycloid (see 141), one of the most celebrated of all special curves, is the locus of a point on the circumference of a circle of radius  $a$  that rolls without slipping along a straight line (see Figure 29). The curve was studied by Galileo (c. 1599), who gave it its name, Roberval in 1634, the English architect Sir Christopher Wren in 1658, Huygens in 1673, Johann Bernoulli in 1696, and others. If the point on the circumference lies in the plane of the circle at a distance  $h$  from the centre ( $h \neq a$ ), the curve (see 142) may be expressed in parametric equations. The curves are trochoids—that is, curtate or prolate cycloids—depending on whether  $h < a$  or  $h > a$  (see Figure 29).

Euler's spiral, or clothoid, or Cornu's spiral (see 143), was discovered and studied by Euler in 1744 (see Figure 30).

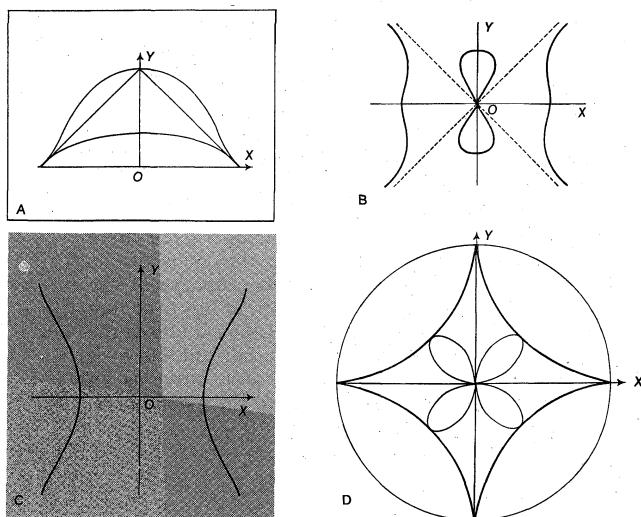

Figure 26: Four plane algebraic curves. (A) Bicorn or cocked hat. (B) Devil's curve. (C) Kampyle of Eudoxus. (D) Astroid or tetracuspid.

The family of spirals (see 144) includes four notable curves (see 145) that result by giving a parameter  $m$  particular values. (A) Spiral of Archimedes, obtained in the case  $m = 1$ , was discussed by him about 225 BC. (B) Fermat's spiral, obtained in the case  $m = 2$ , was discussed by him in 1636. (C) Hyperbolic, or reciprocal, spiral,  $m = -1$ , originated with Pierre Varignon in 1704 and was studied in detail by Johann Bernoulli between 1710 and 1713 and the English mathematician Roger Cotes in 1722. (D) Lituus,  $m = -2$ , originated with Cotes in 1722. It is the locus of the point  $P$  moving in such a manner that the area of the circular sector  $POP'$  remains constant (see Figure 31).

Involute of a circle (see 146) is the roulette of a point on

Figure 27: Watt's curve.

a straight line that rolls on a circle. It was conceived by Huygens when he was considering clocks without pendulums that might be of service to seagoing vessels.

Cochleoid is a snail-form curve with the equation  $r = a \sin \theta / \theta$  (see Figure 32). The points of contact of parallel tangents to the cochleoid lie on a strophoid.

Figure 28: Bowditch curves.

Logarithmic, or equiangular, or logistic, spiral (see 147) was first discussed by Descartes as the curve cutting radius vectors from a fixed point  $O$  under a constant angle  $\phi$ . The form of the curve depends on  $c$  and is independent of  $k$  (see Figure 33). The pole  $O$  is an asymptotic point (Evangelista Torricelli, 1646). The pedal of a logarithmic spiral with respect to its pole is a logarithmic spiral, and its evolute is an equal spiral with the same asymptotic point (Jakob Bernoulli, 1691–93).

Figure 29: Cycloids.

Frequency curve, probability curve, Gaussian curve, and normal curve of error (see 148) are the names applied to the bell-shaped curve. This curve originated, in essence, with the French-born mathematician Abraham de Moivre in 1733; it has been associated more particularly with Laplace and Gauss. The term "frequency curve" is applied to a great variety of other curves.

Logarithmic, or logistic, curve (see 149) originated about 1640. The subtangent of the curve is equal to  $a$ , regardless of the value of  $m$ .

Catenary, or chainette (see 150), is the form that a perfectly flexible chain assumes when suspended by its ends and acted upon by gravity alone (see Figure 34). Its equation was obtained by Leibniz and Huygens in 1691. The tangents at  $P$ ,  $P_1$ , and  $P_2$  on the figure are concurrent. Euler discovered, in 1744, that a catenary revolved about its asymptote generates a catenoid, the only minimal surface of revolution.

Figure 30: Euler's spiral or clothoid or Cornu's spiral.

Tractrix, or tractory, or equitangential, curve (see 151) was studied in detail by Huygens in 1692 and by Leibniz, Johann Bernoulli, and others (see Figure 35). The evolute of the tractrix is a catenary. The tractrix revolved about its asymptote generates a pseudosphere, a surface of constant negative curvature of interest in non-Euclidean geometry.

Quadratrix of Hippias (see 152) is a curve discovered by Hippias of Elis (c. 430 BC) that may have been used by him and by Dinostratus (c. 350 BC) for trisecting an angle and for squaring the circle. The curve may be used for dividing an angle into any number of equal parts.

$$(144) \quad r^m = a^m \theta$$

$$(145) \quad \begin{cases} (m=1); & r = a\theta \\ (m=2); & r^2 = a^2\theta \\ (m=-1); & r\theta = a \\ (m=-2); & r^2\theta = a^2 \end{cases}$$

$$(146) \quad x = a(\cos \phi + \phi \sin \phi), \quad y = a(\sin \phi - \phi \cos \phi)$$

$$(147) \quad \begin{cases} r = ke^{c\theta} \\ c = \cot \phi \end{cases}$$

$$(148) \quad y = (2\pi)^{-\frac{1}{2}} e^{-\frac{1}{2}x^2}$$

$$(149) \quad x = a \log(y/m) \quad \text{or} \quad y = me^{x/a}$$

$$(150) \quad y = \frac{1}{2}a(e^{x/a} + e^{-x/a}) = a \cosh(x/a)$$

$$(151) \quad \begin{cases} y^2(1+y^2) = a^2y^2 \\ \text{or} \quad x = a(\cos u + \log \tan[u/2]), \end{cases} \quad y = a \sin u$$

$$(152) \quad y = x \cot(\pi x/2a) \quad \text{or} \quad r \sin \theta = (2a/\pi)\theta$$

Figure 31: Family of curves derived from  $r^m = a^m \theta$ . (A) Spiral of Archimedes; (B) Fermat's spiral; (C) hyperbola; (D) Illiut.

Anallagmatic curve, first discussed by T. Moutard in 1864, is a curve that is invariant under inversion, such as the limaçon, cardioid, Cartesian, cassinian, strophoid, and trisectrix of Maclaurin.

Brachistochrone is the curve along which a body moves from one point to another under the action of an accelerating force in the least time possible. In 1696 Johann Bernoulli proposed the question as a challenge, the accelerating force being gravity. Leibniz, Newton, Jakob Bernoulli, and L'Hospital found that the cycloid has the required property.

Figure 32: Cochleoid.

Caustic is an envelope of rays; more specifically, when the light rays emanating from a source are reflected by a given curve, the envelope of the reflected rays is the caustic by reflection, or catacaustic, of the given curve with respect to the source in question. When the rays from a source are refracted by a given curve, the envelope of refracted rays is called the caustic by refraction, or diacaustic, of the given curve for the source in question. Catacaustic and diacaustic surfaces may be defined in a similar way. Caustic curves originated with

Figure 33: Logarithmic spiral.

Huygens and Tschirnhausen about 1678; they were studied by Johann and Jakob Bernoulli, L'Hospital, Adolphe Quetelet, J.-L. Lagrange, and others. The catacaustic of a circle is a nephroid, a limaçon, or a cardioid, depending on whether the source of light is at an infinite distance—that is, when the incident rays are parallel (Huygens, 1678); a finite distance (Thomas de St. Laurent, 1826); or on the circumference of the circle (Johann and Jakob Bernoulli, 1692).

Evolute is the envelope of the normals of a given curve or, what amounts to the same thing, the locus of the centres of curvature of the curve. The concept of the evolute originated with Huygens in 1673; however, see Apollonius of Perga, *Conics*, book v. If the evolute of the curve is regarded as the basic curve, then the curve is said to be an involute; an involute of a curve is an orthogonal trajectory of the tangents to the given curve.

Figure 34: Catenary or chainette.

There are an infinite number of such trajectories to a given curve, and they are said to be parallel curves; that is, any two cut off equal lengths on common normals. Parallel curves may be very different in appearance; for example, Cayley's sextic and the nephroid. Leibniz was the first to consider parallel curves. Figure 36 shows two parallel curves, 3 and 4, of an astroid, 2, and also the evolute, 1, of this astroid.

Inverse curves: Given a fixed point  $O$  and a constant  $m$ , if two points  $P_1$  and  $P_2$ , collinear with  $O$ , are such that  $OP_1 \cdot OP_2 = m$ , they are said to be inverse with respect to one another, or homologous, in the inversion  $(O, m)$  having  $O$  for centre and  $m$  for constant of inversion. The points  $P_1$  and  $P_2$  are on the same side of  $O$  if  $m$  is positive and on opposite sides if  $m$  is negative. If one of the points, say  $P_1$ , describes a curve  $C_1$ , then the curve  $C_2$  described by  $P_2$  is the inverse  $C_1$  in  $(O, m)$ . The relation between  $C_1$  and  $C_2$  is obviously reciprocal, and the two may coincide.

Isoptic curve: The locus of the points of intersection of

Figure 35: Tractrix or tractory or equitangential curve.

tangents to a given curve (or a pair of curves) meeting at a constant angle is an isoptic curve of the given curve or curves. When the constant angle is right, the isoptic curve is said to be the orthoptic curve. The orthoptic of a parabola is its directrix, the orthoptic of a central conic is a circle concentric with the conic (the Monge circle), and the orthoptic of a deltoid is a circle.

Pedal, or pedal curve: The locus  $C_1$  of the feet of the perpendiculars dropped from a fixed point  $O$  to the tangents of a given curve  $C$  is said to be the pedal curve of  $C$  for—or with respect to—the point  $O$ . The curve  $C$  is the first negative pedal curve of  $C_1$  for the point  $O$ . The pedal curve  $C_2$  of  $C_1$  for  $O$  is the second positive pedal curve of  $C$  for  $O$ , and so on.

Radial, or radial curve: If through a fixed point recti-

Figure 36: Evolute.

linear segments are drawn equal and parallel to the radius of curvature of a variable point of a given curve  $C$ , the locus of the end points of those segments is the radial curve,  $R$ , of  $C$  (Robert Tucker, 1864). The degree of  $R$  is equal to the degree of the evolute of  $C$ . The radial of a conic is a conic; the radial of a cycloid is a circle.

Roulette is the path of a fixed point—or the envelope of a fixed line—situated in the plane of a curve, that rolls without slipping on a fixed curve or straight line. The term is also applied to the locus of a variable point, such as the centre of curvature of the point of contact of the rolling curve. The roulette of the vertex of a parabola rolling on an equal parabola is a cissoid of Diocles. The pole of a hyperbolic spiral rolling on a straight line traces out a tractrix. A related curve is the glissette, the locus of a point or the envelope of a line fixed in the plane of a curve made to slide between given curves. For instance, the locus of a point on a rod of fixed length whose ends slide on two fixed perpendicular lines is an ellipse. The envelope (glissette) of the rod itself is an astroid.

Tautochrone is a curve down which a particle acted upon by specified forces will descend in the same amount of time from any initial point to the lowest point. When gravity is the force considered, Huygens showed in 1673 that the inverted cycloid with axis vertical has the required property. The astroid and the cardioid are tautochrones under certain conditions.

Clelies: If  $\phi$  and  $\theta$  denote the longitude and colatitude of a point  $P$  on a sphere of radius  $a$ , and if  $P$  moves so that  $\theta = m\phi$  (in which  $m$  is a constant), then the locus described by  $P$  is a clelie. The locus of  $P$  was studied by Grandi in 1728, who used purely geometrical methods. Grandi also applied the term “clelies” to the curves determined by certain trigonometric equations involving the sine function (see 153).

Loxodrome, or rhumb line, or spherical helix (see 154) is usually defined as the curve cutting the meridian of a sphere at a constant angle. The curve was first conceived by Pedro Nunes in 1550. Its equations may be written in terms of  $\beta$ , the constant angle, and  $\phi$  and  $\theta$ , the longitude and colatitude, respectively, of a point on the loxodrome. Nunes believed that a loxodrome joining two points on a sphere was the shortest distance on the sphere between those points. But 19th-century mariners realized that great-circle sailing is preferable for shortening distances.

Helix (see 155) is the curve cutting the generators of a right circular cylinder under a constant angle,  $\beta$ . The helix is mentioned by Geminus (c. 70 BC); a passage in

Proclus (c. AD 460) suggests that it was known to Apollonius (c. 225 BC). It was used by Pappus of Alexandria (c. AD 300) for producing the quadratrix of Hippias of Elis. The orthogonal projection of the helix on a plane parallel to the axis of the cylinder is a sine curve. The curve that cuts the generators of a cone of revolution under a constant angle is a cylindroconical helix, or conical loxodrome (see 156), which was first discussed by Grandi in 1701.

Skew, or gauche, or space, or twisted, cubic is a space curve that may have three points in common with a plane. The skew cubic may result from the intersection of two quadratic cones, or of two ruled quadric surfaces having an element in common. It is in this form that the curve was first noticed by A.F. Möbius, a German mathematician, in 1827. The curve is the locus of the common point of three corresponding planes of three projective axial pencils of planes, or the locus of the common point of two corresponding and coplanar lines of two projective bundles. A skew cubic is determined by six points, no four of them coplanar. The cone that projects a cubic from a point in space is of third degree but reduces to second degree if the point is taken on the cubic. A line in space may be met by four tangents to a skew cubic. A line joining two points, real or conjugate imaginary, of a skew cubic is a secant of the curve, while a line having one point in common with the curve is a semisecant or transversal.

The skew cubic is also referred to as a cubical conic section. The three points of intersection of the curve with the plane at infinity may present the following four cases: (1) the three points are real and distinct; (2) one point is real and the other two are conjugate imaginary; (3) two of the points coincide; (4) all three points coincide. The corresponding curves are: (1) cubical hyperbola; (2) cubical ellipse; (3) cubical parabolic hyperbola; (4) cubical parabola.

## Geometry, Differential

Differential geometry has its origin in the discovery in the 17th century of the infinitesimal calculus, one part of mathematics that deals with limits. The concept of the derivative of a function is essentially identical with that of the tangent line or slope of a curve, and the integral of a function can be geometrically interpreted as the area under a curve. The geometry of curves and surfaces

$$(153) \quad \begin{cases} a \sin \theta = b \sin m\phi \\ a \sin \theta = a - b \sin m\phi \end{cases}$$

$$(154) \quad \begin{cases} x = \sin \phi \cos \theta, & y = \sin \phi \sin \theta, & z = \cos \phi \\ \theta = -\tan \beta \log \tan(\phi/2) \end{cases}$$

$$(155) \quad x = a \cos \theta, \quad y = a \sin \theta, \quad z = a\theta \cot \beta$$

$$(156) \quad x = he^{a\theta} \cos \theta, \quad y = he^{a\theta} \sin \theta, \quad z = he^{a\theta} \cot \beta$$

in space was studied as an application of the calculus, leading to various notions of curvature. Among the main contributors were the 18th-century mathematicians Leonhard Euler of Switzerland and Gaspard Monge of France.

In this article there follows a treatment of differential geometry topics in which, after introductory material, consideration is given to manifolds and tensor bundles, operations on tensor fields, connections, interplay between local and global properties, the Gauss-Bonnet formula, elliptic operators, and, finally, modern development in surface theory.

The equations of a surface  $S$  in a Euclidean space with the coordinates  $x_1, x_2, x_3$  can be given in parametric form (see Box, equations 1). At the point  $(u^1, u^2)$  on the surface the components of a normal vector of unit length can also be given (see 2). The geometrical properties of  $S$  are then completely described by two quadratic differential forms (see 3), referred to respectively as the first and second fundamental forms of  $S$ . The 18th–19th-century German mathematician Carl Friedrich Gauss emphasized the importance of the properties of  $S$  that depend only on the first fundamental form, such as the length of a curve, the area of a domain, the geodesics (*i.e.*, curves of shortest length), and the Gaussian curvature. Another German mathematician, Bernhard Riemann, founded in 1854 what is now known as Riemannian geometry; that is, the geometry in a space of  $n$  dimensions with the coordinates  $u^\alpha$ ,  $\alpha = 1, \dots, n$ , based on a quadratic differential form (see 4). This geometry is of general form and includes as special cases the non-Euclidean geometries. It serves as a model of the physical universe in Einstein's general theory of relativity (see PHYSICAL THEORIES, MATHEMATICAL ASPECTS OF: *Riemannian geometry*; *Relativity theory*).

Modern differential geometry stems from the basis that the objects of study are a class of spaces called manifolds equipped with additional structures. The main problems deal with the global properties of manifolds; *i.e.*, properties that arise only when the manifolds are looked on as a whole. In global differential geometry topology is a major tool.

#### MANIFOLDS AND TENSOR BUNDLES

A manifold is a space that is covered by a finite or a countable number of coordinate charts with each point in a chart described by the real coordinates  $x^1, \dots, x^n$  (called local coordinates) and such that when a point belongs to two charts and has two sets of local coordinates they are related by a transformation (see 5). Here the functions  $f^i$ , with which the transformation is expressed, are dealt with on the basis of having continuous first partial derivatives with a Jacobian determinant (denoted by  $\det$ ), which is not equal to zero (see 6). If all such functions  $f^i$  have continuous partial derivatives of orders equal to or less than  $k$ , the manifold is said to be of class  $k$ . If all such functions have continuous partial derivatives of all orders, the manifold is said to be of class infinity. This definition is necessary because a space can rarely be described by one coordinate system. The local coordinates themselves have no geometrical meaning, and the analytical tool for the study of manifolds must be furnished by concepts that behave in a simple way under a change of local coordinates.

The most important among such concepts are the tensors or tensor fields (see ANALYSIS, VECTOR AND TENSOR). A tensor of contravariant order  $r$  and covariant order  $s$  is defined by specifying its components (see 7) in each coordinate chart. Under a change of local coordinates (in which all the indices run from 1 to  $n$ ) these components follow the conventional transformation rule involving first partial derivatives of the two sets of coordinates (see 8). The tensor is called contravariant if  $s$  equals zero and covariant if  $r$  equals zero. A contravariant (respectively covariant) tensor of order one—*i.e.*, of single order—reduces to a contravariant (respectively covariant) vector. In tensor algebra, a tensor can be multiplied by a scalar quantity and two tensors of the same orders can be added. Moreover, two tensors of

$$(1) \quad x_i = x_i(u^1, u^2), \quad i = 1, 2, 3$$

$$(2) \quad \xi_i(u^1, u^2), \quad i = 1, 2, 3$$

$$(3) \quad \begin{cases} I = ds^2 = \sum_i dx_i^2 \\ II = -\sum_i dx_i d\xi_i, \end{cases} \quad i = 1, 2, 3$$

$$(4) \quad \sum_{\alpha, \beta} g_{\alpha, \beta}(u) du^\alpha du^\beta, \quad \alpha, \beta = 1, \dots, n$$

$$(5) \quad \begin{cases} x^i, x'^j, & i, j = 1, \dots, n \\ x'^i = f^i(x^1, \dots, x^n) \end{cases}$$

$$(6) \quad \frac{\partial(f^1, \dots, f^n)}{\partial(x^1, \dots, x^n)} = \det\left(\frac{\partial f^i}{\partial x^j}\right) \neq 0$$

$$(7) \quad A_{j_1 \dots j_s}^{i_1 \dots i_r}$$

$$(8) \quad A_{j_1 \dots j_s}^{i_1 \dots i_r} = \sum_{k, l} \frac{\partial x'^{i_1}}{\partial x^{k_1}} \dots \frac{\partial x'^{i_r}}{\partial x^{k_r}} \frac{\partial x^{l_1}}{\partial x'^{j_1}} \dots \frac{\partial x^{l_s}}{\partial x'^{j_s}} A_{l_1 \dots l_s}^{k_1 \dots k_r}$$

$$(9) \quad C_{j_1 \dots j_{s+q}}^{i_1 \dots i_{r+p}} = A_{j_1 \dots j_s}^{i_1 \dots i_r} B_{j_{s+1} \dots j_{s+q}}^{i_{r+1} \dots i_{r+p}}$$

$$(10) \quad \begin{cases} A_{ijk} \text{ is symmetric in } i, j, \text{ if } A_{ijk} = A_{jik} \\ \text{antisymmetric in } i, j, \text{ if } A_{ijk} = -A_{jik} \end{cases}$$

contravariant orders  $r, p$  and covariant orders  $s, q$ , respectively, have a product that is a tensor of contravariant order  $r + p$  and covariant order  $s + q$  (see 9). The vanishing of a tensor (*i.e.*, of all the components) is a condition invariant with a change of local coordinates.

A tensor is symmetric (respectively antisymmetric) in two indices if the components remain unchanged (respectively change sign) on a permutation of the indices (see 10). A covariant tensor of order  $s$  is symmetric (respectively antisymmetric) if it is symmetric (respectively antisymmetric) in every pair of indices. The symmetry or antisymmetry of a tensor is again invariant with respect to a change of local coordinates.

All the tensors of given orders at a point form a vector space and the collection of all of them forms a tensor bundle of the manifold  $M$ . In particular, all the contravariant (respectively covariant) vectors form the tangent (respectively cotangent) bundle of  $M$ . The tensor bundles are special cases of a general vector bundle over  $M$ . A vector bundle over  $M$  is a collection of vector spaces over the points of  $M$  such that it is locally a product and that the linear structures on the vector spaces (referred to as fibres) have a respective representation. Two vector bundles  $E$  and  $F$  over  $M$  can be added; their sum,  $E \oplus F$ , is the vector bundle the fibre of which at a point of  $M$  is the direct sum of the fibres of  $E$  and  $F$ , respectively. The set of all vector bundles over  $M$ , with this addition, is a semi-group. By the introduction of "virtual bundles" (analogous to the introduction of negative integers in elementary arithmetic), all the finite linear combinations of the vector bundles over  $M$ , real or virtual, are made into a group. Through the tensor product of vector bundles the group acquires a multiplication representation and has a ring structure. This ring is called the Grothendieck ring (after Alexandre Grothendieck, a French mathematician) or  $K$ -ring of  $M$ ; it is a significant global invariant of  $M$ . For technical reasons a simpler concept is obtained by the consideration of complex vector bundles over  $M$ , although  $M$  is itself a real manifold.

The fibre need not be a vector space. An important example is when it is the space of all frames (*i.e.*, ordered sets of  $n$  linearly independent tangent vectors) at a point  $P$  of  $M$ . The resulting fibre space, the space of all frames

First and second fundamental forms

Tensors of covariant and contravariant order

Principal  
fibre  
space

at all points of  $M$ , is called the principal fibre space; its dimension is  $n^2 + n$ . If  $M$  is the three-dimensional Euclidean space and the vectors of the frame are supposed to form an orthonormal system, then a frame is an oriented rectangular trihedral; the corresponding fibre space plays a basic role in the method of moving trihedrals in the theory of curves and surfaces in Euclidean space and in kinematics (motion without regard to mass or force). The method of moving frames, used extensively and successfully by Élie-Joseph Cartan, a French mathematician, in differential geometry, is a forerunner of the notion of principal fibre space.

#### OPERATIONS ON TENSOR FIELDS; CONNECTIONS

It is important to derive new tensor fields from given ones. If  $f$  is a real-valued function (i.e., a tensor field of order zero), its partial derivatives are the components of a covariant vector field called the gradient of  $f$ . If  $A_i$  is a covariant vector field, then expressions formed by taking differences of relevant partial derivatives (see 11) are the components of an antisymmetric covariant tensor field of order 2, called the curl of  $A_i$ . Generally, if there is given an antisymmetric covariant tensor field of order  $r$ , its exterior derivative is a summation of products of certain of its partial derivatives and the function sign (see 12) in which  $\text{sgn}$  is the sign of the permutation under it and the summation is over all the  $j$ 's. The exterior derivative is best expressed in terms of exterior differential forms. Such a form of degree  $r$  can be represented by a linear combination involving products of differentials (see 13) in which the multiplication of the differentials is antisymmetric (see 14) and the coefficients are supposed to be antisymmetric in their indices so that they are completely determined. By the use of the transformation law of the differentials (see 15) an exterior differential form of degree  $r$  can be identified with an antisymmetric covariant tensor field of order  $r$ . The exterior derivative can then be written (see 16).

The basic reason for the operation of exterior differentiation lies in geometry. In fact, exterior differential forms are the integrands of multiple integrals. The integral of an arbitrary quantity  $\omega$  over an  $r$ -dimensional domain  $D$  includes as special cases, for  $r = 1$ ,  $n = 2$  and  $r = 2$ ,  $n = 3$ , respectively, the line integral in the plane and the surface integral in space. If  $D$  is the boundary of an  $(r + 1)$ -dimensional domain  $F$ , then the integral of  $\omega$  over domain  $D$  is equal to the integral of  $d\omega$  over domain  $F$  (see 17), which is a generalization of the Gauss-Green-Stokes formulas (named after Gauss and the British mathematicians George Green and George Gabriel Stokes).

Another important operation for tensor fields is the Lie derivative, first stated by Sophus Lie, a Norwegian mathematician. If  $X$  is a contravariant vector field with the components  $A^k$  in the local coordinate system  $x^i$ , in which  $i, k = 1, \dots, n$ , and  $f$  is a real-valued function, then  $Xf = \sum A^k (\partial/\partial x^k) f$  is a new real-valued function, the directional derivative of  $f$  relative to the vector field  $X$ . In this way  $X$  can be regarded as a linear differential operator on functions. If  $Y$  is another vector field, it can be shown that the matrix  $[X, Y]$ , equal to  $XY - YX$ , is also a linear combination of  $\partial/\partial x^k$  and defines a vector field. This is called the bracket operation of two vector fields. More generally, a vector field  $X$  defines an infinitesimal transformation  $\delta x^i = A^i \delta t$ ,  $i = 1, \dots, n$ , and the study of the variation of a tensor field under this infinitesimal transformation leads to a new tensor field of the same type. The latter is called the Lie derivative relative to  $X$ . The Lie derivative relative to  $X$  of the tensor field  $B_k^{ij}$  is determined by the components (see 18).

Generally a tensor field cannot be differentiated to give a new tensor field because the local coordinates have no geometrical meaning. A structure on the manifold that makes this possible is called an affine connection or simply a connection. It is given by a set of components  $\Gamma_{ik}^j$  in each chart, which, with a change of local coordinates, follow a transformation rule (see 19). These components do not, therefore, define tensor fields. But

The affine  
connection

$$(11) \quad A_{ij} = \frac{1}{2} \left( \frac{\partial A_i}{\partial x^j} - \frac{\partial A_j}{\partial x^i} \right)$$

$$(12) \quad A_{i_1 \dots i_{r+1}} = \frac{1}{(r+1)!} \sum \text{sgn} \begin{pmatrix} j_1 \dots j_{r+1} \\ i_1 \dots i_{r+1} \end{pmatrix} \frac{\partial A_{j_1 \dots j_r}}{\partial x^{j_{r+1}}}$$

$$(13) \quad \omega = \frac{1}{r!} \sum_{i_1, \dots, i_r} A_{i_1 \dots i_r} dx^{i_1} \wedge \dots \wedge dx^{i_r}$$

$$(14) \quad dx^i \wedge dx^j = -dx^j \wedge dx^i$$

$$(15) \quad dx'^i = \sum_j \frac{\partial x'^i}{\partial x^j} dx^j$$

$$(16) \quad d\omega = \frac{1}{r!} \sum_{i_1, \dots, i_r} dA_{i_1 \dots i_r} \wedge dx^{i_1} \wedge \dots \wedge dx^{i_r}$$

$$(17) \quad \int_D \omega = \int_F d\omega$$

$$(18) \quad [L(X)B]_k^{ij} = \sum_l \left\{ A^l \frac{\partial B_{kl}^{ij}}{\partial x^l} - B_{kl}^{ij} \frac{\partial A^l}{\partial x^k} - B_{kl}^{ij} \frac{\partial A^l}{\partial x^i} + B_{kl}^{ij} \frac{\partial A^l}{\partial x^j} \right\}$$

$$(19) \quad \Gamma_{ik}^{rj} = \sum_{l, m, r} \Gamma_{lm}^r \frac{\partial x^l}{\partial x^i} \frac{\partial x^m}{\partial x^k} \frac{\partial x^j}{\partial x^r} + \sum_l \frac{\partial x^j}{\partial x^i} \frac{\partial^2 x^l}{\partial x^k \partial x^r}$$

$$(20) \quad A_{j,k}^i = \frac{\partial A_j^i}{\partial x^k} + \sum_k \left( \Gamma_{ik}^j A_j^i - \Gamma_{jk}^i A_i^j \right)$$

$$(21) \quad \sum_k A_{j,k}^i \frac{dx^k}{dt} = 0$$

they can be used to derive from a tensor field of contravariant order  $r$  and covariant order  $s$  a new tensor field of contravariant order  $r$  and covariant order  $s + 1$ , called the covariant derivative of a tensor field. In the simple case of a tensor field  $A_j^i$  its covariant derivative has a simply expressed form (see 20). The tensor field is called parallel along a curve  $x^i = x^i(t)$  if a condition is met (see 21). In the special case of the affine space where the connection is defined by  $\Gamma_{ik}^j = 0$ , parallelism of  $A_j^i$  means the constancy of all the components. A Riemannian manifold has a uniquely determined connection, the Levi-Civita connection (named after Tullio Levi-Civita, an Italian mathematician), which is characterized by the two properties: (A) the length of a vector remains unchanged under parallelism; and (B)  $\Gamma_{ik}^j = \Gamma_{ki}^j$ .

#### DE RHAM AND HODGE THEOREMS

The importance of exterior differential forms and their exterior derivatives lies in the fact that they help in solving problems on manifolds in which local and global properties come into interplay with a link furnished by de Rham's theorem (named after Georges de Rham, a Swiss mathematician). An exterior differential form is called closed if its exterior derivative is zero; it is called a derived form if it is the exterior derivative of another. It follows from definition that a derived form is closed. The closed forms can be divided into classes such that two forms belong to the same class if and only if their difference is a derived form. All the classes of closed forms of degree  $r$  form a real vector space  $H^r$ . This space is manageable, in the sense that contrast exists to the space of all forms of degree  $r$  or even that of all closed forms, both of which are "large" and generally infinite-dimensional. If the manifold is compact—i.e., if it can be covered by a finite number of coordinate charts—de Rham's theorem says that the dimension of the space

The Riemannian metric

$H^r$  is the  $r$ th Betti number (named after Enrico Betti, a 19th-century Italian mathematician) of the manifold. The latter is an integer and is a topological invariant of the manifold that describes its connectivity properties.

The presence of a Riemannian metric on a manifold  $M$  gives it an important structure and allows further operations. With  $M$  moreover oriented, the Riemannian metric associates with an  $r$ -vector an orthogonal  $(n-r)$ -vector that is coherently oriented and has the same measure. This operation extends to an operation on exterior differential forms, the so-called star operation. If  $\omega$  is of degree  $r$ , then  $\ast\omega$  is of degree  $n-r$ . In terms of the star operator, the codifferential of an exterior differential form of degree  $r$  is defined by  $\delta$  equal to  $(-1)^{n-r+1} \ast d \ast$ ;  $\delta$  diminishes the degree by one. A form  $\omega$  is called coclosed if  $\delta\omega$  is equal to zero. Since  $dd$  is zero, then  $\delta\delta$  is equal to zero and the Laplace operator  $\Delta$  may be introduced (see 22), which maps a form into one of the same degree. A form  $\omega$  is called harmonic if  $\Delta\omega$  is equal to zero. A form that is both closed and coclosed is harmonic. On a compact manifold the converse is also true. In the special case of a real-valued function  $u(x, y)$  in the Euclidean  $(x, y)$ -plane, the relation  $\Delta u = -u_{xx} - u_{yy}$  applies. Thus, harmonic forms generalize the classical harmonic functions. Hodge's theorem (named after William Vallance Douglas Hodge, a British mathematician) says that on a compact orientable Riemannian manifold there is exactly one harmonic form in every class of closed forms of degree  $r$  (in the sense defined above). The theorem is a wide generalization of fundamental results on compact Riemann surfaces in complex function theory. It has important applications to algebraic geometry.

#### GAUSS-BONNET FORMULA AND CHARACTERISTIC CLASSES

If  $A^i$  is a contravariant vector field on a manifold with an affine connection, the second covariant derivatives  $A^i{}_{,j,k}$  are in general not symmetric in  $j, k$ . The measure of their deviation from symmetry is given by the curvature tensor. More precisely, under the hypothesis that the connection is symmetric— $\Gamma_{ik}^j = \Gamma_{ki}^j$ —the Ricci commutation formula applies (see 23) in which (see 24) the  $R_{ijk}^l$  components are the components of a tensor field of contravariant order one and covariant order three. It is called the curvature tensor of the connection. From the curvature tensor the most significant invariants are built up by first introducing differential forms (see 25; referred to as the curvature forms) and then considering the coefficients of the appropriate polynomial of  $t$  (see 26). The Kronecker index  $\delta_i^j$  is employed here, which denotes the value 1 when  $i$  is equal to  $j$  and zero when  $i$  is unequal to  $j$ . By definition  $p_k(\Omega)$ ,  $k = 1, \dots, n$ , is an exterior differential form of degree  $2k$ , because each  $\Omega_i^j$  is of degree two. From the tensorial behaviour of  $R_{ijk}^l$  there follows immediately that  $p_k(\Omega)$  is independent of the choice of the local chart, thereby being forms defined over the whole manifold  $M$ . Moreover, they are closed.

A fundamental theorem on characteristic classes postulates that for odd  $k$ ,  $p_k(\Omega)$  is a derived form, whereas for even  $k$ ,  $p_k(\Omega)$  determines a class (in the sense of de Rham's theorem) called the Pontryagin characteristic class of  $M$  (named after the Soviet mathematician Lev Semyonovich Pontryagin). The latter class ranks among one of the first global invariants that measure the deviation of the tangent bundle of  $M$  from a product bundle. Thus the local properties of a connection, the curvature tensor, determine in their totality certain global properties, the Pontryagin characteristic classes. In particular, if  $M$  has a flat affine connection for which  $R_{ijk}^l$  vanish identically, all the Pontryagin classes of  $M$  are zero. An example of a manifold with a nonzero Pontryagin class is the complex projective plane; i.e., the complex Euclidean plane with a line at infinity added. Therefore, this manifold, of four real dimensions, cannot be equipped with a flat affine connection. The above theorem on characteristic classes is, however, much more precise, and the following conclusion may be formulated: With  $M$  a compact oriented manifold of dimension four, and

$$(22) \quad \Delta = (d + \delta)^2 = d\delta + \delta d$$

$$(23) \quad A^i{}_{,j,k} - A^i{}_{,k,j} = -\sum_l R_{ljk}^i A^l$$

$$(24) \quad R_{ljk}^i = \frac{\partial \Gamma_{lk}^i}{\partial x^j} - \frac{\partial \Gamma_{lj}^i}{\partial x^k} + \sum_m (\Gamma_{mj}^i \Gamma_{lk}^m - \Gamma_{mk}^i \Gamma_{lj}^m)$$

$$(25) \quad \Omega_i^j = \frac{1}{2} \sum_{k,l} R_{ikl}^j dx^k \wedge dx^l$$

$$(26) \quad \det\left(t\delta_i^j - \frac{1}{2\pi} \Omega_i^j\right) = t^n + p_1(\Omega)t^{n-1} + \dots + p_n(\Omega)$$

$$(27) \quad \text{sign } M = \frac{1}{24\pi^2} \int_M \sum_{i,j} \Omega_i^j \wedge \Omega_j^i, \quad i, j = 1, \dots, 4$$

$$(28) \quad ds^2 = \sum_{i,k} g_{ik}(x) dx^i dx^k, \quad g_{ik} = g_{ki}$$

$$(29) \quad \Omega_{ij} = \sum_k \Omega_i^k g_{jk}$$

$$(30) \quad \Omega_{ij} + \Omega_{ji} = 0$$

$$(31) \quad Pf(\Omega) = \frac{(-1)^p}{2^n \pi^p p! \sqrt{g}} \sum \epsilon_{i_1 \dots i_n} \Omega_{i_1 i_2} \wedge \dots \wedge \Omega_{i_{n-1} i_n}$$

$$(32) \quad \int_M Pf(\Omega) = \chi(M)$$

for two closed forms  $\omega, \theta$  of degree two, the integral over  $M$  of the product of the closed forms is a real number that depends only on the classes to which the forms  $\omega, \theta$  belong in the space  $H^2$  (see above *de Rham and Hodge theorems*). This defines a symmetric bilinear function on  $H^2$ ; its signature—the number of its positive eigenvalues minus the number of its negative eigenvalues—is a topological invariant of  $M$ , called the signature of  $M$ . The relation between characteristic classes and curvature gives an integral formula for the signature of  $M$  (see 27). A generalization of this formula holds for any compact orientable manifold of dimension  $4s$  with an affine connection according to Hirzebruch's signature theorem (named after Friedrich Ernst Peter Hirzebruch, a German mathematician).

When the affine connection is the Levi-Civita connection of a Riemannian metric given by a positive definite quadratic differential form (see 28) the curvature forms have special properties. By one such property, certain forms (see 29) are antisymmetric (see 30). In the case of manifold  $M$  of even dimension,  $n$  equal to  $2p$ , and oriented, an important combination of the curvature forms is given by the Pfaffian (see 31) in which a constant  $g$  is equal to  $\det(g_{ij})$ ; the constants  $\epsilon$  are equal to  $+1$  or  $-1$  according as the subscript is an even or odd permutation of  $1, \dots, n$ , and is otherwise zero; and the summation is over all the  $i$ 's from 1 to  $n$ . For a compact manifold  $M$  without boundary the Gauss-Bonnet formula (see 32; it is named after Gauss and Pierre-Ossian Bonnet, a 19th-century French mathematician) is one in which  $\chi(M)$  is the Euler-Poincaré characteristic of  $M$ , again a topological invariant of  $M$ .

The Euler-Poincaré characteristic has also the following combinatorial interpretation: if  $M$  is subdivided into a complex of cells, of all dimensions from 0 to  $n$ , then it can be written as a sum of terms of the type  $(-1)^r \alpha_r$ , in which  $\alpha_r$  is the number of  $r$ -dimensional cells in the subdivision.

A more general formula holds for the case in which  $M$  has a boundary. In the simple case that  $M$  is two-dimensional and is bounded by a sectionally smooth curve, the Gauss-Bonnet formula (see 33) is one that involves in-

The Pontryagin characteristic classes

integrals and in which  $\pi - \alpha_i$  are the exterior angles at the corners of the boundary curve  $C$  of  $M$ ,  $k_g$  is the geodesic curvature of  $C$ ,  $K$  is the Gaussian curvature, and  $dA$  is the element of area of  $M$ . In the formula, the sum of the exterior angles and integrals of the geodesic curvature and the Gaussian curvature are added to equal a constant times the Euler-Poincaré characteristic of the manifold. If  $K$  is a constant not equal to zero and  $M$  is bounded by geodesic arcs (so that  $k_g = 0$ ), the Gauss-Bonnet formula expresses the area of a geodesic polygon in terms of its angles, a well-known result in non-Euclidean geometry. If  $K$  is zero, the Gauss-Bonnet formula contains the classical theorem that the sum of the angles of a triangle in the Euclidean plane is equal to  $\pi$ .

#### ELLIPTIC OPERATORS

Elliptic differential operators, linear or nonlinear, play an important role in differential geometry. Some of the most important global invariants of manifolds arise from the consideration of elliptic operators. If  $\pi : E \rightarrow M$  be a complex vector bundle—that is, a vector bundle the fibres of which are complex vector spaces—a differentiable section  $s : M \rightarrow E$  is a mapping such that the result is the identity mapping when followed by  $\pi$ . By  $\Gamma E$  is denoted the space of all differentiable sections of  $E$ . Locally  $s$  can be defined by its components  $(s_1(x'), \dots, s_p(x'))$ , in which  $p$  is the dimension of the fibre of  $E$ . If  $\phi : F \rightarrow M$  is a complex vector bundle with the same fibre dimension, a differential operator  $D$  is a mapping  $D : \Gamma E \rightarrow \Gamma F$ , such that  $Ds$ , as a section of the bundle  $F$ , has locally specific components (see 34, 35) in which  $\alpha$  stands for the multi-index (see 36). The differential operator  $D$  is referred to as of order  $q$  if the absolute value of  $\alpha$ ,  $|\alpha|$ , is equal to or less than  $q$ . It is called elliptic in the order  $q$  if a matrix (see 37) is nonsingular whenever  $(\xi_1, \dots, \xi_n)$  is not equal to zero. A simple example of an elliptic operator is the Laplacian in (22).

If  $\ker D$  (kernel of  $D$ ) is the space of all sections  $s \in \Gamma E$  such that  $Ds$  is zero, and if  $\text{coker } D$  (i.e., cokernel of  $D$ ) is the quotient space  $\Gamma F / D\Gamma E$  that is isomorphic to the kernel of the adjoint operator of  $D$ , then by a theorem in the theory of elliptic operators, if  $M$  is compact, both  $\ker D$  and  $\text{coker } D$  are finite-dimensional, and the index of  $D$  can be defined (see 38) in terms of them. An index theorem conceived by the mathematicians Michael Francis Atiyah (British) and I.M. Singer (U.S.) states that the integer index  $D$  can be expressed in terms of topological invariants, depending on the bundles  $E$ ,  $F$ , and the operator  $D$ . The theorem includes as special cases the Gauss-Bonnet formula, the Hirzebruch signature theorem, and the Riemann-Roch theorem for an arbitrary compact complex manifold.

#### ISOMETRIC IMBEDDING, SUBMANIFOLDS, AND MODERN DEVELOPMENTS IN SURFACE THEORY

Although there is a great variety of manifolds, the Euclidean space is generally regarded as the simplest and the one with the most intuitive appeal. Whether a manifold with a certain structure is equivalent to a submanifold of a Euclidean space of sufficiently high dimension is known as the imbedding problem; the determination of the extent to which the submanifold is thus determined is the rigidity problem. When only the differentiable structure is involved, Hassler Whitney, an American mathematician, proved in 1936 that every differentiable manifold of dimension  $n$  can be imbedded in a Euclidean space of dimension  $2n + 1$ . That the same is true for compact real analytic manifolds was proved by another United States mathematician, Charles Bradfield Morrey, Jr., in 1958. The isometric imbedding problem deals with the imbedding of a Riemannian manifold, with whether a given Riemannian manifold is isometric to a submanifold of some Euclidean space. The local problem—the isometric imbedding of a sufficiently small piece of manifold—was solved by the French mathematicians M. Janet and Élie-Joseph Cartan in 1926, under the additional assumption of analyticity. For an  $n$ -dimensional manifold the dimension required of the ambient space is  $n(n + 1)/2$ , a number long conjectured

by a Swiss mathematician, Ludwig Schläfli. Thus a two-dimensional analytic Riemannian metric is locally that of a surface in Euclidean three-space. The global isometric imbedding theorem of nonanalytic Riemannian manifolds was proved by J. Nash, Jr., in 1954–56.

A special case of the rigidity problem is concerned with the question whether two submanifolds in a Euclidean space are congruent when they are isometric as abstract Riemannian manifolds. If the dimension  $n$  of the submanifolds is greater than two, the condition of isometry is strong enough so that they are almost always congruent. A particular case occurs in the classical theory of surfaces in Euclidean three-space. A theorem that was proved in 1927 by S. Cohn-Vossen states that two closed convex surfaces (surfaces with positive Gaussian curvature everywhere) are equivalent under rigid motions if they are isometric. Easy examples show that the convexity assumption cannot be dropped. An important complement to the Cohn-Vossen theorem is a 1971 result of R. Greene and H. Wu that the conclusion remains true when the surfaces have deleted from them a finite number of their points. A related question concerns the behaviour of a continuous family of closed isometric surfaces. Liebmman proved in 1899 that with the additional hypothesis of convexity such a family must be the one obtained by the rigid motion of one of its members. It is yet an outstanding unsolved problem whether or not it is possible to omit the convexity assumption in Liebmman's theorem.

$$(33) \quad \sum_i (\pi - \alpha_i) + \int_C k_g ds + \iint_M K dA = 2\pi \chi(M)$$

$$(34) \quad \sum_{1 \leq j \leq p} \sum_{\alpha} a_{k,\alpha}^j(x') D^{\alpha} s_j, \quad k = 1, \dots, p$$

$$(35) \quad D^{\alpha} = \frac{\partial^{\alpha_1}}{(\partial x^1)^{\alpha_1}} \cdots \frac{\partial^{\alpha_n}}{(\partial x^n)^{\alpha_n}}$$

$$(36) \quad \alpha = (\alpha_1, \dots, \alpha_n), \quad |\alpha| = \alpha_1 + \dots + \alpha_n$$

$$(37) \quad \left( \sum_{|\alpha|=q} a_{k,\alpha}^j \xi^{\alpha} \right), \quad \xi^{\alpha} = \xi_1^{\alpha_1} \cdots \xi_n^{\alpha_n}$$

$$(38) \quad \text{ind } D = \dim \ker D - \dim \text{coker } D$$

The study of submanifolds in a Euclidean (or non-Euclidean) space is an outgrowth of the classical works of Monge and Gauss and has had important developments in recent years. The new feature lies in the emphasis on global properties. The difficulty of the problems can be realized by noting that the geometrical properties are generally expressed by a system of nonlinear partial differential equations or inequalities and little is known about the behaviour of their global solutions. An important part is furnished by the global theory of surfaces in Euclidean three-space. A surface has two important scalar invariants, the mean curvature  $H$  and the Gaussian curvature  $K$ , which are defined by  $H = (k_1 + k_2)/2$ ,  $K = k_1 k_2$ , in which  $k_1$  and  $k_2$  (referred to as the principal curvatures) are the eigenvalues of the second fundamental form relative to the first fundamental form. Surfaces with  $H$  equal to zero are called minimal surfaces, which are characterized by the local property that any small piece has the least area when compared with other surfaces with the same boundary curve. Among minimal surfaces are the catenoids and right helicoids. A famous problem of Joseph Antoine Ferdinand Plateau, a Belgian mathematician, solved by Tibor Rado and Jesse Douglas in 1930–31, is to show the existence of a minimal surface with a given boundary curve, a fact physically demonstrable by soap-bubble experiments. The solution allows minimal surfaces with singular points. In 1970 Robert Osserman, a United States mathematician,

Global properties

The rigidity problem

proved that the solution of this classical Plateau problem must be a minimal surface that is everywhere regular. It may be readily demonstrated that there is no closed minimal surface in space.

The theory of minimal surfaces is closely related to complex function theory because minimal surfaces are characterized by the property that the spherical mapping into the unit sphere is orientation-reversing conformal. Surfaces with  $H$  equal to a constant include the spheres. Whether a closed surface of constant mean curvature is necessarily a sphere is an unanswered question. It was shown in 1955 by Aleksandr Danilovich Aleksandrov, a Soviet mathematician, that a closed surface of constant mean curvature is a sphere if it does not have self-intersections.

A surface with Gaussian curvature  $K$  equal to zero is referred to as a developable surface and generally consists of the tangent lines of a curve. It is therefore non-compact. To have meaningful results on non-compact surfaces the notion of completeness is introduced: it means that every geodesic can be indefinitely extended. Hartman and Nirenberg proved in 1959 that a complete developable surface must be a cylinder that is generated by the lines parallel to a fixed direction. A complete surface of constant positive Gaussian curvature must be closed (theorem of Myers) and must therefore be the sphere (theorem of Liebmann). David Hilbert, a German mathematician, proved that there is no complete surface of constant negative Gaussian curvature; in other words, such a surface must have a singular point. This result was extended, and it was proved in 1964 that a complete surface with Gaussian curvature  $K \leq -c < 0$  ( $c$  is a constant) must have a singular point. More general than the surfaces of constant mean curvature or constant Gaussian curvature are the Weingarten surfaces, or  $W$ -surfaces. These surfaces satisfy a functional relation between the mean curvature and the Gaussian curvature. Some of the above results can be extended to  $W$ -surfaces.

In regard to a high-dimensional Euclidean space, many investigations have been accorded the minimal varieties of the family of submanifolds. These minimal varieties are direct generalizations of the minimal surfaces, and in respect to them a  $k$ -dimensional submanifold is minimal if a sufficiently small piece of it has the least volume compared with other  $k$ -dimensional submanifolds with the same  $(k-1)$ -dimensional boundary. The most important cases are  $k$  equal to 1 (geodesics) and  $k$  equal to  $n-1$  (minimal hypersurfaces), in which  $n$  is the dimension of the ambient space. When  $n$  is greater than three, the solution of Plateau's problem, that of determining a minimal hypersurface with a given boundary, was only carried out by allowing the submanifold to have singularities. E. Bombieri, E. de Giorgi, and E. Giusti proved in 1969 that this is necessarily the case in high dimensions. It is a natural phenomenon in differential geometry that the study of geometrical problems calls for the introduction of objects that are not everywhere smooth. The study of the singularities and their properties according to the problems in question will likely be one of the major concerns of differential geometry in the future.

In contrast to the Plateau problem is the uniqueness problem. In 1914 S. Bernstein proved that a minimal surface in the Euclidean three-space with the coordinates  $x_1, x_2, x_3$ , which has the representation  $x_3 = f(x_1, x_2)$  for all  $x_1, x_2$ , is a plane. This theorem was extended by de Giorgi, Almgren, and Simons (1965-67) to a Euclidean space of dimension equal to or less than eight. They proved that, in a Euclidean space with the coordinates  $x_1, \dots, x_n$ , a minimal hypersurface that has the representation  $x_n = f(x_1, \dots, x_{n-1})$  for all values of  $x_1, \dots, x_{n-1}$  is a hyperplane. The dimension restriction is essential, for Bombieri, de Giorgi, and Giusti constructed examples in 1968 to show that the same statement is no longer true for  $n$  equal to or greater than nine.

#### COMPLEX MANIFOLDS

By allowing the local coordinates of a manifold to be complex numbers a class of spaces is reached that is restrictive. Such a class of spaces is of great importance

in mathematics. A complex manifold is a manifold the local charts of which have coordinates represented by complex numbers such that the local coordinates of the same point in two charts,  $z^i$  and  $z'^k$  respectively,  $i, k = 1, \dots, n$ , are related by a transformation expressed in terms of holomorphic functions with the Jacobian determinant not equal to zero. The integer  $n$  denotes the complex dimension, and the space, as a real manifold, is of dimension  $2n$ . The simplest example of a complex manifold is furnished by the Gaussian plane  $C$ , which is the space of one complex coordinate  $z = x + iy$ . It is the same as the plane with the two real coordinates  $x, y$  but has the additional structure that it is possible, in the Gaussian plane  $C$ , to have the notions of holomorphic (or complex analytic) functions and conformal transformations. The stereographic projection of a sphere  $S$  in the Euclidean space on  $C$  is conformal and makes  $S$  into complex manifold of dimension one. This, which is referred to as the Riemann sphere, can be regarded as the compactification of  $C$ , as a complex manifold, by the addition of a point at infinity. The compactification process is generally of great importance because it reduces the study of a non-compact space to a compact space relative to the ideal set added to the former. The same situation prevails in high dimensions. The complex projective space  $P_n(C)$  of dimension  $n$  is a space whose points are described by  $n+1$  homogeneous coordinates  $(z_0, z_1, \dots, z_n) \neq (0, 0, \dots, 0)$  such that two sets of homogeneous coordinates define the same point if and only if they are proportional. The space is covered by  $n+1$  charts satisfying respectively the condition  $z_i \neq 0$ ,  $i = 0, 1, \dots, n$ , in which the local coordinates are  $z_j/z_i$ ,  $j \neq i$ ,  $j = 0, 1, \dots, n$ . Each chart represents  $P_n(C)$  with a hyperplane deleted and it itself the  $n$ -dimensional complex number space  $C_n$ . In other words,  $P_n(C)$  is obtained from  $C_n$  by the addition of a hyperplane. The complex projective space is the source of an important class of complex manifolds, viz., the nonsingular algebraic varieties. They are defined by a number of homogeneous polynomial equations in the homogeneous coordinates  $z_0, \dots, z_n$ .

Differential geometry plays a role in the transcendental theory of algebraic varieties because of the use made of the Hermitian metric. A Hermitian metric on a complex manifold is given in terms of the local coordinates  $z_i$ ,  $i = 1, \dots, n$ , by the Hermitian differential form (see 39) involving  $h_{ik}$  that are complex-valued  $C^\infty$ -functions in  $x_j, y_j$  ( $z_j = x_j + iy_j$ ,  $j = 1, \dots, n$ ) having the Hermitian property  $\bar{h}_{ik} = h_{ki}$ . In spite of its formal analogy with a Riemannian metric, the Hermitian structure has more refined properties. In particular, there is intrinsically associated with it a real-valued exterior differential form of degree two (see 40) in which the multiplication of differentials is replaced by the exterior product. The Hermitian metric is called Kählerian if  $\Omega$  is closed; i.e., if  $d\Omega = 0$ . The Kählerian metric is said to be of restricted type if the integral of  $\Omega$  over any two-dimensional integral cycle is a rational number. The previously referred to complex projective space  $P_n(C)$  has a Kählerian metric of restricted type, the Fubini-Study metric, which is defined in terms of the homogeneous coordinates  $z$  (see 41). As a consequence, every nonsingular algebraic va-

The compactification process

$$(39) \quad ds^2 = \sum_{i,k} h_{ik} dz_i d\bar{z}_k, \quad i, k = 1, \dots, n$$

$$(40) \quad \Omega = \frac{i}{2} \sum_{i,k} h_{ik} dz_i \wedge d\bar{z}_k$$

$$(41) \quad ds^2 = \frac{\left( \sum_i |z_i|^2 \right) \left( \sum_k dz_k d\bar{z}_k \right) - \left( \sum_i \bar{z}_i dz_i \right) \left( \sum_k z_k d\bar{z}_k \right)}{\left( \sum_i |z_i|^2 \right)^2}$$

$$i, k = 0, 1, \dots, n$$

Complete surfaces

riety of  $P_n(C)$  inherits a Kählerian metric of restricted type. The Kodaira imbedding theorem states that the converse is true: every compact complex manifold with a Kählerian metric of restricted type can be imbedded in a complex projective space of sufficiently high dimension as an algebraic variety.

Two typical problems on complex manifolds are now presented. The first concerns the Abelian differentials, exterior differential forms (see 42), the coefficients of which are holomorphic functions. On a compact complex manifold  $M$  the maximum number of linearly independent forms of this kind of a given degree  $k$  is a finite integer  $h_{k0}$ . Their alternating sum (see 43) is referred to as the arithmetic genus of  $M$ . The relation of the arithmetic genus, which is an analytical invariant, with some of the geometrical invariants of  $M$ , the characteristic classes, is given by the Riemann-Roch-Hirzebruch theorem.

$$(42) \quad \sum a_{i_1 \dots i_k}(z) dz^{i_1} \wedge \dots \wedge dz^{i_k}$$

$$(43) \quad \sum_{0 \leq k \leq n} (-1)^k h_{k0}, \quad n = \dim_c M$$

The second problem is the role played by the measures that arise from the Hermitian metric. In the simple case of a holomorphic curve  $f: M \rightarrow P_1(C)$ , which is the same as a meromorphic function over the Riemann surface  $M$ , the area of the image  $f(M)$  leads to the Nevanlinna order function in the definition of Ahlfors-Shimizu. This and its generalizations are of fundamental importance in the study of holomorphic curves in  $P_n(C)$ .

#### LOCAL AND GLOBAL PROBLEMS

Problems in differential geometry can generally be divided into two types: local problems and global problems. The tangent space at a point and different concepts of curvature are local problems. But the validity of a certain local property throughout the manifold could impose strong restrictions on the manifold as a whole; the determination of such restrictions is a global problem. Thus, there are pieces of surfaces in Euclidean space with constant Gaussian curvature, but the spheres are the only surfaces that have constant Gaussian curvature and that are closed. Also, it is a local property for a curve on a Riemannian manifold to be a geodesic, but the index of a geodesic (i.e., the number of essentially different deformations that shorten the geodesic with the end-points fixed) is a global invariant. Other problems on geodesics concern the existence or nonexistence of closed geodesics and the ergodicity of geodesic flows, both of which are global problems.

**BIBLIOGRAPHY.** Among the books on differential geometry the following may be recommended: SHOSHICHI KOBAYASHI and KATSUMI NOMIZU, *Foundations of Differential Geometry* (1963); JAMES J. STOKER, *Differential Geometry* (1969); FRANK W. WARNER, *Foundations of Differentiable Manifolds and Lie Groups* (1971). For topology and fibre bundles, see EDWIN H. SPANIER, *Algebraic Topology* (1966); and DALE HUSEMOLLER, *Fibre Bundles* (1966). For complex manifolds, see S. CHERN, *Complex Manifolds Without Potential Theory* (1967); and F. HIRZEBRUCH, *Neue topologische Methoden in der algebraischen Geometrie*, 2nd ed. (1962; Eng. trans., *Topological Methods in Algebraic Geometry*, 3rd ed., 1966). For K-theory and the index theorem, see MICHAEL F. ATIYAH, *K-theory* (1964); RICHARD S. PALAIS (ed.), *Seminar on the Atiyah-Singer Index Theorem* (1965); MICHAEL F. ATIYAH and I.M. SINGER, "The Index of Elliptic Operators, I-V," *Ann. Math.*, vol. 88 and 93 (1968-71). Recent papers on minimal varieties include JAMES SIMONS, "Minimal Varieties in Riemannian Manifolds," *Ann. Math.*, 88:62-105 (1968); ROBERT OSSERMAN, "A Proof of the Regularity Everywhere of the Classical Solution to Plateau's Problem," *Ann. Math.*, 91:550-569 (1970); E. BOMBIERI, E. DE GIORGI, and E. GIUSTI, "Minimal Cones and the Bernstein Problem," *Inven. Math.*, 7:243-268 (1969).

## Geometry, Euclidean

One of the outstanding achievements of the ancient Greeks was the construction of a deductive system of geometry, which, beginning with principles that they regarded as obviously true and derived from experience, culminated in quite deep theorems, some of which are still an important part of mathematics. The elementary part of the deductive system of geometry was set forth in Euclid's *Elements*, and, until the early 20th century, Euclidean geometry meant the material in that book and others written in the same spirit. Euclid reasoned on the figure drawn on the page or envisioned in the imagination, and he often assumed details and relations read from the figure that were not explicitly stated. The figure was an important constituent of the proof, although it was never made clear how far it should be used. Partly because Euclid's geometry was considered to be the only geometry, no one bothered to question or examine many of its details.

Toward the end of the 19th century another view emerged, and Euclidean geometry is now regarded as merely one example of an abstract mathematical doctrine. In any deductive theory, because each theorem is proved from preceding theorems, a beginning must be made somewhere with unproved assumptions. These assumptions are called axioms, replacing Euclid's word postulates. Whether, or in what sense, they are "true" is no concern of the theory: any set of axioms may be laid down provided that they do not yield two contradictory theorems. Likewise, as each technical term (e.g., square or perpendicular) is defined by reference to earlier terms, this chain cannot lead backward indefinitely, and a beginning must be made with certain undefined terms. What these terms mean is of no concern in the abstract theory, although they may acquire meaning in some application of the theory. The undefined terms may be elements, such as point, line, or relations such as "lies on" in the statement: the point  $A$  lies on the line  $l$ . If, for example, a triangle  $ABC$  is defined as the set of points on the sides  $BC$ ,  $CA$ ,  $AB$ , together with the points  $A$ ,  $B$ ,  $C$ , then the terms "point" and "side" must either have been defined previously or be taken as undefined. The term set, however, is a concept of logic, and it is assumed that logic has already been developed. Many writers on an abstract doctrine try to reduce the number of undefined terms and of axioms to a minimum.

Until the 20th century the book of Euclid or one of its many variants was used in all schools, a use, however, that was ultimately attacked justifiably from two sides: Euclid was too abstract for beginners, yet not exact enough to satisfy modern requirements. The modern abstract treatment was initiated by mathematicians in Germany and Italy, by Moritz Pasch in 1882, Giuseppe Peano in 1889 and Mario Pieri. The most influential work was that by the well-known German mathematician David Hilbert, *Grundlagen der Geometrie* (1899; *The Foundations of Geometry*, 1902).

Euclid (q.v.), who lived in Alexandria in the time of the first Ptolemy (323-285/283 BC), systematized in his book the work of his predecessors, beginning with Pythagoras (died c. 500 BC) and his followers. It was the basis of the more advanced studies of Apollonius of Perga (3rd century BC) on conics and of Archimedes (q.v.; 3rd century BC) on mechanics and the areas of circles. After the collapse of European civilization the Muslim countries continued the tradition. The *Elements* was translated into Arabic during the reign of Hārūn ar-Rashīd (786-809), and the first Latin version in a complete form was made from the Arabic by the English scholastic philosopher Adelard of Bath about 1120. The book was thus known to some extent in the Middle Ages, but not until the invention of printing in the 15th century was it seriously studied at Oxford and Cambridge. The first complete English translation was that of Sir Henry Billingsley in 1570; other important editions were those of Robert Simson (Latin and English) in 1756 and Isaac Todhunter in 1862. The standard English edition is now that of Sir Thomas Little Heath, published in 1908.

Deductive theory as an abstract mathematical doctrine

The *Elements*

## EUCLID'S WORK

**Euclid's definitions and axioms.** Euclid began his work with definitions, axioms, and "common notions." He describes a point as something with no part, a line (what would now be called an arc, or curve) as length without breadth, and a straight line as one that lies evenly with its points. It is clear that these cannot now be taken as definitions in the modern spirit, referring back, as they do, to notions not only undefined but obscure. His definition of a circle (the usual one), however, can be taken over into the modern abstract theory. It should be noted that straight line in modern geometry means the infinite line, whereas for Euclid it means the portion between two points, now called an interval, which can be "prolonged" in both directions.

The axioms that Euclid explicitly stated were five in number (see Box, axioms 1–5), of which the fifth, since called the parallel axiom, is the most famous. Without explicitly stating it, he assumed that the join between two points is unique.

**Euclid's common notions.** Euclid's common notions are also five in number (see 6–10). The first three concern "equals" or "equal things"; the fourth is interpreted now to mean that if two figures, such as intervals, angles, triangles, or circles, are such that one can be moved to coincide with the other, the figures are equal. They would now be called congruent. Two ideas run through these common notions: (1) that geometrical figures can be treated as magnitudes, and (2) that, if one figure is visibly part of another (perhaps after a motion), then the magnitude of the part is less than the magnitude of the whole.

**Euclid's Book I: congruence of triangles.** Euclid's Book I is in two sections, the first dealing with the congruence of triangles, without any use of parallels. It is interesting to observe that even in his first theorem, in which he constructs an equilateral triangle, Euclid assumes from the figure that two constructed circles intersect. With the aid of this construction he shows that if  $AB$  is a given interval and  $OX$  a given line, then using only the third axiom, an interval  $OP$  can be cut off  $OX$  congruent to  $AB$ . Thus his compasses can be allowed to collapse after a circle is drawn; they need not be used to transfer lengths. His fourth theorem is the first congruence of triangles. It states that if in triangles  $ABC$ ,  $A'B'C'$ , the sides  $BA$ ,  $BC$ , and the angle between them,  $\angle ABC$ , are respectively congruent to  $B'A'$ ,  $B'C'$ ,  $\angle A'B'C'$ , then  $AC$  is congruent to  $A'C'$ . (The word congruent here replaces Euclid's "equal.")

Euclid's  
concept of  
congruence

For proof he takes up triangle  $ABC$  and moves it so that  $B$  falls on  $B'$ , the line  $BA$  lies along  $B'A'$ , and  $C$  lies on the same side of  $B'A'$  as  $C'$ . He concludes that  $C$  falls on  $C'$  and hence  $AC$  on  $A'C'$ . Even putting aside what is meant by motion, this proof would succeed only if it were assumed that  $AC$  maintained a constant length. Since this assumption is just what the theorem is supposed to prove, the reasoning is circular. Euclid himself evidently had doubts, for he employs this "method of superposition" only once again, in the proof of the 24th theorem of the third book, although its use would have shortened many other proofs.

**Euclid's Book I: other theorems.** Once the first congruence has been stated, others, involving three sides, and a side and two angles, follow if it is assumed that the lengths of intervals and the sizes of angles satisfy the common notions. Euclid reads these assumptions from his figures. In the context of verifying the fifth theorem he proves that an isosceles triangle has congruent base angles. The involved proof acquired the name of *pons asinorum* ("asses' bridge," or path over which to guide the obstinate). Later, he solves the two problems, to bisect a given angle or interval and to draw a perpendicular to a line from a point not on it. The proof of theorem 16 shows that if a side of a triangle is produced, the exterior angle is greater than either of the opposite interior angles, and the proof of theorem 18 shows that if a triangle has two unequal sides, the greater side is opposite the greater angle. Following the statement of theorem 20, Euclid proves the intuitive result that the sum

## EUCLID'S AXIOMS

- (1) Given two points there is an interval that joins them.
- (2) An interval can be prolonged indefinitely.
- (3) A circle can be constructed when its centre, and a point on it, are given.
- (4) All right angles are equal.
- (5) If a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which the angles are less than the two right angles.

## EUCLID'S COMMON NOTIONS

- (6) Things equal to the same thing are equal.
- (7) If equals are added to equals, the wholes are equal.
- (8) If equals are subtracted from equals, the remainders are equal.
- (9) Things that coincide with one another are equal.
- (10) The whole is greater than a part.

of the lengths of the sides  $AB$ ,  $BC$  in a triangle exceeds the length of  $AC$ , indicating that he desired to keep the number of axioms as low as possible.

**Euclid's Book I: results independent of the parallel postulate.** It is highly important to note that so far in Euclid's Book I no use has been made of parallel lines, defined as coplanar lines that do not meet. From theorem 16 it can be proved that if  $AB$  is any line and  $P$  a point not on it, at least one line parallel to  $AB$  can be drawn through  $P$ ; and axiom 5 states in a complicated way that this parallel is the only one. The parallel axiom in its strongest form would be: given a line  $AB$  and a point  $P$  not on it, exactly one parallel can be drawn to  $AB$  through  $P$ .

The long series of attempts to prove uniqueness, using only the other postulates and axioms and the first part of Book I, resulted always in failure; but they led ultimately to a far more important success: the creation of non-Euclidean geometry, a landmark in the history of thought. With the use of the concept of parallel lines, theorem 16 can be made more precise: the exterior angle is the sum of the two opposite interior angles.

Basis for  
non-  
Euclidean  
geometry

**Euclid's Books I and II: equivalence of parallelograms and dissection of rectangles.** The rest of Book I deals with the equivalence of parallelograms and will be analyzed later. It culminates in Pythagoras' theorem: if  $ACB$  be a right angle, the square drawn on  $AB$  is the sum of those drawn on  $AC$  and  $BC$ . This concerns the actual dissection and putting together of pieces of squares, not the formula  $c^2 = a^2 + b^2$  on the numerical squares of the lengths of the sides.

In Book II, Euclid gives results on the dissection of rectangles that would now be expressed as algebraical formulas; for example,  $(a + b)^2 = a^2 + 2ab + b^2$ . This book concludes with the construction of a square equivalent in area to a given polygon.

**Euclid's Book V: Eudoxus' treatment of incommensurables.** The reason that compelled Euclid to proceed in this way must now be explained. The Pythagoreans had proved that the diagonal of a square was incommensurate with its sides; i.e., no unit length exists of which both are multiples. In present-day language,  $\sqrt{2}$  cannot be expressed as the quotient of two integers. Thus, the Greeks had to regard lengths as what are now called real numbers; and before such numbers could be multiplied together, a theory of real numbers was needed.

The work  
of Eudoxus

The Greek solution of this very difficult problem is given in Book V. It is usually ascribed to Eudoxus of Cnidus and is completely acceptable even today. Four magnitudes  $a, b, c, d$  of any kind are said to be in proportion if, using modern algebraical notation, not known to the Greeks, the following is true:

If  $m, n$  are any natural numbers, then  $na$  is less than, equal to, or greater than  $mb$ , according as  $nc$  is less than, equal to, or greater than  $md$ .

If this relation between the four terms  $a, b, c, d$ , expressed in words by the Greeks, is written  $a|b \sim c|d$ , then the expected consequences follow; for example,  $b|a \sim d|c$ ,  $a|c \sim b|d$ ,  $(a+b)|b \sim (c+d)|d$ . All of these are proved with complete rigour. The theory of real numbers constructed by the two great German mathematicians Karl Theodor Weierstrass and Richard Dedekind during the 19th century is a modern version of the Greek work.

**Euclid's Books III, IV, VI, XI, XII, XIII.** Much of the theory in books III and IV on circles is still acceptable in today's abstract treatment. Theorem 21 states that if  $A, B, P, Q$  are on a circle with  $P, Q$  on the same side of  $AB$ , then the angles  $APB, AQB$  are congruent. Theorem 31 states that if  $AB$  is a diameter and  $P$  is on the circle, the angle  $APB$  is a right angle. Theorems 35 and 36 state that if  $AB, CD$  are chords of a circle that meet in  $P$ , then the rectangle (the actual figure) the sides of which are congruent to  $PA, PB$  is equivalent to the rectangle the sides of which are congruent to  $PC, PD$ . ("Equivalent" may provisionally be regarded as meaning "of equal area.")

Theorem 11 of Book IV gives an ingenious construction for inscribing a regular pentagon in a given circle. Book VI applies the theory in V to questions of areas and proves essentially in theorem 15 that if a rectangle with sides  $a, b$  is equivalent to one with sides  $c, d$  then  $a|c \sim d|b$ .

Book XI, on solid geometry, uses the parallel axiom throughout, and, consequently, this book does not have the permanent value that Book I has. The work on volumes in Books XI and XII uses the method of exhaustion that is presented in theorem 1 of Book X. In modern form this would read: if  $a$  is any real number, then there is an integer  $n$  such that  $|a2^{-n}|$  is less than any pre-assigned positive number. That some such device is actually needed for volumes, though not for areas of polygons, will be shown later.

The regular  
solids

Finally, Book XIII gives constructions for the regular solids: the tetrahedron, the four faces of which are equilateral triangles; the cube, the six faces of which are squares; the octahedron and icosahedron, the faces of which are, respectively, eight and 20 equilateral triangles; and the dodecahedron, the 12 faces of which are regular pentagons.

#### GEOMETRY AS AN ABSTRACT DOCTRINE

Toward the end of the 19th century the keenest thinkers in the field of geometry became increasingly concerned about the lack of true rigour in Euclid's presentation. Undoubtedly, the invention of non-Euclidean geometries did much to spur the search for a correct and complete treatment of classical geometry. The most notable work of the new type was, as has already been remarked, Hilbert's *Grundlagen der Geometrie*, published in 1899. Hilbert began by stating 21 axioms involving six primitive or undefined terms. He once made a famous comment (not actually published until 1935) to emphasize the importance of keeping the undefined terms totally abstract, that is, devoid of preconceived meaning: "One must be able to say at all times—instead of points, straight lines, and planes—tables, chairs, and beer mugs." Such a viewpoint was not widely accepted until the 20th century and, of course, had never occurred to Euclid or his followers. An Italian, Gino Fano, put it similarly even before Hilbert:

As basis for our study we assume an arbitrary collection of entities of an arbitrary nature; entities which, for brevity, we shall call points, and this quite independently of their nature.

To lay a solid foundation for Euclidean geometry, Hilbert's list of axioms or their equivalents (see 11–49) are not only sufficient but also necessary. It may be possible to manage with fewer, but even slight refinements of assumptions introduce burdensome complications. The content and style of this list are altogether different from Euclid's. A careful examination of such a list gives an idea of the nature of the problems involved when complete rigour is the goal.

The hope that Hilbert's treatment or its equivalent could be substituted for Euclid's in the schools was dashed by what the French geometer René Thom has called in the second half of the 20th century "the dreadful complexity of this work."

The undefined elements are called points, lines, and planes; and the set of all of them is called a space. From the last two axioms of incidence (see 17 and 18), something can be deduced about the dimension of the space. It then becomes possible for a line to be regarded as a set of points, although that is not necessary. It is equally possible for a point to be regarded as a set of lines, all the lines lying on that point (intuitively, concurrent in that point). By means of the axioms of betweenness and order (see 22–27), the abstract points of an abstract line can be shown to have all the properties associated with the intuitive notions of betweenness and order.

A plane can be defined in terms of points and lines, thereby reducing by one the number of completely undefined objects. To all the properties of the plane further properties are adjoined in order to attain three-dimensional space.

Euclid's theorem stating that two triangles are congruent if two sides and the included angle of one are equal, respectively, to two sides and the included angle of the other is replaced by the last axiom of congruence (see 35). This is rather complicated; and it is important to note that it is an axiom, not a theorem. Euclid's statement cannot be proved on the basis of the other axioms alone. That the five axioms of congruence (see 31–35) are, in fact, a sufficient basis for the theory of congruence in the plane and in space was proved by J.L. Dorroh, of the United States. Following work by Henry G. Forder of New Zealand and Pál Szász in Hungary, J.F. Rigby in England proved in the middle of the 20th century that it is possible to replace the last congruence axiom (see 35) by one that is simpler. Rigby also succeeded in weakening the first congruence axiom (see 31), and it may now be the case that the solution to the problem of finding a minimal set of axioms for congruence has finally been achieved.

With the aid of these congruence axioms, Euclid's famous parallel postulate can be restated in a simpler form (see 41).

**Hilbert's division of axioms.** Geometry will now be discussed, consistently with the above remarks, as an abstract doctrine with all assumptions explicit and with nothing read from the figure. Hilbert, in his *Grundlagen*, divides the axioms into five groups dealing, respectively, with incidence, order, congruence, parallels, and continuity.

The undefined elements are of three kinds: points, lines, and planes. Points will be denoted by  $A, B, \dots$ , lines by  $a, b, \dots$ , and planes by the Greek letters alpha, beta,  $\dots$ ; that is,  $\alpha, \beta, \dots$ . The set of all of these elements is called a space. Certain undefined relations that are considered below will hold between certain elements. The symbol  $=$  between two signs will mean that the signs denote the same element. The symbol  $\neq$  will mean that the elements are distinct.

**Axioms of incidence.** There is an undefined relation, incidence, which holds between certain points and lines or between certain points and planes. The relation is symmetric; for example, if  $A$  is incident with  $\alpha$ , so is  $\alpha$  with  $A$ . It will be a convenience of language to say that " $A$  lies on  $\alpha$ ," " $\alpha$  goes through  $A$ ," instead of " $A$  is incident with  $\alpha$ ." Similar phrases will be used for points and planes. Conformably with this usage a line or plane may be regarded as a set of points, though this is not necessary. The axioms of incidence are expressed as eight

Points,  
lines, and  
planes

Concepts  
of  
dimension

separate statements (see 11–18). By one incidence axiom (see 17) that concerns the existence of a second point lying on the intersection of two planes, it can be deduced that space has not more than three dimensions. In fact, in four-dimensional space it is possible for two planes to meet in just one point. The last axiom (see 18) says space has not less than three dimensions. From these axioms the following statements can be deduced: if two distinct lines lie on the same plane, then either no point or just one point lies on both; given two distinct planes, either no point lies on both or just one line lies on both; if a line does not lie in a plane, then either no point or just one point lies on both.

**Order and betweenness.** *Axioms of order.* In any collection of things (for example, points, numbers, men, classes), there may be a relation between certain pairs of elements, which is not symmetrical; that is, if  $a$  stands in that relation to  $b$ , then  $b$  does not stand in that relation to  $a$ . This is the case, for instance, if  $a, b$  are numbers and the relation is “less than.” A general relation of this kind may be denoted by  $<$ , and three axioms (see 19–21) that characterize the relation  $<$  may be assumed. A collection satisfying these three axioms is said to be in linear order. The set of real numbers satisfying the relation “less than” is an example.

*Relation of betweenness.* In geometry there is an undefined relation connecting certain sets of three points, called betweenness.

First, if the relation between three people expressed by “ $A$  prefers  $B$  to  $C$ ” is considered, then with the usual meaning of these words, it is false that  $A$  prefers  $C$  to  $B$ , but human relations might be so nicely adjusted that it always followed that  $C$  preferred  $B$  to  $A$ .

If  $[ABC]$  is written for the statement “ $A$  prefers  $B$  to  $C$ ,” then that  $[ABC]$  is true would imply that  $[ACB]$  is false but  $[CBA]$  is true. The undefined relation between triads of points does, in fact, have these properties.

*Axioms of betweenness.* The symbol  $[ABC]$  shall mean that the points  $A, B, C$  are in the relation of betweenness. Two axioms can be assumed for this relation (see 22, 23). If geometry has already been constructed, the reader may interpret  $[ABC]$  to mean, say,  $AB, BC$  are perpendicular, or  $B$  is the midpoint of  $AC$ , or  $A, C$  are on a circle the centre of which is  $B$ , and consider which of these statements is true. An intuitive interpretation for which these and all the following would be true is:  $B$  is on the line  $AC$  and is between  $A$  and  $C$ .

*Line defined in terms of order.* The term line was undefined in rigorous terms by Euclid. It can now be defined by means of order. If  $A, B$  are distinct points, the line  $AB$  is the set of points  $P$  such that either  $[PAB]$  or  $[APB]$  or  $[ABP]$ , together with the points  $A, B$ . When a line  $XY$  is mentioned,  $X \neq Y$  is assumed. The “segment”  $AB$  is one set of points  $P$  such that  $[APB]$ . The interval  $AB$  is this set with  $A, B$  adjoined. The ray  $AB$  is the set of points  $P$  such that  $[APB]$  or  $[ABP]$ .

The remaining axioms of order, based on betweenness, are expressed in four distinct statements (see 24–27). Figure 1 conveys the meaning of one axiom (see 27).

A lengthy and not very easy argument can be used to show that if there are  $n$  points on a line, they can be named  $A_1, A_2, \dots, A_n$ , so that  $[A_i A_j A_k]$  holds if and only if  $i < j < k$  or  $k < j < i$ . The points of a line defined in the abstract sense now have all the properties associated with the intuitive notion of order.

**Results based on order and betweenness.** *Definition of a plane.* The term plane undefined by Euclid can now be defined. If  $ABC$  is a triangle, the plane  $ABC$  is the set of all points on all lines joining any two points of the triangle. In the presence of the axioms given, this is equivalent to saying that the plane is the set of all points on the lines joining the vertices to the points on the opposite side. From either definition it can be proved that if  $X, Y, Z$  are non-collinear points on plane  $ABC$ , then  $ABC, XYZ$  coincide; i.e., every point on one is on the other. Also, the so-called Pasch’s axiom can be proved: if a line lies in the plane of a triangle  $ABC$  and meets the side  $AB$ , then it either goes through  $C$  or it meets side  $AC$  or side  $BC$ . A side of a triangle is taken to be a segment, not

an interval. Theorems such as these were read by Euclid from his figures, but they cannot be said to have been proved that way.

To get three dimensions, a further axiom can be assumed to the effect (see 28) that not all points are in the same plane. Then if  $A, B, C, D$  be non-coplanar points, the tetrahedron  $ABCD$  can be defined as usual; and the space  $ABCD$  can be defined in a way analogous to the first definition of a plane above. Finally, to restrict space to three dimensions, assume (see 29) that all points are in the same space. These last two assumptions (28, 29) will be referred to as axioms of dimension.

*Theorems concerning polygons.* Theorems on the inside and outside of polygons, assumed implicitly by Euclid, can be formulated and proved from the axioms of order and betweenness. If  $A_1, \dots, A_n$  ( $n > 2$ ) be distinct

#### THE AXIOMS OF INCIDENCE

- (11) Given distinct points  $A, B$ , there is at least one line  $a$  incident with both  $A, B$ .
- (12) There is at most one such line.
- (13) Each line has at least three points incident with it. There are at least three points not on the same line.
- (14) If  $A, B, C$  are three distinct points not on the same line, there is at least one plane incident with all three.
- (15) There is at most one such plane.
- (16) If  $A, B$  are distinct points on a line  $l$  that lies on a plane  $\alpha$ , then all points of  $l$  lie on  $\alpha$ . One writes “ $l$  lies on  $\alpha$ ”, “ $\alpha$  goes through  $l$ ”.
- (17) If a point lies on two distinct planes, at least one other point lies on both planes.
- (18) There are at least four points not on the same plane.

#### AXIOMS OF LINEAR ORDER

- (19) If  $a < b$ , then  $a \neq b$ .
- (20) If  $a < b$  and  $b < c$ , then  $a < c$ .
- (21) If  $a \neq b$ , then at least one of  $a < b, b < a$  holds.

#### AXIOMS OF BETWEENNESS

- (22) If  $[ABC]$  is true, then  $A, B, C$  are distinct.
- (23) If  $[ABC]$  is true, then  $[BCA]$  is false.

#### AXIOMS OF ORDER

- (24) If  $C, D$  are distinct points on the line  $AB$ , then  $A$  is on the line  $CD$ .
- (25) If  $A, B$  are distinct points, there is at least one point  $P$  such that  $[ABP]$ .
- (26) There are (at least) three points  $A, B, C$  not on the same line.
- (27) If  $A, B, C$  are distinct points and  $A$  is not on the line  $BC$  and if  $[BCD], [CEA]$ , then there is a point  $F$  on the line  $DE$  such that  $[AFB]$ .

#### AXIOMS OF DIMENSION

- (28) Not all points are in the same plane.
- (29) All points are in the same space.
- (30) There is a point not in  $S_3$ .

Properties  
of order

Figure 1: Illustration of an axiom of order. In the diagram, if  $A, B, C$  are distinct points and  $A$  is not on the line  $BC$ , and if  $C$  is between  $B$  and  $D$  and if  $E$  is between  $C$  and  $A$ , then there is a point  $F$  on the line  $DE$  such that  $F$  is between  $A$  and  $B$ .

points, no three consecutive points being collinear, then the set of intervals  $A_1A_2, A_2A_3, \dots, A_{n-1}A_n$  form a path with vertices  $A_1, \dots, A_n$ . The path is simple if no two of these intervals have a common point, not a vertex (see below), and no three of them meet in any point. If  $A_1, \dots, A_{n-1}$  are distinct, but  $A_n = A_1$ , the path is a polygon.

A region is a set of points, not all collinear, any two of which can be joined by a path all of whose points are in the set. If  $[X], [Y]$  are sets of points and  $[S]$  a set such that every path from a point of  $[X]$  to a point of  $[Y]$  meets  $[S]$ , then  $[S]$  separates  $[X]$  from  $[Y]$ .

The following can be proved from the axioms of order and betweenness:

If a simple polygon lies in a plane, the points of the plane not on the polygon are separated by the polygon into two regions. One of these regions, the outside, contains lines not meeting the polygon; but any line through any point of the other region, the inside, meets the polygon. Figure 2 is helpful in considering this theorem. As a preliminary, it should first be proved that a line in a plane separates the points not on it into two regions.

Figure 2: The points of a plane that are not on a polygon are separated by the polygon into two regions, the "inside" and the "outside."

Abstract  
concept of  
angle

An angle is a pair of non-collinear rays from a point  $O$ , the vertex. An angle in a plane separates the other points of the plane into two regions, the inside and outside, with the same properties as above. If  $AOB$  be an angle, the rays through  $O$  inside the angle can be ordered by the relation between, using the points at which they meet  $AB$ . Euclid read such relations from his figures.

**Dissection of geometric figures.** A simple polygon can be dissected into triangles with their vertices at the vertices of the polygon; that is, a set of triangles can be found, no two of which have a common inside point, and such that every point inside the polygon is inside or on one of the triangles and every point inside a triangle is inside the polygon. The corresponding theorem for space is false. An eight-faced polyhedron has been constructed, as suggested by Figure 3, which cannot be split into tetrahedra with their vertices at the vertices of the polyhedron because the join of any two vertices, unless it is an edge, lies entirely outside the polyhedron.

When the points on a line are ordered by the betweenness relation, intuition suggests that it should be possible to take a direction on the line so that the points could be put into linear order as discussed in the section *Axioms of order*. This can be done though the work is tedious. So also the theory of the inside and outside of polyhedra can be erected, and it can be proved that any polyhedron can be dissected into tetrahedra, though their vertices may fall inside the polyhedron.

**Certain difficult theorems.** These theorems follow from the axioms of order and betweenness and the first two axioms of dimension. They are not intuitively obvious and are hard to prove.

Figure 3: (Left) A prism whose base is an equilateral triangle transformed by a screw operation and a caving in of the side faces into (right) an eight-faced polyhedron. The resulting polyhedron cannot be split into tetrahedra with their vertices at the vertices of the polyhedron.

If a finite set of points in a plane is such that the line joining any two contains a third point of the set, then all the points lie on one line.

Let a convex polygon be defined as one such that the segment joining two inside points has all its points inside; then if  $n$  points, no three collinear, are in a plane, and all quadrilaterals formed from any four of them are convex, the points are the vertices of a convex polygon.

The  
convex  
polygon

If  $l_1 \dots l_4$  are four lines in space, no three coplanar, and the five pairs following are coplanar:  $l_1l_2, l_1l_3, l_1l_4, l_2l_3, l_2l_4$ , then  $l_3l_4$  are coplanar.

(The Euclidean parallel axiom must not be used here.)

**Congruence.** *Axioms of congruence.* In his axioms of congruence, Hilbert takes as undefined the congruence of intervals and of angles. It is more fundamental to take only the congruence of point pairs as undefined, the pairs being ordered, that is  $(A, B)$  and  $(B, A)$ , are regarded as distinct pairs and always  $A \neq B$ . The undefined relation " $(A, B)$  is congruent to  $(C, D)$ ," written  $(A, B) \simeq (C, D)$ , holds between certain pairs.

Five axioms (see 31–35) are assumed, and these are called the axioms of congruence. If the first four of these

#### AXIOMS OF CONGRUENCE

- (31) If points  $A, B, A', X$  are given, then there is just one point  $B'$  on the ray  $AX$  such that  $(A, B) \simeq (A', B')$ .
- (32) If  $(A, B) \simeq (C, D)$  and  $(C, D) \simeq (E, F)$  then  $(A, B) \simeq (E, F)$ .
- (33) If  $[ABC], [A'B'C']$  and  $(A, B) \simeq (A', B')$  and  $(B, C) \simeq (B', C')$ , then  $(A, C) \simeq (A', C')$ .
- (34)  $(A, B) \simeq (B, A)$ .
- (35) If  $ABC, A'B'C'$  are two triangles and if  $[ABD], [A'B'D']$  and if  $(A, B), (B, C), (C, A), (B, D)$  are respectively congruent to  $(A', B'), (B', C'), (C', A'), (B', D')$ , then  $(C, D) \simeq (C', D')$ .

## ELEMENTARY CONSTRUCTIONS

- (36) Given two distinct points, the line on which both lie can be drawn.
- (37) If two lines meet, their common point can be drawn.
- (38) If  $A, B$  are distinct points,  
 (i). a point  $C$  can be found satisfying  $[ABC]$   
 (ii). a point  $D$  can be found satisfying  $[ADB]$ ,  
 (iii). a point can be found not on the line  $AB$ .
- (39) If  $CD$  is an interval and  $AB$  any ray, a point  $P$  can be found on  $AB$  satisfying  $AP \approx CD$ .

## THE GAUGE CONSTRUCTION

- (40) A fixed interval  $XY$ , the "gauge", is given; and if  $OP$  is any ray, the point  $Q$  on  $OP$  such that  $OQ \approx XY$  is constructable.

## THE WEAKENED PARALLEL POSTULATE

- (41) There is at least one plane that contains at least one line  $l$  such that if  $P$  is any point on the plane and not on  $l$ , not more than one parallel to  $l$  goes through  $P$ .

## THE CONTINUITY AXIOM

- (42) The points of a segment can be put into one-to-one correspondence with the real numbers strictly between 0 and 1. This need be assumed for only one segment.

## ARCHIMEDES' AXIOM

- (43) If  $A_1, A_2, P$  are collinear points, then there is an integer  $n$  such that if  $[A_1 A_2 \cdots A_n]$ ,  $A_1 A_2 \approx A_2 A_3 \approx \cdots \approx A_{n-1} A_n$  hold, then  $[A_1 P A_n]$ .

five axioms of congruence are assumed, then it follows that  $\approx$  is an equivalence relation in the meaning that is now current.

Two sets of points  $[X], [Y]$  will be called congruent if they can be put into one-to-one correspondence in such a way that if  $A, B$  in  $[X]$  correspond to  $A', B'$  in  $[Y]$ , then  $(A, B) \approx (A', B')$ . In particular, for two intervals, it can be proved that  $AB \approx CD$  if, and only if,  $(A, B) \approx (C, D)$ . Since an angle is a pair of rays, then  $\angle ABC \approx \angle A'B'C'$  will hold if, when  $X, Y, X', Y'$  are, respectively, on the rays  $BA, BC, B'A', B'C'$  and  $BX \approx B'X', BY \approx B'Y'$ , then  $XY \approx X'Y'$ ; and triangles  $ABC, A'B'C'$  will be congruent if, and only if, the corresponding sides are congruent.

The only existence statement is in the first congruence axiom (see 31), and it makes the second axiom of order (see 25) superfluous.

**Elementary constructions.** There are four elementary constructions (see 36–39) corresponding to the axioms of betweenness, order, and congruence.

**Theorems that can be proved.** The following can be proved, roughly in the order given: three non-collinear points cannot be congruent to three collinear points; using the elementary constructions, a given angle can be bisected, the bisector is unique; a perpendicular can be

drawn to a given line from a given point, on the line or not on it; this perpendicular is unique; all right angles are congruent in the plane or in space; each interval has a unique midpoint that can be constructed; a unique triangle can be constructed with its base on a given line and lying on a given side of the line, congruent to a given triangle. The theorems in Euclid's Book I on congruent triangles appear here as side issues; but it is interesting to notice that Euclid used circles, which are not used here.

As for the addition of angles, if the ray  $l$  lies inside the angle  $hk$ , the sum of two angles congruent, respectively, to the angles  $hl, lk$  is defined to be an angle congruent to  $hk$ . The usual properties of addition follow, except that the sum of two angles need not exist.

The usual theorems on perpendicular lines and planes in space also follow from the axioms of congruence. In particular, if both planes  $\alpha_1, \alpha_2$  are perpendicular to the line in which planes  $\beta, \gamma$  meet, then they meet  $\beta, \gamma$  in lines that form congruent angles. Thus, the dihedral angle between  $\beta, \gamma$  can be defined.

It also follows that if  $OA, OB, OC$  are non-coplanar rays, then the sum of the angles  $AOB$  and  $BOC$  exceeds  $AOC$ .

The work of Dorroh, Forder, Szász, and Rigby, as mentioned above, has permitted the replacement of the last congruence axiom (see 35) with the following:

If, as in Figure 4(a),  $AC \approx AC', BC \approx BC'$ , and  $[ABX]$ , then  $XC \approx XC'$  (here  $C, C'$  may be on the same side of  $AB$  or on opposite sides, though it is proved later that the first case is impossible), provided there is adjoined the statement [see Figure 4(b)]: if  $OA \approx OB$  and  $Y, Y'$  lie on the rays  $OA, OB$  (or on the opposite rays), and  $OY \approx OY'$ , then  $BY \approx BY'$ .

**Euclid's intersecting circles.** To discuss the intersection of circles, which Euclid read from his figures, the following can be assumed (see Figure 5):

If a circle with centre  $A$  has a point  $X$  on its circumference that is inside and a point  $Y$  outside a circle with centre  $B$  that lies in the same plane, and if  $X, Y$  lie on  $AB$  then the circles have at least one common point on each side of  $AB$ .

Figure 5: Intersecting circles.

If a circle with centre  $A$  has a point  $X$  inside, as well as a point  $Y$  outside, a second circle with centre  $B$ , and if  $X$  and  $Y$  lie on  $AB$ , then the circles have at least one common point on each side of  $AB$ .

In the presence of the congruence axioms the restriction that  $X, Y$  lie on  $AB$  can be removed; it need only be assumed that an intersection exists on one side of  $AB$ . The existence of the other and the uniqueness of both follow. From the above assumption follows the statement:

A line through a point inside a circle and in its plane meets it in just two points.

**A weakening of the parallel axiom.** Euclid's famous fifth axiom, the parallel axiom, can be treated as in Euclid's Book I; but in the presence of the congruence axioms it can be weakened to a simpler form (see 41).

If  $AB, CD$  are parallel, the notation  $AB \parallel CD$  can be used.

**Continuity.** Hilbert assumed a very curious axiom of completeness, which is an axiom about preceding axioms. It can be replaced by an axiom (see 42) concerning continuity of a segment.

From this follows the axiom (see 43) generally attrib-

Geometric constructions in proofs

## PROPERTIES OF PROPORTION

- (44) If any three of  $s, t, s', t'$ , are given, the fourth exists and is unique.
- (45) If  $s|s' \sim t|t'$ , then  $t|t' \sim s|s'$ .
- (46) If  $s|s' \sim t|t'$  and  $t|t' \sim v|v'$ , then  $s|s' \sim v|v'$ .
- (47) If  $s|s' \sim t|t'$ , then  $s'|s \sim t'|t$ . Also  $s|s' \sim t|t'$ .
- (48) The statement  $s|s' \sim t|t'$  implies  $s|t \sim s'|t'$ .
- (49) The statement  $s|t \sim s'|t'$  implies  $(s+t)|t \sim (s'+t')|t'$ .

 Archi-  
medes'  
axiom

uted to Archimedes. The continuity axiom makes possible a great simplification. The continuity axiom and the axioms of betweenness and order alone can be used to prove that lines that do not meet do exist in the plane. The continuity axiom and all of the axioms of order and betweenness and dimension can be used to replace the weakened parallel postulate by the following statement: Given any line  $l$  in a plane, there is a point  $P$ , on the plane and not on the line, through which goes not more than one line not meeting  $l$ . (The point  $P$  may vary as  $l$  varies.)

**Similar triangles.** In this section only the axioms of betweenness, order, congruence, and parallelism will be assumed. The measure of an interval is the set of all intervals congruent to it; or, alternatively, it can be regarded as a common property of all such intervals.

 Use of  
proportion

If  $PQ \cong AB$ ,  $RS \cong BC$ ,  $[ABC]$ , then the sum of the measures of  $PQ, RS$  is defined as the measure of  $AC$ . If  $SOS'$  is a right angle as in Figure 6, and  $T, T'$  lie on rays  $OS, OS'$ , respectively, the measures  $s, s', t, t'$  of  $OS, OS', OT, OT'$  will be said to be in proportion, written  $s|s' \sim t|t'$ , if  $SS' \parallel TT'$ .

Figure 6: Construction for similar triangles (see text).

The elementary properties follow at once (see 44–47). A great part will now be played by special cases of two theorems of projective geometry, the first attributed to the Greek mathematician Pappus of Alexandria (flourished c. AD 300) and the second to the 17th-century French mathematician Girard Desargues.

**Theorem A** (see Figure 7). If  $A, B, C$  lie on a line and  $A', B', C'$  lie on another (coplanar) line, the six points being distinct, and if  $AB' \parallel BA', B'C \parallel CB',$  then  $AC' \parallel A'C$ .

**Theorem B** (see Figure 8). If  $ABC, A'B'C'$  are two triangles, coplanar or not, the six vertices being distinct, and lines through  $AA', BB', CC'$  meet in one point and  $BC \parallel B'C', CA \parallel C'A',$  then  $AB \parallel A'B'$ .

Of these theorems, B follows from Euclid's parallel postulate and the axioms of incidence, provided three dimensions are assumed but not if only two dimensions are assumed.

Although theorem A does not follow from these axioms, it follows from the axioms of betweenness and order, the axioms of congruence and parallelism, and then theorem B in the plane can be deduced from it, without using space. The work below does not use space.

From theorem A two further properties of proportion (see 48, 49) can be proved. The restriction that  $SOS'$  is a

right angle can now be removed, and the main theorem can be proved: if triangles  $ABC, A'B'C'$  have corresponding angles equal, then  $AB|A'B' \sim BC|B'C' \sim CA|C'A'$ . When  $B, B'$  are the vertices of right angles, this theorem follows from the definition of proportion and one of the properties of proportion (48) above. The general case could be proved from this case and theorem B, and conversely theorem B follows from the general case. Hilbert avoided the use of theorem B, the proof of which is lengthy, by using the properties of a triangle and the last of the properties of proportion (see 49). When this main theorem has been proved, the rest is easy.

**The algebra of intervals.** If  $a, b, c$  are the measures of intervals, addition of measures has been defined and it remains to consider multiplication. If a fixed interval  $u$  is called the unit interval, then  $ab = c$  means  $c|b \sim a|u$ . Consequently,  $ab$  is uniquely fixed by  $a, b$ ; in particular  $au = a$ . From a property of proportion (see 48) above,  $c|b \sim a|u$  implies  $c|a \sim b|u$ , and thus  $ab = ba$ . Furthermore,  $ba = ca$  implies  $b = c$ . The following can also be deduced:  $a(b+c) = ab+ac$ ,  $(a+b)^2 = a^2+2ab+b^2$ ,  $a(bc) = (ab)c$ .

Figure 7: Construction for Pappus' theorem (see text).

From the properties of similar triangles, a well-known proof gives the theorem of Pythagoras in the form  $c^2 = a^2 + b^2$ . Thus the whole of Euclid's Book VI can be covered without using the theory of real numbers.

**A sample of theorems.** *Conclusions not based on the parallel axiom.* The first three of the following theorems can be proved on the basis of the axioms of order, betweenness, and congruence, without the parallel axiom but including the two axioms of dimension.

1. If on two lines in the same plane, or skew, points  $A_1, A_2, \dots$  are taken on one line, and  $B_1, B_2, \dots$  on the other, so that  $A_1A_2 \cong A_2A_3 \cong \dots \cong B_1B_2 \cong B_2B_3 \cong \dots$  then the midpoints of  $A_1B_1, A_2B_2, \dots$  lie on a line. Without parallelism it is very easy to prove 2 below and very hard to prove 3:

2. The bisectors of the angles of a triangle meet in a point, the incentre.

3. The lines joining the vertices of a triangle to the midpoints of the opposite sides (the medians) meet in a point.

*Conclusions dependent upon the parallel axiom.* The third theorem can be much more easily proved if, to the axioms mentioned, is added the parallel axiom. With that addition, the following can also be proved.

4. If the angles of any triangle  $ABC$  are trisected as in Figure 9, then  $DEF$  is equilateral.

5. The power of a point  $P$  for a circle  $O$ , radius  $r$ , is defined as  $OP^2 - r^2$ . (That this number is negative when

Figure 8: Construction for Desargues' theorem.

Figure 9: If the angles of triangle  $ABC$  (representing any triangle) are trisected, then triangle  $DEF$  is equilateral.

$P$  is inside the circle is of no consequence because powers are not added.) If a point  $P$  moves so that it has equal powers for two circles, it describes a line called the radical axis of the two circles. If the circles intersect, it goes through their common points. If the circles touch, it is the tangent at the point of contact. Circles with the same radical axis are called coaxial.

6. There are four circles that touch all the side lines of a given triangle. These are all touched by the circle through the midpoints of the sides, the so-called nine-point circle.

7. The pedal circle of a point  $P$  for a triangle is the circle through the feet of the perpendiculars from  $P$  to the side lines of the triangle. (This becomes a line if  $P$  is on the circumcircle of the triangle.) If  $A, B, C, D$  are four points, no three collinear, then the four pedal circles of each point for the triangle formed by the other three have a common point, through which pass also the nine-point circles of the four triangles.

8. If a point  $P$  describes a line, the pedal circles of  $P$  for the triangle are such that there is a point that has equal powers for all the circles. If the line goes through the circumcentre of the triangle, the pedal circles have a common point.

9. A chain of theorems. All the lines of this chain are to be in general position; that is, no two are parallel, no three concur. Starting with four lines (see Figure 10), the circumcircles of the triangles formed by them meet in a point  $P_4$  (the Miquel point) and their centres lie on a circle  $C_4$ . Five lines, taken by fours, yield five circles like  $C_4$ , passing through a point  $P_5$ , and their centres lie on a circle  $C_5$ . Six lines, taken by fives, yield six circles like  $C_5$ , passing through a point  $P_6$ , and their centres lie on a circle  $C_6$ . And so on.

Furthermore, from five lines are obtained five points like  $P_4$ , lying on a circle  $K_4$ . From six lines are obtained six circles like  $K_4$ , with a common point, and so on, point and line now occurring alternately. In special cases, the circles  $C$  and  $K$  might be replaced by lines.

10. Each of the triangles formed by four lines in gen-

The  
Miquel  
point

Figure 10: The Miquel point,  $P_4$ , the common meeting of the circles that circumscribe the triangles formed by four lines.

eral position has four circles touching its side lines. The centres of these 16 circles lie by fours on two orthogonal sets of four coaxial circles. The radical axes meet at the Miquel point of the four lines.

11. Two skew lines (lines that cannot both be contained in a common plane) have just one common perpendicular. If  $l, m, n$  are skew lines, and  $l', m', n'$  are the common perpendiculars of the pairs  $(m, n)$ ,  $(n, l)$ ,  $(l, m)$  and  $l_1, m_1, n_1$  are the common perpendiculars of the pairs  $(l, l')$ ,  $(m, m')$ ,  $(n, n')$ , then  $l_2, m_2, n_2$  have a common perpendicular.

12. If the faces of a convex polyhedron were made of metal plates and its edges were replaced by hinges around which the faces might conceivably turn, the polyhedron would nevertheless be rigid. This so-called rigidity theorem is attributed to the 19th-century French mathematician Augustin-Louis Cauchy. It does not seem to be known, however, to what extent it applies to nonconvex polyhedra.

13. If  $O_1A_1, O_1B_1, O_1C_1$  are any given intervals in a plane, no two on the same line, then a cube exists, the edges  $OA, OB, OC$  of which give these intervals by parallel projection. In general, there are two sets of such parallels but only one if the projection happens to be orthogonal.

#### THE MEASURE OF POLYGONS AND POLYHEDRA

**Questions following from Euclid.** In his treatment, Book II, of the equivalence of polygons, Euclid considered parallelograms  $ABCD, ABEF$  placed as in Figure 11. In the first case,  $ABCD$  can be dissected into  $ABCF$  and  $ADF$ , while  $ABEF$  can be dissected into  $ABCF$  and triangle  $BEC$ , which is congruent to  $ADF$ .

Dissection  
of paral-  
lelograms

Figure 11: Construction for the dissection of parallelograms (see text).

If it is assumed that triangles can be moved about and that a polygon can be dissected into triangles that can be fitted together in some way to make up another polygon, then the polygons are said to be equivalent by dissection. This is the case for the parallelograms in Figure 11, left, but it is not obviously so in Figure 11, right; nevertheless, in the latter case the parallelograms can be obtained by subtracting, respectively, the congruent triangles  $BEC, AFD$  from the complete figure. The parallelograms are then said to be equivalent by subtraction or simply equivalent.

The question arises; are two equivalent parallelograms always equivalent by dissection? Figure 12 suggests a proof that the answer is affirmative, and it can easily be made general and rigorous if it is assumed that when intervals congruent to  $AX$  are stepped off along the side  $AD$ , a point beyond  $D$  is eventually reached; that is, if Archimedes' axiom is assumed. It can be shown that this axiom is essential for the general proof of the theorem.

**Extension from parallelograms to polygons.** With reasoning similar to that of the section above and by using the axioms of betweenness and order, it can be shown that any polygon can be dissected into triangles. If Archimedes' axiom is assumed, it can be proved that equivalent polygons (subtraction being allowed) are always equivalent by dissection. For special cases this axiom is not needed.

As an example (Figure 13, left), consider the right angle  $ABC$  and the squares  $ADEC$  on  $AC$ ,  $AFGB$  on  $AB$ , and  $KGHE$  on  $KG$ . Because the triangles  $ABC, AFD, DEK$ ,

Figure 12: Construction for the proof of equivalency of parallelograms by dissection (see text).

$CHE$  are congruent, the square on  $AC$  is equivalent by dissection to the figure made up of the squares on  $AB$ ,  $BC$ . Here much has been read from the figure in Euclid's fashion, but all of it can be made rigorous.

Again consider a figure much used by Euclid (see Figure 13, right).  $ABCD$  is a parallelogram; through  $E$ , a point on  $AC$ , are drawn parallels to the sides. It follows that the parallelograms  $EB$ ,  $DE$  are equivalent, because the triangles  $ABC$ ,  $CDA$  are congruent,  $EB$  is formed from  $ABC$  by subtracting two triangles, and  $DE$  is formed from  $CDA$  by subtracting two triangles congruent to these.

**Equivalence of measure.** Using the algebra of intervals, the measure of a triangle can be defined as half the product of the measures of a side and the corresponding height. The theory of similar triangles shows that this product is independent of the side chosen. The factor  $\frac{1}{2}$  is introduced so that the unit  $u$  will be the measure of a square the side of which has measure  $u$ .

The measure of a polygon is defined as the sum of the measures of the triangles into which it can be dissected. This redefines the measure of a triangle; and for consistency it must be proved that the same measure is obtained for a polygon no matter how it is dissected into triangles. This is neither obvious nor easy to prove, but it can be proved using the algebra of intervals.

The theories of equivalence and of measure can now be connected. It is not hard to prove that equivalent polygons have the same measure, more difficult to prove that those with the same measure are equivalent; they are equivalent by dissection only if the Archimedian axiom is assumed. In particular, two equivalent triangles with congruent bases have congruent altitudes. In proving this, Euclid assumed one of his common notions in the form that a triangle cannot be equivalent to a subtriangle, an assumption not needed in the modern theory, in which it can be proved.

The attempt to extend this to measures of polyhedra encounters difficulties. The definitions of equivalence by dissection and of equivalence can be taken over, using tetrahedra instead of triangles. It was only in 1943 that Jean-Pierre Sydler (Swiss) proved that equivalence implied equivalence by dissection, assuming the Archimedian axiom.

The measure of a tetrahedron can be defined as one-third of the product of the measures of a face and the corresponding height, and it can be proved that this is independent of the face chosen. The measure of a polyhedron, defined as the sum of the measures of the tetra-

hedra into which it can be dissected, can be proved to be independent of the dissection adopted, though the argument is involved. The real difficulty is that polyhedra of the same measure need not be equivalent. A regular tetrahedron, for example, cannot be equivalent by dissection to a cube of the same measure for the reason that it is not possible in any way to dissect the tetrahedron into subtetrahedra and fit them together to make a cube. This follows from the fact that the dihedral angle of a regular tetrahedron is not a rational multiple of a right angle. Neither does it help if equivalence by dissection is replaced by equivalence, nor does the Archimedian axiom remove the difficulty. It is for this reason that Euclid was compelled to use the theory of exhaustion in dealing with volumes.

A rounded theory can be obtained if two tetrahedra are called equivalent (T) when they have a face and corresponding altitude of the same measure, and equivalence (T) by dissection and equivalence (T) are defined only for pairs of tetrahedra of this kind. Under these suppositions, two polyhedra of the same measure are equivalent (T), although, unless the Archimedian axiom is assumed, they need not be equivalent (T) by dissection.

It can be proved that two tetrahedra equivalent (T) have the same measure if the following substitute for integration is assumed: Cavalieri's principle: If two solids,  $S_1$  and  $S_2$ , lie between parallel planes and each plane parallel to these meet  $S_1$  and  $S_2$  in plane figures with the same measure, then  $S_1$  and  $S_2$  have the same measure. Application to the tetrahedra is simple.

#### TRANSFORMATION GEOMETRY

**Translation and reflection in the plane.** If, in a plane,  $l$  is a given line,  $P$  a point not on it, and  $F$  the foot of the perpendicular to  $l$  from  $P$ , and if  $PF$  is prolonged to  $Q$  so that  $PF \cong FQ$ , then  $Q$  is called the image of  $P$  by reflection in  $l$ . If  $P$  describes a line, so does  $Q$ . If  $P$  describes a circle clockwise, then  $Q$  describes a circle anticlockwise. The transformation is called indirect because it reverses sense.

Figure 14: Reflection of a point  $A$  in a line  $l$  (to yield point  $B$ ) followed by a reflection in line  $m$  (to yield point  $C$ ). The result is a rotation through an angle twice that from  $l$  to  $m$ .

The result of a reflection in a line  $l$  followed by one in  $m$  is direct, because sense is preserved. If  $l \parallel m$  the result is a translation taking any point  $P$  into a point  $Q$ , the distance of which from  $P$  is twice that between  $l$  and  $m$ . If, as in Figure 14,  $l$  and  $m$  meet in  $O$ , the result is a rotation around  $O$  through an angle twice that from  $l$  to  $m$ . Conversely, any translation or rotation can be resolved into reflections in two lines, either of which may be any line perpendicular to the direction of the translation or a line through the centre of the rotation. The other is then fixed. A displacement in a plane is a direct transformation that transforms any figure  $F$  into a congruent figure  $F'$ . If  $F'$  is reflected in a line, the resulting transformation is an indirect displacement.

A direct displacement is always a translation or a rotation; an indirect displacement is the result of a translation and a reflection in a line parallel to the direction of the translation.

The  
measure  
of a tetra-  
hedron

**Homotheties.** If  $O$  is a point in a plane, a transformation that leaves  $O$  fixed and changes any two other points  $A, B$  into  $A', B'$  on  $OA, OB$ , respectively, so that  $AB \parallel A'B'$ , is called a homothety, with centre  $O$ .  $A'$  may be on the ray  $OA$  or on the opposite ray. If  $C$  becomes  $C'$ , then  $AB/BC \sim A'B'/B'C'$  by similar triangles and theorem B above.

If two nonconcentric circles have centres  $A, B$  and unequal radii  $r, s$ , there are points  $I, E$  with  $[AIB], AI/IB \sim AE/EB \sim r/s$ . In consequence, the circles are homothetic in two ways with  $I$  as the internal and  $E$  as the external centre of homothety. These points may both lie inside the circles; but, when each circle lies outside the other,  $I$  and  $E$  are points at which pairs of common tangents meet. For example: If  $ABC$  is a triangle, and  $D, E, F$  are the midpoints of the sides, the internal centre of homothety of the circles  $ABC, DEF$  is the point of concurrence of  $AD, BE, CF$  and the external centre is the point of concurrence of the altitudes of the triangle  $ABC$ . The circle  $DEF$  is the nine-point circle of triangle  $ABC$ .

The result of any sequence of homotheties and translations is a homothety or a translation.

**Similitudes.** If a figure  $[F]$  is transformed by a homothety preceded or followed by a displacement, direct or indirect, the figure  $[F']$  obtained is similar to  $[F]$ ; that is, if  $A, B, C$  in  $[F]$  correspond to  $A', B', C'$  in  $[F']$ , then  $ABC, A'B'C'$  are similar triangles. The transformation is a similitude. This similitude is a homothety if  $AB \parallel A'B'$  always holds. If, as in Figure 10,  $AB, A'B'$  meet in  $C$ , and  $AA', BB'$  meet in  $D$ , and if the circles  $AA'C, BB'C$  meet again in  $O$ , then the triangles  $OAB, OA'B'$  are directly similar; and if the given similitude is direct, it is the result of a homothety with centre  $O$  and a rotation around  $O$ . The other two circles  $ABD, A'B'D'$  also go through  $O$ , the Miquel point.

**An algebra of points.** The transformations can be used to construct an algebra of points. Starting with a fixed point  $O$ , the translation that takes  $O$  into  $A$  is denoted by  $T_A$ ; the result of two translations  $T_A, T_B$  is denoted by  $T_{A+B}$  (see Figure 15, left). The operation  $+$  has the usual properties of addition, and the addition of points can be defined:  $C = A + B$  means  $T_C = T_{A+B}$ .

Figure 15: Effects of transformations used to construct algebras of points: (left) translation, (right) homothety.

If  $OU$  is any line through the fixed point  $O$ , and  $A$  is another point on  $OU$ , then  $X \cdot A$  represents the point  $Y$  into which  $X$  is transformed by the homothety with centre  $O$  that transforms  $U$  into  $A$  (see Figure 15, right). If  $X \cdot A$  is regarded as a product, then  $U \cdot A = A \cdot U = A$ . There is just one point  $X$  with  $X \cdot A = U$ ; it lies on  $OU$ , and  $A \cdot X = U$ .

With addition and multiplication as defined above operating only on points on  $OU$ , all the formulas for a field in algebra follow from theorem B except  $A \cdot B = B \cdot A$ . To prove  $A \cdot B = B \cdot A$ , theorem A is necessary. In the resulting field, the points  $O$  and  $U$  play the parts of zero and the unit element (see Figures 7 and 8).

**A coordinate geometry.** It is now possible to erect a coordinate geometry in the plane (or space) using only the axioms of betweenness, order, parallelism and theorems A and B and the first two axioms of dimension, but not congruence.

Along any two distinct lines  $OU_1, OU_2$  in a plane, the algebra of points can be constructed as above. If  $A$  on  $OU_1$  corresponds to  $A'$  on  $OU_2$  when  $AA' \parallel U_1U_2$ , a one-to-one correspondence is set up such that if  $B$  corre-

sponds to  $B'$  then  $A + B, A \cdot B$  correspond to  $A' + B', A' \cdot B'$ . Thus the fields on  $OU_1, OU_2$  can be identified and their elements denoted by small letters.

If  $P$  is any point in the plane and parallels through  $P$  to  $OU_1, OU_2$  meet  $OU_1, OU_2$  at points  $a, b$  in their fields,  $P$  can be assigned the coordinates  $(a, b)$ . The points  $(x, y)$  on a line then satisfy an equation  $lx + my + n = 0$ , in which  $l, m, n$ , are elements of the field and are called the coordinates of the line.

**Reflections in a plane.** In space a reflection in a plane is a looking-glass reflection. The result of reflections in two planes is a translation if the planes are parallel, a rotation around the common line if the planes meet, and a reflection in the common line if the planes are perpendicular. Conversely, any translation or rotation around a line can be resolved into reflections in two planes, either of which may be any plane perpendicular to the direction of the translation or any plane through the axis of rotation. The other is then fixed. If a reflector plane is interposed perpendicular to both planes, then the reflections in the planes can be replaced by reflections in two lines.

A displacement in space is a transformation that takes a figure into a directly congruent figure. If it has a fixed point  $O$ , it is a rotation around a line through  $O$ . If it has no fixed point and takes  $A$  into  $B$ , it is the result of a translation along  $AB$  and a rotation around a line  $l$  through  $B$ . If the line  $m$  through  $B$  is perpendicular to both  $AB$  and  $l$ , then the translation is the result of reflections in a line  $m_1$ , parallel to  $m$  and in  $m$  itself, and the rotation is a result of reflections in  $m$  and another line through  $B$ . Thus, every displacement is the result of reflections in two lines. If these lines are skew, the displacement is the result of a translation along and a rotation around their common perpendicular line.

The result of two displacements can be found by using item 11 of the section *A sample of theorems*.

Displacements in space

## CONSTRUCTIONS

**Constructions regarded as an existence theorem.** Euclidean construction can be regarded as existence theorems. "To bisect a given angle," for example, can be interpreted as "every angle has a constructible bisector." Some basic constructions must be assumed.

**Gauge constructions.** It is convenient to assume the first three elementary constructions (36–38), but to replace the last construction (39) with the gauge construction (40). It is surprising that although the gauge construction is much weaker than the last of the elementary constructions, nevertheless, the latter can be derived from it by using the axioms of betweenness and order and the axioms of congruence even without the parallel axiom.

It is easy to show that the following constructions can be performed without the parallel axiom:

- Any angle can be bisected.
- If  $C$  is any point on  $OA$ , the point  $D$  on  $OB$  such that  $OD \cong OC$  is constructible.
- A perpendicular can be constructed to  $OA$  from any point on  $OA$ .
- Any interval can be bisected.
- A perpendicular can be constructed to a line through any point outside it.
- An angle with a given side can be constructed congruent to a given angle.
- If one point at which a line and a circle meet is known, the other is constructible if the centre of the circle is given.

With the aid of the parallel axiom, the gauge construction can be weakened to the form: Given a fixed point  $O$ , the gauge can be cut off from  $O$  on any ray through  $O$ . The circle, the centre of which is the fixed point  $O$ , with radius the gauge, is called the gauge circle.

**Construction of radical axis of two nonconcentric circles.** If the centres of two nonconcentric circles and a point on each are given, then their radical axis may be constructed using only the first three elementary constructions and the weakened form of the gauge construction, as follows:

One circle is taken as the gauge circle  $K$ , with centre  $O$ ,

and  $O'$  the centre of the other circle  $K'$ , and  $N'$ , a point on it. If  $N'$  is on  $OO'$  it is to be replaced by its reflection in a line through  $O'$ . Then  $ON \parallel O'N'$ ,  $N$  chosen on  $K$ . If  $NN' \parallel OO'$ , the radical axis is the right bisector of  $OO'$ . If  $NN'$ ,  $OO'$  meet in  $S$ , the homothety, with centre  $S$ , which takes  $O$  into  $O'$ , and  $N$  into  $N'$ , may be considered as in Figure 16. Using the weakened form of the gauge construction, then  $P$  may be constructed along with another point on  $K$ , and the other point  $L'$  at which  $SN'$  meets  $K'$  and the other point  $Q$  at which  $SP$  meets  $K$ . The point  $Q'$  on  $K'$  with  $OQ \parallel O'Q'$  corresponds to  $Q$  in the homothety. It can be proved that  $PN$ ,  $L'Q'$  meet on the radical axis of  $(K, K')$ ; and because this is perpendicular to  $OO'$ , it can be constructed. (If  $PN$  happens to be parallel to  $L'Q'$ , a different point  $P$  can be used.)

Figure 16: A construction of the radical axis of two nonconcentric circles, given the centres and a point on each.

If  $K'$ ,  $K''$  are two circles, not the gauge circle  $K$ , then the radical axes of  $(K, K')$  and of  $(K, K'')$  are to be constructed. If these meet, their common point is on the radical axis of  $(K', K'')$ . If they are parallel, the centres of  $K$ ,  $K'$ ,  $K''$  lie on a line. The circle, the centre of which is not on that line, may then be used instead of  $K$ .

**Linear constructions.** These are the constructions that can be performed by the first three elementary constructions and drawing parallels, assuming the axioms of betweenness and order and Euclid's parallel axiom, or assuming the first three axioms of incidence and Euclid's parallel axiom. If coordinates have been introduced and if  $S$  is a set of points, the coordinates of which are the set  $a_1, a_2, \dots, a_n$ , then any point can be constructed whose coordinates are in  $R = R(a_1, \dots, a_n)$ , the field obtained from  $a_1, \dots, a_n$  by additions, subtractions, multiplications, and divisions. Only points of  $R$  can be found by linear constructions from the given points because a line joining points, the coordinates of which are in  $R$ , has coordinates in  $R$ , and the point at which two nonparallel lines, the coordinates of which are in  $R$ , meet has coordinates in  $R$ .

**Ruler and compass constructions.** Assume now the axioms of betweenness and order, the axioms of congruence and the axiom of parallelism (in the weakened form) as well as the following:

If a coplanar line meets the gauge circle  $K$ , the points of meeting are constructible.

Now if the centre of a circle  $K'$  is given, and a point on it, then  $K, K'$  are related by a homothety or by a translation, and if a line  $l$  goes through a point inside  $K'$ , it corresponds to a line  $l'$  through a point inside  $K$ : The points at which  $l, K$  meet are known, and the homothety gives those at which  $l', K'$  meet. If two circles are given, their radical axis can be found by the first three elementary constructions and the weakened form of the gauge construction, and hence their points of meeting, if they meet, can be found by the first three constructions and the assumption above. If a ruler and compass are actually used, the ruler is an unmarked straight edge, and the compasses must not be used for transferring lengths; they collapse after a circle is drawn. The axes can now be taken as ordinary rectangular Cartesian axes and the radius of  $K$  as the unit length.

With the use of the assumption above, the field ob-

tained, from  $a_1, \dots, a_n$  by additions, subtractions, multiplications, divisions and the extraction of the square roots of positive elements already obtained, may be considered. This enlarges  $R$  to the field  $\Omega_1(a_1, \dots, a_n)$  and now all points the coordinates of which are in  $\Omega_1(a_1, \dots, a_n)$  can be constructed from points the coordinates of which are in  $(a_1, \dots, a_n)$ . Because every circle has an equation of the form  $(x - a)^2 + (y - b)^2 = r^2$ , the algebraical counterpart of its construction is the solution of a series of linear and quadratic equations with real roots. Thus, the coordinates of the points obtained are all in  $\Omega_1(a_1, \dots, a_n)$ .

An example of an element in  $\Omega_1(a_1, a_2)$  is

$$\sqrt{\sqrt{a_1} + \sqrt{a_2} + \sqrt{(a_1 a_2)}}.$$

The elements obtained by changing the sign in front of any square-root sign are also in the field. If an element involves  $n$  square roots after all reductions, then, when rationalized, it satisfies an irreducible equation of degree  $2^n$  the coefficients of which are in  $R$ . It is for this reason that two classical problems cannot be performed by ruler and compass: (1) to construct a cube the volume of which is twice that of a given cube; (2) to trisect a given angle. Both involve cube roots.

The Greek geometers knew how to construct the regular  $n$ -gon with  $n = 3, 4, 5$  or  $6$ . By inscribing these polygons in circles and repeatedly bisecting the sides, regular polygons of  $n \cdot 2^m$  sides can be obtained,  $m$  being the number of bisections. Of polygons other than these, however, nothing was known up to the time of Carl Friedrich Gauss. Pierre de Fermat, who died a century before Gauss was born, had studied numbers of the form  $2^{2^k} + 1$ ,  $k$  being a positive integer. The first five Fermat numbers—3, 5, 17, 257, and 65,537—are primes. No other prime Fermat numbers have been located, and it is possible that all the rest are composite. Gauss's remarkable achievement was to show (at the age of 18) that it is possible with ruler and compass to construct a regular  $n$ -gon if  $n$  is either a prime Fermat number or a product of different prime Fermat numbers (or, of course, the same multiplied by an integral power of two). It was subsequently shown that the converse of Gauss's theorem also holds and that, therefore, these are the only regular polygons that can be so constructed.

**Criterion for gauge construction.** If in a ruler and gauge construction the coordinates of a desired point involve  $n$  square roots, there will always be  $2^n$  solutions, provided all the square roots involved are real for all values of the coordinates  $a_1, \dots, a_n$  of the given points.

The problem of how to draw a circle through two points  $A, B$  touching a given line  $l$  not parallel to  $AB$  may be considered. There are two solutions if  $A, B$  are on the same side of  $l$ , but none if they are on opposite sides.

The field  $\Omega_0(a_1, \dots, a_n)$  for this problem is defined as that obtained from  $R(a_1, \dots, a_n)$  by adjoining  $\sqrt{1 + x^2}$  in which  $x$  is already in the field. It follows that if  $p$  is a known point with coordinates in  $\Omega_0(a_1, \dots, a_n)$ , there can be constructed by the first three elementary constructions and the weakened form of the gauge construction, the point  $(1, p)$ , and then  $\sqrt{1 + p^2}$ , and, in fact, all points, the coordinates of which have the form  $\sqrt{a_1^2 + a_2^2 + \dots + a_n^2}$ , and so all points, the coordinates of which are in  $\Omega_0(a_1, \dots, a_n)$ . The proof that only such points can be drawn by the construction specified above depends on a deep theorem of algebra:

If  $f(p_1, \dots, p_n)$  is a rational function of  $p_1, \dots, p_n$  with rational coefficients and is never negative for real values of  $p_1, \dots, p_n$ , then it can be expressed as the sum of squares of rational functions of  $p_1, p_2, \dots, p_n$  with rational coefficients. (A rational function is a polynomial divided by a polynomial.)

If a regular polygon can be constructed by ruler and compass, then it can be constructed by the first three elementary constructions and the weakened form of the gauge construction. For example, on a base of length 2 a

regular pentagon has height  $\sqrt{5 + 2\sqrt{5}}$  and this is in  $\Omega_0(1)$ , because  $5 + 2\sqrt{5} = (1 + \frac{1}{2}\sqrt{5})^2 + (1 + \frac{1}{2}\sqrt{5})^2 + (\frac{1}{2})^2 + (\frac{1}{2})^2$ .

Construc-  
tion of  
polygons

**Constructions with compasses only.** These start with given points and end with required points. If  $X(Y)$  mean the circle with centre  $X$  passing through  $Y$ , three problems are: Given two pairs of points  $A, B$  and  $C, D$ :

- (i) Find the point (if any) at which the lines  $AB$  and  $CD$  meet.
- (ii) Find the points (if any) at which  $AB$  and  $C(D)$  meet.
- (iii) Find the points (if any) at which  $A(B)$  and  $C(D)$  meet.

Constructions (i), (ii) can be performed by (iii) if the continuity axiom is assumed. It can be concluded that any ruler and compass construction from given points to required points can be performed by compasses only.

**To find a circle touching three given circles.** The problem of finding a circle that touches three given circles  $K_1, K_2, K_3$  may be considered. For simplicity the circles may be mutually external. The radical axes of each pair can be constructed by methods of the section *Construction of radical axis of two nonconcentric circles*. These axes, assumed distinct and no two parallel, all meet in a point  $O$ . The circle  $K$  orthogonal to  $K_1, K_2, K_3$  has centre  $O$  and can be constructed. The external centres of homothety of  $K_1, K_2, K_3$ , taken in pairs, lie on a line  $l$ . If  $m$  is the common chord of  $K$  and  $K_1$ , and if  $P_1$  is the point at which it meets  $l$ , the tangents from  $P_1$  to  $K_1$  touch  $K_1$  at the points of contact of one of the required circles. The other tangent circles are given by a slight modification of this construction.

#### GEOMETRY OF MORE THAN THREE DIMENSIONS

The axioms of betweenness and order may again be considered, but now for clarity the word space is replaced by three-dimensional space or  $S_3$ . Instead of the axiom (29) that restricts space to three dimensions, it may be assumed that there is a point not in  $S_3$  (see 30).

If  $A, B, C, D$  are non-coplanar points, there is a point  $E$  not in the space  $ABCD$ . The points  $A, B, C, D, E$  are the vertices of a polytope, and the join of two of the points is an edge. The triangle, the vertices of which are three of them, is a face; the tetrahedron, the vertices of which are four of them, is a cell. A space  $S_n$  of four dimensions is defined as the set of all points and all lines joining any two points of two cells of the polytope.

All this is completely analogous to the definitions of plane in  $S_2$  and can be continued to  $S_5, S_6, \dots$ . Finally, for some fixed  $n$ , all points are in  $S_n$ .

#### CONVEXITY

**Convexity in Euclidean geometry.** Euclidean plane and solid geometry provide a natural setting for the study of convex sets and convexity. A set  $S$  in Euclidean space is said to be convex if every straight line segment having its two end points in  $S$  lies entirely in  $S$ . In Figure 17, the

Figure 17: Examples of (left) convex and (right) nonconvex sets.

set  $S$  is convex because the line segment joining arbitrary points  $A$  and  $B$  in  $S$  always belongs completely to  $S$ . The other set  $M$  is not convex because there exist at least two points  $A$  and  $B$  in  $M$  the joining segment of which is not completely in  $M$ . The circle and the ellipse bound familiar convex sets in the plane, and in space the solid figures bounded by the sphere and the cube are common examples. It is important to note, however, that a hollow spherical shell is not convex, whereas the solid spherical ball is convex. Egg-shaped solids are convex if, and only if, the interior points are included, together with the

boundary. The isoperimetric problem of antiquity involves convexity. The solution to this problem shows that among all the simple plane regions, the bounding curves of which have the same length, the circle encloses a maximum area. A first step in proving this is to show that every nonconvex plane region is contained in a convex set with shorter boundary and with greater area. Therefore, in solving the isoperimetric problem it suffices to investigate only convex sets; the solution must be found among them.

The beguiling simplicity of the convexity concept has attracted both gifted novices and mature mathematicians. Euclid would have appreciated the theorem to be described later as of the Helly type, which can be paraphrased informally as follows: "If there are more than three flat circular pancakes on a flat plate, and if every trio of pancakes can be impaled simultaneously with the prong of a fork, the point of piercing varying with the choice of the three pancakes, then it is possible to impale all the pancakes simultaneously at one point with a prong of the fork."

A circle has the property that all the chords (diameters) through its centre are of equal length. A point  $P$  of a convex set  $S$  is said to be an equichordal point if all the segments through  $P$  with end points on the boundary of  $S$  have the same length. Whether there exists a plane convex set having two equichordal points is at present unknown. In the study of convexity one encounters many other questions equally easy to state and difficult to answer.

Euclidean space  $E$  itself is convex; and the points, lines, line segments, and planes are convex subsets of  $E$ . This important property more than any other has made convexity an essential part of classical Euclidean geometry. In any space in which two points determine a unique segment of the space, convexity is a natural concept. Vector spaces, with their linear operations of vector addition and scalar multiplication, have, therefore, their convex structures.

The following modern plane separation axiom has influenced geometry at the elementary level: "All the points of the plane that do not belong to a line  $L$  form two convex sets  $P$  and  $Q$  (called half-planes) such that each segment joining a point of  $P$  to a point of  $Q$  intersects  $L$ ." The 19th-century axiom of Pasch states: "In the plane if a line intersects one side of a triangle and misses the three vertices, then it must intersect one of the other two sides." Both of these axioms, which involve notions of convexity, slipped by Euclid as "too obvious to mention."

**Basic concepts of convexity in the development of Euclidean point set topology.** If  $C$  is a circle in the plane with centre  $A$ , then the entire set of points inside the circle is called an open circular neighbourhood of the point  $A$ , or, more briefly, a neighbourhood of  $A$ . Such a neighbourhood is convex. In Euclidean three-space, spherical neighbourhoods play the corresponding role. A point is an interior point of a set  $S$  if it has a neighbourhood entirely in  $S$ . A point  $P$  is a boundary point of  $S$  if every neighbourhood of  $P$  contains points in  $S$  and points not in  $S$ . A set is open if all of its points are interior points and closed if it contains all of its boundary points.

The set of interior points (called the interior) of a convex set  $S$  is also convex, and the set  $S$  with its boundary (called the closure) forms a convex set. Each boundary point  $P$  of a convex set in the plane  $E_2$  is contained in a line  $L$  that supports  $S$ ; intuitively,  $L$  is a tangent line, if the boundary has a tangent at  $P$ . This means that  $S$  lies in one of the closed half-planes bounded by  $L$  (see plane separation axiom above). In fact, if  $S$  is a closed set in the plane having nonempty interior, then  $S$  is convex if, and only if, through each boundary point of  $S$  there passes a line that supports  $S$ . Corresponding statements hold in Euclidean three-space  $E_3$ , so that each boundary point is contained in a plane of support to  $S$ . These results extend completely to  $n$ -dimensional Euclidean space  $E_n$ , in which the analogue of a plane is called a hyperplane. A hyperplane  $H$  separates  $E_n$  in a manner analogous to that in the plane separation axiom, yielding two closed half-spaces having  $H$  as a common boundary. It

The isoperimetric problem

Pasch's axiom

Sets in Euclidean space

Planes and hyperplanes

is notable that both bounded and unbounded convex sets exist, a convex set being bounded if it is contained in some sphere. A half-space, for example, is unbounded, whereas a solid cube is bounded.

A point  $A$  in the boundary of a plane convex set  $S$  having nonempty interior is an exposed point if it is contained in a line of support that intersects  $S$  in exactly one point, namely,  $A$ . A point  $B$  is an extreme point of the convex set if no segment in  $S$  contains  $B$  between its end points. A convex set is strictly convex if its boundary contains no line segments. A point  $B$  is a vertex of  $S$  if it is contained in more than one line of support to  $S$ . If  $S$  contains no vertices, it is said to be smooth. An ellipse bounds a convex set that is both strictly convex and smooth, whereas a square bounds a convex set that is neither strictly convex nor smooth. The above notions extend to  $E_n$  in a natural way.

Because the intersection of two convex sets consists of all points belonging to both, the definition of convexity implies immediately that the intersection is also convex. This is true even if the intersection is empty (null), because the empty set is convex. As a consequence of this basic property, if  $S$  is any set in Euclidean  $n$ -space there exists a smallest convex set containing  $S$  called the convex hull, or convex cover of  $S$ , which is the intersection of all convex sets that contain  $S$ . If  $S$  is convex, then  $S$  is its own convex hull. In a Euclidean space  $E_n$  every closed convex set  $S$  that is not  $E_n$  itself is the intersection of all the closed half-spaces containing  $S$ .

Among the more intriguing theorems of the 20th century is a group of geometric combinatorial theorems of so-called Helly type (see COMBINATORICS AND COMBINATORIAL GEOMETRY), an illustration of which has been given (see above *Convexity in Euclidean geometry*). The corresponding theorem for Euclidean  $n$ -space is: "If  $F$  is a family of more than  $n$  bounded closed convex sets in Euclidean  $n$ -space  $E_n$ , and if every  $n + 1$  members of  $F$  have at least one point in common, then all the members of  $F$  have at least one point in common." The number  $n + 1$  appearing in Helly's theorem is called the Helly number. There exists a great variety of Helly type theorems, of which two follow.

1. If a family of bounded closed parallel line segments in the plane is such that every three are intersected simultaneously by at least one line, then there exists a line that simultaneously intersects all the segments in the family.

2. A picture gallery consisting of several interconnecting rooms can be imagined to have its walls completely covered with small pictures. If for each three pictures there is a point in the gallery from which all three can be seen, then there exists a point from which all the pictures in the gallery can be seen. (Such a region is called star-shaped.) The following is one version of a separation theorem. "A valley contains a flock of (stationary) sheep and goats. If for each set of four animals a straight fence can be built that will separate the sheep from the goats, then all the sheep can be separated from all the goats by a single fence (straight line)." Here the Helly number is four. In  $E_n$  it would be  $n + 2$ . Helly type theorems are closely related to a fundamental theorem of Carathéodory: "Each point in the convex hull of a set  $S$  in  $E_n$  is in the convex hull of  $n + 1$  or fewer points of  $S$ ."

A circle in  $E_2$  has the property that the distance between any two parallel lines of support (which in this case are also tangent lines) is constant. A convex set  $S$  with the property that the perpendicular distance between each pair of its parallel lines of support is constant is called a set of constant width. An ellipse does not bound a set of constant width: the distance between parallel lines of support at the extremities of the minor axis is less than the corresponding width for the major axis. A simple example other than the circle can be constructed as follows: If  $A, B, C$  are the vertices of an equilateral triangle, then with  $A$  as centre the (smaller) circular arc is drawn joining  $B$  and  $C$ . This construction is then repeated with  $B$  and  $C$  as centres. The union of the three arcs thus drawn bounds a convex set of constant width called the Reuleaux triangle (see Figure 18). It has vertices at the points  $A, B, C$ , whereas a circle is smooth. Nevertheless,

Figure 18: The Reuleaux triangle.

cylindrical rollers of cross section having the form of Figure 18 could be used to roll a heavy object, such as a crate, in a horizontal direction over level ground smoothly and without any vertical component of motion. A Reuleaux polygon can be constructed in an analogous manner, but it must always have an odd number of vertices.

Convex functions are closely related to convex sets. A graph is said to be convex if the chord joining any two points  $P$  and  $Q$  of the graph lies above that portion of the graph joining  $P$  and  $Q$ , as in Figure 19. The function  $\{f(x) = x^2, x = \text{real}\}$  representing the parabola is an example of a convex function. In general, if a plane graph has the property that each of its chords  $PQ$  always lies above that portion of the graph joining  $P$  and  $Q$ , then the real-valued function that determines the graph is said to be convex. If a plane graph is convex, then the portion of the plane lying above the graph is a convex set. In higher dimensions a real-valued convex function  $f$  defined on a convex set  $S$  of  $E_n$  has a graph  $F$  in a space  $E_{n+1}$  of one higher dimension such that each vertical two-dimensional plane intersects  $F$  in a plane convex graph.

Figure 19: The graph of a convex function. Each of its chords,  $PQ$ , lies above that portion of the graph joining  $P$  and  $Q$ .

**Convexity in Minkowskian geometry as compared to that in Euclidean geometry.** Minkowskian geometry differs from Euclidean geometry essentially in the fact that the unit of length may vary significantly with the direction in which the measurement occurs. In order to see how the length changes with direction,  $U$  may be taken as a bounded closed convex set in the plane  $E_2$  having an interior point  $O$  as a centre of symmetry; hence, each chord of  $U$  through  $O$  is bisected by  $O$ . As an illustration, if  $U$  is bounded by a square having  $O$  as the central point where the diagonals intersect, then (given  $U$  as fixed and choosing a point  $P$  on the boundary of  $U$ ) by definition the unit of linear measure on all lines parallel to the segment  $OP$  is the Euclidean length of  $OP$ . Because the Euclidean length of  $OP$  can change as  $P$  varies on the boundary of  $S$ , it is interesting to observe that many of the theorems of classical geometry that depend upon the concept of length may be significantly altered. In Minkowskian geometry, two triangles can have all three pairs

Changes of  
Euclidean  
length

Theorems  
of the  
Helly type

The  
Reuleaux  
triangle

of corresponding sides of the same length without the triangles themselves being congruent. The triangle inequality, however, still holds; that is, the sum of the lengths of two sides of a triangle is greater than or equal to the length of the third side. This, together with the fact that  $U$  has a centre of symmetry, implies that a Minkowski space is also a metric space, in which the distances are determined by the convex set  $U$ . The set  $U$  is called the unit disk in the Minkowski plane  $M_2$ , although it may not look like the familiar circular region of Euclidean space. In the Euclidean plane  $E_2$ , a closed convex set  $S$  has the property that for each point  $X$  in  $E_2$  there is a unique nearest point  $P$  of  $S$ . In fact, in  $E_2$  if  $X$  is not in  $S$  the segment  $XP$  is perpendicular to the line of support to  $S$  at the nearest point  $P$ . This fact is not necessarily true for a Minkowski space. It may be supposed that the unit disk  $U$  in  $M_2$  is the square of Figure 20. Some points  $X$  on the outward normal erected at the midpoint of side  $AB$  of the square are equidistant from all points of  $AB$ . This is true because of the peculiar way in which the linear measure changes with direction. By definition, in a Minkowski space, a line  $L_1$  is perpendicular to a line  $L_2$  if the point of intersection of  $L_1$  and  $L_2$  is a nearest point of  $L_2$  relative to the points of  $L_1$ . In  $M_2$  there may exist more than one perpendicular to a line  $L$  at a point  $P$ . A Minkowskian plane the unit disk of which is an ellipse can be shown to be Euclidean, and all others are not Euclidean. A circle is a special case of an ellipse.

Figure 20: A unit disk in a Minkowski space. Some points  $X$  on the outward normal erected at the midpoint of a side  $AB$  are equidistant from all points of  $AB$ .

The concepts of length, area, volume, and angle have meaning in Minkowskian geometry. The length of a polygon is defined as the sum of the Minkowskian lengths of the various segments that determine the polygon. Passage to the limit in the conventional manner yields the Minkowskian length of curves. The area of a Minkowskian plane figure is determined by using the unit disk  $U$  as a basic unit of plane measure. Corresponding procedures are used to determine volumes of figures in Minkowski three-space. The length  $L$  of the boundary of a unit disk in a Minkowskian plane satisfies the inequality  $3 \leq L/2 \leq 4$ . (The unit disk  $U$  always has diameter 2.) If  $U$  is the square, then  $L = 8$ . If  $U$  is the regular hexagon, then  $L = 6$ . In the Euclidean plane  $L = 2\pi$  and, as is well-known,  $3 < \pi < 4$ .

**Geometric inequalities and convexity.** The quantitative aspects of convexity provide a rich source for inequalities and numerical estimates. The surface area  $A$  and the volume  $V$  of a bounded convex set  $S$  in Euclidean  $n$ -space  $E_n$  are connected by the famous isoperimetric inequality,  $A^n \geq n^n UV^{n-1}$ , in which  $U$  is the volume of the unit sphere in  $E_n$ . The equality holds if, and only if,  $S$  is an  $n$ -dimensional sphere. In three space  $E_3$ ,  $A^3 \geq 36\pi V^2$ . In the plane ( $n = 2$ ),  $A^2 \geq 4\pi V$ , in which  $A$  is the length of the boundary of  $S$  and  $V$  is the plane area of  $S$ . Among all the plane convex sets of constant width  $d$  the Reuleaux triangle contains the least area, whereas the circle contains the greatest.

Packing problems are among those easiest to state and hardest to solve. A family of convex sets forms a packing if no two members of the family overlap (their interiors are disjoint). A set  $S$  is covered by a family of convex sets if each point of  $S$  belongs to some member of the family. The percentage of the space or a subset thereof

that is covered by the members of a packing determines a density of the packing. In the plane, the best packing (maximum density) for congruent circles is that in which all the circles are framed by non-overlapping plane-filling regular hexagons, so that every circle touches exactly six circles symmetrically. In three-dimensional space it is possible to bring a sphere simultaneously in contact with 12 other spheres of the same size without overlapping. It is impossible, however, to bring the central sphere into contact with 13 non-overlapping spheres of the same size; the proof is known but not easy. The best packing of congruent spheres in  $E_3$  is still unknown; solutions exist only with certain added hypotheses.

**BIBLIOGRAPHY.** *The Thirteen Books of Euclid's Elements*, 3 vol. (1908; 2nd ed. rev., 1926), is the standard English translation, with extensive commentary by T.L. HEATH; DAVID HILBERT, *Grundlagen der Geometrie* (1899 and later editions; Eng. trans., *The Foundations of Geometry*, 1902), gives a logical account of Euclid's own methods and many new results. The later editions include revised reprints of very important papers of the author. The axiomatic approach now common in all branches of mathematics is due to the influence of this book and to the work of Giuseppe Peano and his school. HENRY G. FORDER, *Foundations of Euclidean Geometry* (1927), expounds in full detail the work of Hilbert, his followers, and of the American and Italian schools. H.S. MACDONALD COXETER and S.L. GREITZER, *Geometry Revisited* (1967), is a pleasant account of theorems in Euclidean geometry. For Euclidean geometry in its setting in general geometry, see HENRY G. FORDER, *Geometry* (1950); H.S. MACDONALD COXETER, *Introduction to Geometry* (1961); DANIEL PEDOE, *A Course of Geometry for Colleges and Universities* (1970); and HENRY P. MANNING, *Geometry of Four Dimensions* (1914), an excellent work. For transformation geometry, I.M. YAGLOM, *Geometric Transformations* (1962; orig. pub. in Russian, 1955), gives a good elementary introduction. Much more detailed is FRIEDRICH BACHMANN, *Aufbau der Geometrie aus dem Spiegelungsbegriff* (1959), based on papers by Hjelmslev. H.P. HUDSON, *Ruler and Compasses* (1916), is a thorough treatment of constructions. For the theory of congruence, not yet incorporated into textbooks, see J.F. RIGBY, "Axioms for Absolute Geometry," *Can. J. Math.*, 20:158-181 (1968). T. BONNESEN and W. FENCHEL, *Theorie der konvexen Körper* (1934), is excellent for the classical theory. For more recent developments the following books are representative: H.G. EGGLESTON, *Convexity* (1958); FREDERICK A. VALENTINE, *Convex Sets* (1964); and I.M. YAGLOM and V.G. BOLTYANSKY, *Convex Figures* (1961; orig. pub. in Russian, 1951). For an interesting collection of modern research papers, see the *Proceedings of the Seventh Symposium in Pure Mathematics* (1963), which includes "Helly's Theorem and Its Relatives," by L. DANZER, B. GRUNBAUM, and V. KLEE; and "Convex Curves of Constant Minkowski Breadth," by P.C. HAMMER. There exists a variety of books dealing with specialized topics in convexity. HERBERT BUSEMANN, *Convex Surfaces* (1958); and R.T. ROCKAFELLAR, *Convex Analysis* (1970), are typical. Additional references on convexity are: EDWIN F. BECKENBACH, "Convex Functions," *Bull. Am. Math. Soc.*, 54:439-460 (1948); RUSSELL V. BENSON, *Euclidean Geometry and Convexity* (1966); L. FEJES TOTH, *Lagerungen in der Ebene auf der Kugel und im Raum* (1953); B. GRUNBAUM, *Convex Polytopes* (1967); HUGO HADWIGER, *Altes und Neues über konvexe Körper* (1955); HUGO HADWIGER and HANS DEBRUNNER, *Kombinatorische Geometrie in der Ebene* (1959; Eng. trans., *Combinatorial Geometry in the Plane*, 1964); HERMANN MINKOWSKI, *Gesammelte Abhandlung* (1911); EDWIN E. MOISE, *Elementary Geometry from an Advanced Standpoint* (1963); T. MOTZKIN, *Beiträge zur Theorie der linearen Ungleichungen* (1936); and CLAUDE A. ROGERS, *Packing and Covering* (1964).

## Geometry, Non-Euclidean

Non-Euclidean geometry is the subject of study that results by making certain assumptions (the axioms) about points, lines, planes, and space and then drawing conclusions (the theorems) generally consistent with one's spatial intuition concerning objects of moderate size and yet rich in certain relationships that affront the intuition, particularly relationships concerning the concept of parallelism extended to large distances. For instance, similar figures (the same shape) are necessarily congruent (the same shape and size): no plan or model or map can be truly accurate. The two principal types of such a ge-

The isoperimetric inequality

ometry are vividly distinguished by referring to the following imaginary construction. Two rays in a plane are drawn from points  $A$  and  $B$ , perpendicular to and on the same side of the line that connects  $A$  and  $B$  (Figure 1). Instead of remaining equidistant they become farther apart or closer together. In the former case, when the rays diverge, the non-Euclidean geometry is said to be hyperbolic (from the Greek *hyperballein*, "to throw beyond"). In the latter case, when the rays converge and ultimately intersect, the geometry is said to be elliptic

Figure 1: Rays having a common perpendicular in hyperbolic and elliptic geometries (see text).

(from *elleipein*, "to fall short"). Because it is impossible in practice to measure how far apart the rays will be when extended millions of miles, it is quite conceivable that man is living in a non-Euclidean universe. (Because intuition is developed from relatively limited observations, it is not to be trusted in this regard.) In such a world, railroad tracks can still be equidistant, but then they will not be perfectly straight.

**Euclid's axioms.** In the language of axiomatic mathematics, non-Euclidean geometry satisfies all of Euclid's axioms except either the fifth or the second. The axioms of Euclid are stated fully under GEOMETRY, EUCLIDEAN. (They have often been called postulates.) The second axiom states that an interval can be prolonged indefinitely. The fifth states that, if a line meets two other lines so as to make the angles  $a$  and  $b$  on one side of it together less than two right angles, the other lines, if prolonged indefinitely, will meet on this side (in Figure 2, the right side).

Axioms of Euclidean and non-Euclidean geometries

In hyperbolic geometry, axiom 5 is denied, because, if the ray from  $A$  in Figure 1 is replaced by one making a very slightly smaller angle with  $AB$ , the new ray from  $A$  and the old one from  $B$  may converge at first, attain a minimal distance, and then diverge (Figure 3). In elliptic geometry, axiom 5 is satisfied trivially, but axiom 2 (interpreted as giving the line an infinite length) is denied, because now the line is closed, like a circle.

**History of hyperbolic geometry.** It has been remarked with some justice that Euclid (4th century BC) was the first non-Euclidean geometer, because of his own evident reluctance to invoke axiom 5. At any rate, he arranged his material so that his first 28 propositions are proved without the aid of this unpleasantly complicated assumption. Such a collection of propositions, based on the first four postulates alone, has been growing ever since Euclid's time and is now known as absolute geometry. (All of these propositions are valid in hyperbolic geometry as well as Euclidean.) Until about 1800, however, all the people who thought along these lines imagined that they were operating within Euclidean geometry so that they would eventually deduce the fifth axiom as a theorem. Many believed that they had attained this goal, though in fact they had merely replaced axiom 5 by other equivalent assumptions, such as "two parallel lines are equidistant" or "three non-collinear points always lie on a circle."

A Jesuit logician named Gerolamo Saccheri of 17th- and 18th-century Italy used a more sophisticated ap-

proach: *reductio ad absurdum* (disproving a false proposition by logically deducing an absurd consequence). He tried to establish axiom 5 by denying it and seeking a consequent contradiction. In the course of his elaborate chain of deduction he discovered many of the theorems of what is now called hyperbolic geometry, although he had started with the sole purpose of demolishing them. At a certain stage he imagined he had deduced the absurdity he was seeking, and thus he narrowly missed the opportunity for a great achievement. He failed because of his pious belief that Euclid's was the only true geometry.

In 1763 the German mathematician Georg Simon Klügel listed nearly 30 attempts to prove axiom 5 and rightly concluded that the alleged proofs were all unsound. Fifty years later, a new generation of geometers, still working on the same problem, were becoming more and more frustrated. One of them, a Hungarian named Farkas Bolyai, wrote in a letter to his son János Bolyai: "I entreat you, leave the science of parallels alone . . . I have travelled past all reefs of this infernal Dead Sea and have always come back with a broken mast and torn sail." The son, refusing to heed this warning, continued to think about parallels until, in 1823, he saw the whole truth and declared, in his youthful enthusiasm, "I have created a new universe from nothing!" He understood that, at a certain stage, absolute geometry branches out in two directions depending on whether axiom 5 is asserted or denied. János Bolyai thus recognized two different but equally consistent geometries and published his discovery as a 24-page appendix to a textbook by his father. George Bruce Halsted called it "the most extraordinary two dozen pages in the whole history of thought." In 1832 Farkas Bolyai proudly presented a copy to his friend Carl Friedrich Gauss, then Germany's greatest mathematician, whose reply to the father had a devastating effect on János and led eventually to much criticism of Gauss. The criticism undoubtedly stemmed from the impression that a man of Gauss's stature could have afforded to acknowledge that both the concept and the confidence of its truth are essential to prior claim in any field of intellectual endeavour. The younger Bolyai had conveyed both concept and confidence by choosing the path of publication, while Gauss in his private papers had recorded only his awareness of the concept. For these reasons it seems worthwhile to quote a considerable portion of Gauss's reply (in H.S. Carslaw's translation):

I am unable to praise this work . . . To praise it would be to praise myself. Indeed, the whole contents of the work, the path taken by your son, the results to which he is led, coincide almost entirely with my meditations which occupied my mind partly for the last thirty or thirty-five years. So I remained quite stupefied. So far as my own work is concerned . . . my intention was not to let it be published during my lifetime . . . On the other hand, it was my idea to write down all this later so that at least it should not perish with me. It is therefore a pleasant surprise for me that I am spared this trouble, and I am very glad that it is just the son of my old friend who takes the precedence of me in such a remarkable manner.

It can now be seen, from his earlier correspondence, that Gauss had indeed been familiar with hyperbolic geometry, even before János was born. For instance, he wrote to the elder Bolyai in 1799: "It might well be possible that, however far apart one took the three vertices of a triangle in space, its area was always under a given limit." Again, a letter to Gauss has been preserved in which his pupil Friedrich Ludwig Wachter (1792–1817)

Figure 2: Illustration of Euclid's fifth postulate (see text).

Questions concerning Euclid's parallel postulate

Figure 3: Ultraparallel lines (see text).

remarked a few months before his tragically early death that, if axiom 5 is denied, a sphere the radius of which tends to infinity approaches a limiting surface on which certain curves (the geodesics) behave just like the lines of the Euclidean plane. This surface, now known as the horosphere, was destined to play a vital role in the development of the subject.

Non-Euclidean geometry and the theory of relativity have so profoundly affected today's philosophic outlook that it can hardly be imagined how shocking the denial of one of Euclid's postulates must have seemed at the beginning of the 19th century. Such considerations may help to explain why Gauss deliberately renounced his potential claim in favour of János Bolyai and his Russian contemporary Nikolay Ivanovich Lobachevsky, whose first published paper is remarkably like Bolyai's, though quite independent of it.

Lobachevsky made a deeper investigation, wrote several books, and became a professor at the University of Kazan. Gauss sent him a letter of genuine praise and arranged a corresponding membership for him in the Göttingen Academy. In marked contrast, the unhappy Bolyai received no recognition during his lifetime. In 1848 he read one of Lobachevsky's books (translated into German) and praised it warmly. Still smarting from the unkind treatment that he imagined he had received from Gauss, however, he was too timid to introduce himself to the prosperous Russian, and there is no evidence that Lobachevsky was aware of his existence. Gauss, who knew them both, was so fully occupied with his own work on other subjects that he never took the trouble to bring them together.

**History of elliptic geometry.** On the surface of a sphere, such as a geographical globe or the Earth itself, the shortest distance between two points is an arc of a great circle. It is natural for navigators to regard such circles as the "lines" of a special kind of two-dimensional geometry, namely spherical geometry: the geometry of figures drawn on the surface of a sphere of radius 1. It will be seen later that this is almost the same as plane elliptic geometry. Spherical geometry was studied by Menelaus of Alexandria about AD 100 and by the Arabs about 1000. Its most famous theorem (discovered by Albert Girard, a French mathematician of the early 17th century) states that the three angles of a spherical triangle (in radian measure) satisfy the inequality  $A + B + C > \pi$  and that the area of a triangle is  $A + B + C - \pi$ . The gigantic step of extending this geometry from two dimensions to three (or more) was taken simultaneously (in the latter half of the 19th century) by Ludwig Schläfli in Switzerland and Bernhard Riemann in Germany. Schläfli regarded spherical three-dimensional space as the "surface" of the "sphere" in Euclidean four-dimensional space (that is, the hypersurface on which the four coordinates satisfy the equation  $x_1^2 + x_2^2 + x_3^2 + x_4^2 = 1$ ). If this three-dimensional continuum represents the astronomical space in which man lives, the unit of measurement (radius of the universe) must be very large; but in terms of this unit the total length of a line is  $2\pi$ . This means, as Riemann remarked, that the unboundedness of space does not necessarily imply infinitely long lines. A sufficiently powerful telescope could theoretically enable an astronomer to observe the back of his own head, apart from the fact that the light reflected from his head would require thousands of millions

of years to reach his eye. This idea, that space could be unbounded without being infinite, was adopted by Einstein in his general theory of relativity (see PHYSICAL THEORIES, MATHEMATICAL ASPECTS OF: *Relativity theory*).

Another German, Felix Klein, at the turn of the 20th century, first saw how to remedy the awkward situation in spherical geometry that two lines through any one point, being two great circles on a sphere, meet again in an antipodal point (or point on the surface of the sphere that is furthest from the first point). He realized that, because every point determines a unique antipodal point, nothing would be lost and much would be gained by abstractly identifying each pair of antipodal points—that is, by changing the meaning of the term "point" so as to call such a pair one point. He gave the name elliptic geometry to this modification of spherical geometry and the name hyperbolic to the geometry of Bolyai and Lobachevsky.

**Projective models.** Although both Bolyai and Lobachevsky were intuitively certain that their investigations would never lead to two contradictory statements, neither of them lived to see a rigorous demonstration of this relative consistency: the fact that hyperbolic geometry is just as logically consistent as Euclidean geometry. This important step was taken in 1868 by the Italian mathematician Eugenio Beltrami. He constructed a Euclidean model of the hyperbolic plane by using the points inside a circle and the chords determined by pairs of these points to represent the hyperbolic points and lines. Points on the circle are regarded as being infinitely far away. Thus the parallel lines of Bolyai and Lobachevsky, which "only just" fail to meet, are represented by chords having a common end, such as  $AN$  and  $MN$  in Figure 4. For any line  $MN$  of the hyperbolic plane and any point  $A$  not on this line, there are two rays from  $A$  parallel to  $MN$ , namely,  $AM$  and  $AN$ . Any line  $p$  through  $A$  inside the angle  $MAN$  intersects  $MN$ , and any line  $l$  through  $A$  in the supplement of this angle fails to intersect  $MN$ . The German mathematician Eduard Study called such a line  $l$  ultraparallel to  $MN$ . Thus, any two lines in the hyperbolic plane are either intersecting, parallel, or ultraparallel.

Beltrami's model of the hyperbolic plane

Figure 4: Rays  $AM$  and  $AN$  from  $A$  parallel to  $MN$  in the hyperbolic plane.

To be quite precise, Beltrami considered points inside the circle having the equation  $x^2 + y^2 = k^2$  and defined the element  $ds$  of hyperbolic distance by a formula in which the square of this element is a quadratic function (with variable coefficients) of the differential elements  $dx$  and  $dy$  (see Box, equation 1). He observed that with this metric the geodesics are of the form  $ax + by + c = 0$  (that is, Euclidean straight lines), while the Gauss curvature has the constant value  $-1/k^2$ . It follows, by setting  $y = 0$ , that a point distant  $r$  from the origin is regarded as being at hyperbolic distance  $k\delta$  when  $\delta$  is expressed by integrating the function  $(1 - x^2)^{-1}$  from 0 to  $r$ , so that  $r = \tanh \delta$  (see 2).

$$(1) \quad ds^2 = k^2 \frac{(1 - y^2) dx^2 + 2xy dx dy + (1 - x^2) dy^2}{(1 - x^2 - y^2)^2}$$

$$(2) \quad \delta = \int_0^r \frac{dx}{1 - x^2}$$

# Conjugate points and lines

Meanwhile, the subject of projective geometry (see GEOMETRY, PROJECTIVE) had been developed by the mathematicians Jean-Victor Poncelet (French) and Karl Georg Christian von Staudt (German) to the stage at which it became clear that the real projective plane admits a polarity—that is, a one-to-one correspondence between all the points  $A$  and lines  $a$  such that incidence is preserved in accordance with the principle of duality. This means that, if  $A$  is the pole of  $a$  and  $b$  is the polar of  $B$ , and if  $B$  lies on  $a$ , then  $b$  passes through  $A$ . Two lines are said to be conjugate if one passes through the pole of the other, and two points are said to be conjugate if one lies on the polar of the other (Figure 5). If no point is conjugate to itself, the polarity is said to be elliptic, and every point behaves just like every other point. The existence of one self-conjugate point, however, ensures that of many others, namely, all the points on a conic, and then the polarity is said to be hyperbolic. The polars of the self-conjugate points are the self-conjugate lines, which are the tangents of the conic. A point not on the conic is said to be inside or outside according as it lies on no tangent or on two tangents. Analogous results hold in three dimensions, with planes instead of lines and a surface instead of a curve.

Developing an idea of the English mathematician Arthur Cayley who had translated some of Schläfli's work, Klein observed that, when one polarity (the "absolute" polarity) is assumed to play a special role, real projective geometry becomes non-Euclidean, namely, elliptic or hyperbolic according to the nature of the absolute polarity. The precise connection is that conjugate lines (or planes) become perpendicular lines (or planes). In the elliptic plane, for instance, all the lines perpendicular to a given line  $a$  pass through one point  $A$ , the pole of  $a$ . (On a sphere, all the great circles perpendicular to the equator pass through the north and south poles, which Klein identified so as to form one pole.) Thus, the pole of a line  $AB$  is the point of intersection of the lines through  $A$  and  $B$  perpendicular to  $AB$  (Figure 1).

Similarly, hyperbolic geometry is determined by a hyperbolic polarity and hence by an absolute conic (or quadric). The hyperbolic plane (or space), however, is not the whole projective plane (or space) but only the region inside the absolute conic (or quadric). In other words, the lines of hyperbolic geometry are the chords of this conic (or quadric), and the two ends of such a chord are the points at infinity, or ends, of the hyperbolic line. (This projective model is thus a generalization of Beltrami's.) The condition for two lines of the hyperbolic plane (or space) to be parallel (in the sense of Bolyai and Lobachevsky) is that they have one end in common; and the set of all lines with a common end, being the set of all lines parallel to a given ray, is a pencil (or bundle) of parallels. David Hilbert, German mathematician, first used the word end in this sense so

Figure 5: Conjugate lines ( $a$  and  $b$ ) and conjugate points ( $A$  and  $B$ ).

Figure 6: Three planes perpendicular to one line and their inverse models, three coaxial (non-intersecting) circles.

that each line has two ends, both infinitely far away but distinct, in contrast to the customary introduction to projective geometry, in which it is said that a line has only one point at infinity. Hilbert also gave both kinds of non-Euclidean geometry their first rigorous axiomatic treatment.

It can be seen at once from Figure 4 that any two ultraparallel lines, such as  $AP$  and  $MN$ , have a unique common perpendicular (represented by the polar of the ultra-infinite point of intersection  $P$  of the two ultraparallel lines). Hilbert gave a long and ingenious proof of this theorem, using his axioms without any appeal to the projective model.

Regarding the hyperbolic plane  $AMN$  as one plane in hyperbolic space, one can draw through each line a plane perpendicular to  $AMN$  and thus deduce properties of pairs of planes. It can be concluded that there are just three kinds of plane pairs: intersecting, so that the two planes contain a common line; parallel, having one common point at infinity, such as  $N$ ; and ultraparallel, so that they have a common perpendicular. In the projective model, parallel planes intersect in a tangent line of the absolute quadric.

**Inversive models.** In the above-mentioned projective model of Cayley and Klein, the points and lines of hyperbolic space are represented by the interior points and chords of a quadric surface in real projective space. This quadric may be conveniently regarded as a sphere: a celestial sphere that surrounds the observer and is so large that he may be regarded as being at its centre even when he changes position. In this manner, the three-parameter family of planes in space is represented by the three-parameter family of circles on the sphere, with no distinction made between great and small circles—that is, by the three-parameter family of circles in the inversive plane. Each pair of intersecting planes is represented by a pair of intersecting circles; the line of intersection is represented by two points, arising from the two ends of the line; and the two supplementary dihedral angles (formed by the two intersecting planes) are represented by the angles of intersection of the circles. The three kinds of circle-pair—intersecting, tangent, and non-intersecting—represent three kinds of plane-pair: intersecting, parallel, and ultraparallel. Thus, the space under consideration is hyperbolic, not Euclidean.

Though this representation of hyperbolic space by the inversive plane was mentioned casually by mathematicians in England, Germany, and the United States, its first systematic development was in Germany by Heinrich Liebmann in his *Nichteuklidische Geometrie* (Leipzig, 1905, p. 54).

It is still necessary to find an appropriate meaning for the distance  $AB$  between two points  $A$  and  $B$  of the hyperbolic space. By "appropriate" it is meant that it should be properly additive so that, if  $A, B, C$  are on a line  $l$ , with  $B$  between  $A$  and  $C$ ,  $AB + BC = AC$ . Let  $\alpha, \beta, \gamma$  symbolize the planes through  $A, B, C$  that are perpendicular to  $l$ . Having a common perpendicular, these planes are ultraparallel in pairs and are represented by non-intersecting coaxial circles to which the same symbols  $\alpha, \beta, \gamma$  may be assigned (Figure 6). The line  $l$  is

Inversive model of hyperbolic space; inversive distance

$$\begin{aligned}
 (3) \quad & \left| \frac{a^2 + b^2 - c^2}{2ab} \right| \\
 (4) \quad & \cosh 2\delta = \left| \frac{a^2 + a^2 - (2p)^2}{2a^2} \right| = 2\left(\frac{p}{a}\right)^2 - 1 \\
 (5) \quad & \cosh \delta = \left| \frac{a^2 + b^2 - b^2}{2ab} \right| = \frac{a}{2b} = \frac{a}{a^2/p} = \frac{p}{a} \\
 (6) \quad & \begin{cases} \text{From Figure 8: } \csc \theta = \frac{AQ}{ON} = \frac{p}{a} = \cosh \delta \\ \qquad \qquad \cot \theta = \sinh \delta \\ \text{From trigonometry: } \tan \frac{1}{2}\theta = \csc \theta - \cot \theta \\ \text{Conclusion: } \tan \frac{1}{2}\theta = e^{-\delta} \end{cases}
 \end{aligned}$$

represented by the pair  $LL'$  of limiting points. (For, every plane through  $l$  is perpendicular to all three planes, and every circle through  $L$  and  $L'$  is orthogonal to all three circles.) It is therefore natural to identify the distance  $AB$  (which is the shortest distance between the planes  $\alpha$  and  $\beta$ ) with the inversive distance between the circles  $\alpha$  and  $\beta$ .

For any two circles  $\alpha$  and  $\beta$  (in the Euclidean plane) with radii  $a$  and  $b$  and distance  $c$  between their centres, an expression involving  $a$ ,  $b$ ,  $c$  can be found (see 3) which is an inversive invariant such that, if the circles intersect, it is the cosine of their non-obtuse angle of intersection. Further, if the circles are tangent, the same expression is equal to 1; if they are non-intersecting, it is equal to  $\cosh \delta$ , in which  $\delta$  is their inversive distance. This is the natural logarithm of the ratio (larger to smaller) of two concentric circles into which  $\alpha$  and  $\beta$  can be inverted. This kind of distance,  $\delta = (\alpha\beta)$ , is properly additive for coaxial circles—that is, if three circles  $\alpha$ ,  $\beta$ ,  $\gamma$  occur in this order in a non-intersecting pencil, their mutual inversive distances satisfy the equation  $(\alpha\beta) + (\beta\gamma) = (\alpha\gamma)$ . In particular, the inversive distance between a circle and a line is half the inversive distance between two congruent circles (namely, the given circle and its image by reflection in the line). Thus, if a circle of radius  $a$  has its centre distant  $p$  from a line ( $p > a$ ), their inversive distance  $\delta$  is given by the formula  $\cosh \delta = p/a$  (see 4).

Alternatively, let  $O$  be the centre of the circle  $\alpha$  and  $A$  the foot of the perpendicular from  $O$  to the line, as in Figure 7. After inversion in  $\alpha$ ,  $\alpha$  remains unchanged, but the line becomes a circle having diameter  $OA' = a^2/p$ , that is, a circle  $\beta$  for which  $b = c = a^2/2p$ . Hence, the inversive distance  $\delta$  is given by  $\cosh \delta = p/a$ , as before (see 5).

Let  $2\theta$  be the angle subtended by the circle  $\alpha$  at  $A$ , the nearest point on the line (i.e.,  $\theta = \angle OAN$ , in which  $AN$  is one of the tangents from  $A$ , as in Figure 8). Then the formula  $\tan \frac{1}{2}\theta = e^{-\delta}$  can be deduced by trigonometry (see 6). This formula will be used later.

It can also be found from inversive geometry that, if three circles  $\alpha$ ,  $\beta$ ,  $\gamma$  are not coaxial, they span a bundle  $\alpha\beta\gamma$  (that is, the smallest set of circles that includes these three and, with any two of its members, the whole of the pencil [of coaxial circles] spanned by them). There are, in fact, three kinds of bundle, depending on whether the constant power of their radical centre is negative, zero, or positive. The circles of an elliptic bundle, like the great circles on a sphere, all intersect one fixed circle in pairs of diametrically opposite points of the fixed circle. The circles of a parabolic bundle all pass through one fixed point. If this point is the point at infinity, the bundle consists of all the lines in the Euclidean plane. Finally, the circles of a hyperbolic bundle are all orthogonal to one fixed circle, or to one fixed line (if the centres of  $\alpha$ ,  $\beta$ ,  $\gamma$  happen to be all on one line).

Returning to the representation of planes in hyperbolic space by circles in the inversive plane, it is seen that the circles belonging to the three kinds of bundle—elliptic, parabolic, and hyperbolic—represent the lines in three kinds of plane—elliptic, Euclidean, and hyperbolic. In fact, the circles of an elliptic bundle, regarded as great circles on a sphere, represent planes through one point, the centre of the sphere, and such an ordinary bundle of planes behaves the same way in hyperbolic space as in Euclidean space. Second, the circles of a parabolic bundle are, in one special case, all the lines in a Euclidean plane; the corresponding planes in the hyperbolic space are all the planes parallel to one ray, and thus such planes behave like the lines in a Euclidean plane.

Third, the circles of a hyperbolic bundle, being orthogonal to one circle, represent all the planes perpendicular to one plane  $\omega$  (omega) and thus equally well represent the  $\omega$ -sections of these planes, which are all the lines in this hyperbolic plane  $\omega$ . This is, perhaps, the simplest way to obtain the French mathematician Henri Poincaré's representation of the lines of the hyperbolic plane by all the circles orthogonal to one circle  $\omega$  (including all the diameters), or by all the circles and lines orthogonal to one line  $\omega$ . Each point of the hyperbolic plane, being the intersection of two lines, is represented by two points that are images of each other by inversion in the circle  $\omega$  or by reflection in the line  $\omega$ . To obtain a one-to-one representation of points, Poincaré restricted attention to the inside of the circle  $\omega$  or to the upper half-plane bounded by the line  $\omega$ . In either form of this model, angles are still represented without distortion, while distances appear as inversive distances between suitable pairs of circles.

**The angle of parallelism.** In the hyperbolic plane, if  $BN$  is a ray perpendicular to  $AB$  and  $AN$  the ray from  $A$  parallel to  $BN$  (see Figure 9), then, in the notation and terminology of Lobachevsky, the angle  $\Pi(\delta) = \angle BAN$  is the angle of parallelism corresponding to the distance  $\delta = AB$ . Using Poincaré's circle model,  $A$  can be represented by the centre of his circle  $\omega$ ,  $B$  by a suitable point inside  $\omega$ , and  $BN$  by an arc of the circle through  $B$  orthogonal to both  $\omega$  and  $AB$ . The point  $N$ , at which this arc meets  $\omega$ , represents the end of the hyperbolic ray  $BN$ , and the parallel ray from  $A$  appears as the radius  $AN$  of  $\omega$ , which is tangent to the arc  $BN$  at  $N$ . Comparing Figure 9 with Figure 8, it is seen that the angle of parallelism  $\theta = \angle BAN$  can be expressed in terms of the hyperbolic distance  $\delta$  by the formula  $\tan \frac{1}{2}\Pi(\delta) = e^{-\delta}$ , discovered independently by Bolyai and Lobachevsky.

**Comparison of the inversive and projective models.** Figure 9 exhibits hyperbolic distances  $AB = \delta$  and  $AN = \infty$ . It is of some interest to compare these with the corresponding Euclidean distances. For simplicity,  $AN$  may be taken to equal 1, so that  $\omega$  is the unit circle with centre  $A$  in the Euclidean plane. Figure 10 shows the complete circle  $MBNB'$  that represents the line  $MN$  perpendicular to  $AB$ . Because this circle is orthogonal to  $\omega$ ,  $B$  and  $B'$  are inverse points in  $\omega$ . So, if  $AB = x$ ,  $AB' = 1/x$ .

Writing  $AO = p$  and  $ON = a$ , as in Figure 8, one finds

Relation to  
hyperbolic  
distance

 Figure 8: Circle  $\alpha$  subtending angle  $2\theta$  at  $A$ .

that  $x = \tanh \frac{1}{2} \delta$  (see 7). This is the desired relation between the Euclidean and hyperbolic distances  $AB$  when the hyperbolic line  $MN$  is represented by the arc  $MN$  orthogonal to  $\omega$ .

If the same unit circle  $\omega$  represents the absolute circle in Beltrami's model (with  $k = 1$ ), it is necessary to replace this arc  $MN$  by its chord. If  $P$  be the midpoint of the chord, as in Figure 11, then the Euclidean distance  $r = AP$  represents  $\delta$  in this other model, and it is seen that  $r = \cos \theta = \tanh \delta$ . Thus, the inversive and projective models represent the hyperbolic distance  $\delta$  (measured from the point represented by the centre of  $\omega$ ) by  $\tanh \frac{1}{2} \delta$  and  $\tanh \delta$ , respectively.

$$(7) \quad \begin{cases} 2p = \frac{1}{x} + x, & 2a = \frac{1}{x} - x \\ \cosh \delta = \frac{p}{a} = \frac{1+x^2}{1-x^2}, & x = \tanh \frac{\delta}{2} \end{cases}$$

**Circles and spheres.** The inversive plane has been used in two distinct, though related, ways. Following Poincaré, the circles (and lines) orthogonal to one circle (or line)  $\omega$  represent the lines of the hyperbolic plane, and the points inside the circle (or in the upper half-plane bounded by the line) represent the points of the hyperbolic plane. Second, following Liebmann, all the circles (and lines) in the inversive plane represent the planes of hyperbolic space. In this case, lines are represented by point-pairs, but points are not represented at all, unless it can be said that they are represented by elliptic bundles. The relation between these two representations is seen by taking Poincaré's  $\omega$  to be the Liebmann representative of one particular plane in the hyperbolic space and considering the lines in this one plane, which is, of course, a hyperbolic plane.

Because either of Poincaré's models provides a point of the inversive plane for each point of the hyperbolic plane and provides a circle (or line) orthogonal to  $\omega$  for each line, it is natural to ask what curve in the hyperbolic plane is represented by a circle (or line)  $\alpha$  not orthogonal to  $\omega$ . The circles (or lines)  $\alpha$  and  $\omega$  may be intersecting, tangent, or non-intersecting. If they are non-intersecting, no generality is lost by taking them to be con-

centric circles, in which case the curve is what naturally is called a circle, because it is orthogonal to its diameters, which are all the lines through its centre. More precisely, in the notation of Figure 10, a hyperbolic circle of radius  $\delta$  is represented by a circle (concentric with  $\omega$ ) of radius  $AB = x = \tanh \frac{1}{2} \delta$ . Because Poincaré's circle model remains valid when transformed by inversion in any circle orthogonal to  $\omega$ , it follows that any circle  $\alpha$  inside  $\omega$  represents a hyperbolic circle. The radius  $\delta$  of this hyperbolic circle is determined by the inversive distance  $-\log \tanh \frac{1}{2} \delta$  between  $\alpha$  and  $\omega$ . (Because  $\tanh \frac{1}{2} \delta$  is less than 1, its logarithm is negative.) When  $\alpha$  and  $\omega$  are not concentric, the centre of the hyperbolic circle is represented by one of the limiting points of the coaxial pencil spanned by  $\alpha$  and  $\omega$ , not by the Euclidean centre of  $\alpha$ .

If  $\alpha$  and  $\omega$  are tangent, no generality is lost by taking them to be two parallel lines in the Euclidean plane. Thus, in terms of the half-plane model,  $\alpha$  is a line, in the upper half-plane, parallel to  $\omega$ . The corresponding curve in the hyperbolic plane, being the limiting form of a circle when its centre moves off to infinity, is called a horocycle. Its diameters, cutting it orthogonally, are a pencil of parallels (that is, the set of all lines parallel to one ray or the set of all lines having one common end), represented by the lines perpendicular to  $\omega$ , which are, of course, parallel in the Euclidean sense.

Finally, if  $\alpha$  and  $\omega$  are intersecting, no generality is lost by taking them to be intersecting lines or, more precisely, by using the half-plane model and considering two rays, from a point  $A$  on  $\omega$ , making angles  $\theta$  and  $\pi - \theta$  with  $\omega$ , as in Figure 12. These rays represent a curve having two branches, like a hyperbola, except that they are concave as seen from a point between them. It is called an equidistant curve, because it is the locus of points at a constant distance  $\delta$  from a fixed axis  $o$ , represented by the line through  $A$  perpendicular to  $\omega$ . To prove this constancy, it is observed that the lines along which  $\delta$  is measured are the "diameters": a pencil of ultraparallels (all perpendicular to  $o$ ), represented by the circles with centre  $A$ . If  $AN$  (in Figure 12) is the radius of one such circle, the distance along the corresponding diameter is the in-

Figure 10: Poincaré's circle model.

versive distance from the line  $o$  (perpendicular to  $\omega$ ) to the circle that touches  $AN$  at  $N$  and has its centre on  $\omega$ . Comparison with Figure 9 shows that this distance is  $\delta = -\log \tan \frac{1}{2} \theta$ , regardless of which circle with centre  $A$  is used. In other words, the two branches of the equidistant curve with radius  $\delta$  are represented by two lines making angles  $\Pi(\delta)$  and  $\pi - \Pi(\delta)$  with  $\omega$ . (The two branches of the curve are distant  $\delta$  from its axis, one on each side.) More generally, any two circular arcs making angles  $\Pi(\delta)$  and  $\pi - \Pi(\delta)$  with  $\omega$  at two points  $A$  and  $B$  represent such an equidistant curve.

Recalling the Euclidean theorem that any three distinct points lie either on a line or on a circle, it is seen that the hyperbolic counterpart is as follows: Any three distinct points lie either on a line or on a circle or on a horocycle or on one branch of an equidistant curve. Alternatively, if both branches are allowed: Each vertex of a triangle

Figure 9: The angle of parallelism.

Figure 11: Beltrami's circle model.

lies on one branch of an equidistant curve such that the remaining two vertices lie on the other branch. (The axis joins the midpoints of the two sides involving the first vertex.)

For representing hyperbolic space, a useful variant of Liebmann's model is obtained by regarding each circle as the bounding equator of a hemisphere in a half-space bounded by his plane  $\lambda$  (lambda). The planes and lines of the hyperbolic space are then represented by spheres (or planes) and circles (or lines) orthogonal to  $\lambda$ , and the points are represented by the points of the half-space. It follows that a sphere not intersecting (nor touching)  $\lambda$  represents a sphere (obtained by rotating a circle about a diameter); a sphere tangent to  $\lambda$  represents a horosphere, obtained by rotating a horocycle about a diameter; and a sphere intersecting  $\lambda$ , or, more precisely, the lens bounded by two such spheres, images of each other by reflection in  $\lambda$ , represents an equidistant surface, obtained by rotating an equidistant curve about a diameter. In particular, a plane parallel in the Euclidean sense to  $\lambda$ , being a sphere whose point of contact with  $\lambda$  is the point at infinity, represents a horosphere. Moreover, this representation of the whole horosphere by the whole plane is isometric, or faithful, in the sense that equal arcs of the horosphere measured along horocycles correspond to equal line segments of the Euclidean plane. (In the language of differential geometry, the horosphere is a developable surface—that is, a surface the Gauss curvature of which is zero.) This is the above-mentioned discovery made by Wachter in 1817.

**Coordinates in spherical and elliptic space.** Euclidean space of four dimensions can be explored by means of Cartesian coordinates  $x_r$  ( $r = 1, 2, 3, 4$ ), in terms of which a single linear equation represents a three-dimensional

subspace or "hyperplane" which passes through the origin  $(0, 0, 0, 0)$  when the constant on the right is zero (see 8). The distance between two points  $(x_1, x_2, x_3, x_4)$  and  $(y_1, y_2, y_3, y_4)$  is the square root of  $\sum (x_r - y_r)^2$ . The hypersurface  $\sum x_r^2 = c^2$  is called a sphere (of radius  $c$ ) or, more precisely, a 3-sphere (to distinguish it from the 2-sphere, which is an ordinary sphere; a 1-sphere, which is a circle; and a 0-sphere, which is a pair of points). The section of the 3-sphere by a plane or hyperplane through its centre  $(0, 0, 0, 0)$  is called a great circle or great sphere, respectively. The great circles and great spheres on the unit 3-sphere  $\sum x_r^2 = 1$  are the lines and planes of spherical space, from which the more familiar elliptic space can be derived by identifying all pairs such as  $(x_1, x_2, x_3, x_4)$  and  $(-x_1, -x_2, -x_3, -x_4)$ . The angles  $\theta$  and  $\pi - \theta$ , in which  $\cos \theta = \sum x_r y_r$ , can be regarded either as the angles subtended by two such pairs of points at the origin or as the two distances between the points  $(x)$  and  $(y)$  of the elliptic space. Similarly, the angles  $\phi$  and  $\pi - \phi$ , where  $\cos \phi = \sum X_r Y_r$ , can be regarded either as the angles between two hyperplanes  $\sum X_r x_r = 0$  and  $\sum Y_r x_r = 0$  of the Euclidean 4-space or as the angles between two planes  $[X]$  and  $[Y]$  of the elliptic space. The plane  $[X]$ , meaning  $\sum X_r x_r = 0$ , is regarded as having coordinates  $[X_1, X_2, X_3, X_4]$  (tangential or envelope coordinates) so that the equation  $\sum X_r x_r = 0$  expresses the fact that the plane  $[X]$  and point  $(x)$  are incident, the plane passing through the point and the point lying in the plane. It follows that the pole of the plane  $[X]$  is the point  $(X)$  that has the same coordinates.

The surface in spherical space with equation  $x_1^2 + x_2^2 = x_3^2 + x_4^2 = \frac{1}{2}$  yields the rectangular Clifford surface in elliptic space (discovered by the English mathematician William Kingdon Clifford in 1873). In terms of two parameters  $u$  and  $v$ , which range independently over the

$$(8) \quad X_1 x_1 + X_2 x_2 + X_3 x_3 + X_4 x_4 = c$$

$$(9) \quad \begin{cases} x_1 = \sqrt{\frac{1}{2}} \cos(u+v), & x_2 = \sqrt{\frac{1}{2}} \sin(u+v) \\ x_3 = \sqrt{\frac{1}{2}} \cos(u-v), & x_4 = \sqrt{\frac{1}{2}} \sin(u-v) \end{cases}$$

$$(10) \quad dx_1^2 + dx_2^2 + dx_3^2 + dx_4^2 = du^2 + dv^2$$

$$(11) \quad \begin{cases} x_1 \cos v + x_2 \sin v = x_3 \cos v - x_4 \sin v \\ -x_1 \sin v + x_2 \cos v = x_3 \sin v + x_4 \cos v \end{cases}$$

interval from 0 to  $\pi$ , this surface is given by four parametric equations (see 9). It is a developable surface, like the horosphere, for  $u$  and  $v$  can be regarded as Cartesian coordinates in a Euclidean plane (see 10), and thus the surface can be developed into the region of the plane enclosed by the lines  $u = 0$ ,  $v = 0$ ,  $u = \pi$ ,  $v = \pi$ , which form a square. The periodicity of the parameters makes each side of the square coincide with the opposite side; thus the Clifford surface, as defined above, has the topology of a torus (a doughnut-shaped surface that is generated by bending a square into a cylinder with two circular ends and then bending the cylinder until the two ends meet), even though it is a homogeneous surface (like a plane or a 2-sphere): the neighbourhoods of all its points are exactly alike.

Elimination of  $u$  from the parametric equations (see 11) shows that the line along which  $v$  takes any constant value is straight—that is, a great circle on the 3-sphere, cut out by a plane through its centre. Similarly, there is a straight line for each constant value of  $u$ . After development onto the Euclidean plane, these lines are parallel to the sides of the square. Thus, two such lines of the same type on the Clifford surface are equidistant from each other throughout their length and have infinitely many common perpendiculars of the other type. This occurrence of parallel lines in elliptic space seems paradoxical

The horosphere

 (19) \quad & \alpha' = \frac{1}{2} \pi - \alpha, \quad A, \quad \gamma, \quad B, \quad \beta' = \frac{1}{2} \pi - \beta \\
 (20) \quad & \tan \alpha' \tan \gamma = \sin A = \cos \beta' \cos B \\
 (21) \quad & \tan A \tan B = \sin \gamma = \cos \alpha' \cos \beta' \\
 (22) \quad & \cot A \cot B = \cosh c = \cosh a \cosh b \\
 (23) \quad & 1 + \frac{1}{2} c^2 + \dots = \left(1 + \frac{1}{2} a^2 + \dots\right) \left(1 + \frac{1}{2} b^2 + \dots\right)
 \end{aligned}$$

until it is remembered that they are skew lines, not lying in one plane. They are called Clifford parallels. More precisely, lines of one type are right parallels, of the other type left parallels, and this distinction can be maintained by continuous variation over the elliptic space. In fact, for any line  $l$  in the space, and any point  $A$  not on  $l$  (nor on the polar line of  $l$ ), there are just two lines through  $A$  that are Clifford parallel to  $l$ : one right parallel and one left parallel.

Allowing  $A$  to vary, Clifford found also that all the lines right (or left) parallel to  $l$  are right (or left) parallel to one another, and among them, those that intersect an arbitrary line  $m$  do so at a constant angle, say  $\theta$ , and generate a ruled quadric surface, called a Clifford surface, whose generators of the other system are left (or right) parallel to  $m$  and to one another. (The rectangular Clifford surface is the special case when  $\theta$  is a right angle.) Moreover, the segments of the generators of either system intercepted between two generators of the other system all have the same length. Thus, any Clifford surface can be developed isometrically onto a Euclidean plane, the two systems of generators appearing as two systems of parallel lines (parallel in the Euclidean sense) inclined at the angle  $\theta$ . Because each line has total length  $\pi$ , however, the whole surface is mapped onto a finite part of the Euclidean plane, namely, a rhombus of side  $\pi$ , the angles of which are  $\theta$  and  $\pi - \theta$ . It follows that the general Clifford surface is topologically a torus and its total area is  $\pi^2 \sin \theta$ .

**Coordinates in the hyperbolic plane.** Klein showed that the hyperbolic plane can be explored by means of coordinates  $x_\nu$  and  $X_\nu$  ( $\nu = 0, 1, 2$ ), in terms of which the absolute conic has the locus equation  $x_0^2 - x_1^2 - x_2^2 = 0$  and the envelope equation  $X_0^2 - X_1^2 - X_2^2 = 0$ . In this notation,  $(x)$  or  $(x_0, x_1, x_2)$  is a point,  $[X]$  or  $[X_0, X_1, X_2]$  is a line, and these are incident (the point lying on the line) if  $\Sigma X_\nu x_\nu = 0$ . The polar of  $(x)$  is  $[x_0, -x_1, -x_2]$ , which is the same as  $[-x_0, x_1, x_2]$ . The line  $[1, 0, 0]$  or  $x_0 = 0$  has no intersection with the conic; therefore, its pole  $(1, 0, 0)$  is inside the conic.

Because all the proper points of the hyperbolic plane are inside, like this one, their coordinates satisfy the inequality  $x_0^2 - x_1^2 - x_2^2 > 0$ .

Because all the proper lines are secants (or chords), their coordinates satisfy the inequality  $X_0^2 - X_1^2 - X_2^2 < 0$ . Accordingly, it is convenient to normalize the coordinates (multiplying them by suitable constants) so that they cease to be homogeneous (see 12).

In terms of such normalized coordinates, the distance  $\delta$  between points  $(x)$  and  $(y)$  can be simply given (see 13), and the distance  $\delta$  from the point  $(x)$  to the line  $[X]$  takes a convenient form (see 14).

Two lines  $[X]$  and  $[Y]$  are intersecting, parallel, or ultraparallel, according as a number  $[XY]$  constructed from the coordinates (see 15) is less than 1, equal to 1, or greater than 1. In the first case they are inclined at angles  $\theta$  and  $\pi - \theta$ , where  $\cos \theta = [XY]$ . In the last case, when the lines are ultraparallel, the distance between them is  $\delta$ , where  $\cosh \delta = [XY]$ .

These results about lines in the hyperbolic plane have obvious analogues for planes in hyperbolic space, obtained by inserting an extra term  $x_3^2$  or  $X_3^2$  or  $x_3 y_3$  or  $X_3 Y_3$  in the appropriate position.

**Hyperbolic trigonometry.** For a right-angled triangle  $ABC$  with  $A$  at  $(1, 0, 0)$  and  $AC$  along  $[0, 0, 1]$ , as in Figure 13, it is seen at once that the vertex  $C$ , at which the right angle occurs, is  $(\cosh b, \sinh b, 0)$ , while the side  $AB$  runs along the line  $[0, -\sin A, \cos A]$  and the side  $BC$  along  $[\sinh b, -\cosh b, 0]$ . Hence, the remaining vertex  $B$ , distant  $c$  from  $A$  along  $AB$ , can be expressed in terms of hyperbolic and trigonometric functions (see 16). Because the distance from  $B$  to  $AC$  is  $a$ , and the acute angle between  $AB$  and  $BC$  is  $B$ , this distance and angle can be calculated in terms of  $A, b, c$  (see 17). Lobachevsky preferred to avoid the use of hyperbolic functions by expressing such relations in terms of angles of parallelism (see 18). Analogy with Napier's rules for a right-angled spherical triangle prompted the German mathematician Friedrich Engel's observation that any relation between the sides and angles of a right-angled hyperbolic triangle will remain valid when the five "parts" are cyclically permuted (see 19). In this way, the above relations, in trigonometric form (see 20), yield four more pairs of relations (such as 21) that can also be expressed in terms of  $a, b, c$  (see 22).

This last relation expresses the hypotenuse in terms of the other two sides and is the hyperbolic counterpart of the theorem of Pythagoras. In fact, when  $a, b, c$  are all small (see 23) and terms of the fourth or higher degree are neglected,  $c^2 = a^2 + b^2$  remains. In other words, Euclidean geometry holds in an infinitesimal neighbourhood of any point.

**Transformations.** According to the so-called Erlangen program of Klein, formulated in 1872, a geometry is distinguished by its group: the group of transformations under which its theorems remain true. Thus, the group for Euclidean geometry is the group of similarities, generated by all the reflections and central dilatations.

The group for hyperbolic geometry is generated by reflections alone. For instance, the product of reflections in two planes, intersecting, parallel, or ultraparallel, is a rotation, a parallel displacement, or a translation, respectively; and the most general displacement, or motion, is a twist, the product of a rotation about a line and a translation along the same line. The essence of the inverse model lies in the happy accident that this group of

The right-angled triangle

Types of transformations

Figure 13: A right-angled triangle.

Figure 14: Three nested circles and their inverses.

hyperbolic isometries is isomorphic to the inversive group of circle-preserving transformations, which is generated by inversions in circles, including reflections in lines as a special case. The product of inversions in two circles, intersecting, tangent, or non-intersecting, is a rotary, parabolic, or dilative homography (for instance, a rotation, translation, or central dilatation); and the most general homography is the loxodromic transformation, the commutative product of a rotary homography and a dilative homography. (The most familiar instance is the dilative rotation, or spiral similarity.)

From this point of view, although the hyperbolic space and the inversive plane are isomorphic, the former may seem more familiar than the latter because of its striking analogy with Euclidean space, in which the distinction between a parallel displacement and a translation disappears. In particular, there is an interesting property of the mutual inversive distances between any three nested circles  $\alpha$ ,  $\beta$ ,  $\gamma$  (such that every circle intersecting both  $\alpha$  and  $\gamma$  intersects  $\beta$  too): they satisfy the nontriangle inequality,  $(\alpha\beta) + (\beta\gamma) \leq (\alpha\gamma)$ , with equality only when the circles are coaxial. This theorem of inversive geometry is fairly difficult to prove by either inversive or Euclidean methods, but it becomes almost obvious when expressed in terms of planes  $\alpha$ ,  $\beta$ ,  $\gamma$  in hyperbolic space. Because the circles are nested, the plane  $\beta$  separates  $\alpha$  and  $\gamma$  in the sense that every line joining a point of  $\alpha$  to a point of  $\gamma$  intersects  $\beta$  too. Because the circles have a common orthogonal circle, it is possible to replace the planes  $\alpha$ ,  $\beta$ ,  $\gamma$  by lines  $a$ ,  $b$ ,  $c$ , which are their sections by a plane perpendicular to all of them. In other words, the circles  $\alpha$ ,  $\beta$ ,  $\gamma$  are Poincaré's model for the lines  $a$ ,  $b$ ,  $c$  in the hyperbolic plane. If the circles are not coaxial, the shortest distances between pairs of the lines are alternate sides of a crossed hexagon whose angles are all right angles, as in Figure 14. Because these shortest distances are equal to the inversive distances between pairs of the circles, the inequality  $(\alpha\beta) + (\beta\gamma) < (\alpha\gamma)$  can be seen from the fact that the line segment marked  $(\alpha\gamma)$  is the sum of two parts, one greater than  $(\alpha\beta)$  and the other greater than  $(\beta\gamma)$ .

## Geometry, Projective

Geometry is a branch of mathematics concerned with the properties of space and of objects in space. The discipline arose in response to such practical problems as those found in surveying. Its name is derived from Greek words

meaning earth measurement. Later, it was realized that geometry need not be limited to the classical study of flat surfaces (plane geometry) and rigid three-dimensional objects (solid geometry), but that even the most abstract thinking and imaginings of people might be represented and developed in geometric terms. Thus, various types of geometries evolved, one of which is now called projective geometry.

From the Greek period to the end of the 18th century, two momentous geometrical discoveries were made. Both concerned what was destined to be projective geometry. One was a theorem (stated in detail below) that was discovered and proved in 1639 by a French mathematician named Girard Desargues. The other was a significant broadening of a theorem (first known to Pappus of Alexandria in the 4th century) by Desargues' fellow countryman Blaise Pascal, in 1640. Yet, until the discovery of the basic postulates of projective geometry by Jean-Victor Poncelet, again of France, nearly 200 years later, Desargues's and Pascal's theorems seemed like parts of Euclidean geometry that were unlike other parts. It is significant that in their statements the only relation that mattered was that of the incidence of points and straight lines; distance, angle, congruency, or similitude played no part. (The use of the relation of incidence in the two theorems was the first indication that within the general discipline of geometry there are properties that depend on measurement—those involving distance, angle, and so forth were to be called metrical properties—and others that do not, which became the characteristics of projective geometry.) Despite the simplicity of the statements of these two basic theorems, an unusual amount of care had to be taken in proving (and even formulating) the theorems as soon as due regard was paid to what happened when two or more lines referred to in the theorems, instead of intersecting, became parallel.

The difficulties encountered in generalizing the theorems of Desargues and Pappus–Pascal were overcome; and, in effect, projective geometry was founded when Poncelet postulated points at infinity, such that every straight line is extended with a point at infinity and every plane with a line at infinity, this new point (or line) being the same point for distinct parallel lines (or planes). All infinite elements of space were supposed to lie on the infinite plane of space. The plane so defined was called the “projective plane,” and, by logical extension to the next dimension, the corresponding space was called “projective space.” Afterward, the distinction between original and added elements (the infinite elements) faded out. Parallelism disappeared as a relation; the only relation still left from the variety of Euclid's relations (such as betweenness, order, congruence, incidence) was that of incidence (or lying on). It is unclear why Poncelet's step was not made centuries earlier. The revival and growth of geometry in the 19th century was psychologically due to the striking simplicity of projective geometry.

After Poncelet's contribution, the major problem was to free projective geometry from its Euclidean substrate and to found it independently. This problem seemed to have been solved when Karl Georg Christian von Staudt, in Germany, started in 1847 with such incidence axioms as: two points determine one straight line; three points, not on a straight line, determine a plane; two planes intersect in a straight line, and so on. Though von Staudt's performance was admirable, he still took the relations of order (such as there being at least one point between two distinct points) in line and plane for granted without feeling the need for explicit formulations. Even worse, he in effect assumed that things proved for commensurable ratios (those expressible as rational numbers) were valid for all ratios, though centuries earlier Archimedes had provided an axiom granting the possibility of bracketing incommensurable ratios by larger and smaller commensurable ones. In 1873 a German mathematician named Felix Klein discovered the gap in von Staudt's reasoning. Though convinced of the possibility of founding projective geometry independently, Klein did not succeed in filling the gap; he did, however, make other essential contributions to the subject.

A final solution for founding projective geometry independently required the following types of postulates: the incidence axioms of the type suggested above, axioms that order the points on the projective line in such a way that the order is cyclic (or as though on a circle) and axioms that preserve this order, and, finally, some type of Archimedes axiom of the kind mentioned in the previous paragraph. This solution was possible after Georg Cantor and Richard Dedekind, German innovators in mathematics, re-examined the ancient problem of incommensurables. Their main contributions in this direction were in 1871 and 1872. About 1880 Moritz Pasch and Otto Stolz of Germany recognized the import of the Archimedean axiom. Most European geometers of the 19th century made some contributions to the study of projective geometry in general. The axioms and logical structure of the subject have been studied by many mathematicians.

#### PROJECTION

**Perspective projection.** The distinctive procedure of projective geometry is the representation or mapping of one line  $l$  or plane  $\pi$  onto another ( $l'$  or  $\pi'$ ) by perspective projection from any point  $O$  not lying in either (see Figures 1 and 2). This is essentially what is done when a plane object is drawn or photographed from any viewpoint. The construction whereby the image of any point  $P$  of the object  $\pi$  (or  $l$ ) is obtained as the intersection of  $\pi'$  (or  $l'$ ) with the line  $OP$  is not limited (as in drawing a picture) to any finite portion of  $\pi$  (or  $l$ ).

From a point of view that emphasizes basic concepts, the object of projective geometry is the study of those properties of figures that are not altered by this mapping; i.e., properties that are the same for the "picture" as for the object and are not altered by any number of repetitions of the mapping. If, for instance, a plane  $\pi$  is mapped by projection from  $O_1$  onto a plane  $\pi_1$ , this in turn from  $O_2$  onto a plane  $\pi_2$ , and so on, until a mapping on a plane  $\pi'$  is reached, this mapping of  $\pi$  onto  $\pi'$  is called a general projective mapping, and any property of a figure that is unaltered by the first projection will be the same in  $\pi'$  as in  $\pi$ . With certain exceptions, considered below, each point of  $\pi$  has an image point in  $\pi'$ , and each line of  $\pi$  is mapped onto a line of  $\pi'$ .

**Points at infinity.** It is familiar that in an ordinary perspective drawing of  $\pi$  or  $\pi'$  there are certain points (and one line) in  $\pi'$  that correspond to nothing in  $\pi$ . That is, the images of a family of parallel lines in  $\pi$  are lines in  $\pi'$  all passing through one point, which is thus not the image of any point of  $\pi$ ; and all the points of  $\pi'$  that thus arise from different parallel families in  $\pi$  lie in one line  $h'$ , the so-called horizon of the picture. Similarly, there is a horizon  $k$  in  $\pi$  that has no image in  $\pi'$ ; but all the lines that pass through one point of  $k$  have images in  $\pi'$  that are parallel.

Figure 1: Central projection of one line on another (see text).

This situation causes confusion, awkward exceptions to otherwise very general theorems, and similar inconveniences. These difficulties are overcome by adding to each plane fictitious or ideal points to correspond with those of the other plane that have actually no images. It is agreed conventionally that every line contains just one ideal point—i.e., a point postulated as being at infinity—which

Figure 2: Central projection of one plane on another.

can be approached (though, of course, not reached) by travelling very far along the line in either direction; that all lines parallel to one another contain the same point at infinity; that all points at infinity in one plane form a line called the line at infinity; and that all planes parallel to one another contain the same line at infinity. Thus, the horizon  $h'$  is the image of the line at infinity in  $\pi$ , and similarly the image of the line  $k$  is the line at infinity in  $\pi'$ . Finally, all the points and lines at infinity in space form a single plane at infinity.

(It is not suggested, of course, that these ideal points, lines, and planes have any physical existence; but then, neither have any of the pure concepts of geometry; e.g., the point that has position without magnitude or the line that has length without breadth.)

This concept of the ideal not only gives every point and line in  $\pi$  an image in  $\pi'$  and makes every point and line in  $\pi'$  the image of one in  $\pi$  but also removes troublesome exceptions from many general propositions; e.g., that every two lines in the same plane intersect in a point, every two planes intersect in a line, and so on. These, with similar propositions (e.g., that every two points are joined by a line and every two intersecting lines by a plane), are clearly basic to projective geometry, and, when the subject is treated axiomatically, such are the axioms assumed; they are known as the projective axioms, or axioms of incidence.

**Projective theorems.** Theorems dealing solely with intersections of lines and of points belonging to the same line include the following, which may be cited as playing an important role in any logical development of projective geometry.

**Desargues' theorem.** If  $ABC$ ,  $A'B'C'$  are two triangles, in one plane, such that  $AA'$ ,  $BB'$ ,  $CC'$  meet in a point, the intersections of  $BC$  with  $B'C'$ , of  $CA$  with  $C'A'$ , and of  $AB$  with  $A'B'$  are all in one line (see Figure 3).

**Pappus' (Pascal's) theorem.** If  $A$ ,  $B$ ,  $C$  are in one line and  $A'$ ,  $B'$ ,  $C'$  in another line in the same plane, the intersections  $BC'$  with  $B'C$ , of  $CA'$  with  $C'A$ , and of  $AB'$  with  $A'B$  are all in one line (see Figure 4).

**Duality.** In the plane there is a kind of symmetry between points and lines called duality. In the statement of any proposition or the specification of any figure, if the words "point" and "line," "lies in" and "passes through," "intersect in" and "are joined by," etc., be interchanged throughout, a new proposition or figure is obtained, called the dual of the first. For instance, the axioms "any two points are joined by a unique line" and "any two lines intersect in a unique point" are dual to each other. It is possible to frame the axioms for a logical treatment of projective geometry in pairs dual to each other; if this is

Basic  
theorems  
of  
Desargues  
and  
Pappus

Figure 3: Desargues' theorem.

done, then for any theorem that is true, its dual is also true, for the translation indicated above need only be made all through the proof.

Dual to the line, thought of as consisting of all the points in it, is the figure of all lines through a point—say,  $L$ . This is called a pencil of lines and can be denoted by  $(L)$ . Dual to the mapping of one line  $l$  on another  $l'$  by projection from a point  $O$  is the mapping of a pencil  $(L)$  on another  $(L')$ , so that lines  $a, b, c, \dots$  in the one intersect their images  $a', b', c', \dots$  in the other in points all lying in a fixed line  $o$  (see Figure 5).

In solid geometry there is the same sort of duality, not between points and lines but between points and planes, lines being dual to lines. Thus the axioms "any two points are joined by a line" and "any two planes intersect in a line" are dual to each other, as are "any two lines in one plane intersect in a point" and "any two lines through one point are joined by a plane." The dual of a plane, regarded as consisting of all the points and lines in it, is called a star and consists of all the planes and lines through a point. Geometry in a star is closely similar to that in a plane, lines and planes playing the roles of points and lines, respectively. A star can be projectively mapped on another star or on a plane; for instance, the star can be mapped on any plane  $\pi$  not belonging to it by taking as the image of any line or plane of the star its point or line of intersection with  $\pi$ . The dual of a line of points consists of all the planes through one line and is called a pencil of planes.

**Projectively generated loci.** Geometry, of course, contains many figures besides those consisting only of points and lines (and planes, in solid geometry); for example, the circle. If a plane  $\pi$  is mapped projectively on a plane  $\pi'$ , the image of a circle is generally not a circle but a curve called a conic section (see GEOMETRY, ANALYTIC AND TRIGONOMETRIC) or, more briefly, a conic; and the image of any conic is likewise a conic. The conic can be defined in projective terms as follows:

If two pencils of lines in one plane be taken, say  $(O)$  and  $(O')$ , and the one be mapped projectively on the other, in general—i.e., unless the line  $OO'$  in  $(O)$  has itself as image in  $(O')$ —the aggregate of intersections of a line with its image consists precisely of the points of a conic; this is the definition of a conic in projective geometry.

Many other curves and surfaces can be defined similarly. For instance, if two lines  $l, m$  are skew (i.e., are not in one plane and do not intersect) and if  $l$  is mapped projectively on  $m$ , the lines joining each point of  $l$  to its image generate a surface called a ruled quadric; i.e., the points of the surface are all the points of all the lines. This family of lines, called a regulus, can also be defined as consisting of all lines that intersect not only  $l$  and  $m$  but a third line  $n$ , skew to both  $l$  and  $m$ . The important ruled quadric theorem states that any line intersecting three lines of a regulus intersects all of them. Such lines form a second regulus, generating the same surface, of which  $l, m, n$  are members.

Again, if a pencil of planes is mapped projectively on two others, the points of intersection of a plane with its two images are in general the points of a curve, called a twisted cubic; and, if a star is mapped projectively on two others, the points of intersection of a plane with its two images are the points of a cubic surface.

#### HOMOGENEOUS COORDINATES

**Coordinates and transformations.** Coordinates, or sets of numbers that specify the location of a point in a space,

are useful in projective geometry, since they allow problems to be formulated as equations and solved by algebraic methods. In an ordinary Cartesian coordinate system, however, in the plane, where the coordinates of a point are distances measured along lines parallel to two fixed perpendicular axes, the coordinates  $(x, y)$  of a point at infinity are in general both infinite but have a definite ratio to each other,  $x/y$ , depending on the direction of the parallel lines through the point. Calculations with infinite quantities of this kind are confusing, and it is convenient to represent each point not by the two numbers  $(x, y)$  but by three numbers  $(x_0, x_1, x_2)$ , such that  $x = x_1/x_0$ ,  $y = x_2/x_0$ . If  $k$  is any number except zero,  $(kx_0, kx_1, kx_2)$  then denote the same point as  $(x_0, x_1, x_2)$ . If now  $x_0 = 0$ , then  $x = x_1/x_0$  and  $y = x_2/x_0$  are infinite but have the definite ratio  $x/y = x_1/x_2$ ; the numbers  $(0, x_1, x_2)$  thus denote a point at infinity, obviating calculation with infinite coordinates.

Such a method of representing points is called a homogeneous coordinate system, because any equation in  $(x, y)$  is equivalent to a homogeneous equation (i.e., one in which all the terms are of the same degree) in  $(x_0, x_1, x_2)$ ; for instance, any line has an equation of the form  $a_1x + a_2y + a_0 = 0$ , which on substituting  $x_1/x_0, x_2/x_0$  for  $x, y$  and multiplying by  $x_0$  becomes  $a_0x_0 + a_1x_1 + a_2x_2 = 0$ . (The line at infinity, incidentally, has also an equation of this kind, namely  $x_0 = 0$ .)

As well as the homogeneous coordinate system  $(x_0, x_1, x_2)$ , however, any other can equally be used, say  $(x'_0, x'_1, x'_2)$ , derived from it by a linear transformation, or set of three equations that are linear in  $x_0, x_1, x_2$ , each with three coefficients (see Box, equations 1), in which the nine coefficients are sufficiently general to let these equations be solved, so as to express  $(x_0, x_1, x_2)$  in a similar form that is linear in  $x'_0, x'_1, x'_2$  (see 2). Such a transformation leaves the equation of a line still linear and, indeed, does not alter the degree of any algebraic equation in the coordinates.

The transformation can, however, be thought of in another way. When it is a change of coordinate system  $(x_0, x_1, x_2)$  and  $(x'_0, x'_1, x'_2)$  are the coordinates of the same point in two different homogeneous coordinate systems; but they can also be taken as the coordinates of two different points,  $P, P'$ , in the same system. The equations then define a mapping of the plane onto itself; the first equations define for every point  $P$  a unique image  $P'$  (see 1), and the second equations show that every point  $P'$  is the image of a unique point  $P$  (see 2). This expression is in fact the general one for a projective mapping of the plane onto itself.

In the same way, if  $(x, y, z)$  are Cartesian coordinates of a point in space, this can be denoted instead by the homogeneous coordinates  $(x_0, x_1, x_2, x_3)$ , in which  $x = x_1/x_0$ ,  $y = x_2/x_0$ ,  $z = x_3/x_0$ . Every plane has an equation  $a_1x + a_2y + a_3z + a_0 = 0$  in the Cartesian coordinates, and hence  $a_0x_0 + a_1x_1 + a_2x_2 + a_3x_3 = 0$  in the homogeneous coordinates; in particular,  $x_0 = 0$  is the equation of the plane at infinity. A transformation like the one referred to—but consisting, of course, of four equations each with four terms on the right—can in the same way be used either to define a new homogeneous coordinate system or to specify a mapping of space onto itself, in which the image of any point  $(x_0, x_1, x_2, x_3)$  is the point  $(x'_0, x'_1, x'_2, x'_3)$ . This proceeding maps every plane projectively onto a plane and every line projectively onto a line, and it is called a projective mapping of space.

$$(1) \quad \begin{cases} x'_0 = a_{00}x_0 + a_{01}x_1 + a_{02}x_2 \\ x'_1 = a_{10}x_0 + a_{11}x_1 + a_{12}x_2 \\ x'_2 = a_{20}x_0 + a_{21}x_1 + a_{22}x_2 \end{cases}$$

$$(2) \quad \begin{cases} x_0 = b_{00}x'_0 + b_{01}x'_1 + b_{02}x'_2 \\ x_1 = b_{10}x'_0 + b_{11}x'_1 + b_{12}x'_2 \\ x_2 = b_{20}x'_0 + b_{21}x'_1 + b_{22}x'_2 \end{cases}$$

Figure 4: Pappus' (Pascal's) theory.

Duality  
expressed  
in terms of  
coordinates

Duality finds a very simple expression in terms of coordinates. In plane geometry, if the equation of a line  $l$  is  $a_0x_0 + a_1x_1 + a_2x_2 = 0$ , then  $(a_0, a_1, a_2)$  are called the homogeneous coordinates of  $l$ , and the equation is regarded as the condition for the line  $(a_0, a_1, a_2)$  to pass through the point  $(x_0, x_1, x_2)$ . What is called a dual mapping of the plane onto itself can be defined by taking as the image of every point  $P$  the line with coordinates that are the same as those of  $P$ ; the images of the points in a line  $l$  will then be the lines through the point  $L$ , with coordinates that are the same as those of  $l$ . This dual mapping can be defined in purely geometrical terms, but the definition in terms of coordinates is simpler.

Duality in space can be similarly treated, the homogeneous coordinates of a plane being the coefficients  $(a_0, a_1, a_2, a_3)$  in its equation  $a_0x_0 + a_1x_1 + a_2x_2 + a_3x_3 = 0$ .

**Geometry of one dimension.** Similarly, a homogeneous coordinate system  $(x_0, x_1)$  can be used in a line, the position of a point in the line being determined by the ratio  $x_0/x_1$ , and a linear transformation giving either a transformation of coordinates or a projective mapping of the line on itself (see 3). Because, however, there is only one point at infinity to consider, there is no serious inconvenience in using the single coordinate  $z = x_0/x_1$ , in terms of which the equations expressing the transformation involve only  $z$  and its image (see 4). Such a transformation as this is known as a homographic transformation.

If  $z = \alpha, z = \beta, z = \gamma, z = \delta$  are the coordinates of four points  $A, B, C, D$  of the line, a simple ratio constructed with these coordinates (see 5) is found to be unaltered by the homographic transformation and, thus, represents a property of the four points that is independent of the coordinate system and that is unaltered by a projective mapping. This number is called the cross ratio of the four points. If  $z$  is a Cartesian coordinate, differences such as  $\alpha - \gamma$  that occur in the ratio are proportional to the segments such as  $AC$ ; thus, if in any projective mapping of the line on another line or on itself the images of  $A, B, C, D$  are  $A', B', C', D'$ , a ratio involving lengths of segments such as  $AC$  will be preserved under the mapping (see 6), although, of course, neither the length of a segment  $AC$  nor the ratio of two segments such as  $AC/AD$  will, in general, be equal to  $A'C'/A'D'$ , respectively.

**The fundamental theorem.** If  $A, B, C$  are any three points of one line and  $A', B', C'$  are any three points of either the same or another line, a projective mapping may be constructed in which the images of  $A, B, C$  are  $A', B', C'$ , respectively. This construction can be made in a great variety of ways; but the fundamental theorem of projective geometry states that the actual mapping will always be the same; i.e., however the construction is made, the image of any fourth point  $D$  will be a unique point  $D'$  that is deducible from an equation that results from the previous discussion (see 6). This condition is closely re-

Figure 5: Mapping of a pencil of lines.

lated to the fact that a transformation of coordinates can be made such that any three chosen points shall have assigned values for their coordinates; in particular, if the values  $z = \infty, z = 0, z = 1$  are assigned to  $A, B, C$ , the value of  $z$  at any other point  $D$  will be equal to the cross ratio of the values given for  $A, B, C, D$ .

**Harmonic pairs.** Especially important is the case in which the cross ratio has the value  $-1$ ; i.e., when  $C$  and  $D$  divide the segment  $AB$  internally and externally in the same ratio. In this case  $C, D$  are said to separate  $A, B$  harmonically. If  $A, B, C$  are given in a line, the point  $D$  can be constructed, such that  $C, D$  separate  $A, B$  harmonically by a purely projective construction (Figure 6). Lines are drawn through  $A, B, C$  to form a triangle  $PQR$  ( $QR$  passing through  $A, RP$  through  $B$ , and  $PQ$  through  $C$ ); then, if  $S$  is the intersection of  $AP$  with  $BQ$ , that of  $RS$  with  $ABC$  is the required point  $D$ .

$$(3) \quad x'_0 = ax_0 + bx_1, \quad x'_1 = cx_0 + dx_1$$

$$(4) \quad z' = \frac{az + b}{cz + d}, \quad z = \frac{dz' - b}{-cz' + a}$$

$$(5) \quad \frac{(\alpha - \gamma)(\beta - \delta)}{(\alpha - \delta)(\beta - \gamma)}$$

$$(6) \quad \frac{A'C' \cdot B'D'}{A'D' \cdot B'C'} = \frac{AC \cdot BD}{AD \cdot BC}$$

$$(7) \quad cz^2 + (d - a)z - b = 0$$

All these ideas and results can be transferred to the points of a conic or of a twisted cubic curve, to the lines of a pencil or a regulus, or to any other aggregate that can be mapped projectively on a line. Such a mapping is simply taken, and each member of the aggregate is given the same coordinate as its image point; four members have the same cross ratio as their image points, two pairs separate each other harmonically if their image points do so, and so forth.

#### COMPLEX GEOMETRY

There are many geometrical problems that, when attacked algebraically by means of coordinates, require the solution of a quadratic equation; for instance, in elementary analytic geometry, that of finding the intersections of a line with a circle or with any conic. A more important problem is that of finding the fixed points (i.e., those that are their own images) in any projective mapping of a line onto itself. If  $z' = z$  in the equations that involve  $z$  and its image (see 4) a quadratic equation in  $z$  will follow (see 7), so that if and only if  $z$  satisfies this quadratic equation, the point with coordinate  $z$  will be its own image in the mapping.

As long as operation is confined to real numbers, a quadratic equation may have two solutions, or only one, or none at all. Correspondingly, in the plane of a circle there are lines that meet it in two points (the chords), in one point (the tangents), and not at all (those completely outside the circle). In algebra, however, great simplification is obtained by enlarging the concept of number to include what are called complex numbers; i.e., numbers of the form  $a + ib$ , in which  $a$  and  $b$  are real numbers and  $i$  is an imaginary quantity with its square equal to  $-1$ . Every quadratic equation with coefficients that are complex numbers has two solutions that are themselves complex numbers; these may, however, be equal. In particular, if the coefficients are real, either both solutions are real or neither is.

A similar simplification is obtained in geometry by the conventional introduction of complex points, taking in fact any set of three (or, for solid geometry, four) complex numbers to be the homogeneous coordinates of a point. It can then be said, for instance, that in a plane

Fixed  
points in a  
projective  
mapping

Introduc-  
tion of  
complex  
points

Figure 6: Projective construction of harmonic-pair division with cross ratio of  $-1$  (see text).

every line meets every conic in two points (which may coincide, the line being then a tangent of the conic). If from the elementary point of view, and as seen in a figure, there are no common points, then the points are imaginary and the equations make it possible to write down definite imaginary values for their coordinates. In the same way, every projective mapping of a line on itself has two fixed points that may coincide.

This conventional extension of complex geometry is logically similar to the addition of points at infinity, and such an extension has similar advantages in making it possible to state results in a more general form, without the necessity of enumerating many alternative cases of each theorem.

**Projective mappings.** In plane geometry, a bodily rotation about a fixed centre, whereby each line through the centre is turned through the same angle, is a projective mapping of this pencil of lines on itself. The fixed lines of this mapping are imaginary and have always the same two directions; *i.e.*, those given in any Cartesian coordinate system by the equations  $y = ix$ ,  $y = -ix$ . Lines having either of these directions are called isotropic; they have the paradoxical properties that every isotropic line is perpendicular to itself and that the distance between any two points joined by an isotropic line is zero.

The points at infinity in these two directions are often called the circular points at infinity, because every circle in the plane cuts the line at infinity in these same two points. In particular, a circle of radius zero (which in Euclidean geometry consists only of its centre) in complex geometry consists of the two isotropic lines through its centre.

**Group properties.** The set of all projective mappings of a plane on itself forms a group; projective geometry consists of the study of those properties of figures that are unchanged by all the operations in this group. If, however, within this group is considered the smaller group (or subgroup) consisting only of those mappings in which the circular points at infinity are their own or each others' images, then every figure is the same shape as its image, though they may differ in size or scale, as well as in orientation and position. Euclidean geometry, in which the basic measurable quantities are the size of an angle and the ratio of two lengths, thus turns out to be the study of properties of figures that are unchanged by all operations of this smaller group, called the similarity group. All the ordinary properties of a figure can be expressed as its projective relations to the circular points and to the line at infinity that joins them. In particular, the angle between two lines can be expressed in terms of their cross ratio with the two isotropic lines through their intersection, and they are perpendicular if they separate the isotropic lines harmonically.

Intermediate between the similarity group and the full projective group is what is called the affine group, consisting of all mappings in which the line at infinity is its own image. Properties unchanged by these include parallelism and the ratio of parallel segments but not angles or other length ratios.

If the imaginary circular points are replaced by two real points, the similarity group then becomes that of the so-called Lorentz transformations in relativity theory; and if, instead, the mappings in which a particular conic is its own image are considered, then non-Euclidean geometry is obtained.

#### ABSTRACT GEOMETRIES

At this stage, points have little resemblance to the intuitive idea of a point in a drawable figure. They are nothing but sets of numbers (coordinates), and the geometrical theorems about them are only a peculiar way of stating algebraic results about homogeneous equations. But algebraically there is no more interest in equations in three variables (plane geometry) or four (solid geometry) than in those in any number of variables. It is, therefore, a convention to call a set of  $n + 1$  numbers,  $n$  being any given number,  $(x_0, x_1, \dots, x_n)$  a point of  $n$ -dimensional space, always with the proviso that if  $k$  is not zero,  $(x_0, x_1, \dots, x_n)$  and  $(kx_0, kx_1, \dots, kx_n)$  are the same point. The sets that satisfy  $r$  independent linear homogeneous equations ( $p$  is a number) are those of an  $(n - r)$ -dimensional space lying in the whole space. All the propositions about joining spaces and intersections can be summed up in the following intersections theorem: If two spaces of  $p$  and  $q$  dimensions are joined by an  $r$ -dimensional space and intersect in an  $s$ -dimensional space, then  $r + s = p + q$ ; if they have no intersection, the formula is satisfied by the conventional value  $s = -1$ .

The idea of projective geometry can be extended by choosing coordinates from a wide variety of algebraic systems. Any set of symbols that can be added, subtracted, multiplied, and divided in the usual way is called a field; for instance, the real numbers are a field and the complex numbers are another field, and the difference between the geometries obtained by using coordinates from these two fields has been shown. Many other kinds of field are possible, however. Some consist of only a finite number of elements; the simplest consists only of 0 and 1, with the relation  $1 + 1 = 0$ —this system being what ordinary arithmetic reduces to if all even numbers are called 0 and all odd numbers are called 1. When coordinates are chosen from this field, a geometry is obtained consisting of only seven points and seven lines (three points in each line and three lines through each point). Similarly, it is possible to construct a solid geometry of 15 points, 35 lines, and 15 planes.

Algebra also offers systems of symbols that can be added, subtracted, multiplied, and divided nearly in the usual way but in which a product  $ab$  is not necessarily equal to  $ba$ . These are called skew fields. Using such a system for coordinates, a geometry can be constructed in which the usual joining and intersecting relations are valid but in which certain theorems of ordinary geometry—notably that of the 4th-century Greek geometer Pappus of Alexandria and what have been called the fundamental and ruled quadric theorems—are no longer true.

The topic can be approached from a different point of view by saying that any (finite or infinite) aggregate of things that fall into classes satisfying relations of a certain kind can be regarded as the points of a projective geometry. For instance, if a number of men belong to a number of clubs, and if every two men belong to just one club, and every two of the clubs have just one common member, then—to give a projective plane geometry—the men can be called points, and the clubs can be called lines. Seven men— $A, B, C, D, E, F, G$ —and seven clubs with three members each—say  $(ABD)$ ,  $(BCE)$ ,  $(CDF)$ ,  $(DEG)$ ,  $(EFA)$ ,  $(FGB)$ ,  $(GAC)$ —form a geometry that is structurally indistinguishable from that constructed from the field consisting of 0, 1 only; in fact, coordinates belonging to this field can be attached to each man so that each club is defined by a linear equation.

Similarly, if there are objects called points, grouped into classes of various sizes called lines, planes, etc., then, if these classes satisfy certain relations (of which the chief is what has been called the intersection theorem), this classification gives a geometry the number of dimensions of which depends on the number of different sizes of classes. Much modern research has been devoted to the classification of all kinds of abstractly possible geometries in this sense and to the discovery of what groups of theorems are equivalent; *i.e.*, such that in any geometry where one holds, the others hold also. For instance, Pappus' theorem and the ruled quadric and fundamental theorems are equivalent in this sense.

The idea of projective geometry extended

There are three known main categories of projective geometry:

1. Those in which both Desargues' and the Pappus group of theorems hold. These can be of any number of dimensions and can consist of either a finite or an infinite number of points. This class includes the ordinary real and complex geometries. Every geometry of this kind is structurally equivalent to that constructed with some definite field, and its properties completely determine (and are completely determined by) those of the field.

2. Those in which Desargues' theorem holds but not Pappus' theorem nor those that go with it. These, likewise, can be of any number of dimensions and can be similarly constructed from a skew field. They always contain an infinity of points. All geometries of three or more dimensions belong to one of these two classes.

3. There can also be plane geometries, however, in which not even Desargues' theorem holds. A good many examples, both finite and infinite, have been constructed; but any general classification of these has proved to be one of the most intractable problems in modern geometry.

**BIBLIOGRAPHY.** Introductory general works include DIRK J. STRUIK, *Lectures on Analytic and Projective Geometry* (1953); H.S.M. COXETER, *The Real Projective Plane*, 2nd ed. (1955), a meticulous but very readable exposition of the axiomatic approach to real projective geometry of two dimensions; A. ADRIAN ALBERT and RUEBEN SANDLER, *An Introduction to Finite Projective Planes* (1968); CHARLES W. O'HARA and D.R.B. WARD, *Introduction to Projective Geometry* (1937); and GEORGE B. MATHEWS, *Projective Geometry* (1914), an easy and comparatively unsophisticated account for beginners. REINHOLD BAER, *Linear Algebra and Projective Geometry* (1952); and ABRAHAM SEIDENBERG, *Lectures in Projective Geometry* (1962), are more advanced texts. ALFRED N. WHITEHEAD, *The Axioms of Projective Geometry* (1960); and AREND HEYTING, *Axiomatic Projective Geometry* (1963), are studies from the axiomatic approach. LUIGI GREMONA, *Elementi di geometria proiettiva* (1873; Eng. trans., *Elements of Projective Geometry*, 3rd ed., 1913, reprinted 1960), is a classic in the field. OSWALD VEULEN and JOHN W. YOUNG, *Projective Geometry*, 2 vol. (1910–18), is the classic work in English on the axiomatic approach to projective geometry in two and three dimensions. BENIAMINO SEGRE, *Lectures on Modern Geometry* (1961), combines and contrasts the axiomatic and algebraic approaches to projective geometry, with a substantial algebraic introduction, and a good deal of attention to finite, non-Pappian, and non-Desarguesian geometries.

(P.DuV.)

## George III of Great Britain

King of Great Britain from 1760 to 1820, George III had one of the longest reigns in British history. During its course, Britain won an empire in the Seven Years' War but lost its American colonies. It underwent the first stages of the Industrial Revolution and fought a long and bitter struggle against revolutionary and Napoleonic France. The country emerged at the end of his reign as the leading power in Europe, but as one faced with an outmoded constitution and the threat of social revolution. On the personal side, George III's reign was a tragedy. He felt it to be his duty as king to hold an administration together, but he lacked the necessary intellectual power or emotional stability to achieve any long-term objective. Modern party politics grew out of his early efforts to form a stable ministry. He grew politically shrewder in later years, but eventually the pressures of office, dissension within his family, and recurring attacks of a hereditary nervous disorder left him bereft of his sanity.

**Early years.** George III, the son of Frederick Louis, prince of Wales, and Princess Augusta of Saxe-Gotha, was born on June 4, 1738 (new style). From his parents and their entourage, the young George imbibed an unreasonable dislike of his grandfather, King George II, and of all his policies. George was a child of strong feelings but of slow mental development. This unequal growth of brain and heart made him difficult to teach and too easy to command and produced in him an appearance of apathy; he could not read properly until he was

George III, painting by Peter Edward Stroehling, 1807.

By gracious permission of H.M. Queen Elizabeth II

11. His affection for his immediate family circle dominated his life.

George was 12 when his father died, leaving him heir to the throne. It is clear that, in beginning with his 18th birthday to prepare conscientiously for his future responsibilities, he tormented himself with thoughts of his inadequacy. The curious blend of obstinate determination with self-distrust, a feature of his maturity, was already evident. His method of screwing up his courage was to set himself an ideal of conduct. This ideal George thought he had found personified in John Stuart, 3rd earl of Bute, who became his inspiration, his teacher, and later his chief minister.

George was potentially a better politician than Bute, for he had tenacity and, as experience matured him, he could use guile to achieve his ends. But at his accession in 1760 in the midst of the Seven Years' War (1756–63), George did not know his own capacity nor the incapacity of his hero. As king, in 1761, he asked for a review to be made of all eligible German Protestant princesses "to save a great deal of trouble," as "marriage must sooner or later come to pass." He chose Charlotte Sophia of Mecklenburg-Strelitz and married her on September 8, 1761. Though the marriage was entered into in the spirit of public duty, thanks to the king's own need for security and his wife's strength of character, it lasted unblemished for more than 50 years. Bute's only other useful contribution to his royal pupil was to encourage his interest in botany and to implant in the court more respect for the graces of life, including patronage of the arts, than had been usual for the past half century.

**Political instability, 1760–70.** Politically, Bute encouraged the most disastrous of George's delusions. The government of England at the time lacked effective executive machinery, and members of Parliament were always more ready to criticize than to cooperate with it. Moreover, the ministers were, for the most part, quarrelsome and difficult to drive as a team. The King's first responsibility was to hold coalitions of great peers together. But under Bute's influence he imagined that his duty was to purify public life and to substitute duty to himself for personal intrigue. The two great men in office at the accession were the elder Pitt and Thomas Pelham-Holles, duke of Newcastle. Bute and George III disliked both. Pitt was allowed to resign (October 1761) over the question of war against Spain. Newcastle followed into retirement when his control of treasury matters seemed to be challenged. The two former ministers were each dangerous as a focal point for criticism of the new government under the touchy captaincy of Bute. The government had two principal problems: to make peace and to restore peacetime finance.

The influence of Lord Bute

The end of  
the Seven  
Years' War

Peace was made, but in such a way as to isolate Britain in Europe, and for almost 30 years the country suffered from the new alignments of the European powers. Nor was George III happy in his attempt to express the agreed purposes of the country that to Bute had seemed so clear. George III might "glory in the name of Briton" but his attempts to speak out for his country were ill-received. In 1765 he was being vilified by the gutter press organized by the parliamentary radical John Wilkes, while "patriotic" gentlemen, moved by Pitt or Newcastle, suspected that the peace had been botched and that the King was conspiring with Bute against their liberties. For Bute the way out was easy. He resigned (April 1763).

George realized too late that his clumsiness had destroyed one political combination and made any other difficult to assemble. He turned to George Grenville, to his uncle, William Augustus, duke of Cumberland, to Pitt, and to the 3rd duke of Grafton for help. All failed him. Grenville bullied him and offended his feelings for his mother, the princess dowager. Cumberland's nominee, Lord Rockingham, could neither combine with Pitt nor force his own cabinet to agree. Pitt (now Lord Chatham) was frustrated both in his European and his American projects and lapsed into a temporary insanity. Grafton succeeded only in involving the King in further charges of tyranny over John Wilkes. The first decade of the reign was one of such ministerial instability that little was done to solve the basic financial difficulties of the crown, made serious by the expense of the Seven Years' War. Overseas trade expanded, but the riches of the East India Company made no significant contribution to the state. The attempt to make the American colonists meet their own administrative costs only aroused them to resistance. Nor was there consistency in British colonial policy. The Stamp Act (1765) passed by Grenville was repealed by Rockingham in 1766. Indirect taxes, in the form of the Townshend Acts (1767), were imposed without calculation of their probable yield and then repealed (except for that on tea) as a manoeuvre in home politics.

Beginning  
of the  
party  
system

George III was personally blamed for this instability. According to the Whig statesman Edmund Burke and his friends, the King could not keep a ministry because he was faithless and intrigued with friends "behind the curtain." Burke's remedy was to urge that solidity should be given to a cabinet by the building up of party loyalty: the King as a binding agent was to be replaced by the organization of groups upon agreed principles. Thus the early years of George III produced, inadvertently, the germ of modern party politics. In truth, however, the King was not guilty of causing chaos by intrigue. He had no political contact with Bute after 1766; the so-called king's friends were not his agents but rather those who looked to him for leadership such as his predecessors had given. The King's failure lay in his tactlessness and inexperience, and it was not his fault that no one group was strong enough to control the Commons.

By 1770, however, George III had learned a good deal. He was still as obstinate as ever and still felt an intense duty to guide the nation, but now he reckoned with political reality. He no longer scorned to make use of executive power for winning elections nor did he withhold his official blessing from those of whose characters he disapproved.

**North's ministry, 1770–82.** In 1770 the King was lucky in finding a minister, Lord North, with the power to cajole the Commons. North's policy of letting sleeping dogs lie lulled the suspicions of independent rural members who were always ready to imagine that the executive was growing too strong. As a result, 12 years of stable government followed a decade of disturbance.

Unfortunately, issues and prejudices survived from the earlier period that North could muffle but not cure. Wilkes, in spite of the King's complaints, was allowed to go unharmed, but America was the greatest and the fatal issue and North could not avoid it because the English squires in Parliament agreed with their King that America must pay for its own defense and for its share of the debt remaining from the war that had given it security.

George III  
and the  
American  
colonies

George III's personal responsibility for the loss of America lies not in any assertion of his royal prerogative. Americans, rather, were disposed to admit his personal supremacy. Their quarrel was with the assertion of the sovereignty of Parliament, and George III was eventually hated in America because he insisted upon linking himself with that Parliament. North would have had difficulty in ignoring the colonists' insults in any case; with the King and the House of Commons watching to see that he was not weak, he inevitably took the steps that led to war in 1775.

By 1779 the typical English squires in Parliament had sickened of the war, but the King remained obdurate. He argued that though the war was indefensible on economic grounds it still had to be fought, that if disobedience were seen to prosper, Ireland would follow suit. He argued also, after the French had joined the Americans in 1778, that French finances would collapse before those of Britain. So the King prolonged the war, possibly by two years, by his desperate determination and by his pressure upon Lord North. The period from 1779 to 1782 left a further black mark upon the King's reputation. By 1780 a majority in Parliament blamed North's government for the calamities that had befallen the country, yet this government remained in power. As yet there was no responsible or acceptable alternative, for the opposition was reputed to be both unpatriotic and divided, but at the time people believed that corruption alone supported an administration that was equally incapable of waging war or ending it. This supposed increase in corruption was laid directly at the King's door, for North wearily repeated his wish to resign, thus appearing to be a mere puppet of George III. When North fell at last in 1782, George III's prestige was at a low ebb. The death of Rockingham in July 1782, after four months in office, and the failure of Shelburne's ministry (1782–83) reduced George to the lowest point of all in 1783. North joined with the liberal Whig Charles James Fox to form a coalition government. North seemed to accept Fox's aim of giving a stout knock to royal control. The King was not consulted in the making up of a team of junior ministers. The intrigues of politicians in party politics were gaining importance at the expense of royal direction and George even contemplated abdication.

**George and the Younger Pitt, 1783–1806.** Yet within a year the King had dramatically turned the tables, carrying out amid applause the most high-handed act of royal initiative in 18th-century England. When Fox and North produced a plan to reform the East India Company, which aroused fear that they intended to perpetuate their power by controlling Eastern patronage, the King re-emerged as the guardian of the national interest. He let it be known that anyone who supported the plan in the House of Lords would be reckoned his enemy. The bill was defeated. The ministers resigned. The King was ready with a new "patriotic" leader, William Pitt, the Younger. This initiative was dangerous. Pitt's government was in a minority in the Commons and the discarded ministers were in a mood to threaten a constitutional upheaval. Everything depended on the verdict of a general election in March 1784. The country, moved by real feeling as well as by treasury influence, overwhelmingly endorsed the King's action. The King did not go on after his victory to further demonstrations of power. Though many of Pitt's ideas were unwelcome to him, he contented himself with criticism and a few grumbles. Pitt could not survive without the King and the King, if he lost Pitt, would have been at the mercy of Fox. They compromised, but the compromise left most power, with the King's willing assent, in Pitt's capable young hands. In part, this was because George had no ambitions to raise his own constitutional status but was satisfied to have a minister he could trust to act cautiously and patriotically; in part, it arose from the King's domestic preoccupations.

Pitt's ap-  
pointment

George loved his children possessively and with that hysterical force that he had always shown in relations with those close to him. He was depressed by the Prince of Wales's coming of age in 1783 as it meant emancipa-

tion from the family. The King's ruefulness was soon converted into rage. The Prince associated politically with Fox's Whigs and socially with Fox's gaming friends. In contrast to George III's rather straitlaced court, the Prince's circle was gay and dissolute. As his sons escaped him, one by one, George oscillated between excitement and despair. In the crises of his reign he frequently talked of abdication; but in 1788 it was announced that it was his reason that had fled its throne.

**Mental breakdown** The stresses endured by this hard-working man seemed sufficient to account for his violent breakdown. Twentieth-century medical investigation, however, has suggested that the King had an inherited defect in his metabolism known as porphyria. An excess in purple-red pigments in the blood intoxicated all parts of the nervous system, producing the agonizing pain, excited overactivity, paralysis, and delirium that the King suffered in an acute form at least four times during his reign. The porphyria diagnosis is not universally accepted by medical opinion, and whatever the reason, the King appeared mad to his ministers.

The King's incapacity produced a political storm. But while Pitt and Fox battled over the powers that the Prince of Wales should enjoy as regent, the King suddenly recovered in 1789. He was left with the fear that he might again collapse into the nightmare of madness. For the last decade of the 18th century, he was bothered more about the details than about the main lines of policy. Pitt, whose policies contented him more and more, gradually absorbed in his own following most of North's old following and even some of Fox's. After the outbreak of war with revolutionary France in 1793, all but the most radical Whigs joined the government, leaving Fox in hopeless, if eloquent, opposition.

**War with France** The war with France seemed to most of the aristocracy and the upper middle class to be waged for national survival. The old King, an object of compassion in his collapse and obviously a well-meaning man, was soon a symbol of the old English order for which the country was fighting. Although his potential power in politics was greatly increased, his will to wield it was enfeebled. George enjoyed himself in encouraging farmers to grow more food; or he talked for hours (ending his sentences rhetorically and fussily with the repeated words "what, what, what?") about past conflicts, or military tactics, or even of the shortcomings of Shakespeare; or he played to himself on his harpsichord; or he regulated the lives of his daughters, who found it so much less easy to escape than did his sons. From such quiet occupations he was aroused to activity by Pitt's Irish policy at the turn of the century.

The French war had made the issue of Catholic emancipation urgent. Rebellion in Ireland, in Pitt's view, could not be cured simply by the union of the British and Irish Parliaments. Conciliation, by the political emancipation of the Roman Catholics, was a necessary concomitant of union. George III believed this proposal to be radical ruin and used all his personal prestige to have emancipation defeated. Pitt resigned (1801) and George persuaded Henry Addington (later 1st Viscount Sidmouth) to form a less adventurous cabinet. The collapse of Addington's administration in 1804, after the short Peace of Amiens (1802-03), brought Pitt back into office (1804-06), but he returned at the cost of giving up his emancipation proposals. The King was decisive in this crisis only because it was an issue upon which he felt most deeply and upon which he instinctively expressed the feelings of the majority of the backbenchers in the House of Commons, though Pitt never pushed the matter to a real trial of strength.

**Last years, 1806-20.** On the death of Pitt (January 1806), the King accepted Fox as foreign secretary in a coalition "ministry of all the talents" (1806-07). He even came to feel affection for Fox and sincerely to lament his death in 1806. During this short period of Whig administration, the King allowed his ministers to discuss (abruptly) peace with Napoleon and to abolish the slave trade; he asserted himself and forced their resignation only when they dared to propose some amelioration of

the laws against Catholics. This second break on the Catholic issue came about in circumstances which witnessed to George's declining abilities. Still strong in body, he had become almost blind. He needed the help of a secretary in the task, which he would not reduce, of reading all the official papers. Lord Grenville thought the King had agreed to a paper which proposed the grant of higher rank in the army for papists. The King thought that his ministers were trying to trick him and that Sidmouth alone had explained to him the significance of the paper. He demanded from his ministers a promise not to bring up the subject again, for he feared he might be deceived into betraying his sworn duty to the Church of England. The perfectly proper refusal of ministers to pledge themselves for the future led to their supersession by the Tories, under Lord Portland (1807-09), Spencer Perceval (1809-12) and Lord Liverpool (1812-27), successively.

Much of the remainder of the King's lifetime was a living death. The death of his youngest child and frequent companion, Princess Amelia, in 1810, was a bitter blow; she had, in part, consoled him for his disappointment about his sons. Worse still was the return of the King's illness. In 1811 it was acknowledged that he was violently insane. The doctors continued to hope for recovery but Parliament enacted the regency of the Prince of Wales and decreed that the Queen should have the custody of her husband. He remained insane, with intervals of senile lucidity, until his death at Windsor Castle on January 29, 1820. George III's reign, on its personal side, was the tragedy of a well-intentioned man who was faced with problems too great for him to solve but from which his conscience prevented any attempt at escape.

**BIBLIOGRAPHY.** The best account of George III's character is JOHN BROOKE, *King George III* (1972). ROMNEY SEDGWICK's introduction to his edition of *The Letters from George III to Lord Bute, 1757-1766* (1939), vividly relates the character to the political situation. Other valuable collections of George III's letters are SIR JOHN FORTESCUE, *The Correspondence of George III from 1760 to December 1783*, 6 vol. (1927-28); but see also SIR LEWIS B. NAMIER, *Additions and Corrections to Sir John Fortescue's Edition of the Correspondence of George the Third* (1937); and A. ASPINALL, *The Later Correspondence of George III*, 5 vol. (1962-70). Two quite wide surveys are RICHARD PARES, *King George III and the Politicians* (1953); and J. STEVEN WATSON, *The Reign of George III* (1960). There has been a great deal of scholarly controversy about the nature of politics in the early years of George III's reign, in which the work of SIR LEWIS B. NAMIER has been outstanding. The major works are *The Structure of Politics at the Accession of George III*, 2nd ed. (1957), and *England in the Age of the American Revolution*, 2nd ed. (1961). This approach to the political history of George III's reign has been sharply and pertinently criticized by SIR HERBERT BUTTERFIELD in *George III and the Historians* (1957). Less interest has been displayed in the latter part of George III's reign, but JOHN EHRLMANN, *The Younger Pitt*, 2 vol. (1969), deals very thoroughly with the relations of George III with his most successful prime minister, William Pitt the Younger. The question of the nature of George III's illness has been raised by IDA MACALPINE and RICHARD HUNTER, *George III and the Mad Business* (1969), but their arguments for porphyria as against insanity are not fully accepted by medical opinion.

(J.S.W.)

## Georgia

The largest of the American states east of the Mississippi River, Georgia was founded in 1732, at which time its boundaries were even larger—including much of the present-day states of Alabama and Mississippi. It was by many years the youngest of the 13 former English colonies whose rebellion created the United States. Its landscape presents numerous contrasts, with more soil types than any other state as it sweeps from the Appalachian Mountains in the north (on the borders of Tennessee and North Carolina) to the marshes of the Atlantic Coast on the southeast and the Okefenokee Swamp (which it shares with Florida) on the south. The Savannah and Chattahoochee rivers describe much of Georgia's eastern and western boundaries with South Carolina and Alabama, respectively.

Georgia's 58,876 square miles (152,488 square kilometres) had a population at the start of the 1970s of more than 4,500,000, of whom over 1,000,000 were black; of the total population 60 percent lived in urban areas. For most of the 19th century the state was the capital of the cotton empire of the South, but by the 1970s poultry products accounted for many times the income from cotton. Though industry has far outstripped agriculture in economic importance, 70 percent of the industrial workers remain in farm- or forestry-connected jobs.

Pre-  
eminence  
of Atlanta

For decades Atlanta, the capital, has been the economic and cultural focus of the Southeast. Its name evokes the largely romantic legends of the pre-Civil War South, of the traditions of Southern gentility, and of white-columned mansions along Peachtree Street, its most famous thoroughfare. The people of Georgia and the history of the state have been scarred for more than 100 years by that conflict, which was made real in Georgia by many major battles, by the Confederate prison at Andersonville in which nearly 13,000 Union prisoners died, and by the burning of Atlanta and the devastating "march to the sea" by Federal forces under Gen. William T. Sherman.

Though Atlanta by the 1970s had become very much a nationally oriented city, attracting major corporations as well as citizens from all parts of the United States, race and politics remained inextricably bound together throughout the state. Many forms of discrimination remain realities, as they do in most parts of the United States, though many Georgians in the 1970s saw their state as being in the midst of a slow but definite transition, both socially and politically. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; and CIVIL WAR, U.S.)

#### THE HISTORY OF GEORGIA

**Settlement.** Georgia was granted a charter as a colony by George II in 1732, well after the great English migrations of the 17th century. The prime mover in obtaining the charter was the English general and philanthropist James Edward Oglethorpe, who sought to found a colony where the poor of England could get a new start. He and other trustees encouraged the settlers to produce wines, silks, and spices, to relieve England of a dependency on foreign sources. The colony also would serve as a bulwark against the Spanish and French in the lands beyond the Carolinas.

Settlement was made at Savannah in 1733. Some colonists paid their way; the colony's trustees paid the expenses of others. Oglethorpe directed affairs in the colony, with his primary interest in military operations. Government was informal, the economy not generally successful, and military frustration was frequent; the trustees surrendered power to the royal government in 1752, a year before their charter was to expire.

**Revolution and growth.** With the pre-Revolutionary westward thrust of American migration, substantial settlement of Georgia began, first in a thin band along the west side of the Savannah River. Georgia's response to the revolutionary tensions of the 1770s was confused, and the war period was chaotic. After the Revolution, settlement expanded rapidly, especially westward from Augusta through the future "cotton counties" of middle Georgia. Speculations in public lands, acquisitions of more and more Indian lands, and final removal of the Creeks and Cherokees from the state paralleled the development of a largely commercial agriculture and a concomitant transportation system. The Indian removals themselves provided a poignant and traumatic chapter to the state's history. The states of Alabama and Mississippi were already settled by whites, and the Indians' move beyond the Mississippi River was a long one. It left in its wake what came to be known as the Cherokee Trail of Tears.

**Civil War and aftermath.** As disunion approached there was reluctance and division of feeling. Much of northern Georgia never accepted secession, and Union

sentiment was high there throughout the Civil War. The state contributed many regiments and many officers to the Confederacy, but its civil leadership was divisive and querulous. Georgia was in most respects a typical Southern state during the Reconstruction period. The Atlanta cotton expositions and the city itself rapidly became symbols of the new South that arose from the ashes of the old.

After Reconstruction, agriculture became even more commercialized. With rising cotton prices after 1900, the agricultural economy functioned at its best, though briefly. In the 1920s came the scourge of the cotton boll weevil that, with succeeding depression and war, radically altered the economic structure of the state. Since the 1920s, problems of integration have come increasingly to the forefront of Georgia's social and political life, but the state has continued to solidify its position of dominance in the regional as well as national economy and culture.

#### THE NATURAL AND HUMAN LANDSCAPE

**The natural environment.** The most southerly portions of the Blue Ridge section of the Appalachian Mountains cover northeastern and north central Georgia, whereas in the northwest a limestone valley-and-ridge country predominates above Rome and the Coosa River. The higher elevations extend southward down into the state about 75 miles, with peaks such as Kennesaw and Stone mountains near Atlanta rising starkly from the floor of the upper Piedmont. The highest point in the state, Brasstown Bald in the Blue Ridge, reaches 4,784 feet (1,458 metres) above sea level. Below the mountains the Piedmont extends to the Fall Line of the rivers—the east-to-west line of Augusta, Milledgeville, Macon, and Columbus. Along the fall region, nearly 100 miles wide, sandy hills reach in a narrow, irregular belt from Augusta to Columbus. Below these hills the rolling terrain of the coastal plain levels out to the flatlands near the coast, the "pine barrens" of the early days.

Surface  
features

**Soils.** From the coast to the Fall Line, sands and sandy loams predominate, gray near the coast and increasingly red with higher elevations. In the Piedmont and Appalachian regions these traits continue, with an increasing amount of clay in the soils. North Georgia lands are referred to colloquially as "red land" or "gray land." In the limestone valleys and uplands in the northwest, the soils are of loams, silts, and clays and may be brown as well as gray or red.

**Rivers and lakes.** About half the streams of the state flow into the Atlantic Ocean and most of the rest through Alabama and Florida into the Gulf of Mexico. A few streams in north Georgia flow into the Tennessee River and thence via the Ohio and Mississippi into the Gulf. The river basins have not contributed significantly to the regional divisions, which have been defined more by elevations and soils. The inland waters of Georgia consist of 20 artificial lakes, some 70,000 small ponds created largely by the federal Soil Conservation Service, and natural lakes in the southwest near Florida. These have fostered a widespread recreational water culture.

**Climate.** Maritime tropical air masses dominate the climate in summer, but in other seasons continental polar air masses are not uncommon. The average January temperature in Atlanta is 39° F (4° C), in August, 79° F (26° C). Farther south, January average temperatures rise by 10° F (6° C), but in August only about 3° F (2° C). In north Georgia rain usually averages about 50 inches (1,270 millimetres) annually. The east central areas are drier, with about 44 inches. Precipitation is more evenly distributed through the seasons in north Georgia, whereas the southern and coastal areas experience more summer rains.

**Vegetation and animal life.** The mountains-to-the-sea topography of the southeastern states gives Georgia a natural vegetation from maple and hemlock, birch and beech near Blairsville in the north to the cypress, tupelo, and red gum of the stream swamps below the Fall Line and to the marsh grass of the coast and islands. Through most of the Appalachians, chestnut, oak, and yellow

Variety of  
natural life

poplar are dominant. Much of this area is now national forest. The region from Tennessee to the Fall Line is of oak-pine dominance, except for an area of pines in the west. Below the Fall Line and out of the swamps are the pines—longleaf, loblolly, and slash—exploitation of which for pulpwood is a leading economic activity. Much of the land, which had been cleared of trees for agriculture, has gone back to trees, scrub, and grasses.

Georgia's wildlife is profuse. There are alligators in the south; bear, with a hunting season in five counties near the Okefenokee Swamp; deer, with restricted hunting in most counties; grouse; opossum; quail; rabbit; raccoon; squirrel; sea turtles, with no hunting allowed; and turkey, with quite restricted hunting. In general, wildlife is in a period of transition. Deer have been seen in suburban counties and bears on golf courses in Atlanta; but solid stands of pine and unbroken pasture are not ideal for wildlife, and its future seems open. Stocking of game birds and fish is extensive. The major fish of the southern coast, except snook and bonefish, are in waters off the Georgia coast, and all major freshwater game fish of the U.S. are in Georgia's streams and lakes.

**Traditional regions.** Migrations and historical change have blurred the traditional regions of Georgia. In earlier times, the coastal mainland and islands were distinct, separated from middle Georgia by the pine barrens of the lower coastal plain. Rice and sea island cotton were major crops. There was a summer exodus of white families from the plantations to the southern highlands and to the North: a Savannah family might well know more people in Boston, New York, or Philadelphia than in Augusta, Macon, or Columbus. The coastal region and sea islands still support the unique culture of blacks known in South Carolina as Gullah, in Georgia as Geechee.

The early subsistence farmers known as "crackers" lived in the thinly populated pine barrens just above the coastal area. There the soil is sandy and poorly drained, and the farms and plantations existed amid near-frontier conditions through much of the 19th century.

Beyond the pine barrens to the north and west, a fabulous cotton culture flourished for more than a century. The classic period of cotton plantations and farms before the Civil War was brief in several counties. The white-columned houses generally were built in the county seats, or "courthouse towns," whereas most rural houses could be termed no more than substantial farm-homes. Mountainous northern Georgia was an area of small subsistence farms and few slaves.

Blacks were long identified with the commercial agriculture producing sea island cotton and rice on the coast and upland cotton in middle Georgia. Some modern historians use the term "black belt" as a demographic description of middle Georgia where slavery predominated, though its origin stemmed from the dark soils of Alabama.

**Patterns of settlement.** Plantations were cultivated by supervised group labour before the Civil War. After the war a family-plot system, called sharecropping or tenant-farming, replaced the larger labour groups and reduced immediate supervision. There were two basic arrangements in the sharecrop system with variations: in middle Georgia, the division by halves system gave the landowner control of management and sales. The more independent north Georgian, if he did not own a small farm himself, rented by thirds and fourths and had control.

Rural Georgia was settled in a pattern of separate farms without villages or unified communities. Area names suggested such centres, but these generally were derived from the names of creeks, mountains, militia districts, and the like. Schools, churches, and stores drew people, often near neighbours, in different directions, producing a highly diffused rural community life. Urban settlements originally served political and commercial purposes as county seats and cotton markets. The Fall Line cities became railroad points, and later they and some courthouse towns in the upper Piedmont had cotton mills.

Elsewhere, the country general store and small local

cotton gins declined as larger towns gradually absorbed the slight commerce and industry. Later, better roads drew people from these smaller locales to the even larger towns and cities. Today the shopping centre, neon-lighted restaurants, and service stations are scattered through both rural and urban areas in much of the state.

#### THE PEOPLE OF GEORGIA

**Population composition.** The Georgia colony languished under the trustees, and in 1752 it numbered only about 5,000 inhabitants, including English, Jews, blacks, Salzburger from Austria at New Ebenezer and Savannah, Scottish Highlanders at Darien, and New England Congregationalists at Sunbury and Midway. Settlement was concentrated on the coast and up the Savannah River to the Augusta area. The westward movement began under the English crown, and the census of 1790 counted 82,548 persons—52,886 whites and 29,662 blacks. In each decade until the 1850s the population increased between 31 and 55 percent. During that period, the cotton counties of middle Georgia were settled. At the start of the Civil War, Georgia had nearly 1,100,000 inhabitants, about 56 percent white, 44 percent black.

**Demography.** Irish, German, and other massive immigrations into the United States during the 19th century affected Georgia little, and by 1910 only about 15,000 foreign-born whites resided in the state.

Churches play a significant role in the various subcultures of Georgia. The early movement for racial integration convulsed the churches even more profoundly than other institutions.

Georgia lost more people than it gained through migration in each decade from 1870 to 1960, but the total population increased steadily because of high birth rates. More whites than blacks left until 1910, generally for other Southern states to the west; since 1910 the black exodus has been greater, generally for longer distances and to the cities of the North. The first impact on the cotton economy of the boll-weevil plague of the 1920s caused massive departures of both races. The white emigration loss almost stopped in the 1950s, and in the 1960s there was a net migration gain for the first time in nearly a century. Emigration of blacks has not slowed significantly, however, and there is little prospect of change.

Mechanized and chemically controlled agriculture and abandonment of cultivated farmlands to pastures and pine forest have been major causes of migrations, as well as the black's rarely realized hopes that elsewhere he will find fewer ingrained patterns of discrimination.

In the 1930s, the first full decade that Georgia was in the national registration, Georgia's birth rate was just above 20 per 1,000 and death rates about half that. By the 1950s and 1960s the births were about two per 1,000 more than the national average and deaths were slightly less. Differences between white and nonwhite birth and death rates diminished during the 1960s. Hookworm, once an endemic infestation, was so reduced by the early 1970s that statistics were no longer kept.

#### THE STATE'S ECONOMY

Georgia's economy has so changed since 1940 as to cause a shift in the meaning of such words as "farm" and "industry"; and "agri-business" is a term in wide use. More people work in industry than on the farm, but a great majority of industrial jobs depend on farm or forest products. Income from poultry is regarded as farm income despite the fact that chickens are raised in factory-like structures; feed prices are quoted for 150-ton lots, and financing is by complex base-and-incentive arrangements—all indicating an extensive and highly developed "agri-business."

More conventional industries, notably automobile assembly, exploit Atlanta's nearness to southeastern markets. Three decades of prosperity have also increased commerce, and New York stores have located branches in Atlanta. Service industries are lagging, and per capita income is only about 85 percent of the national average, but overall the state's economy has become similar to that of the nation as a whole.

Patterns of  
migration

Land  
divisions  
and town  
growth

Quarrying  
and  
forestry

**Exploitation of natural resources.** Marble and granite quarries in northern Georgia provide one of the nation's major sources of building stone, as well as great quantities of crushed stone. The white clay known as kaolin is taken from vast pits in middle Georgia, processed, then shipped in tank cars for use in such products as ceramics and paper. Phosphate deposits in the south are largely unexploited, but this region's reserves of artesian-well water, the largest in the nation, are beginning to prove useful for agricultural irrigation.

Georgia's virgin timberlands have been cut over, but the state ranks second only to Washington state in growth of timber. Taxation of timber-growing lands has become an internal political issue, with growth rates versus tax rates a crucial argument. Lumber, plywood, and paper are major products; but Georgia is especially known for its large production of naval stores—tars and resins—from its pine forests.

Georgia lies south of the states benefitted by the dams of the Tennessee Valley Authority, but rivers contribute almost 20 percent of its electrical energy. Coastal waters provide working grounds for only a small number of fishermen, with shrimp the main catch, though there are commercial sturgeon fisheries on the Coosa and Oosau-la rivers around Rome in northwestern Georgia.

**Manufacturing.** Cotton textile production has occupied a major sector of Georgia's economy since the late 19th century. In the 1970s, the continuation of this specialization in textiles was evidenced by the great number of rug and carpet mills in northern Georgia, the concentration of looming and weaving skills of which make the state the major textile producer in the nation. Manufactures representing modern, sophisticated living include airplane and automobile assembly, mobile homes, chemicals, and food processing.

**Agriculture.** With the continuing consolidation of farms into fewer but larger units and the advent of a pervasive "agri-business," Georgia has followed nationwide trends in agriculture. Much of the poultry industry is conducted by large companies that parcel out their work to small farmers—many of whom would otherwise be unemployed—and supply them with modern poultry-raising facilities. Cattle and swine raising are important, especially in the south. Cotton is still a major crop, though far below the peak years of the early 20th century, and Georgia is the leading state in peanut production and high in tobacco. Peaches have become especially identified with Georgia, and pecans and watermelons are grown nearly everywhere in the state.

**Governmental presence.** The federal government affects Georgia's economy through direct purchases from industry but even more through payrolls at the several major military installations throughout the state. It produces some hydroelectric power and regulates its sale, much of it to rural electric cooperatives, and controls more than 2,000,000 acres of forests and waters.

The state government, on the other hand, functions in the economic sphere largely to promote further industrial development or financial investment in the state, which continues to rely heavily on outside money. Atlanta is the financial centre of the Southeast and headquarters of the Sixth District of the Federal Reserve Bank. Nearly three-quarters of state taxes are levied on sales, most of the rest on personal and corporate incomes. Local governments rely mainly on general property taxes.

**Labour and management.** Only about 15 percent of Georgia's workers are members of unions. This is below the national average. Unions are strongest in construction, the textile trades, and the steel, automotive, aircraft, and other machine industries. Racial tensions exist within union organization, but traditionally blacks have been employed in such building trades as carpentry, painting, and masonry. Unionization is hampered by a solidly entrenched "right-to-work" law prohibiting compulsory union membership in any trade or industry and by the recent rural origins of many union members that prevent them from achieving a rapid acclimatization to modern industrial procedures.

Worker  
and  
employer  
organiza-  
tions

Employer groups vary from broad-based organizations striving for a good general business climate to one-industry groups with hard-line lobbies at the state and federal levels. "Agri-business" presses hard for exports to European countries, while the cotton-fabrics industry strives as determinedly against foreign imports.

**Transportation.** Water transportation determined the location of Georgia's earliest cities. Milledgeville was briefly the centre of an emerging road system for the settled counties in eastern Georgia and for the old military and post road running through Indian country to Alabama. Atlanta, originally called Terminus on the early railroad survey maps, had a near-optimum location for all but water transport, thus making it a hub of railroad transportation for the Southeast. With the advent of highways and then of air traffic, the city maintained its focal position.

In the 1970s, Georgia had about 5,500 miles of main and branch rail lines. Petroleum, natural gas, and butane pipelines come into the state from the Southwest. More than 500 trucking lines serve the state, and the Atlanta Airport served more than 1,000 flights daily. Twelve other cities in the state have commercial air service. Though urban transit has declined to the point of crisis, in 1971 two Atlanta-area counties voted to begin a rapid-transit service.

Navigation of 500 miles of inland waterways has been revived, and Augusta, Columbus, and Bainbridge have barge service. A state ports authority is constructing facilities at these river ports and at the harbours of Savannah and Brunswick for the distribution of numerous chemical, wood, and mineral products.

#### ADMINISTRATION AND SOCIAL CONDITIONS

**Governmental structure.** The structure of state government tends to sever governmental from political processes and thereby prevents a strong executive. Most of the activities of modern state government are controlled by elected boards, which make more than 85 percent of the state's expenditures.

The Georgia legislature was restructured in 1971 to comprise a 56-member Senate and 180-member House; districts replaced counties as units of representation. Basic units of the judiciary are a court of ordinary for probate and guardianships, and a superior, or circuit, court of general trial in each county, with auxiliary county and municipal courts. At the top of the pyramid, the Court of Appeals and the Supreme Court hear appeals from lower jurisdictions. Uniform procedures for supervision or coordination of the superior courts do not exist. Some circuits may try a case within two months, others, within 20 months. There are strong pressures for revision of administrative procedures in the courts.

**Local administration.** Georgia's local governments are many: in 1972 there were 159 counties, 530 municipalities, and over 350 special districts. Counties remain viable units, often performing municipal-type services. Alone and through multicounty cooperative districts, they operate forestry units, airports, hospitals, and libraries. By the early 1970s, the counties and the municipalities had organized 19 area planning and development commissions that may create corporations for housing and industrial development and that are concerned with planning for health and criminal justice.

Atlanta provides an outstanding example of the weak-mayor form of government, but an increasing number of cities have strong executives. Relations between cities and their suburbs, in which race is and will continue to be significant, remain largely unsolved.

**Politics and race.** A county-unit system characterized Georgia politics from 1917 to 1962. In Democratic primaries, counties were allotted two unit votes for each seat they held in the lower house of the legislature, where 121 smaller counties each held one seat, 30 middling counties held two, and the eight most populous counties held only three each. Candidates received the unit votes of counties in which they received electoral pluralities. This system extended the rural domination of the legislature to nominations in statewide Democratic primaries;

County,  
regional,  
and  
municipal  
govern-  
ment

the process was used also in congressional districts. The county-unit system tended to create alliances between candidates for governor and the "courthouse rings" of the local elite, which could carry counties, at a time when distribution of highway money among the counties played a major role in politics. Since 1962, governors have gained nomination by campaigning, with less dependence on "courthouse rings," and have also lost much of their former dominance over the legislature.

Georgia politics has been in flux since the 1950s. Voting patterns have changed, and distinctions among local, state, and national politics have increased. Republican or third-party presidential candidates carried the state after 1960. Local politics and the courthouse rings remain almost universally Democratic, and Democrats, while remaining shy of identification with the more liberal national party, continued to win all statehouse offices in the same period. Republicans, however, have won seats in Congress.

The political idiom has changed as well. Explicit racial demagoguery is no longer in evidence. Campaigns are long, and, with only occasional captive audiences, gubernatorial candidates must stump and shake hands throughout the state in a way once unnecessary.

Black  
voting and  
civil rights

Black precincts in Atlanta and Macon that were 80 to 90 percent Republican in 1956 are now Democratic by that margin or more. Whites in rural and less affluent urban areas may vote for candidates on racial issues, whereas rural elites and affluent suburbanites may vote for either party depending on the local, state, or national nature of the contest and the commitments of the candidates. Black candidacies in Atlanta have strained a long-time local coalition between blacks and the affluent. More blacks are voting in each election, but an astute black congressional candidate would want a district at least 70 percent black for a chance of winning. In the early 1970s, more than 50 blacks held elective office in Georgia.

The civil rights movement in Georgia has been characterized by legal action, many nonviolent and a few violent confrontations, selective buying campaigns, voter registration, and education. The movement has touched life in rural Georgia very little. In cities and in settings of high visibility—airports, stores, restaurants, and schools—blacks are seen in dramatically different circumstances from earlier decades. Discrimination continues, but the new head of the state patrol announced in 1971 that the mission of the patrol is to enforce the law, not custom.

**Education.** State-endowed county academies were created in the 1780s, but state support was not continued. Academies and numerous colleges were characteristic of the period before the Civil War, but no sustained statewide program of public education existed. Some state funds were allocated for tuition for the poor, and some counties had public schools. In 1850, 80 percent of whites were literate. The Reconstruction constitution of 1868 provided for free public education and the gradual founding of the school system from the 1870s. The public high schools have developed largely since 1912. State support of public schools is, since 1964, for nine months, and compulsory ages, since 1945, are from seven to 16 years. The racial integration of public schools increased private-school enrollments dramatically. Georgia ranks 36th among the states in expenditures per pupil and 20th in school-age children in attendance in public schools.

The public institutions of higher learning, under a unified board of regents, are headed by the University of Georgia (chartered 1785; opened 1801) in Athens and Georgia Institute of Technology (1885) and Georgia State University (1913), a downtown university, both in Atlanta. Other state colleges and new junior colleges are increasing the crisis of private colleges in the state. Rather than incorporating these colleges into the university system, the state pays Georgia students' tuition at the private colleges. The four undergraduate colleges and the graduate and professional schools of Atlanta University Center, now all on one campus, and Paine College in Augusta provide higher education primarily for blacks.

**Health and welfare.** There are beginnings of a new program in mental health. The old central state hospital has an increased staff and fewer patients. Another hospital has been opened on two campuses. Regional hospitals for evaluation, emergency, and short-term treatment are being established throughout the state to serve communities within a 50-mile radius. In addition, there are 60 community health-care centres for outpatient treatment, and a number of other general hospitals have been built through federal programs.

Georgia has imaginative programs in family and children's services. There are state and regional youth-development centres, and no child is committed to a jail. The state aids colleges in training welfare workers, whose activities are supplemented by a widespread volunteer program.

Housing remains inadequate, with poorer people, both rural and urban, continuing to live in flimsy structures. In the housing census of 1960, more than 40 percent of the dwellings were classified as substandard. Housing is a main concern for the area planning commissions; some of these planning commissions actively sponsor new building and renovation.

Housing  
problems,  
urban and  
rural

#### CULTURAL LIFE AND INSTITUTIONS

**The arts.** Atlanta rapidly is becoming the artistic centre of the Southeast. Its memorial centre, completed in 1968, brings together a major museum and a school of the visual arts with performing facilities for a major symphony orchestra and a professional resident theatre, both of which have premiered new works in music and drama. Atlanta also has cooperative galleries run by painters and sculptors and an active group of film makers.

Elsewhere in the state, there are regional ballet companies, and community theatres perform in more than 30 towns. In addition to instruction in theatre, dance, the visual arts, and music in many colleges, Georgia Institute of Technology has a school of architecture, and the University of Georgia teaches landscape architecture. Eight public museums and numerous college galleries exhibit art, and Atlanta University has a notable Afro-American collection.

**Folk culture.** Georgia is rich in traditional arts and crafts, especially in the mountainous north. The craft of tufted fabrics was a major factor in attracting the carpet industry that settled around Dalton. Other handcraft workers find sales opportunities through country fairs in Hiawassee and nearby Gatlinburg, Tennessee, at the Plum Nelly Clothesline in Rising Fawn-Trenton, and at many other art festivals across the state. A mountain arts cooperative has a store in Tallulah Falls, and craft shops are attached to several art galleries. A bulletin of the state Agriculture Department gives free advertising for crafts, and a quarterly publication describes many of the old craft techniques.

Traditional music is sung by authentic folk groups in the sea islands and in the mountains. Country-music conventions are held in north Georgia—with some tension between purists and users of electronic equipment. The ancient sacred harp songs of the northwest, heard in what is known as "fa-so-la" singing, have been collected, and throughout the area many prayers and sermons are delivered in singsong.

**Communications.** Throughout Georgia, 34 daily newspapers, five semiweeklies, and more than 200 weeklies are published. Though generally conservative, the press has tended to support the more liberal statewide candidates in recent decades. *The Atlanta Constitution* long has been recognized as among the nation's outstanding newspapers. A well-edited "underground" newspaper in Atlanta reflects many of the views of the youth culture that took over a section of Peachtree Street known as the Strip in the late 1960s. There are more than 200 radio and 15 commercial television stations in the state as well as an unusually well-directed system of educational television.

**Prospects.** Paradoxically, Georgia's economy continues an overall prosperity while the counties of middle

Georgia, the classic cotton country, continue to lose people and economic status to northern counties. Its location—at the heart of the Southeast—is expected to remain an asset, both economically and culturally. An end to the state's transitional political and social condition was not in sight in the mid-1970s, though black leaders with greater political orientation and sophistication were replacing the ministers who led the drives for equality in the two preceding decades.

**BIBLIOGRAPHY.** ELLIS MERTON COULTER, *Georgia: A Short History*, rev. ed. (1960), the best one-volume history of the state for the general reader; KENNETH COLEMAN, *The American Revolution in Georgia, 1763–1789* (1958), the definitive study of Georgia through three decades of crisis; HORACE MONTGOMERY, *Cracker Parties* (1950), a revealing study of politics in antebellum Georgia; NUMAN V. BARTLEY, *From Thurmond to Wallace: Political Tendencies in Georgia, 1948–1968* (1970), an excellent study, especially of voting; HENRY T. MALONE, *Cherokees of the Old South: A People in Transition* (1956), the definitive study of Georgia's best known Indians; T. CONN BRYAN, *Confederate Georgia* (1953), a thorough and scholarly study of Georgia during the Civil War; ALAN CONWAY, *The Reconstruction of Georgia* (1966), a study of the social and economic aspects of Reconstruction, written by a Welsh scholar; DEWEY W. GRANTHAM, *Hoke Smith and the Politics of the New South* (1958), an account of the leadership of Georgia in the New South movement; JAMES C. BONNER, *A History of Georgia Agriculture, 1732–1860* (1964), and WILLARD RANGE, *A Century of Georgia Agriculture, 1850–1950* (1954), valuable as complementary scholarly studies.

(G.He.)

## Georgian Soviet Socialist Republic

Lying at the eastern end of the Black Sea just to the south of the great barrier formed by the Caucasus Mountains, the Georgian Soviet Socialist Republic, or Georgia, lies in the southernmost region of the European section of the Soviet Union, at the same latitude as Rome. Formed in 1921, it has been since 1936 one of the 15 Soviet union republics. With the notable exception of the fertile plain of Kolkhida—ancient Colchis, where the legendary Argonauts sought the Golden Fleece—the Georgian terrain is largely mountainous (85 percent of the total area) and a third is covered by forest or brushwood. There is a remarkable variety of landscape, ranging from the subtropical Black Sea shores to the ice and snow of the crest line of the Caucasus. Such contrasts are made more noteworthy by the relatively small size of the republic, which, at 26,900 square miles (69,700 square kilometres), ranks 10th among the union republics.

The roots of the Georgian people, who numbered about 4,900,000 in the mid-1970s, are deep in history. Their cultural heritage is equally ancient and rich. During the 20th century Georgia has experienced a major transformation from an economically backward outpost of the tsarist Empire to a modernized and diversified economy.

The republic is bounded to the north, at the Caucasian crests, by the Russian Soviet Federated Socialist Republic. Azerbaijan and Armenia lie to the east and southeast, and a portion of the Soviet frontier with Turkey is to the south. Georgia includes two autonomous Soviet Socialist republics, the Abkhaz (principal city Sukhumi) and the Adzhar (principal city Batumi), as well as the Yugo-Ossetian Autonomous Oblast, a unit centred on Tskhinvali. The Georgian capital is at Tbilisi (Tiflis). (For related information, see RUSSIA AND THE SOVIET UNION, HISTORY OF; SOVIET UNION; CAUCASUS MOUNTAINS; and CAUCASIAN LANGUAGES.)

### THE LAND

**Topography.** The rugged Georgia terrain may be divided into three bands, all running from east to west.

*The Great Caucasus Range.* To the north lies the wall of the Great Caucasus, consisting of a series of parallel and transverse mountain belts, rising eastward, and often separated by deep, wild gorges. Spectacular crest line peaks include Shkhara (16,627 feet [5,068 metres]), Rustaveli (16,273 feet [4,960 metres]), Tetnults (15,918 feet [4,852 metres]), and Ushba (15,420 feet [4,700 metres]).

The cone of the extinct Kazbek (Mqinvari) volcano dominates the northernmost Bokovoy Range from a height of 16,512 feet (5,033 metres). Farther south, the central range thrusts out a number of important spurs, including those of the Lomissky (Lomisi) and Kartliysky (Kartli, Kartalinian) ranges at right angles to the general Caucasian trend. From the ice-clad flanks of these desolately beautiful high regions flow many streams and rivers.

*The central trough.* The southern slopes of the Great Caucasus merge into a belt of lowlands formed on a great structural depression. The Kolkhida lowlands, near the shores of the Black Sea, are covered by a thick layer of river-borne deposits, accumulated over thousands of years. Rushing down from the Great Caucasus, the major rivers of western Georgia, the Inguri, Rioni, and Kodori, flow over a broad area to the sea. The Kolkhida lowland was formerly an almost continually stagnant swamp. In a great development program, drainage canals and embankments along the rivers have been constructed and afforestation plans introduced; the region has now become of prime importance through the cultivation of subtropical and other commercial crops.

To the east, the structural trough is crossed by the Meskhetsky (Meskheti) and Likhsky (Likhi) ranges, linking the Great and Little Caucasus and marking the watershed between the Black and Caspian Sea basins. Beyond, in central Georgia, between the cities of Khashuri and Mtskheta (the ancient capital), lies the inner high plateau known as the Kartalinian Plain. Surrounded by mountains on all sides and covered for the most part by deposits of the loess type, this plateau extends along the Kura (Mtkvari) River and its tributaries.

*The Little Caucasus.* The southern band of Georgian territory is marked by the ranges and plateaus of the Little Caucasus, which rise beyond a narrow, swampy coastal plain to reach 10,830 feet (3,301 metres) in the peak of Didi-Abuli.

**Climate.** *Altitude and climate.* The Caucasian barrier protects Georgia from cold air intrusions from the north, while the republic is open to the constant influence of warm, moist air from the Black Sea. Western Georgia has a humid subtropical, maritime climate, while eastern Georgia has a range of climate varying from moderately humid to a dry subtropical type.

Altitudinally, too, there are marked zones. The Kolkhida lowland, for example, has a subtropical character up to about 1,600–2,000 feet, with a zone of moist, moderately warm climate lying just above; still higher is a belt of cold, wet winters and cool summers. Above about 6,600–7,200 feet, there is an alpine climatic zone, lacking any true summer; above 11,200–11,500 feet, snow and ice reign perpetually. In eastern Georgia, farther inland, temperatures are lower than in the western portions at the same altitude.

*Western Georgia.* Western Georgia has heavy year-round rainfall, totalling 40 to 80 inches (1,000 to 2,000 millimetres) and reaching a maximum in autumn and winter. Southern Kolkhida receives the most rain, and humidity decreases to the north and east. Winter in this region is mild and warm; in regions below about 2,000–2,300 feet, the mean January temperature never falls below 32° F (0° C), and warm, sunny winter weather persists in the coastal regions, where temperatures average about 41° F (5° C).

*Eastern Georgia.* In eastern Georgia, precipitation decreases with distance from the sea, reaching 16 to 28 inches (400 to 700 millimetres) in the plains and foothills but, nevertheless, increasing to double this amount in the mountains. The southeastern regions are the driest areas, and winter is the driest season; the rainfall maximum occurs at the end of spring. The highest lowland temperatures occur in July (about 77° F), while average January temperatures over most of the region range from 32° to 37° F.

**Plant and animal life.** The republic's location and its diverse terrain have given rise to a remarkable variety of landscapes. The luxuriant vegetation of the moist, subtropical Black Sea shores is relatively near to the eternal snows of the mountain peaks. Deep gorges and swift

Kolkhida

Altitudinal  
zones

Autonomous  
S.S.R.'s  
and oblast

## Forests

rivers give way to dry steppes, and the green of alpine meadows alternates with the darker hues of forested valleys. Soils, too, present a great variety, ranging from gray-brown and saline semi-desert types to richer red earths and podzols, with man-made improvements adding to the diversity.

About a third of the republic is covered by forests and brush. In the west, relative constancy of climate over a long period has preserved many relict and rare items, including the Pitsunda pines (*Pinus pithyusa*). The forests include oak, chestnut, beech, and alder, as well as Caucasian fir, ash, linden, and apple and pear trees. The western underbrush is dominated by evergreens (including rhododendrons and holly) and such deciduous shrubs as Caucasian bilberry and nut trees. Liana strands entwine some of the western forests. Citrus groves are found throughout the republic, and long rows of eucalyptus trees line the country roads.

Eastern Georgia has fewer forests, and the steppes are dotted with thickets of prickly underbrush, as well as a blanket of feather and beard grass. Herbaceous subalpine and alpine vegetation occurs extensively in the highest regions. Animal life is very diverse. Goats and Caucasian antelope inhabit the high mountains; rodents live in the high meadows; and a rich birdlife includes the mountain turkey, the Caucasian black grouse, and the mountain and bearded eagles. The clear rivers and mountain lakes are full of trout.

Forest regions are characterized by wild boar and roe and Caucasian deer, brown bear, lynx, wolf, fox, and jackal, and hares and squirrels. Birds range from the thrush to the black vulture and hawk. Some of these animals and birds also frequent the lowland regions, which are also the home of introduced raccoon, mink, and nutria. The lowland rivers and the Black Sea itself are also rich in fish.

## THE PEOPLE

## The Georgians

**Composition and distribution.** The likelihood is great that the Georgians (whose name for themselves is Kartveli, "Georgian" having been derived from the Persian name for them, Gorj) have always lived in this region, known to them as Sakartvelo. Georgia embraced Christianity in the 4th century. From the 6th century on, a succession of feudal states emerged there. A population of almost 5,000,000 was achieved by the 13th century, but invasions by outsiders, among whom were the Mongols, much reduced this total. More peaceful conditions followed the annexation by Russia between 1801 and 1864. By the turn of the 20th century, the population had risen to 2,000,000, and by 1975 it was estimated to be 4,923,000.

Ethnically, contemporary Georgia is not homogeneous but reflects the intermixtures and successions of the Caucasus region. Two-thirds of the people are Georgians; Armenians form nearly 10 percent, followed by Russians (about 8.5 percent), Azerbaijanis (4.6 percent), and smaller numbers of Ossetes, Greeks, Abkhaz, and a number of other minor groups.

The republic is one of the first among the union republics in terms of population density. About 90 percent of the population lives below 3,300 feet, with average density approaching 290 per square mile (112 per square kilometre) at the census of 1970. The density decreases sharply with increasing altitude.

The Georgians, a proud people with an ancient culture, have through the ages been noted as warriors as well as for their hospitality, their love of life, and their lively intelligence and sense of humour. Physically, they tend to be taller than average, with athletic, wiry bodies, complexions ranging from fair or ruddy to sallow, and generally dark hair, though fair-haired persons are seen. Their eyes are commonly hazel, with some blue and some gray. The nose shape varies, those in the east tending to be hooked, those in the west straight and thin. The standard of looks is high, and the beauty of Georgian women is legendary; many of them graced the harems of the Ottoman sultans and the shahs of Iran. The Georgians are often also remarkably long-lived.

**Demographic trends.** During the Soviet period the Georgian population has not only increased but has also shown a marked trend toward urbanization. From 666,000 in 1913, the urban component increased 3.6 times to some 2,398,000, or almost half the total, in 1974, while the rural component increased by only a quarter. Further, a considerable portion of the population that is defined as rural is, in fact, engaged in the urban economy of nearby cities. Enterprises for primary processing of agricultural products are being constructed in the villages, while ore-processing plants and light industry are also increasing in number. As a result, many of the slow-paced traditional villages have developed into distinctly modern communities. The number of rural inhabitants remains high because of the wide distribution of such labour-intensive branches of the economy as the tea and subtropical crop plantations.

By the mid-1970s, there were about 50 cities and a like number of towns. Tbilisi, the capital, an ancient city with many architectural monuments mingling with modern buildings, lies in eastern Georgia, partly in a scenic gorge of the Kura River. Other major centres are Kutaisi, Sukhumi, Batumi, and Tskhinvali.

## THE ECONOMY

Georgia has a well-developed industry alongside a diversified and mechanized agriculture. It stands out as a region of waterpower, mineral extraction, and developing machine production. During the Eighth Five-Year Plan (1966-70) the republic's exports doubled in volume, and a hundred or more different products are now exported all over the world.

**Resources.** The interior of Georgia has coal deposits (notably at Tkvarcheli and Tkibuli), petroleum (at Kazeti), and a variety of other resources ranging from peat to marble. The manganese deposits of Chiatura rival those of India, Brazil, and Ghana in quantity and quality.

Its waterpower resources are considerable. The total annual river capacity has been evaluated at an average of 15,500,000 kilowatts, giving a theoretical electrical energy potential approaching 136,000,000,000 kilowatt-hours. The deepest and most powerful rivers are the Rioni and its tributaries, the Inguri, Kodori, and Bzyb. Such western rivers account for three-quarters of the total capacity, with the eastern Kura, Aragvi, Alazani, and Khrami accounting for the rest.

**Industry.** *The fuel and power base.* The fuel and power foundation developed in Georgia has served as the base for industrialization. Dozens of hydroelectric stations, including the V.I. Lenin Zemo-Avchala, Rioni, and Sukhumi plants, as well as many stations powered by coal and natural gas, have been constructed. All are now combined into a single power system, an organic part of the Transcaucasian system. Under the 1966-70 Five-Year Plan, Georgia's power capacity increased 30 percent, while electric power went up 60 percent. The Inguri hydroelectric complex, under construction high in the mountains in the mid-1970s, with an 890-foot arched dam, has a planned capacity of 1,600,000 kilowatts. This station alone will produce more electric power than all the earlier stations built in Georgia.

*Raw material extraction and processing.* The coal industry is one of the oldest mineral extraction industries, centred on the restructured Tkibuli mines. Deposits found in Tkvarcheli and Akhaltsikhe have increased production.

Manganese and nonmetallic minerals, ranging from talc to marble, supply various industries throughout the Soviet Union.

*Metallurgy and machine building.* The Rustavi metallurgical plant, located near the capital, produced its first steel in 1956. Its laminated sheet iron and seamless pipe products are used throughout the Soviet Union, and by the 1970s Georgia was also producing cast and sheet iron. Zstafoni is the second major metallurgical centre.

The machine-building industry now turns out a diverse range of products, from electric railway locomotives, heavy vehicles, and earth-moving equipment to lathes and

## Water-power

precision instruments. Specialized products include tea-gathering machines and anti-hail devices for the republic's plantations. The industry is centred in the major cities.

**The chemical and building industries.** The chemical industry of Georgia produces mineral fertilizers, synthetic materials and fibres, and pharmaceutical products. The building industry, using local raw materials, supplies the republic with cement, slate, and many prefabricated reinforced-concrete structures and parts.

**Light industry.** Commonly used manufactured goods were previously imported, in large part, from other union republics, but a ramified system of light industries set up in major consumption areas in Georgia now produces cotton, wool, and silk fabrics, as well as items of clothing.

**The food industry.** Products of the food industry include tea, wine, and tobacco, as well as canned foods. Georgia leads the Soviet Union in labelled table and dessert wines, producing 1,200,000 barrels (14,300,000 decalitres) annually by 1970. Cognac and champagne production is also well developed. The canning industry is developing, with the number of cans of processed foods increasing fivefold between 1950 and 1970. Other food industry activities include dairy products.

**Agriculture.** A distinctive feature of the Georgian economy is that agricultural land is both in short supply and difficult to work; each patch of workable land, even on steep mountain slopes, is valued highly. The relative proportion of arable land is less than that in almost any other union republic. The importance of production of labour-intensive (and highly profitable) crops, such as tea and citrus fruits, is a compensatory factor, however. The introduction of a system that now contains some 1,150 collective farms (*kolkhozy*) and 270 state farms (*sovkhozy*) has radically altered the traditional structure of landowning and working (though a considerable portion of Georgia's agricultural output still comes from private garden plots). Contemporary agriculture uses modern equipment supplied under a capital investment program, which also finances the production of mineral fertilizers and herbicides, as well as afforestation measures.

**Tea, fruit, and wine.** Tea plantations cover 158,000 acres (63,900 hectares), and the annual commercial tea leaf harvest accounts for around 95 percent of all Soviet production. Citrus trees occupy space equal to about a sixth of the tea area.

The vineyards of the republic cover 274,000 acres, and the production of wine is one of the oldest and most important branches of Georgian agriculture, and perhaps the best loved. Centuries of trial and error have produced more than 500 varieties of grape.

Orchards now occupy 310,000 acres throughout the republic. Georgian fruits are varied, even slight differences in climate and soil affecting the yield, quality, and taste of the fruit.

**Other commercial crops.** Sugar beets and tobacco are especially significant among other commercial crops. Essential oils (geranium, rose, and jasmine) are also grown to supply the perfume industry. Grains, including wheat, are important, but quantities insufficient for the republic's needs are raised and wheat must be imported. Growing of vegetables and melons has developed in the suburbs.

**Stockbreeding.** Livestock raising is marked by the use of different summer and winter pastures. Sheep and goats, cattle, and pigs are raised. Poultry, bees, and silkworms are also significant.

**Transportation.** Georgia has a dense transportation system. More than 60,000,000 tons of freight are carried annually by rail, but in the mountainous regions road transport remains the principal means of moving both passengers and freight. The road network is about 12,900 miles (20,800 kilometres), three-quarters of which is hard-surfaced.

The seaports of Batumi and Poti are of major economic importance for the whole of Transcaucasia, and air-route links with major Soviet centres have become increasingly important.

#### ADMINISTRATION AND SOCIAL CONDITIONS

**The constitutional and political framework.** The unicameral, 400-member Supreme Soviet, elected for four years from a single list of candidates, is the highest government organ; the Presidium, its working organ, consists of a chairman, two vice chairmen, a secretary, and 11 members. Local authorities are the councils of deputies in, respectively, the cities, the *raionebi* (districts), and the *aulebi* (villages).

The Supreme Court is the highest judicial organ, supported by regional and city people's courts. Criminal codes taking fuller account of the national characteristics of the republic were adopted in 1960, and their observance is supervised by a republican procurator, who serves for five years.

The Communist Party of Georgia is the only political party and, under the Communist Party of the Soviet Union, establishes policy. Georgians are dominant in the party, constituting more than three-fourths of its membership (while constituting only two-thirds of the total population).

**Living conditions and social services.** During the 1966–70 Five-Year Plan, average monthly wages registered a 23 percent increase, and the available consumer goods increased by half. Housing construction also had more attention. Payments from public funds (a large part of which are derived from a turnover tax on consumer goods) further provide free education, medical services, pension grants, and stipend payments and free or reduced-cost accommodation in rest homes and sanatoriums, as well as holiday pay and the maintenance of kindergartens and day nurseries.

Georgia ranks high in the level of medical services, with a ratio of 38 doctors for each 10,000 persons. The republic is famed in the Soviet Union as a health centre, a reputation stemming from the numerous therapeutic mineral springs, the sunny Black Sea coast climate, the pure air of the mountain regions, and a wide range of resorts. The Tskhaltubo baths, with warm radon water treatment for rheumatism sufferers, are especially noted.

Educationally, Georgia also ranks high in the Soviet Union; by some indexes it ranks higher than any other union republic. In 1971 there were 4,521 general education schools, with more than 1,000,000 enrolled. In about 70 percent of these schools Georgian is the language of instruction (1965–66 school year), in 7 percent Russian, and in 6 percent Armenian; for the Georgians, these figures are very favourable when compared with the relative proportions of these nationalities in the total population. Among students enrolled in specialized secondary schools (50,649 students in 1969–70), 81 percent were Georgians; in institutions of higher education (18 institutions, 90,121 students in 1969–70), Georgians constituted 83 percent. No fewer than 711 out of every 1,000 working people have had at least some kind of secondary or higher education. There are about 170 students at this level per 10,000 persons. Tbilisi State University was founded in 1918, during the period of the independent Georgian republic, and by the mid-1970s enrolled about 16,000 students each year. The Academy of Sciences (founded 1941) is made up of 44 separate scientific institutions, 38 of which conduct research throughout the republic. This educational system is backed up by an extensive library system of about 200 large units as well as many libraries in technical institutes and in the villages. About three-quarters of all books and brochures (2,486 titles in 1971), magazines (22), and newspapers (126) published are in the Georgian language.

#### CULTURAL LIFE

Georgia is a land of ancient culture, with a written language that was developed in the early 5th century AD. Kolkhida (Colchis) early housed a school of higher rhetoric in which Greeks as well as Georgians studied. By the 12th century, academies in Ikalto and Gelati, the first medieval higher-education centres, disseminated a wide range of knowledge. The national genius was demonstrated most clearly in *Vepkhis-tqaosani* (*The Knight in the Tiger's Skin*), the epic masterpiece of the 12th-century

Health facilities

Georgian viticulture

poet Shota Rustaveli. Major figures in later Georgian literary history include a famed 18th-century writer, Sulikhan-Saba Orbeliani; the novelist and poet Ilia Chavchavadze, author of *Do You Call This a Man?*; the lyric poet Akaki Tsereteli; Alexander Qazbegi, novelist of the Caucasus; the nature poet Vazha Pshavela; Mikheil Javakhishvili, Paolo Iashvili, and Titsian Tabidze, all executed during the Stalin era; and Giorgi Leonidze and Irakli Abashidze. Important workers in other arts include the painters Niko Pirosmani (Pirosmanashvili), Irakli Toidze, Lado Gudiashvili, and Sergo Kobuladze; the composers Zakaria Paliashvili and Meliton Balanchivadze, and the founder of Georgian national ballet, Vakhtang Chabukiani. Georgian theatre, in which outstanding directors of the Soviet period are Kote Mardzhanishvili and Sandro Akhmeteli, has had a marked influence in the Soviet Union and beyond. Amateur theatre and other art forms are also very popular. There is an active Georgian film industry, and a Georgian film, *The Wedding*, directed by Mikheil Kobakhidze, won the Grand Prix for best short film at the Cannes festival in 1966.

The ancient culture of the republic is reflected in the large number of architectural monuments, including many monasteries and churches; indeed, Georgian architecture (with Armenian) played a considerable role in the development of the Byzantine style.

Maintained by preservation schemes, these buildings are attracting an increasing number of Soviet and foreign tourists.

#### PROBLEMS AND PROSPECTS

The 1971-75 Five-Year Plan was designed to increase industrial production by about 42 percent, with development rates highest in the nonmetallurgical and the chemical industries. Two very large industrial complexes, the Inguri Hydroelectric Station and the Madneulski (Madneuli) copper combine, were already in partial operation by the early 1970s. A noteworthy feature of current development plans is an added emphasis on further drainage and irrigation schemes. Tea production is also to be increased.
