## Evidence, Law of

To the end that court decisions are to be based on truth founded on evidence, a primary duty of courts is to conduct proper proceedings so as to hear and consider evidence. The so-called law of evidence is made up largely of procedural regulations concerning the proof and presentation of facts, whether involving the testimony of witnesses, the presentation of documents or physical objects, or the assertion of a foreign law. The many rules of evidence that have evolved under different legal systems have, in the main, been founded on experience and shaped by varying legal requirements of what constitutes admissible and sufficient proof. Although evidence, in this sense, has both legal and technical characteristics, judicial evidence has always been a human rather than a technical problem. During different periods and at different cultural stages, problems concerning evidence have been resolved by widely different methods. Since the means of acquiring evidence are clearly variable and delimited, they can result only in a degree of probability and not in an absolute truth in the philosophic sense. Only Soviet doctrine, under the influence of philosophical materialism, expresses a belief that absolute, objective truth can be attained through evidence. In common-law countries, civil cases require only preponderant probability and criminal cases, probability beyond reasonable doubt. In civil-law countries so much probability is required that reasonable doubts are excluded.

### THE EARLY LAW OF EVIDENCE

Characteristic features of the law of evidence in earlier cultures were that no distinction was made between civil and criminal matters or between fact and law and that rational means of evidence were either unknown or little used. In general, the accused had to prove his innocence.

**Nonrational sources of evidence.** The appeal to supernatural powers was, of course, not evidence in the modern sense but an ordeal in which God was appealed to as the highest judge.

Trial by  
ordeal and  
battle

The judges of the community determined what different kinds of ordeals were to be suffered, and frequently the ordeals involved threatening the accused with fire, a hot iron, or drowning. It may be that a certain awe associated with the two great elements of fire and water made them appear pre-eminently suitable for dangerous tests by which God himself was to pass on guilt or innocence. Trial by battle had much the same origin. To be sure, the powerful man relied on his strength, but it was also assumed that God would be on the side of right.

**Semirational sources of evidence.** The accused free person could offer to exonerate himself by oath. Under these circumstances, in contrast to the ordeals, it was not expected that God would rule immediately but rather that he would punish the perjurer at a later time. Nevertheless, there was ordinarily enough realism so that the mere oath of the accused person alone was not allowed. Rather, he was ordered to swear with a number of compurgators, or witnesses, who confirmed, so to speak, the oath of the person swearing. They stood as guarantees for his oath but never gave any testimony about the facts.

The significance of these first witnesses is seen in the use of the German word *Zeuge*, which now means "witness" but originally meant "drawn in." The witnesses were, in fact, "drawn in" to perform a legal act as instrumental witnesses. But they gave only their opinions and consequently did not testify about facts with which they were

acquainted. Nevertheless, together with community witnesses, they paved the way for the more rational use of evidence.

**The influence of Roman-canonical law.** By the 13th century, ordeals were no longer used, though the custom of trial by battle lasted until the 14th and 15th centuries. The judicial machinery destroyed by dropping these sources of evidence could not be replaced by the oath of purgation alone. With the decline of chivalry, the flourishing of the towns, the further development of Christian theology, and the formation of states, both social and cultural conditions had changed. The law of evidence, along with much of the rest of the law of Europe, was influenced strongly by Roman-canonical law elaborated by jurists in northern Italian universities. Roman law introduced elements of common procedure that became known throughout the continental European countries and became something of a uniting bond between them.

Under the new influence, evidence was, first of all, evaluated on a hierarchical basis. This accorded well with the assumption of scholastic philosophy that all the possibilities of life could be formally ordered through a system of a priori, abstract regulations. Since the law was based on the concept of the inequality of persons, not all persons were suitable as witnesses, and only the testimony of two or more suitable witnesses could supply proof.

The formal theory of evidence that grew out of this hierarchical evaluation left no option for the judge: in effect, he was required to be convinced after the designated number of witnesses had testified concordantly. A distinction was made between complete, half, and lesser portions of evidence, evading the problem posed by such a rigid system of evaluation. Since interrogation of witnesses was secret, abuses occurred on another level. These abuses were nourished by the notion that the confession was the best kind of evidence and that reliable confessions could be obtained by means of torture.

Despite these obvious drawbacks and limitations, through the ecclesiastical courts, Roman-canonical law gained influence. It contributed much to the elimination of nonrational evidence from the courts, even though, given the formality of its application, it could result only in formal truths often not corresponding to reality.

### A COMPARATIVE SURVEY OF THE PRINCIPLES OF LEGAL EVIDENCE

A comparison of the principles of evidence under different legal traditions can best be made by examining the rights and obligations of the plaintiff and the defendant in civil proceedings and of the prosecutor and the accused in criminal proceedings. The position of the judge is also crucial. Historically, two systems developed.

**The inquisitorial system.** The first, which may be called the inquisitorial system, had its origins in medieval Roman-canonical proceedings. It is distinguished by the active part played by the judge, who by virtue of his office, himself searches for the facts, listens to witnesses and experts, examines documents and orders the taking of evidence. In continental European countries, and those other countries that derive their law from them, this system has generally been retained for criminal proceedings. The prosecutor and the accused, of course, give their recital of the facts and indicate their evidence for specific assertions. But by virtue of his role in the case, the judge must make further investigations if he deems them necessary to obtain the truth. Under the Soviet code of civil procedure of 1964, this system is also applied to civil pro-

The judge's  
role in  
continental  
Europe

ceedings. Other Socialist countries have followed this example. In some western European countries, there is a definite inclination toward employing this inquisitorial system in all legal proceedings that have, or could have, a substantial public legal impact; e.g., matrimonial, status, administrative, social, labour, and financial matters.

**The accusatorial (adversary) system.** The second system, which employs what are usually called accusatorial or adversary principles, is used in the common-law countries for all civil and criminal cases. In this system, the parties and their attorneys are primarily responsible for finding and presenting evidence. The judge does not himself investigate the facts. Only if the efforts of the parties are incomplete must the judge make inquiries with regard to questions that have remained unanswered.

In civil matters, most continental European countries follow a mixed system of both principles. In some of these countries, the judge can, for example, hear witnesses who have not been designated by the parties, and in all countries he can, by virtue of his office, hear the parties and experts and order documentary evidence or the actual inspection of evidence. In contrast to criminal cases, the continental European judge is always bound by the motions and assertions of the parties—a situation that does not, however, obtain under Soviet law.

**Oral proceedings.** Under both systems of presenting and obtaining evidence, oral proceedings are generally accepted. The written proceedings favoured during the Middle Ages have been abolished, although the parties prepare their lawsuits through briefs, and parts of the preliminary proceedings can be handled in writing. The interrogation of witnesses, however, is oral. The Roman-based countries and Sweden, Austria, and the Soviet Union do not permit any exceptions, while other countries, such as Germany, permit written statements by witnesses in special cases and with the consent of the parties. In the common-law countries, an exception is made to the principle of oral proceedings for certain types of affidavits, and, particularly in civil cases, the practice has steadily gained in importance.

Direct interrogation of witnesses by the deciding court is an aspect of the law of evidence closely connected with oral proceedings. Generally, in continental European countries, witnesses are interrogated by the judges who decide the verdict, but a number of countries have an investigation procedure according to which another judge, or only one member of the judging body, interrogates the witnesses. Under both the inquisitorial and the accusatorial systems, the principle of direct interrogation is of special importance in the free consideration of evidence. In the common-law countries, the function performed by the judge in this regard is handled by attorneys for the prosecution or defense, with the judge's role restricted almost entirely to overseeing the questioning.

Another principle of substantial importance is the public trial, which was one of the aims of the French Revolution. The right to a public trial, long established under the common law, is now accepted by all continental European countries. There may be exceptions, however, if questions of morals or public order are involved, and public trials in the full sense need not be provided in circumstances in which the evidence, rather than being taken in open court, is heard before a *juge d'instruction* or examining magistrate.

One major influence that has shaped the law of evidence has been the jury system. At least one writer has said that law of evidence is the child of the jury. Oral proceedings, direct interrogation and the public trial are much less problematic under the Anglo-American system than under the civil-law system to the extent that evidence is heard before the jury. But this system has spawned a large number of regulations for the admissibility of evidence in order to guarantee due process and fair procedure and to protect the jury from being misled. The initiative of the parties determines the handling of these regulations, for they must raise objections if, in their opinion, any of the numerous exclusionary rules is being violated. The judge then rules on the objection. By the complex working of this arrangement, the Anglo-

American system has become more formalistic in many respects than the continental European system.

**The burden of proof.** The burden of proof is a manifold and somewhat ambiguous concept in the law of evidence.

The burden of producing evidence means that in general the party that cites specific facts for the substantiation of its claim also has the burden of producing the evidence to prove these facts. This burden depends on the substantive law governing the claim. Permissible presumptions and legal rules can shift the burden in various situations.

The burden of conviction, on the other hand, comes into play at the end of the hearing of evidence, if doubts remain. This is simply to recognize that the evidence is not sufficient to convince the jury or the judge and that, in general, the party having the burden of pleading and producing facts favourable to itself and of giving evidence also carries the so-called burden of conviction.

Whereas, in civil proceedings, it is generally the plaintiff who has the burden of proof for facts supporting a claim, unless this burden has been shifted to the defendant through rules or presumptions, in criminal proceedings it is the prosecution that bears the burden of proof for all relevant facts. What this means is that the defendant cannot be found guilty as long as proof has not been supplied or as long as doubts still remain. In continental European law, no distinction is made between civil and criminal cases with regard to the standard of proof. In both, such a high degree of probability is required that, to the degree that this is possible in the ordinary experience of life itself, doubts are excluded and probability approaches certitude. In the common-law countries, the degree of probability required in civil cases is lower than that called for in criminal matters. Since, according to socialist rules of civil procedure, the judges themselves must search for the facts, it is dubious whether one can speak at all of a burden of proof under socialist law.

**Relevance and admissibility.** In civil proceedings that are determined by the adversary principle, evidence is both ascertained and simultaneously restricted by the assertions of the parties. If the allegations of one party are not disputed or contested by the other, or if the allegations are even admitted, then no proof is required. Proof would, in fact, be irrelevant. Evidence offered to prove assertions that are not in issue nor probative of the matter in issue would also be irrelevant. The only evidence that is, therefore, relevant, is evidence that to some degree advances the inquiry and has a probative value for the decision. While continental European judges, in ordering the hearing of evidence or in deciding on evidence, indicate the facts to be proved and thereby strictly eliminate irrelevant facts, Anglo-American judges first give the parties an opportunity to furnish any evidence that they deem suitable. If, during the hearing of witnesses, irrelevant questions are put, they are rejected after the adversary has objected to them.

It has been said that relevance depends on logical considerations and that admissibility depends on the law. In contrast to continental European law, the common law has developed a large number of rules governing the admissibility of evidence. Relevant evidence is not admissible, for example, if the witnesses are excluded from testifying because of incompetency, or if they are protected by privileges against self-incrimination, or in instances in which they would have to divulge confidential or professional communications that have a privileged status or government secrets, or, again, when the evidence is excluded by the rules against hearsay.

In criminal cases in which the adversary principle does not govern, relevance relates to such questions that are so far removed from the case that they have no evidence value at all. Admissions and confessions do not exclude further evidence. According to Anglo-American law, the accused may be a competent witness under the admissibility rules, but, in contrast to an ordinary witness, he has the privilege of not taking the witness stand. According to continental European law, the accused is neither a party nor a witness. He can be heard, but he cannot be forced to answer questions of fact. In general, Anglo-

Difference between the burden of proof in civil and criminal proceedings

Influence of the jury

American rules of admissibility apply to criminal proceedings much as they apply to civil cases.

**The free evaluation of evidence.** Freedom to evaluate all the evidence produced was established in Roman law but fell into disuse as a principle during the time of the formalistic Roman-canonical law of evidence that characterized the Middle Ages. Remnants of the medieval formal theory of evidence survive in various countries.

Conviction  
intime: the  
judge's  
opinion

In countries where remnants of the medieval formal theory of evidence are still preserved, the principle of free evaluation of the evidence by the judge generally dates from the French Revolution. The French introduced the concept of the judge's *conviction intime* (inner, deep-seated conviction) in contrast to rules of formal evidence that prescribed exactly when the evidence amounted to proof. The primacy this gave to the personal conviction of the judge meant that it was not even necessary to state the reasons for the inner conviction. This total dependence on the judge's discretion aroused a great deal of criticism, and, as a result, various judicial codes prescribed that in giving the grounds on which judgment was based, the judge had to specify in writing why he was convinced in each case. *Conviction intime* in its original sense is limited to the testimony of witnesses and experts and to the explanations of the parties. Both kinds of formal oaths made by parties to a case, the supplementary oath and the tendered oath, are still valid in Roman-law based countries, and both may lead to formal solutions, since the judge must follow the legal consequences of the oath. But these survivals of medieval formal evidence theory have been weakened. In France, for example, the judge's latitude under the principle of *conviction intime* has been extended to allow him to pass on the affirmation oath of the party, which formerly had to be given a certain value, regardless of his opinion of its worth. In other states, such as Austria, Germany, and the Scandinavian countries, the formal oath of the parties was abolished and replaced by the free depositions of the parties. Even if the parties take an oath on their testimonies during this process, the judge is not bound by it but may still make his own evaluation of the evidence. In addition, some remnants of the formal evidence theory have been preserved with regard to documentary proof where rules of procedure contain presumptions as to the conclusiveness of certain documents. Since reliance on documentary evidence prevails in some countries, these formal evidence rules are still of special importance.

In Anglo-American law the problem of free evaluation of evidence can be understood through the institution of the jury. Obviously, the evidence must be convincing to the common sense of the jury members, who form their judgment on the basis of free conviction. The function of the jury, however, is to decide questions of fact, rather than questions of law, which are left to the judge. The jury's verdict can be overturned by the judge if it is inconsistent with the evidence, or with his instructions as to the law governing the case. The judge's relationship to the jury therefore plays a role in the decisions, and there are difficult questions in which it is unclear whether the jury or the judge should consider the evidence. Some formal rules of evidence survive in Anglo-American law. In some cases evidence must be corroborated before it can constitute proof. In homicide cases, for example, a confession must be supported by additional evidence. In addition, evidence by witnesses is sometimes excluded by rules of admissibility.

Soviet and  
Swedish  
innovations

In recent years, some new principles for the evaluation of evidence have become evident in the law of Sweden and the U.S.S.R. Both countries have rejected all remnants of the formal theory of evidence, and both have tried to render the judges' conviction objective. Sweden demands that its judges undertake a discursive analysis of all the evidence. The Soviet procedure calls for judges to form their conviction on the strength of the evidence and according to their "socialist legal conscience."

#### THE CLASSIC MEANS OF PROOF

According to Anglo-American law, the classic means of proof are witnesses, documents, and real evidence (de-

rived from the actual inspection of objects). As a result of historical development, the status of witness was accorded to experts and to the parties in a civil lawsuit, and even to the accused in criminal proceedings. The development of continental European law has taken a different course. Parties cannot be witnesses, and evidence by experts is subject to special procedural rules. Consequently, there are essentially five separate sources of evidence: witnesses, parties, experts, documents, and real evidence.

**Oral testimony.** The oral testimony of witnesses competes in a sense with documentary evidence to the extent that one may exclude or supplement the other.

The importance of documentary evidence in some continental European countries goes back to the year 1566 and the French Ordinance of Moulins, which stated that contracts above a certain value could only be concluded in writing with the aid of a notary. This preference for documentary proof has persisted in articles of the French code of civil procedure and in other civil codes. According to the French practice, evidence by witnesses is excluded in the case of contracts above a certain value. But this strict regulation has been made more flexible by the growth of doctrine permitting evidence by witnesses once the origin of written proof is furnished and is not sufficient, or if the contracts in question are commercial in nature, or if it is impossible for one party to prove its claim through documents. Facts extrinsic to the document cannot be proved through witnesses. Even Soviet law prescribes that in special cases proof can be furnished only through documents.

**Eligible witness.** Under Anglo-American law, almost anyone can be a witness, including the parties and experts; even insane persons, children, and convicted felons may testify. Grounds once used for excluding such persons as witnesses are now used only to impeach their credibility. Continental European countries, as has been said, do not treat either the parties or experts as competent witnesses, and they are still suspicious of interested witnesses. Some of them, influenced by the Roman-based school, deny, on the whole, the capacity of those persons having a certain degree of relationship to the parties. Some consider insane persons incompetent to testify, others grant them the competency but exclude their testimony on the grounds of credibility. The capacity to be a witness does not depend on whether or not the person can testify about questions relevant to the specific case. In general, the tendency has been to utilize all persons who can testify about facts that will help to establish the truth. Competency as a witness has therefore been extended to as many persons as possible. On the other hand, many persons are protected by law from being forced to testify. This type of protection derives either from privilege, or from the right to refuse to give evidence, either case distinguishable from incapacity to testify. Whereas privilege or the right to refuse to give evidence may be either requested or waived, incapacity to testify takes effect automatically; *i.e.*, it must always be officially considered by the court.

**Privileges.** Privileges under Anglo-American law must be distinguished from the right to refuse to give evidence under particular circumstances as it exists in continental European practice. The latter is granted to witnesses for either personal or objective reasons. The personal reasons are the same as those that result in incapacity to testify under Roman-based law; *i.e.* relationship, affinity, and marriage. The objective reasons concern persons who, as a result of their profession (for example, clergymen, physicians, attorneys, journalists, etc.), have been put in possession of confidential facts. Such confidants have a limited right to refuse to give evidence so long as the person protected does not give his consent (the German solution). In some cases they are not admitted as witnesses without the consent of the protected person (the Swedish solution). Thus the Swedish judge officially decides whether the protected person has given his consent, whereas the German judge leaves the decision whether to testify up to the confidant. In addition, witnesses may refuse to testify if their testimony would cause direct financial damage to themselves or to their

Refusal  
to testify

families, or if it would publicly disgrace them or expose them to criminal prosecution. All persons may make their own decision as to whether or not they wish to testify, but judges are obliged to inform them about their specific rights in the matter. These procedural regulations have developed in order to avoid the situation in which the person protected becomes caught in a conflict between the truth and his personal interests. The interests of the protected person—perhaps partly out of realism—are thus given a higher value than the search for the facts. In this regard, Soviet law has adopted a different attitude, which places a higher value on objective truth than on the personal rights of third persons who, though not parties to a suit, may become involved as witnesses.

The Anglo-American privileges differ from the continental European right to refuse to testify insofar as privileged persons cannot decide whether or not they wish to testify. They may only cite their privileges, and the judge decides if they must testify. Under a system that stresses the free evaluation of evidence, the obligation to testify is subject to only a very few exceptions.

*Self-incrimination.* The privilege against self-incrimination has a twofold nature in Anglo-American law because, in civil proceedings, parties may appear as witnesses and, in criminal proceedings, the accused may appear as a witness. The privilege of an ordinary witness is considerably limited. He must submit to being designated and sworn in as a witness in all instances and must answer all questions except those which are self-incriminating. Consequently, either he or his attorney must sift out the incriminating questions that will evoke the privilege. This is not always easy, particularly since it is only the witness, and not the party or the party's attorney, who may cite the protecting privilege. Critics have called this privilege a sentimental institution, but it is worth noting, in this regard, that the privilege against self-incrimination was included in the U.S. Bill of Rights.

*Personal and professional privilege.* Privileges deriving from personal and professional relationships are generally not granted on principle, though historically a privilege for the protection of marital communications has developed. In England, an 1853 law decreed that a husband could not be forced to testify concerning information that his wife may have given him during the course of the marriage. This, naturally, also applies to the wife. In the United States, the courts contended that laws concerning testimony on matrimonial communications contained only a statement of the common law. Only the beneficiary of the privilege may cite it, and it is not applicable where criminal offenses by one spouse against the other or against the children are concerned, or in the case of a divorce proceeding.

Attorneys are considered to be under an obligation to refuse to testify about confidential communications with their clients. The privilege, however, protects the client, not the attorney, and, therefore, the client may waive it. This privilege is only properly explained in terms of the adversary system, which, so to speak, makes the attorney his client's champion.

Clergymen are likewise under obligation to refuse to answer questions concerning information given them in the secrecy of the confessional by believers. Again, the privilege protects the believer. This custom has been sanctioned by legislation in many U.S. states. In England, however, there is no common-law rule for this privilege.

Physicians, as a rule, must answer all questions since there is no common-law privilege regarding confidential information furnished by the patient. In some states an appropriate privilege has been created by legislation. In these states, it is again the patient who is protected and only he may waive the privilege.

Journalists, like physicians, occupy a position that is not entirely clear. In some jurisdictions they may refuse to testify about their sources of information, and in a number of U.S. states such a privilege has been specifically created by statute. In other U.S. states and in England the question does not yet seem to have been settled.

*Privilege in civil and criminal cases.* Differences between civil and criminal proceedings regarding the avail-

ability of privilege grow out of the protection from self-incrimination. It has already been pointed out that the accused no longer lacks competence as a witness but may exercise the privilege of refusing to be called or sworn as a witness. Unlike ordinary witnesses, the defendant may invoke this privilege with considerable latitude. But, if he does decide to step into the witness box, he renounces his privilege and may be interrogated as if he were an ordinary witness. The question arises, however, whether the waiving of the privilege against self-incrimination is limited to testimony concerning crimes of which he presently stands accused, or whether he must answer all questions regarding criminal acts. It appears to have become fairly well established that the prosecutor can, in fact, interrogate the defendant about previous criminal offenses. In civil cases, the parties have the same privilege for protection from self-incrimination as other witnesses; i.e., they need not answer incriminating questions.

*Methods of establishing the credibility of witnesses.* Means for establishing the credibility of witnesses assumed a great deal of importance at the point when medieval formal evidence theory was replaced by the free judicial consideration of evidence.

The oath, perhaps the oldest means for encouraging truthful testimony, antedates this point, of course. The oath, in some sense, forms a link between court proceedings and religious belief since, in its usual form, witnesses swear by Almighty God that they are speaking the truth. Though the effectiveness of such an act has certainly diminished in secular societies, this appeal to God has for centuries been considered the surest means of obtaining truth. There are two kinds of oaths, the preliminary and the subsequent. In Anglo-American practice, the witness is sworn in before testimony. Under the German and other continental procedures, the swearing-in may occur after testimony as well. The latter method allows the judge to use his own discretion in individual cases as to whether or not the witness should be ordered to swear. In current German practice, very few witnesses are sworn in for testimony in civil proceedings, whereas in criminal proceedings all witnesses have to swear. Some continental European countries allow witnesses who object to oaths to substitute a solemn affirmation, and Denmark has abolished all oaths in legal procedures. Only Soviet law, intent on breaking with tradition, forbids any oath or solemn affirmation. The oath of a witness does not have the formal effect of binding the judge or the jury. They must evaluate it and testimony freely.

*The cross-examination.* Common-law judges and attorneys regard the opportunity to cross-examine as a guarantee of the reliability and completeness of testimony by a witness. Under the perfect operation of the adversary system it is not the judge but rather the parties or their attorneys who interrogate the witnesses. The plaintiff's attorney begins the "examination in chief," which is subject to a number of restrictions. Leading, misleading, and argumentative questions, for example, are not permitted. After the plaintiff's attorney concludes his interrogation, the defendant's attorney may cross-examine the same witness. This cross-examination generally consists of leading questions posed with the intent of weakening or invalidating the impression created by the direct testimony of the witness. The cross-examination must ordinarily be limited to subjects covered during direct interrogation. There is a recognizable tendency, however, for cross-examination to become as open-ended as possible. The plaintiff's attorney has the option, finally, to re-establish the credibility of his witness by re-examination. These interrogations are formally regulated and require a great deal of skill and experience on the part of the attorneys. Such formal questioning of the witness is unknown to the continental European rules of procedure, even though cross-examination is common. Continental rules of procedure require the judge to interrogate the witness first. Frequently, the witness begins with a free narration. Then, after the judge has finished his interrogation, the attorneys of both parties may question the witness. All this is done in an informal manner, and almost any question is permitted. In Roman-law countries

The  
swearing  
of  
witnesses

The  
journalist  
and his  
source

the interrogation of witnesses is, however, rather formalistic because it is generally limited to questions concerning allegations specified in the evidence judgment. But here too, there is a tendency for the court to allow questions at its discretion.

*The witness as "real evidence."* Scientific examinations of witnesses are especially common in paternity and status proceedings with regard to blood-typing. These methods have now been so much improved that the suspicion of paternity may be definitely dismissed in many cases. In Germany and elsewhere, opinions based on biological and hereditary evidence are used for these same purposes. The use of fingerprint and ballistics evidence, among other types, has become quite customary in criminal cases. In the United States, there are varying opinions about the admissibility of lie-detector tests as evidence. The results of such tests are not yet admissible in the continental European countries.

*The hearsay rule.* The hearsay rule is perhaps the most characteristic feature of the Anglo-American law of evidence. It has also been said that, next to trial by jury, the hearsay rule constitutes the most important and original contribution of this system's practice.

Despite the obvious dangers involved in its use, free evaluation of the evidence furnished by hearsay testimony continues to be characteristic of continental European law. This somewhat surprising fact may be explained by reference to the historical development already traced here. Until the 19th century, the medieval formal evidence theory strictly prescribed when the judge had to be convinced by the testimony of a witness. Moreover, there was no jury in the continental countries to be protected by rules of evidence and therefore no need to introduce rules of hearsay. When the formal evidence theory was replaced by the requirement that the judge freely consider the evidence, his discretion naturally extended to hearsay testimony.

The creation of a body of rules for the exclusion of hearsay evidence was motivated by the arguments that such testimony could tend to mislead the jury, that the hearsay observer, unlike the legal witness, was not under solemn oath and was inaccessible to cross-examination, that such testimony furnished third-hand evidence, and that it violated the best evidence rule.

Over the years, exceptions to the prohibition of hearsay testimony had to be permitted, however, and these have become so numerous that the opinion has sometimes been expressed that no exhaustive list of such exceptions could even be compiled. The judge must decide in each case whether testimony based upon hearsay is admissible under an exception to the rule—a further indication that regulations governing the admissibility of evidence are far more important in Anglo-American law than in continental law. The most commonly cited exceptions to the rule of hearsay relate to statements made by dead or absent persons, statements in public documents, and to confessions and admissions by parties.

*Confessions.* Confessions, as a source of evidence, are distinguished from admissions. Whereas a confession is a complete acknowledgment of guilt in criminal proceedings, an admission is a statement of fact in either a civil or a criminal case. In former times, the confession was considered the ultimate form of evidence. As soon as the accused confessed—often under duress—no further proof was required. In time, involuntary confession came to be rejected as evidence under English law, and the burden of proving that a confession was voluntary lay with the prosecutor. In the United States, the federal rule that confessions are inadmissible if obtained while the defendant was unlawfully detained has not gone quite so far, though the law is still in a state of considerable flux. Involuntary confessions, however, are not admissible for any purpose under Anglo-American law. In continental European law, on the other hand, confessions of the accused are always freely considered by the judge.

Differences between criminal and civil proceedings regarding admissions result mainly from the adversary principle governing civil proceedings. In Anglo-American procedure, if one party in a civil suit admits facts con-

trary to his interest, such an admission is conclusive and obviates the need for further evidence on the point. The same result follows in German or Swedish courts. Under the Roman-based laws of such countries as France, Italy, and Spain, an admission made before the court is a form of evidence that leads to conclusive proof binding upon the court. But admissions made out of court are subject to free evaluation by the judge and do not exclude further evidence. Only Soviet law gives no binding effect to admissions.

*Party testimony in the continental European countries.* Oral testimony by the parties in civil proceedings was introduced in Austria in 1895. Norway followed suit in 1915, Denmark in 1919, Germany in 1933, and Sweden in 1948. Party testimony is generally heard in the same way as the evidence of other witnesses, but there are some essential differences. For one thing, the interrogation of parties is a subsidiary source of evidence to be used only when all other means have been exhausted, but it may be also used together with other means of proof. In some countries, both parties must be heard; in others, only one party may be heard upon motion of the opponent. In most cases, the parties do not have to confirm their testimony by oath, but the court may decree that one of the parties must swear. In Swedish law, for example, the parties must solemnly declare that they have told the truth. In Soviet law, however, the interrogation of parties is completely informal.

In criminal proceedings under continental European law, the defendant may be heard, but his formal position is that of neither a witness nor a party. His depositions, nevertheless, do have value as evidence.

*Expert evidence.* Expert witnesses must have specialized knowledge, skill, or experience in the area of their testimony. For the most part, they do not testify concerning facts but draw inferences from them. With a few exceptions, they are treated in Anglo-American law as ordinary witnesses and are brought before the court by the parties in the same manner as other witnesses. Although ordinary witnesses are generally allowed to testify only concerning facts and not to express opinions, an exception to this rule is made for the expert, who must, of course, be allowed to give his opinion.

Generally speaking, anyone with special knowledge may be an expert in his respective field. In Anglo-American law, the expert is designated by the party, while in continental European law the court decides who may be an expert, generally selecting from a list on file in the court so as to guarantee that the experts designated are impartial. Experts may not, therefore, be cited by the parties.

The oral interrogation of experts is customary in Anglo-American law, and proceeds, with a few exceptions, under the same rules for the interrogation of ordinary witnesses.

Under continental rules of procedure, on the other hand, expert opinions are generally given in written form. Experts are allowed a rather wide scope of discretion, especially when the opinion involves scientific findings that often cannot be checked by the judge. But under some continental European rules, the parties or their attorneys may request that the experts testify before the court to defend their written opinion and tell how they arrived at it.

*Documentary evidence.* Documentary evidence is in many respects considered better than the evidence furnished by witnesses, about which there has always been a certain amount of suspicion. Documentary evidence differs considerably from the evidence of witnesses and is dealt with under special rules.

Criteria for establishing the authenticity of documents are only important if authenticity is contested. This is often impossible, however, if a presumption favouring the authenticity of a public document exists—which it frequently does under continental European law. Under Anglo-American law, a party may serve the adversary with a written request to corroborate the authenticity of any relevant document. Direct evidence of authenticity may be gotten through the testimony of persons who

The exceptions to the rule against hearsay

Qualifications of an expert witness

signed the original documents. This is often impossible, however, and in this case circumstantial evidence is permitted. Under Roman-based law, documents are proved genuine by special proceedings. In other continental European countries, a document may be proved genuine by any type of evidence.

The obligation to present documents in the Anglo-American system derives from what is known as the best evidence rule. If the original document is in the hands of a third person or the opponent, the party that must supply proof can ask the court for a writ of *sub poena duces tecum* compelling the third party to produce the document in court. If the original is not produced after this, second-hand evidence of its existence is then permitted. In continental law, there is no similar obligation to produce documents. The adversary or third persons can only be ordered to do so if there is a positive obligation under the substantive law. Among European countries, only Sweden has developed any extensive obligation for the parties to produce documents. Soviet law has gone farthest in this regard, extending the rule to all kinds of documents regardless of the interests of third parties.

Extrinsic proof of the contents of documents in Anglo-American law is admitted only in special cases, since oral evidence is inadmissible to vary, contradict, or add to the terms of a written agreement—a rule that makes many documents conclusive as evidence. The method of Anglo-American law in this particular area is consequently negative, since evidence outside the content of the document is on principle not admissible. Continental law follows the medieval method, by attributing a certain value as evidence to particular documents, which is binding on the judge.

The consideration of documentary evidence by the judge therefore tends to be restricted, since the document itself furnishes conclusive proof if evidence by reference to facts outside the document is inadmissible. In most continental laws, judges are bound by presumptions in this respect, and only in Swedish and Socialist law are there no provisions restricting free judicial consideration of documentary evidence.

**Real evidence.** The remaining form of evidence that needs brief mention in this survey is so-called real evidence, also known as demonstrative or objective evidence. This is naturally the most direct evidence, since the objects in question are inspected by the judge or jury themselves. Problems arise in this area over who is obliged to present objects for inspection or to actually undergo inspection. The use of the jury system in Anglo-American law has made it necessary that any real evidence be shown to be both logically relevant and completely genuine before it may be admitted as proof. The exhibit of real evidence may sometimes be directly connected with the case (for example, when a weapon is shown to the court), or it may involve something used to illustrate testimony, as, for example, a model or skeleton to clarify testimony about an injury. In any case, real evidence may not be accepted as legal proof unless it is authenticated by the testimony of witnesses.

#### ADAPTATIONS OF THE BASIC SYSTEMS

Generally speaking, two different systems of the law of evidence are prevalent all over the world: the Anglo-American and the Continental European systems. The latter can be subdivided into three variants: the Germanic, the French or Roman, and the Socialist patterns. The Germanic variant tries to utilize all means of proof; it follows the principle of formlessness and balances between the accusatorial and the inquisitorial principles. The French or Roman variant favours evidence by documents and is dominated by a very formal procedure of "enquête" or investigation. The Socialist variant makes believe that objective truth might be ascertained by evidence. It therefore favours the inquisitorial principle and does not protect witnesses, parties, and experts by privileges or procedural rights.

Japan provides an interesting example of mixture of the Continental European system (Germanic and Roman variants) with the Anglo-American system with the con-

tinental model dominating, however. This can be seen historically. With the Meiji revolution in 1868 Japan began to adopt Western practices, including European law; so that eventually Japanese ideas of the law of evidence were replaced by European ones. The drafters of the first civil code of procedure in 1890 surveyed many legal systems, including the French, taking something from each. Their final product is, however, characterized as following the first draft of the German civil code. In its subsequent development, the Japanese legal system remained true to these sources, even in the development of a new code in 1929.

After the Second World War under American influence this code of civil procedure was changed in many respects; at the same time the Japanese code of penal procedure was changed.

In criminal procedure the Anglo-American influence can be found in several rules. The inquisitorial principle, for instance, lost its dominating place in favour of the accusatorial principle; it is not the judge but the defendant and his counsel who question witnesses. Evidence by hearsay is no longer allowed. Instead of the inquisitorial hearing of the defendant there is the hearing of the defendant as a witness. The fusion of the Continental European with the Anglo-American system of evidence leads to an unique combination of the interests of the defendant with the principle of impartiality of the court.

In Japanese civil procedure, however, the Continental European law of evidence still dominates. The Japanese adhere to the five classical means of proof: witnesses, experts, parties, documents, and real evidence. The hearing of witnesses is done by the parties and their counsels. The party that asked for the hearing of any person will start with the examination; thereafter the other party will cross-examine. But contrary to the Anglo-American law of evidence there are no strong admissibility rules regarding examination, cross-examination, and re-examination. Contrary to criminal procedure, the hearsay rule is allowed in civil cases. When the parties have finished their examinations, the judge can put questions to the witness or experts. As in the Continental European system, persons on the witness stand have no special privileges, though they have the right to refuse to give evidence that might lead to self-incrimination, the incrimination of relatives, or the revelation of state secrets.

There seem to be no current moves to change the law of evidence as it is now in force in Japan, perhaps because it was changed too often during the last hundred years.

## Evolution

Man's interest in his own origin, that of all living things, and that of the universe must be as old as man himself. It is reflected in literary form (which must itself be based on much older creeds) in legends of creation popular among the peoples of antiquity—Sumerians, Egyptians, Greeks, and Hebrews, whose sacred book, the Old Testament, contains two descriptions of the creation and traces of a third. The omnipotence that primitive peoples ascribed to their deities made it natural for them to believe that whatever is was created. This is the reason that problems surrounding the origins of the earth, heavens, seas, plants and animals, men and women were wrapped in unquestioned and unquestionable dogmas, some of which still hold sway. It is only comparatively recently, in societies and civilizations possessed of scientific knowledge and methods of investigation, that such dogmas have come under question. The Copernican system dethroned the geocentric view of the universe. Evolution, the changes that living beings are now known to have undergone since the origin of life on earth, has led to an even more profound revolution in the history of ideas because it has revealed the affinity of man to all other living beings and has shown that change, not stability, is the rule of life.

Evolution is the kernel of biology. It is significant that, before Charles Darwin established evolution as an inescapable fact and showed how it was brought about, biology was in a state of chaos. Organisms are found only as species, groups of individuals that resemble one another more than they resemble any others and that breed only among themselves, a concept that first became precise in the 17th century, when, however, each species was regarded as a product of the original creation, and no explanation was provided or even sought for the countless puzzles that presented themselves: why species differ from one another, what relation there was between living forms and the fossils found in the crust of the earth, why some organisms are found only in certain regions, why internal parasites such as the tapeworm infest man, and many other questions. Evolution provided the first unifying, general principle applicable to all living beings, which are as they now are because they have become what they are, having undergone modification during descent from other species.

Another aspect of the significance of evolution is that any fact discovered about one species may be applicable to other species, and, as the study of biology progressed and became diversified into many branches—including comparative anatomy, embryology, paleontology, genetics, physiology, etc.—each of these branches may have lessons for the others. The understanding of any biological phenomenon is helped by knowledge of evolutionary principles and mechanisms, and many phenomena are inexplicable without evolution.

Evolution also has practical significance for man. The art and practice of medicine are the outcome and integration of studies in many branches of biology and would make no progress without a realization of, for example, evolutionary changes in bacteria and viruses. Agriculture, including plant cultivation, animal domestication, and selective breeding, depends heavily on the application of evolutionary principles. Ethology, the study of behaviour, has yet to find the evolutionary basis for man's aberrant conduct that allows him to kill members of his own species wholesale, which other species do not do. The social importance of evolution in understanding human conduct in the past and in providing guidelines for the future is enormous.

This article is divided into the following sections:

- I. History of evolutionary theory

  - Hominization and sexual selection
  - Humanization: psychosocial evolution
  - Natural selection in man
- VIII. Social evolution
  - Sociology before Darwin
  - Sociology after Darwin
  - Evolutionary genetics of society
  - Eugenics
- IX. The acceptance of evolution

### I. History of evolutionary theory

An understanding of modern evolutionary theory requires examination of ideas that preceded those of Darwin. Some classical Greek philosophers held views that have been thought to have foreshadowed the concept of evolution; but they were abstract speculations not based on objective studies of facts in nature, and, until the 18th century, nobody dreamed of questioning that species had been created as they are.

The discovery in Java of flying lemurs (colugos, *Galeopithecus*), then regarded as bat-winged monkeys, led the French political philosopher Montesquieu to write in 1721:

This would seem to corroborate my feeling that the differences between animal species can daily increase and similarly decrease; in the beginning there were very few species and they have multiplied since.

This acceptance of the possibility that species might change into other species was the kernel of the concept of *transformisme*, transmutation, or evolution.

Studies of abnormal or monstrous births and the transmission of striking hereditary traits (especially polydactyly, the possession of extra digits) led a French mathematician, Pierre-Louis de Maupertuis, in 1751 to envisage the multiplication of species as being due to fortuitous recombinations of elementary particles of organisms that lead to offspring deviating from their ancestral forms. This was not only an acceptance of evolution but also a crude attempt to explain it. The French philosopher Denis Diderot, in 1753, added the notion of community of descent:

If we consider the animal kingdom, and we notice that among the quadrupeds there is none whose physical parts and functions, particularly the internal ones, are not quite similar, may we not readily believe that there was never more than one primeval animal, the prototype of all, while nature only lengthened, shortened, transformed, multiplied, or obliterated some of its organs?

In a monumental work on natural history, Georges Buffon, one of the leading naturalists of the 18th century, raised the question of the possibility that the ass is related to the horse, with which it can breed. He asked if these two species might not, perhaps, have been descended from a common ancestor; but the opposition of the theological faculty of the Sorbonne made him recoil:

If we once agree that the ass belongs to the horse family, and differs from the horse only because it has degenerated, it could equally well be claimed that the ape belongs to man's family, that the ape is a degenerate man, and that ape and man had a common ancestry.

He went on to consider the possibility that all animals, including ape and man, could be regarded as related, and he answered himself, no doubt with tongue in cheek, No, it is certain from Revelation that all animals shared in the grace of Creation, and that each emerged from the hands of the Creator as it is today.

Linnaeus, the founder of modern biological nomenclature, expressed the same orthodox view in his early writings but by 1760 had been driven by his own observations to admit that species could vary. He thought, however, that genera were immutable.

Erasmus Darwin, the grandfather of Charles, by 1794

Early ideas about evolution

had concluded that evolution had occurred. He based his conclusion on changes undergone by animals during development (chrysalis into moth, tadpole into frog) and on changes by plants and animals under cultivation and domestication as well as on vestigial organs, crossing, monstrous births, and resemblances in comparative anatomy. He tried to explain evolutionary changes by imagining that desires and aversions, pleasures and pains, led to wants "due to lust, hunger, and danger" and that their satisfaction brought about modifications of species through "the power of acquiring new parts, attended with new propensities, directed by irritations, sensations, volitions, and associations."

Lamarck's inability to distinguish between species

A similar view was reached quite independently by the naturalist Lamarck, who experienced such difficulties in distinguishing between species and varieties that he concluded that there was no real difference between them and that, if enough closely related species were studied together, they merged into one another and differences between them could no longer be made out. In this he is known to have been wrong; however difficult the barrier between species may be to detect, it nevertheless exists. In 1809 Lamarck's views enabled him to propose a system of evolution and to draw up an evolutionary tree, from microanimals to man, with branches indicating community of ancestry between different groups. To explain evolution, Lamarck invoked two factors. The first was a supposed tendency to complexity and perfection (incompatible with the fact of evolution of degenerate forms), which meant that simple organisms alive in Lamarck's time must have arisen recently by spontaneous generation (which was disproved under the conditions of the time by the experiments of an Italian naturalist, Lazzaro Spallanzani, and the French microbiologist Louis Pasteur). His second factor was an imagined *sentiment intérieur*, which, he supposed, caused movements and introduced habits that produced new organs that satisfied the animals' needs. This was an unfounded speculation, and, since Lamarck provided no evidence in support of his views, they found no acceptance. It is perhaps regrettable that the term Lamarckism is not applied to evolution itself. However erroneous, his was the first systematic presentation of the subject. Instead, the term is now taken to describe a theory of the supposed heritable effects of use and disuse of organs ("the inheritance of acquired characters") and the direct action of environmental factors, which Lamarck was not the first to suggest and which are now known not to be inherited.

Georges Cuvier, another French naturalist, rejected evolution because he knew of no fossil forms intermediate between existing species and because 5,000-year-old mummified animals found by Napoleon's expedition in Egyptian pyramids were identical with existing forms. In rock strata of the Paris Basin, the lowest and earliest layers contained fossil faunas "ready-made," which Cuvier attributed to creation; their complete absence from later strata he attributed to catastrophe. He was, however, obliged to accept the fact that the fossils found in upper beds showed an advance in complexity over those in lower beds; this phenomenon, called progressionism, was left unexplained.

Etienne Geoffroy-Saint-Hilaire, who accepted the concept of evolution, was the first to use this word in the modern sense (it earlier had been used to denote embryonic development), in 1831, in a work on fossil reptiles found near Caen, France. In the following year, the British paleontologist Sir Charles Lyell used it in the same sense, although he rejected evolution, because his theory of uniformitarianism (long-continued action of existing geological causes) killed catastrophism, and he mistakenly regarded progressionism as associated with catastrophism.

The contribution of Charles Darwin

Lyell's uniformitarianism acted as an unexpected ferment in the mind of Charles Darwin, who, during the voyage of HMS "Beagle," was led to abandon the orthodox notion of the fixed nature of species and to accept a belief in evolution instead. This change of belief was based on four sets of observations that he had made: the presence in adjacent areas of a continent of related but

different species; the similarity of structure between fossil and living forms in the same areas; the resemblance of species on isolated islands to those on the nearest continent; and differences between species on closely adjacent islands of the Galapagos Archipelago in relation to their modes of life and feeding. All these facts, Darwin felt, could be explained only if species were not specially created but had been descended with modification from common ancestral species.

Darwin realized that it would be useless to argue that evolution had occurred unless he could explain how the process itself and, in particular, the adaptations behind it had arisen. He solved this problem in 1838. The details are so closely involved in the process of natural selection that a description of the line of his thought is best deferred until the process itself is considered (see below *Natural selection*). In Darwin's day there was complete ignorance of mechanisms of heredity and of the origin and nature of heritable variation. After constructing his theory in 1838, Darwin remained silent about it for 20 years. During that interval, views favourable to evolution were expressed by others in Switzerland, Scotland, and Austria. Alfred Russel Wallace, working in the East Indies, formed a theory virtually identical to Darwin's in 1858, and papers by the two men were presented at the same meeting of the Linnean Society in 1858. Darwin's *Origin of Species* was published the following year.

It was not until the mid-20th century that a British statistician, Sir Ronald Fisher, and a number of others integrated information from many different areas of biology into a synthetic theory of evolution.

## II. The evidence for evolution

The evolution of living organisms has gone on for 3,000,000,000 years, and the 20 years during which Darwin studied the subject before publishing the *Origin of Species* was a ridiculously short space of time for modifications of species to be observed. It must be stressed that Darwin himself never claimed to provide proof of evolution or of the origin of species; what he did claim was that if evolution has occurred, a number of otherwise inexplicable facts are readily explained. The evidence for evolution was, therefore, indirect. Recently, however, direct evidence of evolution has been observed.

The indirect evidence for evolution is based primarily on the significance of similarities found in different organisms, which are explicable only if they have derived the features in question, structures or functions, from a common ancestor during descent with modification, for the laws of probability insist that fundamental similarities can be traced only to one single origin.

Evidence from structural similarities

Comparative anatomy provides the first set of witnesses. There are a quarter of a million different species of flowering plants, but all of them (except for a few parasitic forms) share the basic structures of roots, stem-bearing branches, leaves containing the green pigment chlorophyll, and flowers composed of modified leaves, sepals, petals, stamens, and pistils. They differ in detail between different species, but all are built on the same plan and live in the same way, absorbing salts in water through the roots and fixing carbon dioxide in the green plastids of the leaves in sunshine to synthesize more of their substance. The similarity of plan is easily explicable if all descended with modification from a common ancestor, by evolution, and the term homologous is used to denote corresponding structures formed in this way.

There are over three-quarters of a million species of insects. Despite broad variations in the details of their body plans, they all show a division of the body into head, trunk, and abdomen; they have three pairs of legs and two pairs of wings; and their mouthparts, whether used for sucking or for biting, are built on the same basic plan. In vertebrate animals, the skeleton of the forelimb is a splendid example of homology, in the bones of the upper arm, forearm, wrist, hand, and fingers, all of which can be matched, bone for bone, in rat, dog, horse, bat, mole, porpoise, or man. The example is all the more telling because the bones have become modified in adaptation to different modes of life but have retained the

# Evidence from development

same fundamental plan of structure, inherited from a common ancestor.

Embryology provides further examples. The German embryologist K.E. von Baer wrote:

In my possession are two little embryos in spirit, whose names I omitted to attach, and at the present I am quite unable to say to what class they belong. They may be lizards or small birds, or very young mammals, so complete is the similarity in the mode of formation of the head and trunk in these animals.

Darwin supplied the answer to the problem by showing that this embryonic similarity was due to the inheritance of the structure of these embryos from the embryo of a common ancestor.

Comparative anatomy and embryology present the phenomenon of transformed organs, structures that have changed their form and function with evolution. Among flying insects, the flies (Diptera) differ from most others in having one instead of two pairs of wings. The posterior pair have been modified into gyroscopic organs (halteres) that help in flight. Some fish have utilized the electrical potential of specialized muscles in organs whose electrical discharge is strong enough to serve as a sort of radar emission. The echo, perceived by certain sense organs, enables the fish to sense the proximity of objects in the water. Other fish have increased this function to such an extent that their electric organs are powerful enough to kill or paralyze predators and prey. Only descent with modification can explain the existence of such structures.

Some organs are called abortive or degenerate because they no longer serve a function. The possession of wings by ostriches, which cannot fly, is explicable if ostriches were descended from flying birds, in which the wings were functional. That this is, in fact, the case is evidenced by the structures of the cerebellum, the bones of the wing, and the tail, which show adaptations characteristic of flight. The appendix of man has no useful function, but it corresponds to the cecum of the alimentary canal of herbivorous mammals (and of man's ancestors) in which it is a sac in which bacteria digest the cellulose cell walls of vegetable food. Other examples are the vestiges of hind limb bones in snakes and of teeth in the jaws of young whalebone whales. Some marsupials, mammals that have been viviparous (live bearing) for 100,000,000 years, still show in their embryos vestiges of the egg tooth with which the embryo of the oviparous (egg-laying) ancestor cracked the eggshell.

# Evidence from behaviour

Ethology (the study of behaviour) reveals similarities between different species that affirm their community of descent. This is the case, for example, in regard to the instincts in ants, bees, and wasps and to nest building among birds. Thrushes of separate species in Britain and in South America line their nests with mud in the same manner. Hornbills in Africa and in India both plaster up the female in a hole in a tree. In some cases it is possible to discern how instincts evolve. The three-spined stickleback has a complicated ritual of courtship behaviour, which resembles that of the ten-spined stickleback. The latter, however, utilizes simpler components of behaviour, demonstrating the evolutionary origins of the more complex acts performed by the three-spined stickleback.

The chemical characteristics of organisms are no less typical of their species than are their structures, embryonic development, or behaviour. Serology (the study of blood serum) provides evidence of the degree of divergence between the chemical composition of the blood of different animals. Human blood injected into a rabbit makes the latter produce antihuman serum, which, when mixed with human blood, causes clumping and settling (precipitation) of 100 percent of the blood protein. This antihuman serum precipitates blood of other species in the following percentages: gorilla, 64%; orangutan, 42%; baboon, 29%; ox, 10%; deer, 7%; horse, 2%; kangaroo, 0%. These figures serve as measures of chemical resemblance and affinity. It has been shown that seals resemble dogs, and whales resemble even-toed ungulates (e.g., cattle)—results that, expressed as relative degrees of affinity, agree with the evidence from comparative anatomy, embryology, and paleontology.

Figure 1: Homologies of the forelimb among vertebrates, giving evidence for evolution. Although the bones correspond, they are adapted to the specific mode of life of the animal. The abbreviations are: h, humerus; r, radius; u, ulna; c, carpals; m, metacarpal; p, phalanx. The Roman numerals indicate corresponding digits.

Biochemistry provides countless further examples of similarities between species, of which one of the most instructive is the structure of the pancreatic enzyme insulin, which is made up of 51 amino acids, arranged in a particular order that varies in details in different related species. At the site where the insulin of cattle has serine, that of sheep has glycine; where insulins of both these species have alanine and valine, insulins of horse and pig have threonine and isoleucine, respectively. The general resemblance of the molecules of insulin in all these species is explicable as due to their descent from a common ancestor; the differences between them are due to adaptation evolved by each species.

An essential constituent of living cells is the protein enzyme cytochrome c, which carries out part of the process of respiration and has the same general chemical structure in bacteria, fungi, plants, and animals, but with differences in the arrangement of some of its constituents. The degrees of these differences make it possible to classify the organisms, in accordance with their evolutionary positions, into a phylogenetic tree (a diagrammatic indication of evolutionary pathways). Assuming a fixed rate at which changes occur in evolution, it has been possible to calculate the time elapsed since the different forms of cytochrome c diverged from a common ancestor. In other words, the time lengths of the branches of the phylogenetic tree can be estimated.

The above results throw a new light on an old branch of biology: systematics, which is concerned with classification (see CLASSIFICATION, BIOLOGICAL). The basic biological unit in which organisms exist is the species; but species are not casually distributed as grains of sand on a beach or fancifully assorted as imaginary constellations

# Biochemical evidence

in the sky. Rather, species fit naturally into successively larger groupings: genera, families, orders, classes, and phyla. As more is known about individual species, the groupings make sense only if they are based on the natural pattern of the evolution of these species from common ancestors.

Evidence  
from para-  
sitology

The study of parasites provides further evidence of evolution. Most parasites have retained evidence of their specialization from an ancestral, free-living form, from which they evolved by becoming adapted to live on, in, and at the expense of other living organisms, losing organs essential for living a free life. Biologists recognize that, to support the view that species did not evolve but were created, it would be necessary to conclude that man was created with poliomyelitis virus in his nerve cells, malaria parasite in his blood, and tapeworms in his intestines.

Parasitology provides yet another line of evidence. Internal parasites (and external ones that live under a layer of fur or feathers) inhabit a constant environment, a condition under which evolution may proceed slowly. But the hosts harbouring the parasites live in a changing external environment and may have evolved fast enough for the relationships between them to have been obscured by structural changes. The affinities between the grossly different hosts may sometimes be elucidated from the affinities existing between their parasites. Thus, pythons have certain internal parasites similar to those of monitor lizards, and pigeons have feather lice similar to those of parrots. *Herpes simplex* virus is found only in man and monkeys and lice of the genus *Pediculus* only in man and chimpanzee. In all these cases, the presence of closely related parasites confirmed the existence of relationships established by structural comparisons.

Biogeo-  
graphical  
evidence

The geographical distribution of plants and animals was first studied by Buffon, who noticed the differences in flora and fauna between America and the Old World. Buffon's studies provided Darwin with some of the questions that led him to abandon belief in the fixity of species and creation. He wondered why the fauna of Cape Verde Islands has an African composition while that of the Galapagos Islands has South American characteristics. These similarities could be explained only by the evolution of Cape Verde species from African ones and Galapagos species from South American ones. The mechanism now understood for the origin of species makes it certain that each species originated only once and in only one area. There are many forms whose modern geographical distribution is discontinuous; for example, tapirs, now limited to South America and the East Indies. Lungfish are found only in South America, South Africa, and Australia. In each case, the distribution can be explained easily if the animals dispersed from the region where they originated and subsequently became extinct in intermediate regions. Extinct animals can often be found as fossils; fossil tapirs have turned up in North America, Asia, and Europe, and fossil lungfish have been found even more widely.

Evidence  
from paleon-  
tology

Paleontology occupies a key position in evolutionary studies; the fossils in the earth's crust are objective evidence of the course taken by living organisms in their evolutionary history, or phylogeny (see PHYLOGENY). By themselves, fossils do not "prove" evolution, for it could be argued that they had all been specially created and then succumbed to catastrophes, as Cuvier believed. But such a view fails altogether to explain why the fossil forms in lineages studied on sufficient material fall in obvious series; nor does it explain why the feet, teeth, and body sizes of fossil horses are so closely correlated with the successive and different climatic conditions of their environment.

With the help of radioactive dating of the deposits in which they lie, it has been possible to determine the absolute ages of the fossils and to measure the rates at which different groups have evolved. The data are still approximate, but they provide an estimate of the dimensions of the fact and pageant of evolution and of its problems.

The earliest evidence of life in the crust of the earth

does not always consist of organisms themselves but may be found in chemical substances that are the result of the life of organisms, such as layers of oxidized iron and other chemical "fossils." In the atmosphere, the two stable isotopes of carbon, carbon-12 and carbon-13, are in a ratio of 99 to 1. Photosynthesis carried out by organisms, using sunlight energy, converts carbon dioxide into organic carbon compounds with a higher ratio of carbon-12 to carbon-13 than is found in ordinary rocks, thus indicating the former presence of living organisms, as in the Fig Tree deposits in Rhodesia, about 3,000,000,000 years old, in which traces of structure of bacteria and blue-green algae have been found, some surrounded by concentric layers of limestone secretion. Undoubted stalked bacteria and blue-green algae have been discovered in the Gunflint iron deposits of Ontario, nearly 2,000,000,000 years old. In the Bitter Springs Cherts of Australia, 1,000,000,000 years old, true green algae and fungi have been recognized. The oldest known fossil animal is an already well-developed wormlike form, *Xenusion*, 800,000,000 years old, from the Precambrian of Sweden. The first animals must have been soft and incapable of preservation as fossils. When the Cambrian Period began, 600,000,000 years ago, many forms of algal plants and invertebrate animals were already developed.

It would require very special pleading to pretend that paleontology does not present objective evidence for evolution, but more direct evidence is now also available, first from cytogenetics. In long chromosomes of the fruit flies of the genus *Drosophila*, the genes in one species form a linear series that may be labelled ABCDEFGHI. In another species, the corresponding genes are in the order AEDCBFGHI; the section BCDE has been inverted. A third species has the order AEHGFBDCI; here the section DCBFGH of the second species has been inverted, which indicates that the third species was derived from the second, and it from the first.

evidence

### III. The process of evolution

#### NATURAL SELECTION

Evolution is the product of improvement in adaptation, and it was adaptation that Darwin felt that he must explain before he could convince anyone of the fact of evolution. The logical approach to the principle of natural selection, therefore, begins with a consideration of adaptation.

Adaptation is a word with two meanings, one referring to a process and the other to its product. It is the biological process by which advantage is conferred on those organisms that have structures and functions enabling them to cope successfully with the conditions of their environment. The ecological position occupied by an organism, relative to the entire range of environmental variables, is called the niche. The word adaptation is also used to denote those structures and functions specialized for a particular role.

All living organisms are adapted to their modes of life in a general way, and each is adapted to the characteristics of its own niche. A plant depends on its roots, by which it absorbs water and inorganic salts in solution and by which it is anchored; it requires a stem, balanced by the geometrical distribution of its branches, as a result of which the plant is able to maintain a vertical position and support its leaves; and the leaves, in turn, are vital as sites of photosynthesis, the process whereby the energy from the sun is used to synthesize organic chemical compounds.

In addition to the general adaptations, which are common to all species in large groups of related organisms, there are also special adaptations that some species have and others lack, and it was for an explanation of the origin and cause of these adaptations that Darwin looked. A woodpecker, for example, possesses the gross adaptations common to flying birds: feathers, wings, beak, clawed, scaly feet, etc. As adaptations for subsistence on insect grubs hidden under the bark of trees, the typical woodpecker has four structures that make its search for food more efficient: two toes on each foot are turned backwards (instead of the usual one), enabling the bird to

Figure 2: Adaptive pressures that affect the size of a warm-blooded animal.

get a firm foothold on the bark of the tree; the tail feathers are stiff and serve to prop the bird in position while it bores; boring and flaking are done by a stout and strong beak, with which a hole is chiselled through the bark and into wood; finally, an exceptionally long tongue enables the bird to take the insects at the bottom of the holes. Among woodpeckers, each species has further specializations that adapt it to its own segment of the bark-foraging niche.

Another example is mistletoe, any of about 80 species of parasitic plants (the familiar species being in the genera *Phoradendron* and *Arceuthobium*) that live intimately spliced onto branches of trees, from which, not having true roots, the mistletoe obtains water and salts in solution while the chlorophyll in its green leaves enables it to carry on photosynthesis. In order to survive, mistletoe is dependent on three factors: an insect to pollinate its flowers; a bird to disseminate its seeds by eating the berries and depositing them with its droppings on the branches of suitable trees; and an appropriate tree on which the parasitic relationship can be established. These adaptations are held to have arisen from natural selection of heritable variations.

The change that can be achieved through selective breeding of parents possessing particular characters has been known since the Neolithic Period, when man began to cultivate plants and domesticate animals, increasing their size, yield, and other desired qualities. In Darwin's thinking, an important example of selection working on heritable variation was the comparison between wild bison (*Bison bison*) and Indian domestic cattle (*Bos indicus*) with humps, for the structural differences between them would certainly be recognized as of the value at least of separate species if they were found in nature, and one of them was not the result of artificial selection by man. Darwin was sure that the cause of change was selection and that those organisms that were better fitted to withstand the struggle for existence, which goes on everywhere, would prosper and perhaps oust those less well fitted. But how such a system of selection could operate in nature, long before any man was there to supervise it, baffled him until 1838, when he read English economist Thomas Malthus' *An Essay on the Principle of Population* and happened on the statement that, since human population, if unchecked, would increase in geometrical progression and double in 25 years while food supply increased only in arithmetical progression, famine, misery, and mortality constantly threatened the human race, and particularly its poorer classes.

Darwin saw that, since plants and animals are quite unable to increase their food supplies artificially, the principle of mortality automatically imposed by nature would apply to them in full force. Natural selection was entirely Darwin's idea, not derived from Malthus. The latter's theory of human population limitation did not take into account the great increases in per-acre food production made possible by modern agricultural tech-

niques and, therefore, requires modification in order to be entirely valid. It is, however, valid when applied to organisms in nature, and it explains how selection works in nature, in its most direct form, by killing the insufficiently adapted. Hence the term natural selection.

The basic principle of natural selection is fairly simple. Most organisms produce more offspring (eggs, seeds, or young individuals) than live to maturity. The number of individuals in most species remains more or less constant from year to year. There must be, therefore, a high rate of mortality (from starvation, predation, disease, malformation, and accidents of the physical environment), eliminating individuals at various stages of their lives: as eggs, embryos, larvae, juveniles, and adults. Within a population, individuals are not identical but show variation that may affect any character, structure, or function at random. Some variations have characters that allow their possessors to function more efficiently in the struggle for existence than those that lack these characters. In other words, they are better adapted, even by ever so little, to the conditions of their ecological niches. They live longer, leave more numerous and healthier offspring, and provide the majority of the parents of successive generations. Heredity ensures the resemblance between parents and offspring. By natural selection of heritable variation, successive generations will maintain and even improve on the degree of adaptation achieved by their parents.

Adaptations thus confer survival and reproductive value on their possessors, and the ecological conditions of the environment determine at every stage which variations are adaptive and which not. Natural selection therefore rams better adapted variants into their ecological niches under pressure and ejects other variants, thereby providing more available, unoccupied niches. The case of the woodpecker is explained by random variations in the foot, tail feathers, beak, and tongue, selected in the direction seen. It is relatively simple, but the same principle is involved in the complicated cases of parasites, such as malaria or tapeworm, both of which involve the interposition of an intermediate host (mosquito or fish) in the life history.

#### VARIATION

Darwin never tired of repeating that without heritable variation natural selection could do nothing at all, and there would be no evolution. But neither Darwin nor anyone else at the time the *Origin of Species* was published had objective knowledge of variation, its nature and its origin, or of heredity. It was known that variation existed, and the only hypothesis then available was that of "blending inheritance," by which it was supposed that offspring struck an average between the characters of their parents. This meant that, at each generation, variance was halved and that after ten generations all variations would have been levelled off and obliterated. This meant, in turn, that the numerous observed variations would

The mechanism of natural selection

Primitive views on variation

have to be recent. For instance, all the differences between two full brothers whose heredities were identical could only be explained as the result of variations that had arisen in their own early lifetimes.

It was known that "sports," now known as mutations (sudden changes in genetically controlled features), occurred and were inherited. It was also known that environmental factors and the effects of use and disuse could evoke bodily changes in individuals. It was then supposed that such effects also could be inherited, for one of the oldest folk beliefs (and fallacies) was the inheritance of acquired characters. (In Greek mythology, for example, when Phaethon drove the sun-chariot so close to the earth over Africa that it scorched the inhabitants black, they transmitted this character to their descendants, the Negro race.) It was found in the Old Testament, in the story of Jacob and Laban's sheep and goats, on which Jacob induced visual impressions to work at the time of conception. In some countries it was forbidden to show hares in shop windows in case pregnant women should see them and give birth to children with harelips.

In spite of faked results and the neglect of proper precautions in experiments, no case whatever is known of the inheritance of any modified character impressed on the body of a multicellular organism by the effect of the environment or use or disuse of organs. The proviso of multicellularity is necessary because in the reproduction of unicellular organisms, when the parent divides, part of its body (on which the environment may have induced a modification) passes straight into the bodies of the offspring, which may still show the environmental effect. This is not what is meant by inheritance, which results only from the transmission of genetic material in reproductive cells.

Mendelian  
genetics

The Moravian monk Gregor Mendel filled the gap in Darwin's scheme in 1865, when he showed that characters are controlled by particles, now called genes, which exist in pairs (alleles), one member of each pair derived from each parent. He demonstrated that the particles do not become contaminated but remain pure and separate (segregate) at germ-cell formation, so that not more than one of each pair enters any one germ cell, and that they recombine at random at fertilization. At each cell division, genes copy themselves exactly but occasionally undergo sudden changes (mutations), after which they continue to copy themselves exactly in their changed state until they mutate again.

A further important fact discovered by Mendel was that some genes are stronger, more penetrant, than others and can make their effects visible in the offspring when such genes are inherited from one parent only—that is, are present in "single dose"; such genes control dominant characters. The weaker genes can manifest themselves in offspring only if inherited from both parents—that is, in "double dose"; such genes are called recessive, and when one is present in an organism paired with its dominant allele, its effects are hidden.

Mendel's work was ignored until 1900, when it was rediscovered. During the first 20 years of the present century, it was confirmed completely by a number of workers who showed that genes are carried in linear order in the chromosomes, which are visible in the nucleus at division. Genes carried on different chromosomes segregate at random exactly as required by Mendel's system, but genes carried on the same chromosome show "linkage" and are transmitted together unless the chromosome undergoes "crossing-over," when the linked genes become separated and segregate. The mechanism of the chromosomes provides exactly what is required to explain the distribution of Mendelian genes.

To understand the role of inheritance in evolution, it is necessary to consider the relation between genetic transmission of factors (genes) and embryonic development of expressed characters, for it is only through embryonic development that characters arise at all. The genes of the organism, inherited from its parents, constitute its genotype, which determines and limits its capacity to respond to normal and abnormal environmental fac-

tors and to factors within the developing organism. Every event in embryonic development is a reaction and a response. No character is solely inherited and none solely acquired. Fish have had paired eyes in their heads since the Silurian Period, 400,000,000 years ago, yet today it is only necessary to add magnesium chloride to the water in which a fish is developing to obtain an abnormal fish with a median cyclopic eye. This means that 400,000,000 years of inheritance and the same period of the action of normal environmental factors have not fixed the development of paired eyes. Development is only normal in a normal environment. The product of development, the mature organism, is called the phenotype, and it is the result of interaction between the genotype and the environment. All that the genotype can do is to set the limits within which development takes place. Here attention must be turned to the problem of evaluating a variation that appears in a population, a problem that can only be solved by experiment. If the variation appears only when environmental conditions are changed (as when the organisms are moved from one climate to another or when the diet is changed) and disappears when the original environmental conditions are restored, the variation is nonheritable. It has not been incorporated into the genotype and is known as a modification or phenotypic variation. If the variation arises without any change in environmental conditions and continues to appear in the offspring, it is heritable and is known as a mutation or genotypic variation. Only genotypic variation provides heritable variation on which evolutionary change can be based; but the ability of an organism to undergo nonheritable modification in response to environmental factors may "cushion" it against some of the rigours of natural selection, and this ability itself may be genetically controlled.

Mutation is therefore the inception of heritable variation. It may affect only a single gene, as a result of imperfect replication of the molecule of deoxyribonucleic acid (DNA), of which the gene is composed, or it may affect whole chromosomes by duplicating one or more of them as extras, following imperfect cell division. In man the presence of one supernumerary chromosome is responsible for the serious disorder mongolism. When the complete set of chromosomes is increased two, three, four, or more times, the resulting condition, polyploidy, can play an important part in speciation in plants by producing genetic isolation between populations.

In addition to genotypic variation there is a category of "nongenetic" inheritance due to structures present in the extranuclear (cytoplasmic) part of the reproductive cell or fertilized egg. Such cytoplasmic transmission therefore does not involve Mendelian genes in chromosomes and is solely maternal, for the sperm has no cytoplasm. An example is the inheritance by plastids or plasmagones (small bodies in the cytoplasm) that can be seen in some plants whose branches, normally green, change to white, and seeds from flowers born on such white branches give solely white plants. This type of inheritance does not have much potential for evolutionary change.

#### THE SYNTHETIC THEORY OF EVOLUTION

Even when Mendel's work was first rediscovered and was still imperfectly understood, it caused great controversy. On one side Mendelian geneticists maintained that their mutations were the only source of heritable variation and that their new characters appeared, ready-made, without any previous selection. The Darwinian selectionists objected that mutations were deleterious, if not pathological, that the sudden changes that they caused were incompatible with the slight gradual changes that Darwin's theory required, and that mutations, which bore no relation whatever to environmental conditions, were utterly incapable of explaining the origin and improvement of adaptation to those environmental conditions.

Such was the state of evolutionary studies when an English statistician, Sir Ronald Fisher, observed that the great majority of mutations controlled characters that were both recessive and deleterious and concluded that they were recessive because they were deleterious—in

The evolution of dominance and recessiveness

Genotype  
and  
phenotype

other words, that they had become recessive from a previous condition intermediate in character. That this view was correct was shown by experiments in which it was clear that the action of any one gene in controlling its character is itself under the control of the other genes, which form what is called the gene complex. The composition of the gene complex is constantly reshuffled at every fertilization when the segregated genes recombine at random. If a deleterious mutation appears, those gene complexes that reduce the effect of that mutation give survival value to their possessors; possessors of gene complexes that do not do this perish. This explains the remarkable situation of the dominant "eyeless" gene in the fruitfly (*Drosophila melanogaster*), a gene with obviously deleterious effects. Some individuals with "eyeless" genes can breed, but there is great mortality in the offspring. It is possible to establish a pure eyeless strain by careful maintenance of the breeding colony. If such breeding is continued for a few generations, flies are eventually produced that possess normal eyes. This does not mean that there has been any contamination of the eyeless gene, as is proved by crossing such genotypically eyeless (but phenotypically eyed) individuals with other individuals of the original wild type (the normal gene complex). The offspring of such crosses show the eyeless effect of the gene in all its original virulence. During the generations of breeding eyeless flies, there has been reshuffling of the gene complex at each generation with heavy mortality, but some gene complexes have obliterated the deleterious effects of the eyeless gene. This selection of gene complexes received experimental proof when the English geneticist E.B. Ford, studying the currant moth (*Abraxas grossulariata*), selected the same gene in opposite directions, making it dominant in one line and recessive in the other.

When one gene of a pair of alleles becomes recessive, the other necessarily becomes dominant, which is why the genotype of the "wild type" of organism found in nature contains so many dominant genes that mask recessives. These recessive genes are a contingency reserve for possible future use, any of which may be favoured by selection when conditions change, as they always do, unpredictably.

The rates at which mutations of genes occur in nature have been estimated in organisms as diverse as bacteria, maize, flies, and man and found to be of the order of once in each gene pair, in each generation, in 500,000 individuals. This rate can be increased by physical and chemical mutagenic agents (X-rays, mustard gas, etc.), and in some cases the rate is itself subject to genetic control. In nature it is a slow rate, but it builds up into a stock of genetic diversity that supplies the heritable variation on which natural selection works.

The astronomical quantities of potential variation that can be produced by the Mendelian mechanism of segregation and recombination of genes is shown by Mendel's own example of the number of different genotypes produced in two generations when parents differing in only seven pairs of genes are mated; the number is 2,187. As the numbers of genes in higher organisms run into thousands, the number of genotypes resulting from their segregating and recombining at fertilization is three raised to the power of the number of differing genes. More heritable variation could be produced than ever is actually produced. This is the solution to the difficulty imposed on Darwin solely by the errors of the notion of "blending inheritance," the problem of accounting for a sufficient supply of heritable variation for natural selection to work on. Mutation maintains variation, while "blending inheritance" would annihilate it.

If mutations took place more frequently than they do, variants would be lost before natural selection had had time to derive from them what potential advantages they might present. Mutation not only need not but must not be too frequent.

Fisher's researches showed that the system of Mendelian genes that mutate occasionally, segregate, and recombine at random provides exactly the mechanism required to explain evolution by natural selection. They showed that

if the majority of mutant genes are recessive because they have become recessive, one may conclude that natural selection has acted against them (under the conditions that existed when they mutated). There is no "favourable breeze" of mutations, nor are mutations directed in any advantageous sense. When they first occur, mutations are not adaptive. This demonstration of the initial suppressive effect of natural selection on mutants means that all theories that include the concept directed variation (Lamarckism, program fulfillment, orthogenesis, providential guidance, and others) and that seek to explain evolution as a result of control of the direction in which mutation occurs, whether by supposed effects of use and disuse, satisfaction of needs, environmental factors, inherited "memory," or "inner urges," are contradicted flatly by the observed fact that natural selection acts against new mutants.

Mutation, at the rates at which it occurs, is quite incapable of establishing a character in a population if there is the slightest degree of selection exerted against it, and the forces of selection, or selective pressure, can be measured. The short-term effect of mutation on evolution is therefore minimal or nil. It has been calculated that previous mutations have already set up such a stock of potential heritable variation that if mutation were to stop altogether today, evolution would go on from now as far into the future as it has come in the past. It is selection, not mutation, that controls the direction, rate, and intensity of evolution. This conclusion, based on experiments in genetics, is confirmed from work in paleontology.

The way in which the character of organisms are affected by environmental changes is well illustrated by the evolution of the horse (Figure 3). At the start in Early Tertiary times (about 65,000,000 years ago), the habitat of the ancestral horses was swampy and the vegetation luxurious with leafy plants. To this environment the horse's ancestors (*Hyracotherium*) were adapted by feet with four splayed toes that did not sink in the mud and short teeth for browsing on and eating the soft leaves of trees and shrubs. Later, in the Miocene, the vegetation in many areas changed to grass, which contains silicon and would wear down short teeth. The horse's ancestors (*Merychippus*) then became adapted to this food by the evolution of long high-crowned teeth, capable of uninterrupted growth. At that time the ground was dry and hard, and the number of toes in the feet became reduced, finally to one, with a hoof and a spring joint. These animals were thus able to exploit the grassland niche, as it became more prevalent.

The evolution of the horse was never in a straight line. First many-toed, low-crown toothed browsers changed

The relative importance of selection and mutation

Figure 3: Evolution of the horse.

into fewer-toed, high-crown toothed grazers; lastly, one-toed grazers were the surviving type. This evolution was correlated in each case with the changed conditions of the environment, both vegetable and physical, and as the various directions are different, the effect on the whole lineage is called "zig-zag" to stress the difference between this fact and the mistaken notion of "orthogenic" (straight line) evolution. In other words, it was adaptive, and in bringing it about natural selection acted opportunistically. Those forms that persisted in an old trend as the environment changed became extinct. Examination of a large number of specimens has shown that the direction and the speed of the various stages in the evolution of the horse were not correlated with the coefficients of variability of the organisms, nor with the length of life or generation time. At the start of the Tertiary, variability in *Hyracotherium* was great but tooth evolution slow; in the mid-Tertiary, teeth were evolving fast from the browsing to the grazing type, but variability was then small. As for generation time, it occupies only a few years in the opossums, which have evolved only little in the 60,000,000 years since the Eocene, during which time elephants, with a generation time of several decades, have evolved very rapidly.

Only natural selection, therefore, is left as the agent responsible for controlling the speed, direction, and intensity of evolution.

Attempts  
to in-  
validate  
natural  
selection

On different grounds, attempts have been made to discredit natural selection, particularly by those who shy from its automatic mode of action. It has been alleged that structures of great complexity, such as the eye, would require an impossible degree of mathematical improbability if they were formed by "chance." But such a view betrays a misunderstanding of the problem. The eye was not produced out of nothing; ancestors of animals with eyes had simpler eyes, even single cells sensitive to light such as are found in the most primitive organisms. Improvement of function confers increased survival value from the start, and the same is true of all other cases subjected to rigorous analysis: electric organs, the origin of flight in birds, the parasitic habit of the cuckoo, the adaptation of whales to life in deep water, and the evolution of colour-vision. In each case, new functions and new organs were developed out of old ones. In colour-vision, the ability to distinguish colour is a by-product of two other improvements: accuracy of sight, and sight at low thresholds of light. Gradations can be made out, even in the evolution of such an organ as the eye. This is important because adaptations are not perfect and leave room for further improvement.

With regard to improbability and "chance," while mutation and recombination of genes are random, fortuitous, and haphazard, which means that heritable variation cannot be correlated with any known internal or external factor, it is not heritable variation but natural selection that controls evolution and produces adaptation. The effect of natural selection is rigorously determined by the conditions of viability of the organism and of the ecological niche in which it lives. Adaptations are not the result of any favourable deviations from the laws of probability, such as casino patrons dream of inventing. Natural selection works, on the contrary, by the continuous, and cumulative, action of those laws of probability, on which casino proprietors successfully rely for their profits.

The feature of natural selection, whereby only favourable variations are preserved, has led to the apparently paradoxical situation that it is an automatic mechanism for producing results which, if considered beforehand, would have seemed highly improbable. Although it works blindly and opportunistically, in accordance with the day-to-day situations that arise, natural selection does not produce its results by chance at all; its working conditions are strictly determined, and what they do is to channel fortuitous variation into adaptive directions, thereby simulating the appearance of purposive design.

Improbability is worth considering from the different points of view of time before and time after. The statistician Sir Ronald Fisher pointed out that the probability

that a given man alive today should in the future have sons, grandsons, and successive descendants in the male line, uninterruptedly for 100 generations, is extremely small. By the very nature of sexual reproduction, however, every man alive today is living proof that such an uninterrupted line has in fact occurred, however improbable it might have been 100 generations ago.

The concept of purpose is another stumbling block for some in regard to natural selection, for adaptations are useful; they serve a purpose. In the eyes of those who, like the eighteenth century philosopher William Paley, believed that adaptations were evidence of the existence of a divine designer, an adaptation was the fulfillment of a design, and a proof of teleological purpose. Paley was uncomfortable in trying to reconcile the horrible cruelty and suffering in the animal kingdom with divine purpose. But the word purpose has two meanings. In the first, the concept of the end result to be achieved precedes the means used to achieve that end, as in theological teleology. In the second, the word purpose describes the use for which anything may serve, without implying that it came into existence in order to serve for that use. This is applicable to any structure or function that has arisen by natural selection of random and fortuitous variations. The opportunistic quality of natural selection rules out any teleological definition of purpose. The term teleonomic has been introduced to describe the purpose served by an adaptation.

It has been argued that natural selection cannot account for the evolution of beauty. Beauty is a subjective aesthetic impression, with which natural science is not competent to deal. Organisms which man calls beautiful can be explained on wholly functional grounds. Flowers are often cited to illustrate beauty. It may be noted that no plant that is pollinated solely by the wind has a coloured flower; coloured flowers were evolved as adaptations to attract insects, which serve for cross-pollination. In the same way, coloured fruits were evolved, attracting birds which eat them and disseminate the seeds. In each case, the selective advantage is obvious.

Several writers have suggested that, in addition to the "microevolution" that produces species, there is also a process of "macroevolution" that, through a sudden and major genetic change, may produce a whole new organism, assignable to a different major taxonomic category from that of its parents and founding a new line; but no evidence from nature has been offered to support such a theory, which appears to run counter to the wealth of information on natural selection. The evidence that all evolution has gone through the mill of speciation appears to be overwhelming.

#### NATURAL SELECTION IN ACTION

One of the most striking examples of observable evolution is the phenomenon known as industrial melanism, the prevalence in a normally light-coloured species of black or dark (melanic) individuals, due to environmental changes brought about by industry.

Until the middle of the 19th century, the British peppered moth (*Biston betularia*) was known only in its grey form, admirably adapted by its coloration and habits to escape detection by birds when stationary in daylight on the lichens on the bark of trees. About 1850 an occasional black mutant (given the subspecific name *carbonaria*) appeared and was so conspicuous that black individuals were rapidly taken by bird predators on the bark of trees and the mutation was largely suppressed. Like most mutations, it was recurrent (further evidence of the non-adaptive nature of mutations) and the mutant moths suppressed. Meanwhile, the Industrial Revolution brought about a marked change in the environment in several parts of Britain, especially in manufacturing districts, where air pollution by carbon dust and soot killed the lichens on the trees and blackened the trunks and branches. Now it was the *carbonaria* mutant that was favoured, and the original pale *betularia* form penalized.

Direct observations of feeding birds by H.B.D. Kettlewell provided a measurement of the survival rates of the two forms in normal and in industrial areas. Some obser-

Industrial  
melanism

vations indicated that *carbonaria* survived 17% worse in unpolluted areas, and 10% better in polluted areas, where the populations of peppered moth were now completely dark by 1950. The dark moths are now blacker than those affected by the original mutation, due to reinforcing action of the gene-complex.

Here, then, is a mutation which conferred disadvantage on its possessors under the environmental conditions in which it arose, but which, as a result of an unpredictable change in those environmental conditions, now confers marked advantage in survival. It has resulted in the evolution of the moth from grey to black in a short space of time, under human observation. Similar changes have been observed in nearly 100 other species of insects and spiders, which reveal the opportunistic working of natural selection.

#### Sickle cell

A gene called "Sickle" controls the synthesis of an abnormal hemoglobin in man's red blood cells and deforms them so that instead of disc-shaped they are elongated like sickles and liable to break down, resulting in anemia, thrombosis, or death. The gene is prevalent among inhabitants of West Africa, and is intermediate between dominance and recessiveness. When one sickle-gene is present, and the other gene is the normal allele, pathological effects are produced only in extreme conditions of oxygen deficiency: in shortness of breath, or at high altitudes. When two sickle-genes are present, pathological effects are manifest in normal conditions. The abnormal hemoglobin in the sickle red cells, however, has the unexpected property of preventing the malaria parasite *Plasmodium falciparum* from entering the cells and completing its life cycle in them. Sickle therefore confers immunity to malaria, and a balance is struck between the danger of death from malaria without sickle, and death from thrombosis with two sickle-genes. The condition of one normal and one sickle-gene is therefore favoured, and the equilibrium frequency of sickle in West Africa is about 20% of the population. Among Negroes in the United States, where there is no endemic malaria, the frequency has dropped to 9%. The change has taken place, under natural selection, in less than three centuries, and such a change in gene frequency in a population is itself evolution. Here again a deleterious mutation has come to confer survival value under the unpredictable environment factor of malaria.

#### Intensity of selection

The mathematical implications of natural selection were worked out by Sir Ronald Fisher, geneticists J.B.S. Haldane and Sewall Wright and others. A coefficient of selective advantage is obtained by calculating the number of individuals of one form of variant that survive to breed, relative to the number of another. Selection coefficients are difficult to determine in natural populations, but in a few cases of strikingly evident variants, such as the melanic form of the peppered moth, figures have been gained by direct observations. Assuming a coefficient of 0.1% (1,001 of one type surviving for every 1,000 of the other) and assuming the mutant is dominant it would take 11,739 generations to increase the number of individuals in a population from one individual in one million to 500,000 in a million; if the mutant is recessive the number of generations required to achieve the same result is 321,444. Mutants, thus, have to become dominant if they are to spread through a population. These calculations are for a very weak coefficient of selection; but the peppered moth shows that the amount of change produced in the populations in the time observed, from 99% grey to 99% black in polluted areas, indicates a much higher selective advantage, which can reach 30%. This value can also fluctuate at different seasons. The peppered moth has evidently been subjected to intense selective pressure in polluted areas, to change the mean of the population from grey to black in only about 200 generations. This is an example of dynamic selection resulting, as always, from change in environmental conditions.

When an environment remains constant for an appreciable time, advantage accrues to the optimal phenotype already built up to that environment by natural selection, and variation from that phenotype is penalized. An ex-

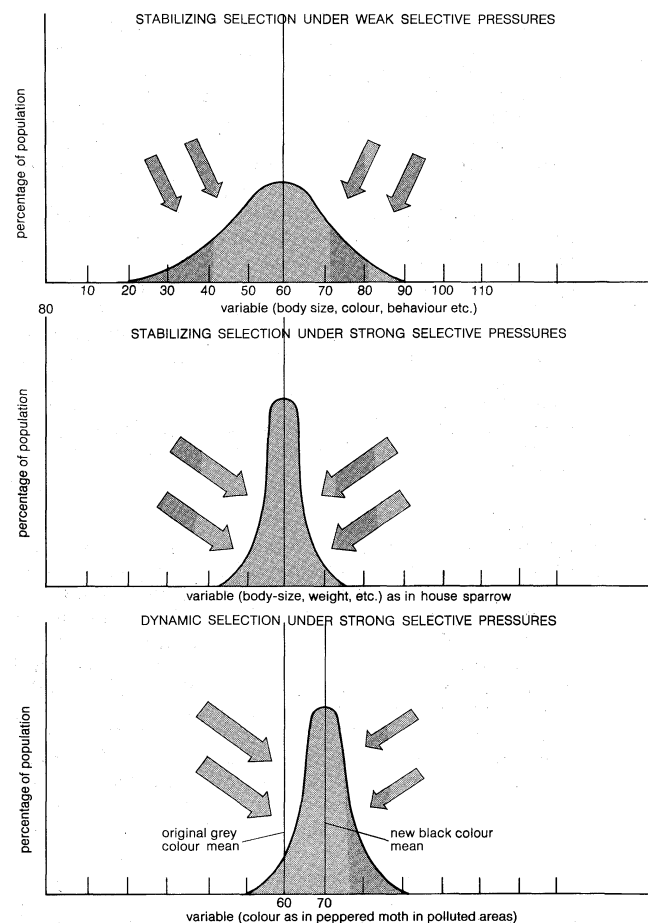

Figure 4: Effects of variation selective pressure of different strengths, under stabilizing and under changing conditions. Arrows indicate selective pressure.

ample is the observation of the viability of house sparrows picked up after very severe weather, and comparison of the characters of the survivors with those of the dead. The survivors were more uniform in size, weight, etc., and the dead more variable. Too big or too heavy was as bad as too small and too light. This is an example of stabilizing selection (also called centripetal), which can also vary in intensity and allow a population a wide or a narrow margin of tolerance in variation, according to the number and activity of predators or the rigour of physical conditions. At the same time it must be remembered that the many characters of an organism are exposed to selection in different directions; the phenotype is a compromise.

For theologians like Paley, adaptations were *ex hypothesi* perfect. This was not Darwin's experience, for in many of the places he visited on the voyage of the "Beagle," he found that recently introduced species had become more numerous than the old indigenous species, which meant that the latter were not perfectly adapted, and that others could do better. Adaptations may be imperfect in spite of the purpose which they generally serve. An example of a gene that is frequently maladaptive is the RH blood group (Rhesus factor) in man. An Rh+ fetus in the uterus of an Rh- mother produces antigens that cross the placental barrier into the mother's blood stream. The mother produces antibodies which pass back to the fetus and may cause fatal hemolytic disease. No positive adaptive value has yet been discovered for the Rh system. Mammals have been viviparous for a hundred and fifty million years, but the immunological mechanism has not yet become adapted to the Rh blood-group genes. The importance of the existence of imperfect adaptations is that it provides scope for further evolution; if adaptations were perfect, no improvement and no evolution would be possible.

On the other hand, adaptation may in other cases have

Imperfect and excessive adaptation

become so minutely precise that when the conditions under which the adaptation arose become changed, the organism may be incapable of readaptation to new conditions, and become extinct. This is probably what happened to the huia (*Heterolocha acutirostris*), the male of which had a stout beak, with which it chiseled holes in decaying wood, in search of insect larvae. The female had a long, slender, down-curved beak, not strong enough to do the initial chiseling, but long enough to reach the grubs exposed by the male. The deforestation of New Zealand resulted in a great decrease in rotten logs and the associated insects, depriving the huia of their food supply. The rapidity of environmental change coupled with the birds' narrow food niche and inability to change their habits may have been a prime cause of extinction.

The extent of extinction since life originated can be seen from the estimate that the number of species of organisms now living is less than one percent of those that have existed.

#### THE RATE OF EVOLUTION

The rate of mutation or of heritable variation, from a recombination of genes, does not control the rate of evolution, which is dependent on the impact on a population possessing genetic diversity, of selection dynamic or stabilizing. This is well shown by a comparison of the average ages of related groups (orders, families, genera) of marine and terrestrial animals. In millions of years the ages of orders are 65 for mammals as against 270 for fish; 180 for insects, 410 for crustaceans; 100 for land-snails, 400 for sea-slugs. In each case, the land animals evolved faster than their marine relatives. Extreme examples of this fact are the so-called "living fossils": *Lingula* (lamp-shell) practically unchanged for 500,000,000 years, *Latimeria* (coelacanth, a member of the primitive fish order Crossopterygii) for 400,000,000 years, *Limulus* (horseshoe crab) for 180,000,000 years. In the evolution of horses during 60,000,000 years, the average rate per genus was 7,500,000 years.

Another method of estimating rates of evolution is to calculate the number of new genera known to have originated per million years. During approximately 60 million years of the Tertiary, the figure for mammals was 30, and for fishes only six. There are two reasons for this difference between marine and terrestrial animals in evolution rate. First, the marine environment has changed little and slowly; a form living in it is subjected more to stabilizing than to dynamic selection. On land, geological, physical, and biological (food-supply) factors have constantly changed, and unless a population could respond efficiently to the dynamic selection to which it was exposed, it became extinct. The second reason is that the waters in the oceans are continuous, resulting in less isolation of populations, an important factor in speciation.

It can be shown that the rate of evolution is also correlated with new possibilities of ecological advantage. The conquest of a new medium (freshwater, dry land, or air) by a successful group gives opportunities for rapid adaptive radiation (the attainment of diversity in an evolutionary line) such as was shown by early land plants, land animals, and by birds. In insects and flowering plants the ecological advantages are reciprocal; since the Jurassic, when both of these groups originated, adaptations of each group have been closely interrelated with those of the other. Insects get pollen and nectar from the flowers, and plants benefit from the cross-pollination that the visiting insects ensure. On the other hand, plants have had to contend with attacks by insects, and insects have had to adapt to the defense mechanisms of plants.

Adaptation to a new food supply is correlated with evolutionary acceleration, as shown by whales, which diversified rapidly at the start of the Tertiary. The large teeth of primitive whales, such as the Eocene *Protocetus*, enabled them to feed on large prey. Later, some whales took to feeding on small cuttlefish and evolved smaller dentition, as in modern beaked whales (Physeteridae). Finally, one line of toothed whales evolved baleen, al-

lowing them to take advantage of the enormous supply of tiny shrimplike crustaceans (krill) by turning their gaping mouths into shrimp nets. Each of these changes coincided with a bout of more rapid evolution.

The rate of evolution is also influenced by the place that an animal occupies in the food chain of its environment. Small organisms that drift about in the sea (plankton), algae, larvae, or krill have no chance against their predators, and their survival depends on high reproductive rate and acceleration of development to make up for losses. But in the case of animals that actively accomplish or resist capture by the use of efficient sense organs, nervous coordination, and muscular movement, as in mammals and birds, at the top of their food chains, evolution is rapid, and the reproductive rate usually is low.

These factors have played a part in the location of centres of evolution. Natural selection has most heritable variation to work on in species whose populations have large numbers of individuals, in which the incidence of recombination of genes and of mutation is greatest. Such populations cover wide areas, which is why the major centre of evolution of land animals was in the tropical regions of the Old World. There, with evolution occurring faster and natural selection more intense, the survivors became dominant groups while their predecessors, less efficient, were driven away to the ends of the landmasses, western Europe, South Africa, Australia, and South America. It is in these remote areas that discontinuous geographical distribution of relic faunas is principally found. Marsupials, which originally had a universal distribution, have become restricted to America and to Australasia, where they radiated, protected from the more efficient placental mammals by a water gap. There have been other centres of evolution for smaller groups. Elephants evidently originated in northeastern Africa and southern Asia, whence they spread all over the world. These far-flung elephant populations, despite adaptations for habitats other than that at the centre of origin, were mostly extinct by the end of the Pleistocene. It is possible that some may have been extirpated by Neolithic man. Horses and camels apparently originated in North America, then spread over the world, and later became extinct in North America. Man's centre of origin was East Africa.

It is evident, therefore, that selection has controlled the speed, intensity, and direction of evolution, in populations with genetic diversity. Selection has been able to do this because the Mendelian mechanism on which it works is able, as circumstances require, to produce either stability or change: stability because genes do not contaminate each other, are often "linked," and mutate only seldom; change because genes do mutate, can undergo "crossing-over," segregate at germ-cell formation, and are recombined at random at fertilization.

In view of the paramount part that natural selection has played in evolution, by acting on heritable variation in such a way as to originate and improve adaptation, it may be asked whether all characters of organisms are or were adaptive. The answer to the question is complex. For the majority of cases it is yes; for some special cases it may be no.

It cannot be doubted that, in general, characters were adaptive under the conditions in which they evolved. But conditions change, and characters that were advantageous can become neutral or even disadvantageous. An example of an adaptation that became a handicap is the antlers of the Irish elk (*Megaloceros*), which became extinct, possibly because the exaggerated size of their antlers impeded their movement in forests. Sir Julian Huxley has shown that the size of the antlers is a result of the mechanism of allometric growth—i.e., that the growth of a part (the antlers) is an exponential function of the growth of the animal as a whole. Selection pressure in favour of the size of the animal (as in most ungulates) was then counterbalanced by selection against the excessive size of the antlers, and these are no longer adaptive but, instead, were harmful. This illustrates two principles: that characters that confer advantage in early adult life may become harmful in postreproductive stages

Nonadaptive and adaptively neutral mechanisms

and that characters controlled by an allometric growth mechanism may increase against selection pressure until it becomes too strong for the genotype as a whole.

Another method by which characters can arise without being selected for is by means of the fact that many genes have multiple effects (pleiotropy), and if they are selected favourably for some effects, others even if selectively neutral or slightly disadvantageous can arise and persist, provided that they do not become sufficiently harmful to outweigh the advantages of other effects, in which case natural selection would act against their possessors. Species can overcome this difficulty by rendering the advantageous effects of such pleiotropic genes dominant and their disadvantageous effects recessive or by the selection of other genes that mask the deleterious effects of the pleiotropic ones.

A method of short-term bypassing of natural selection and producing structures that appear to be nonadaptive is seen in those cases in which sheer reproductive ability of a member of a species results from characters that appear to be maladaptive. In birds of paradise, the fantastic ornamental feathers of the males may, through preferential sexual selection by females (see below), result in the greater reproductive success of the most extravagantly decorated males, to the detriment of the viability of the species, protected by lack of predators. In plants a comparable condition is found in which the greater speed of growth of the pollen tubes, from the stigma of the flower to the ovule, may result in reproductive advantage in spite of whatever disadvantageous genes the pollen tubes may carry. But natural selection eventually catches up with such bad characters when conditions harden. Great reproductive ability confers advantage only when it is the result of adaptation of the species as a whole to its environment.

Genetic  
drift

"Random genetic drift" has been proposed as a principle providing for the possibility that in isolated populations, so small that the laws of probability do not apply in the usual manner, random survival of characters may occur without selection, which would allow for the existence and survival of nonadaptive characters. But it would be possible only where the selective disadvantages of such survivals were extremely small and could not be effective against the most mild adverse pressure of selection in populations exceeding 500 individuals. So-called genetic drift cannot, therefore, be of more than negligible importance in evolution.

#### IV. Speciation

The origin of new species and evolution are not synonymous. A certain amount of evolution can take place, as in the peppered moth, without the end product ceasing to be of the same species. It therefore becomes necessary to define the species in modern terms: it is an interbreeding gene pool, such that a mutant that appears anywhere in its range is, in principle, capable of spreading to any other part of the range. This is why evolution can also be defined as a statistical change in the gene pool.

A new species arises when part of a population has undergone sufficient evolution (*i.e.*, has accumulated enough genetic change) along the lines of adaptation to its own environment that interbreeding with other populations of the ancestral species is rendered at first unusual and later impossible (see SPECIES AND SPECIATION). The key criterion in determining whether or not speciation has occurred is whether the populations are reproductively isolated.

The usual first step toward speciation is the formation of different local races, a process that has been well studied in the spread of the house sparrow (*Passer domesticus*, also called English sparrow) in North America. First introduced about 1850 into the northeastern United States, this species spread to Mexico and the Pacific coast and became diversified into a number of distinguishable populations, differing mostly in accordance with certain ecological "rules." One of these, enunciated in 1847, states that body size in any species of warm-blooded animals is larger in populations inhabiting in colder climates than in those of warm climates. The adaptive significance

of larger body size involves the reduction of heat loss by reduction of surface-volume ratio. It has also shown in 1833 that black pigment is reduced in hot, dry climates and brown pigment is reduced in cold damp climates. North American populations of the house sparrow have produced recognizable differences in fewer than 100 generations. It is doubtful that the differences are sufficient to affect interbreeding.

Populations actually in the process of speciation are seen in certain gulls of the genus *Larus* that occupy a U-shaped range around the North Pole, with the two ends of the loop overlapping in Great Britain, where the western end of the loop is occupied by the European lesser black-backed gull (*L. fuscus*), a medium-sized gull with a dark-gray mantle. Populations of the dark-mantled birds intergrade gradually eastward into those of the herring gull (*L. argentatus*), a light-mantled species of Siberia and North America. The herring gull extends across the Atlantic Ocean to England and Scandinavia, where it coexists with the lesser black-back. The British species also differs ecologically: the lesser black-backed gull breeds inland on moors and is migratory; the herring gull breeds on cliffs and is resident. The pitch and frequency of their calls are different. Here, then, are two gulls at opposite ends of their geographical range that still belong to the same gene pool if a mutant can be imagined as passing from gull to gull round the North Pole but that in Europe have become adapted to different ecological niches. The gulls are an example of both geographical and ecological isolation. Geographical and ecological isolation also is found in the ground finches of the Galapagos Islands, which drew Darwin's attention to the possibility of evolution.

Genetic isolation is produced when an organism multiplies the number of its chromosomes (polyploidy). This is particularly important in producing hybrids that cannot breed with either parental stock because of the incompatibility of their sets of chromosomes with each parental species. A hybrid primrose formed by crossing *Primula floribunda* with *P. verticillata* underwent a doubling of the number of chromosomes possessed by the parental species, which meant that each chromosome then had a compatible partner for the mechanism of cell division. This polyploid hybrid was then able to set fertile seed and develop into a plant with its own constant characters, whose offspring bred true. The new plant was intersterile with both its parent species. It therefore fulfilled all the requirements of a new species and is *Primula kewensis*, formed in the laboratory.

#### V. Major steps of evolution

##### THE ORIGIN OF LIFE

Whether the earth cooled from a molten mass or condensed out of cold dust, life could not have existed when the earth was formed some 5,000,000,000 years ago; it must have originated since. Several well-known scientists have shown that the primitive atmosphere must have been a reducing one (*i.e.*, without free oxygen). When a sample atmosphere of hydrogen, water vapour, ammonia, and methane was subjected to electric discharges and ultraviolet light, large numbers of organic compounds—fatty acids and amino acids, the building blocks of proteins—were obtained by automatic synthesis. This proved that a prebiological synthesis of complex compounds was possible. It is now believed that phosphates, enzymes, and nucleic acids were formed in this way on the primeval earth under ultraviolet light energy. Enzymes accelerate the synthesis of complex compounds out of simple substances and nucleic acids replicate. As both processes are the characteristic of life, it is not unreasonable to suppose that life originated in a watery "soup" of prebiological organic compounds and that living organisms arose later by surrounding quantities of these compounds by membranes that made them into "cells." This is usually considered the starting point of organic ("Darwinian") evolution.

These organisms must have fed on compounds in the water in which they were bathed, as primary heterotrophs (food takers). But as the supply of compounds would be-

come exhausted, the next stage must have been the development of mechanisms of synthesis, utilizing chemical energy (as in some bacteria) or light energy (as in other bacteria and blue-green algae), thus converting the organisms into autotrophs (food makers). In bacteria and blue-green algae the genetic material, deoxyribonucleic acid (DNA), was not organized into nuclei; such cells are called procaryotes.

#### SEX, PLANTS, AND ANIMALS

The fundamental basis of sex is not sexual differences but the interchange of genetic material (syngamy) between individuals, resulting in heritable variation through recombination. No such interchange has been observed in blue-green algae, which have remained virtually unchanged for 3,000,000,000 years. Bacteria show primitive and incomplete interchange.

Following the envelopment of living material in a membrane, the next step was the organization of DNA into nuclei in each cell, with chromosomes bearing the genes in linear order. Such organisms are called eucaryotes and include all organisms above bacteria. The mechanism of Mendelian genetics was then able to work and to increase enormously the scope of variation, on which natural selection acted. Another advance was the development of the green pigment chlorophyll, which enabled organisms to build up organic compounds from carbon dioxide in the air and salts in water in the soil, under the action of sunlight. Photosynthesis evolved in one-celled organisms (protists), which produced the higher plants (tracheophytes). Plants are complete autotrophs, the prime producers of proteins, carbohydrates, and fats.

Life involves not only synthesis but also the degradation of organic compounds, in which some bacteria play a part. Other organisms make use of decomposing matter as a source of supply and have lost the power of photosynthesis; these are fungi, which may be a separate evolutionary line. Other organisms obtain their food ready-made by eating living plants or other organisms that, like themselves, eat plants. These are animals that have completely lost the power of synthesizing their substance from simple compounds and, as secondary heterotrophs, are ultimately entirely dependent on plants for their existence.

#### VIRUSES

Viruses, very minute particles of nucleic acid surrounded by protein shells, present a problem. Their simplicity has led some to believe that they are relics of a precellular stage of organic evolution, but this is unlikely. Viruses are incapable of free existence and can persist only as parasites inside living cells. Their DNA behaves like genes and mutates (producing new strains of viral diseases) and their enzymes force the host-cells that they parasitize to synthesize more viruses out of the host cell's materials. Unlike living organisms that multiply only by some form of division of their own bodies, the "bodies" of viruses do not divide to produce the next "generation" of viruses. Instead, the new generation is the result of synthesis enforced on the parasitized organism. The prevailing view of virologists is that viruses were derived by degenerate evolution from portions of nuclei or even genes of parasitic bacteria or protozoa in living host-cells.

#### MULTICELLULAR ORGANIZATION, DEATH, AND EMBRYONIC DEVELOPMENT

Unicellular organisms, reproducing by division, are potentially immortal, barring accidents, and, being single cells, exchange genetic material by temporary fusion in pairs. In order to fuse, germ cells must be able to move and to meet, but in order that the fertilized egg about to embark on embryonic development can live, it must contain a supply of food to last until the developing organism can feed itself. This led to a differentiation between large germ cells containing food materials but incapable of movement (eggs) and small germ cells consisting of little more than a nucleus but capable of movement (sperms). Subsequent sexual differences follow from the

dimorphism between egg-producing females and sperm-producing males.

The multicellular stage of life arose, allowing greater size and differentiation of parts of the body, with different structures and functions, all of which conferred survival value. Syngamy, with its all-important production of variability for selection to work on, can take place only between single cells whose nuclei fuse and genes recombine. In multicellular organisms a division of labour has arisen, with single germ cells serving for reproduction of the organism and the whole of the rest of the body functioning to support and protect the germ cells. Syngamy, which is the fertilization of these germ cells (gametes, whose genetic material is potentially immortal), produces the next generation, by growth and differentiation to build up bodies similar to those of their parents. But the price to be paid for the advantages of multicellularity is that the multicellular body must die.

#### COLONIZATION OF LAND

After 2,500,000,000 years of life in water, organisms began to colonize land, about 500,000,000 years ago. At that time consequences of the different methods of feeding of plants and animals became conspicuous. Plants, needing nothing but ubiquitous carbon dioxide and salts in solution, remained stationary. Animals, requiring living food, had to move to obtain it and so evolved muscles and skeletal structures, sense organs to find the food, and nervous systems to coordinate the impulses from sense organs and transmit appropriate responses to muscles. Movement is most efficient along one axis in one permanent direction; the front end becomes a head and, in it, a brain. These features were already present in water, but in land animals they became accentuated.

The first plants and the first animals established on land were still in need of water for the sperm to swim in and find the eggs, as in the modern mosses, horsetails, ferns, and Amphibia. In the Amphibia, water remained necessary for the embryo to develop in. With the formation of pollen grains (containing the sperm) and ovules (containing the eggs), fertilization (pollination) in plants could take place in dry habitats. In animals, internal fertilization and the enclosure of the embryo in an eggshell likewise made life on dry land possible. Mammals improved on this system by retaining the fertilized egg within the mother's body.

When plants were established on dry land, ovule-producing and pollen-producing leaves, surrounded by coloured petals and protective sepals (also leaves), resulted in flowers that attracted insects that performed cross-pollination. Seeds are embryos packed up ready for dissemination.

### **VI. Patterns of evolution**

*Improvement and adaptive radiation.* In the evolution of a lineage (a long continuous genetic line), it is possible to make out five stages. First comes divergence of parts of the species from the original stock. This splitting is the start of cladogenesis (the initiation of a new clade, or evolutionary line). Next comes improvement of the adaptation in relation to the environment. This can mean the degeneration associated with extreme parasitism, but in the vast majority of cases, improvement results in increased complexity and differentiation (anagenesis). If the improvement enables a lineage to break through and colonize a new environment (land, air), where there are usually very numerous and diverse ecological niches yet unfilled, there is a rapid increase in numbers and variation, and multiple divergence (adaptive radiation). Examples are seen in the succession of dominant forms in geological times: seed ferns, conifers, flowering plants; amphibia, reptiles, mammals, and birds. Next comes a phase of stability (stasigenesis) leading to persistent types (coelacanths) or "living fossils." Finally, extinction may overtake the lineage when conditions change, variability is insufficient to allow readaptation, and natural selection takes its toll.

*Paedomorphosis and clandestine evolution.* Embryos of related animals show great similarity, evidence of their

Figure 5: Anagenesis and adaptive radiation.

descent from a common ancestor whose embryonic development they repeat for early stages. The 19th-century German biologist Ernst Haeckel believed that in their embryonic development, the embryos of descendants recapitulated the evolutionary stages that their ancestors occupied as adults; the earlier the embryonic stage the more remote the adult ancestor. This theory, the reverse of the truth, would mean that evolutionary novelties were added only to the end stages of the development. Far from the young descendant representing the adult ancestor, it is much more important that in many cases the adult descendant resembles the young ancestor, by retardation of development, retention of the ancestral juvenile features, discarding the ancestor's adult stage, and evolving a new adult stage of its own. This process is known as pedomorphosis and is found in lineages that have led to markedly successful cases of evolution, with extensive adaptive radiation. It is a method of avoiding excessive specialization and has been suggested as a possible mode of origin of insects from young millipedes, of vertebrates from young (larval) echinoderms, and of man from juvenile apes.

Paedomorphosis has an important consequence for paleontology. It means that the evolutionary changes that will lead to the next step take place in the young stages, but these often lack hard skeletal structures and are not preserved as fossils. When the old adult stage is lost and a new adult stage takes its place, the new form arises without "paleontological warning," by clandestine evolution—one reason that the great successful groups appear more or less suddenly in the fossil record, with a gap between them and the ancestral form. The Carpoidea, fossils from the Lower Cambrian, hitherto classified with echinoderms, have been shown to have had gill slits and fishlike brains and to be related to ancestors of vertebrates. They are now called Calcichordata.

**Mosaic evolution.** In the evolution of each of the five classes of vertebrates, the fossil record has preserved forms that are roughly intermediate between two successive grades. The most important of these is *Archæopteryx*, the remarkable feature of which is that some of its structures are purely reptilian (small brain, long tail, free fingers), others are purely avian (feathers, wing, furcula or wishbone, reversed fourth toe). In the transition from reptile to bird there was no general and gradual conversion of all the parts at the same time, but some remained reptilian while others became completely transformed to the bird type. This pattern is called mosaic evolution. It

can be recognized in the other intermediate forms, between fish and amphibia, amphibia and reptiles, reptiles and mammals, and also in the evolution of man.

Mosaic evolution can also be recognized in plants. In the seed ferns that formed the bulk of the coal forests, the stem and fronds were like those of true ferns from which they probably evolved, but the seeds were like those of cycads (flowering plants allied to conifers), into which they evolved.

**Parallel and convergent evolution.** Some groups of animals that have diverged can later evolve lineages that show resemblances. The simplest case of this is in parallel evolution. Marsupials were the dominant form of mammals in late Mesozoic times. In the Tertiary the greater efficiency of placental mammals resulted in the elimination of many marsupials, but in Australasia, protected from the placentals by a water gap, marsupials underwent adaptive radiation. A carnivorous marsupial, the Tasmanian wolf (*Thylacinus*), filled an ecological niche like that filled by the placental true wolf (*Canis*), and the two are similar in shape, teeth, and habits.

In some cases organisms from two or more unrelated or only distantly related lines show remarkable resemblances, a type of evolution called convergence. An excellent example is provided by marine reptiles and mammals that became fishlike. Reptiles as a group of land animals evolved from fish through amphibians. Several lines of reptiles have returned to the aquatic environment, and one group, the Mesozoic ichthyosaurs (literally, "fish-reptiles"), were fishlike in body shape and had dorsal and caudal (tail) fins. During the Triassic, when the ichthyosaur line was radiating in the marine environment, another line of reptiles, the terrestrial synapsids, produced the mammals. Several mammalian lines subsequently became adapted to the marine environment. Dolphins and porpoises especially, while preserving the basic mammalian characters, show close similarity to the fishes and ichthyosaurs in body shape and fins. Adaptation to a predacious life in a similar medium, through natural selection, resulted in this convergent evolution. In general, parallel evolution is the result of similar selection pressures on different but closely related forms. When not closely related, the result is convergent evolution.

Figure 6: Convergence of the stem reptile.

## VII. The evolution of man

### HOMINIZATION AND SEXUAL SELECTION

The evolution of man (hominization) shows some unique features, though traceable to processes found in other mammals (see MAN, EVOLUTION OF). Human ancestry began with small quadrupedal arboreal animals like the tree shrews (Tupaiaidae) about 60,000,000 years ago. That man's ancestors had tails is shown by the vestige of a tail in the human embryo (representing the tail not of the adult ancestor but of the ancestor's embryo). Becoming larger, primates next resembled the tarsier, developing a vertical position of the trunk by claspings tree trunks with the fore and hind limbs. The next stage was the acquisition of the habit of brachiation, swinging from branches by the hands and moving in this way in forests, a habit that left its mark in the wide thorax, flat back, legs in line with the trunk, and almost universal joint of the arms at the shoulders, which are very wide apart, in man.

The brachiating stage persisted a long time in apes, as shown by the exaggerated lengths of their arms and the inefficiency of the legs in walking, but man's direct ancestors cannot have remained brachiators for long. They did not adopt the specializations of the apes but evolved a method of locomotion of their own, by taking to a terrestrial existence on the ground. These manlike primates, the australopithecines, of about 3,000,000 years ago, showed marked mosaic evolution. Some of their characters were purely apelike (small brain volume, massive projecting jaws, large molar teeth) and other features quite human (smooth, rounded forehead in juveniles, teeth arranged in a semicircular arch, molars worn in a way that showed the human method of chewing, arms delicately built, hip girdle and thigh bones showing vertical stance and gait). This upright posture supported solely by the legs, freed the hands from locomotor duties, and made possible their adaptation for manipulation.

These submen had a social structure (as have apes) that was of fundamental importance for their descendants. Although small, devoid of offensive structures like tusks or horns, and slow movers, they relied on their superior intelligence to enable them, in bands of 100 or 200 individuals, to outwit their enemies and to capture their prey and gather food. They made and used simple pebble tools. All these adaptations, particularly the increased brain power, were the result of natural selection. The australopithecines had conquered a new ecological environment in which brain rather than brawn conferred advantage, and they had no competitors. The result was rapid increase in numbers and a high rate of variability, which is seen in the number of different types of australopithecines found in East Africa. A calculation of the probable number of individuals in the population of man's ancestors 1,000,000 years ago, approximately the time when these manlike apes were turning into apelike men, has produced the figure of 125,000.

As human evolution continued along the same lines, with increased brain size, neurological complexity, and mental powers, the threshold of the genus *Homo* was crossed by forms such as Java Man, Peking Man, Heidelberg Man, and many others, collectively known as pithecanthropines. It is now realized that their general similarity to modern man makes it inadvisable to give them all Linnean generic and specific names (which would imply that they were intersterile), and they are included in the species *Homo erectus*. From this arose men called neanderthaloids, because they were more generalized than the later Neanderthal type (*Homo neanderthalensis*) and more like modern man (*Homo sapiens*) to whom they were doubtless ancestral.

The skulls of adult australopithecines (*Paranthropus* and *Australopithecus*), pithecanthropines, and neanderthaloids were apelike, with heavy brow ridges; but young forms of these types (like the young chimpanzee) have no brow ridges but instead a vertical forehead like an adult modern man. This may be interpreted as due to the part paedomorphosis has played in the evolution of man.

As compared with the great apes, which are the only related living forms with which he can be equated, modern

man shows such a marked retardation in the rate of development that infancy, childhood, and adolescence occupy twice as long a time as in the apes. The features involved include growth period, eruption of teeth, age of puberty, and time of closure of sutures of the bones of the skull. The human newborn is not only utterly helpless but is almost in the condition of an "extra-uterine fetus," born prematurely with a year to go before it attains the anatomical and physiological condition of the newborn ape. The adaptive value of the premature birth is that the size of the brain and skull in man is so great that if birth were delayed, the infant would not pass through the bony ring of the mother's pelvis. Retardation of development being of such importance in man, it would be made of negative adaptive value if twin births were normal, for there would be competition between the twins for space and maternal blood supply, and the more precocious would receive advantage. Such precocity is contrary to the adaptive value of retardation in human evolution, which has been helped by the simpler structure of the human uterus. This structure, with a single chamber, increases the hazard of gestation for both fetuses if there are more than one. This is why the normal number in a human litter has been reduced to one.

Another biological principle operative in the evolution of man and many other animals has been sexual selection. In its original form, this process was conceived as the success of some males over others in obtaining mates, because of striking structure, coloration, or behaviour, and leaving more offspring than their less ornate rivals. This undoubtedly has taken place in some forms, such as the birds of paradise, and in man. It is a mistake to imagine that this process implies attributing to the females of non-human animals the power of aesthetic choice. The importance of sexual selection lies in the raising of the physiological state of sexual excitement in the female to the level at which she accepts to mate. In man, sexual selection has been mutual, intensified by the visual results of the adoption of the human mating position, consequent on the acquisition of upright stance, and it has affected the bodily distribution of fat, hair, and probably the development of a melodious voice. Darwin related how men of an African tribe choose their wives by lining them up and selecting the one who "projects most *a tergo*" (behind). It is easy to understand how a female could evolve features like those of the Paleolithic statuette "Venus of Brassempouy" (a small obese figurine), and later those of Venus de Milo.

There is a physiological function that has played a part in the biological process of hominization. In man, as in the great apes, the periodicity of ovulation and of female sexual excitement controlled by the hormonal mechanism of estrus has been succeeded by that of menstruation. Instead of being restricted by the periods of the estrous cycle without any sexual activity in intervening periods, mating can occur any time, a freedom of behaviour important for the social organization of man.

### HUMANIZATION: PSYCHOSOCIAL EVOLUTION

The human newborn and child, utterly helpless for a considerable time, is entirely dependent for its survival on the care and skill of its parents. There is thus an overlap of many years between the generations, during which the development of the infant is not only protected but completed, and the parents are the most important factor in the survival of their offspring. They are able to play this role because the freedom of women from the sexual restrictions of the estrous cycle of lower mammals has made monogamy acceptable to men, and the family became a stable unit in society.

It is not only milk and, after weaning, other nourishment that the infant receives. In addition to affection and the psychological ties that bind mother and infant to each other, the latter, in its family, and surrounded by social stimuli, completes and perfects its own neurological mechanism, in a sort of cultural matrix that continues on a new and different plane the embryological development that the fetus underwent in the womb. Lack of this cultural matrix in early infancy leads to permanent mental

Sexual  
selection

# The evolution of cultures

incompleteness, as shown by the occasional wild children brought up by female animals and children sequestered by inhuman parents.

The term inhuman in the last sentence is apt because it is by means of the cultural matrix of the family that man, hominized by natural selection, becomes humanized by what Sir Julian Huxley has called psychosocial evolution. In addition to the ordinary physiological aspects of child care, the infant becomes educated and slowly acquires a knowledge of the world into which it has been precipitated. At some stage in man's evolution, the superior mental powers of the brain, evolved through natural selection, gave him a wide range of abilities, all of which have a social bearing. Speech enabled him to communicate with his fellows, and reasoning enabled him to envisage deliberate aims; the patterns of flint implements found even in the earliest Paleolithic levels are evidence of the fact that a model was being followed for a purpose, and for the first time on earth, teleological purpose made its appearance. Reasoning produced experience, and memory converted this into tradition, the handing on of knowledge from person to person, most important, from parent to child.

Figure 7: Radiation of beak shape in Hawaiian honeycreepers.

The fundamental difference between biological and psychosocial evolution is that, whereas biological information is transmitted automatically through the genes, whose variations are exposed to natural selection, psychosocial evolution does not involve biological heredity; it has to be imparted fresh at the start of each generation, from parents to child. The child, therefore, starts its effective behaviour and learns to recognize and react to wants, pains, satisfaction, and pleasure; it also begins to learn objective lessons from the outer world. Instincts are more or less sufficient to protect the young of animals with a very short infancy from hatching or birth to adulthood, but human childhood is so prolonged that no instincts could suffice to protect the child in the much more variegated condition of its environment. This is why a principle of authority acceptance by the child has conferred survival value by lowering accident rate.

Another difference between biological and psychosocial evolution is that, whereas the former is slow and has taken over 3,000,000,000 years to produce man, psychosocial evolution is alarmingly rapid and is accelerating. It has taken only 10,000 years for man to pass from bows and arrows to thermonuclear weapons, and the production of the latter has taken only 20 years.

Finally, psychosocial evolution is the producer of civilization. It has been selected in different directions in accordance with different ideologies, as may be seen by comparing the policies of ancient Sparta with those of a welfare state.

The most important difference between man and animals is his moral sense, and this presents difficult evolutionary problems. He claims to be the only species to

have behaviour patterns aiming at the welfare and good order of society, in which he is less successful than lower vertebrates with their hierarchical organization, known as the "pecking order," which regulates priorities in access to females, food, and prestige, protected by natural selection simply because it conduces to good order and reduces casualties. This leads to the paradox that, despite his claimed moral sense, man is the only species in the animal kingdom that will perform wholesale massacres of its own members; animals are protected from doing this by innate behavioral control of aggression. Perhaps it is because man is a recent species, lately descended from australopithecines who owed their survival to aggressive behaviour in bands, with all that that implies in the way of mob psychology.

In view of this, it may seem premature to inquire how moral conduct originated when it fails so lamentably, but it nevertheless exists. Ethical behaviour develops in the child, and it has evolved in societies during their histories. Darwin believed that morals had also evolved from simple prototype components in the behaviour of lower organisms such as maternal affection and paternal self-sacrifice, through the advantage to the community of the social instincts of sympathy and the advantage that they would confer, leading to the well-known golden rule, "... whatever you wish that men would do to you, do so to them."

## NATURAL SELECTION IN MAN

For all his professed civilization, natural selection continues to act in man, but with restrictions imposed by ethical standards. Medicine saves the lives of ill persons, surgery through Caesarian section enables birth to take place artificially, with the result that the genotypes whose phenotypes would not survive without these artificial aids are preserved and perpetuated.

It has been said that modern man is so far removed from "nature" that if he were plunged back into Paleolithic conditions he would perish quickly. On the other hand, Paleolithic man would not survive long in modern civilized conditions either, for he would succumb at once to epidemics to which modern man is fairly well adapted as part of his adaptation to living in highly populated towns. When, in Neolithic times, man started to live in crowded sedentary dwellings, with problems of sewage disposal, and closely associated with domestic animals, he became a prey to diseases caused by internal parasites, bacteria, and viruses, scourges from which the small roving bands of Paleolithic men must have been free, especially as concerns killer viruses that would have destroyed themselves as well as their victims, which were their only condition for continuance. These viruses originated in domestic animals, in which they (and their hosts) became adapted so as not to cause death.

There is another sanction that natural selection hangs over man's head. He is the only species that has broken out of ecological control of the birthrate, which in animals and Paleolithic man was kept down to the scale at which the territory occupied by each breeding unit limited the food supply available for young and adults.

## VIII. Social evolution

### SOCIOLOGY BEFORE DARWIN

The state of opinion on social questions in the 18th century was unpolarized. The Age of Enlightenment, largely the work of French speculative philosophers, envisaged the perfectibility of man, but the traditions of society and the precepts of theology prevented wide appreciation of the problems of sociology, which received a further deterrent from the excesses of the French Revolution. In 1795 appeared the French social thinker Marquis de Condorcet's *Sketch for a Historical Picture of the Progress of the Human Mind*, in which he distinguished nine epochs in the history of man, from the pastoral state to that of Liberty, Equality, and Fraternity that the Revolution had brought about. Each epoch passed to the next by jettisoning theological, social, and moral "prejudices" that had impeded progress. This was an optimistic example of conjectural history, and not the last.

Appalled at the ravages of the guillotine and terrified that the progress of the ungodly might establish a bridgehead in Britain, two clergymen set themselves the task of stemming it. Malthus endeavoured to show that man was unimprovable and that if the population increased too fast the poor would suffer famine and death and if too slowly the poor would have no incentive to work. It followed that medicine was antisocial and charity an "economic sin." Paley, in his *Natural Theology*, tried to show that adaptation implied a divine designer; his examples served Darwin as a catalogue of the products of natural selection. It is one of the great ironies in the history of ideas that Malthus and Paley, who did not believe in evolution, provided Darwin with exactly what he required to produce a successful theory, the reverse of their aims.

Meanwhile some Scottish philosophic historians had made conjectures on the economic stages in human history: hunting, pastoral, agricultural, and commercial, which are interesting to compare with the conjectural stages put forward by Marxists. The Scottish philosophers also used the method of comparison between existing savage tribes and hypothetical early stages of civilization to trace its conjectural development: an acceptance of the possibility of evolutionary change.

In 1797 John Frere found flint implements in Suffolk and concluded that they had been "used by a people who had not the use of metals." In 1819 a Danish archaeologist, Christian Thomsen, coined the terms Stone Age, Bronze Age, and Iron Age to denote successive stages in human prehistory. In 1846 a French antiquarian, Jacques Boucher de Perthes, founded prehistoric archaeology by his discoveries of flint implements.

Speech is a human attribute, and its study has revealed evolutionary possibilities. The English Orientalist Sir William Jones showed in 1786 that there were similarities between Sanskrit, Greek, and Latin that could only be explained if these languages had descended from an original language, perhaps dead. This hypothesis was confirmed and extended in 1816 by a German philologist, Franz Bopp, who introduced the term Indo-European to include the whole family of languages related to Sanskrit.

Auguste Comte, a follower of Condorcet and pioneer of philosophical positivism, gave an impulse to sociology conceived as a science or "social physics," excluding revealed religion and substituting humanism and ethics, based on history and aimed at improvement of human conditions. A great influence in social studies was Herbert Spencer, tireless exponent of evolutionary philosophy, who in 1852 published his belief in evolution, under the title of "The Development Hypothesis." This was based not on analysis of scientific evidence but on the *reductio ad absurdum* of alternative explanations.

All of these developments took place before 1859 and therefore without knowledge of Darwin's work. The study of sociology has frequently been concerned with what has been called "Social Darwinism," an attempt to consider human social interactions in terms of the struggle for existence. Sociology owes nothing to Darwin.

#### SOCIOLOGY AFTER DARWIN

The mechanism of natural selection, when taken out of its proper biological context by nonbiologists and made to apply to sociology, has had unfortunate results. Spencer, who coined for natural selection the unlucky phrase survival of the fittest (tautological and inaccurate), used it for his contention in favour of radical laissez-faire (uncontrolled) private enterprise, which should properly be called "social Spencerianism," applying the struggle for existence to individuals in society. Such views were widely held in the United States, where American clergyman Henry Ward Beecher wrote to Spencer, "The peculiar condition of American society has made your writings far more fruitful and quickening here than in Europe." Following his thesis to lengths of excess, Spencer extrapolated from the organic evolution of individuals to the "super-organic evolution" of societies of individuals, on the view that society was an organism.

Conversely, at the hands of Karl Marx, natural selection was made to serve as a "scientific" justification for the

class war. In both cases the mistake was to imagine that a biological principle that works on organisms in nature can be made to apply to societies of men. In his naïve way, devoid of any historical sense, Darwin expressed this fact whimsically when he wrote to Baron von Scherzer, "What a foolish idea seems to prevail in Germany on the connection between Socialism and Evolution through natural selection."

#### EVOLUTIONARY GENETICS OF SOCIETY

It has been shown by English geneticist C.D. Darlington that studies in prehistory, history, and genetics make possible a sketch of the evolutionary origins of the genetic patterns of society. The important point is that without genetic diversity, resulting from crossbreeding, heritable variation is limited, adaptability to changed conditions is reduced, and survival of the population is precarious. Human societies have had to strike a balance between incestuous inbreeding, against which horror has generally prevailed because of its disastrous genetic results (accentuation of deleterious traits), and excessive outbreeding, which would impair the cohesion of the social unit.

In the Paleolithic expansion, groups were small, with a simple breeding pattern. The Neolithic expansion involved the spread of socially undifferentiated groups of matriarchal agriculturists and patriarchal herdsmen. Their rapid increase in numbers, added to by mixtures of populations, resulted in increased genetic diversity, in the Bronze Age; and by the social differentiation resulting from the discovery of metals, castes of metal smiths, warriors, priests, and scribes arose, claiming possession of professional secrets and tending to breed among themselves. Peasants, original mainstays of Neolithic societies, remained at the bottom of the social scale, where they have been ever since.

The stratification of societies into classes, each specialized for particular occupations, is traceable to internal differentiation, mixing of populations, or forcible capture and incorporation of slaves. In India the castes originated in an (unsuccessful) attempt by the Brahmins to breed men genetically adapted to their different occupations. To this end they divided the invading Aryan and the invaded populations into a large number of groups, each internally bound by rules of religious purity affecting diet and marriage, cooperating but never interbreeding with other groups. This class separation was combined with national unity, but at the genetic cost of reduction of the benefits of genetic diversity. The result has been that Hindu society has changed less than any other. Elsewhere, particularly in the China of Confucius, the possibilities of promotion and demotion to different levels in the social scale, favouring gene diffusion, has safeguarded those benefits, and new social structures arose.

#### EUGENICS

It was assumed by the English scientist Francis Galton, who believed in the hereditary nature of intelligence, that matings between parents possessed of especially favourable heredities would improve the genetic legacy of society, while the converse would deteriorate it. This notion, traceable to Plato, became the aim of a eugenics movement, launched in 1883. There are two approaches: positive eugenics, the enhancement of desirable characters through favourable matings, and negative eugenics, the suppression of deleterious genes by preventing their possessors from breeding. More recently some geneticists have stressed what American geneticist Hermann J. Muller called the "duty on the part of individuals to exercise their reproductive function with due regard to the benefit or injury thereby done to society." They have then gone on to suggest that sperm banks, supplied by outstanding men, and subsequent artificial insemination would not only allow of progeny testing but produce more men of genius. This program of positive eugenics suffers from the fact that the segregation and recombination of genes means that outstanding fathers may have inferior children and that the mother is as important as the father in transmitting genes. Sociologically, nobody is agreed on the qualities the ideal mass inseminator should have.

Negative eugenics suffered from ignorance of the action of the gene complex (see above) in suppressing the effects of disadvantageous genes, which invalidates the "scientific Calvinism" that supposed the impossibility of parents carrying unfavourable recessive genes producing any but socially undesirable progeny. Negative eugenics therefore has only limited acceptability. It would nonetheless be inadvisable for a person whose family contained a case of xeroderma pigmentosum (face cancer) to marry a freckled partner, especially a near relative, for fear of carcinoma in the offspring. The same prudence applies to families connected with hemophilia.

### IX. The acceptance of evolution

Evolution is accepted by all biologists and natural selection is recognized as its cause by English-speaking biologists and others, though not widely in western continental Europe. Objections to evolution have come from theological and, for a time, from political standpoints.

Darwin did two things: he showed that evolution was a fact contradicting scriptural legends of creation and that its cause, natural selection, was automatic with no room for divine guidance or design. Furthermore, if there had been design, it must have been very maleficent to cause all the suffering and pain that befall animals and men. In 1860 T.H. Huxley demolished the arguments of Bishop Samuel Wilberforce. In the famous "monkey trial" conviction of schoolteacher John T. Scopes in 1925, a Tennessee law banning the teaching of evolution was upheld, but years later, in 1968, the United States Supreme Court ruled that anti-evolution laws were unconstitutional.

The Vatican leaves open the question of the evolution of man's body, provided it be believed that the body was derived from other living matter, that all mankind is descended from one pair (Adam and Eve), that man's soul was created by God, and that evolution took place under the dispensation of Divine Providence. Science cannot comment on the soul, but the other provisos are unacceptable to evolutionary biologists.

Political obstacles to scientific acceptance of evolution were for a time erected in Russia, where the ideological insistence that all characters are determined by the environment led to the stigmatizing of Mendelian genetics as bourgeois, metaphysical, reactionary, and leading to religion. The Soviet agronomist T.D. Lysenko attacked Darwin's theory as "metaphysical at base" and nothing but "flat evolutionism" because it worked so slowly. Lysenko contended that wheat plants produce seeds of rye and that cuckoos lay no eggs of their own but make foster parents' eggs grow into cuckoos. These views are now disregarded in the Soviet Union and elsewhere.

In more than a century since the appearance of Darwin's *Origin of Species*, the science of evolution has answered many questions and raised many more. Although new information frequently forces a re-examination of certain aspects, such as the rate of evolutionary change or the availability of genetic variation within populations, the main body of the synthetic theory of evolution remains firmly established.

**BIBLIOGRAPHY.** J.W. BURROW, *Evolution and Society* (1966), discusses social evolutionary theory before and after Darwin. SIR W.E. LE GROS CLARK, *History of the Primates*, 8th ed. (1962) and *Man-Apes or Ape Men?* (1967), present readable accounts of the ancestry of the primates and of man, respectively. C.D. DARLINGTON, *Evolution of Genetic Systems*, 2nd ed. rev. (1958), is a rather technical account of the relationship between genetics and evolution. CHARLES DARWIN, *On the Origin of Species* (1859), is the classic work on natural selection and well worth reading. A facsimile edition, with an introduction by E. MAYR, was published in 1964. A revision, *The Origin of Species*, 6th ed. (1872), was reprinted in 1963, with an introduction by SIR GAVIN DE BEER. See also Darwin's *The Descent of Man* (1871, 2nd ed. rev. 1930), an important discussion of human evolution. SIR GAVIN DE BEER, *Embryos and Ancestors*, 3rd ed. (1958), discusses the relation between embryological development and evolution; his *Atlas of Evolution* (1964), is a well-illustrated introduction to the subject, his *Handbook on Evolution*, 4th ed. (1970), a short popular manual. T.G. DOBZHANSKY, *Genetics and the Origin of Species*, 3rd ed. rev. (1951), is a standard work for the advanced stu-

dent; *Mankind Evolving* (1962), an account of human evolution for the general reader. SIR RONALD A. FISHER, *The Genetical Theory of Natural Selection* (1930), provides the classic foundation of the synthetic theory of evolution. E.B. FORD, *Mendelism and Evolution*, 8th ed. (1965), is a short account of evolutionary genetics; his *Ecological Genetics* (1964) demonstrates the value of field genetic studies to evolutionary theory. J.B.S. HALDANE, *The Causes of Evolution* (1932), is a stimulating exposition on the subject of the title. D.L. LACK, *Evolutionary Theory and Christian Belief* (1957), provides a simple account of the conflict between biology and religion. E. MAYR, *Animal Species and Evolution* (1963), is a classic work on the mechanisms of speciation and the formation of higher categories; his *Populations, Species, and Evolution* (1970), is an abridged edition for the general reader. G. MENDEL, *Versuche über Pflanzenhybriden* (1866; trans. edited by J.H. BENNETT, *Experiments in Plant Hybridisation*, 1965), provides the groundwork for all subsequent studies in heredity. K.P. OAKLEY, *Frameworks for Dating Fossil Man*, 2nd ed. (1966), presents a chronology of man's evolution. B. RENSCH, *Neuere Probleme der Abstammungslehre*, 2nd ed. (1954; Eng. trans., *Evolution Above the Species Level*, 1959), is a classic work on the principles of evolution. G.G. SIMPSON, *The Major Features of Evolution* (1953), is a major work on paleontology, adaptation, and rates of evolution; G. LEDYARD STEBBINS, *Variation and Evolution in Plants* (1950), a standard reference work on plant speciation, and *Processes of Organic Evolution*, 2nd ed. (1971).

(G.de B.)

## Exchange and Payments, International

Economic life does not stop at national boundaries but flows back and forth across them. The money of one country, however, cannot as a rule be used in another country; the flow of payments must be interrupted at national boundaries by exchange transactions in which one national money is converted into another. These transactions serve to cover payments so long as there is a balance between them: local money can be exchanged against foreign money only insofar as there is a counterbalancing offer of foreign money in exchange.

This article is organized as follows:

- I. Foreign exchange markets
  - Equilibrating movements
    - Arbitrage
    - Short-term movements
    - Forward exchange
  - Disequilibrating movements
    - Covering
    - Hedging
    - Speculation
  - Proposals for more flexible rates
    - Freely floating rates
    - Flexible rates with official intervention
    - Crawling peg
- II. Balance of payments accounting
  - The current account
  - The capital account
    - Long-term flows
    - Short-term flows
  - Assessing the balance
- III. Adjusting for fundamental disequilibrium
  - The classical view
  - Contemporary views
    - Monetary and fiscal measures
    - Incomes policy
    - Devaluation and revaluation
    - Trade restrictions
    - Restrictions on capital exports
- IV. International cooperation
  - The International Monetary Fund
    - Drawing rights
    - The scarce currency problem
  - Other efforts at financial cooperation
    - The Group of Ten
    - The Basel Group
    - The OECD
    - Swap agreements
- V. International reserves
  - Gold and reserve currencies
  - Special Drawing Rights
- VI. The system of floating rates
  - The crisis of the dollar
  - The Smithsonian Agreement and after

In the Soviet Union and other countries with the Soviet kind of economic planning, there are no legal markets for foreign exchange; in those countries the state has a monopoly of the business of foreign trade, which is generally conducted through formal agreements on a country-by-country basis. While the currencies of the Communist countries have official par values in terms of gold, these bear no particular relationship to their purchasing power or to the prices at which goods are exchanged. The international economic relationships of those countries therefore fall outside the scope of this article; they will be found elsewhere in discussions of international trade and economic planning.

### I. Foreign exchange markets

The  
buying and  
selling of  
currencies

A foreign-exchange market is one in which those who want to buy a certain currency in exchange for another currency and those who want to move in the opposite direction are able to do business with each other. The motives of those desiring to make such exchanges are various. Some are concerned with the import or export of goods between one country or currency area and another, some with the purchase and sale of services. Some wish to move capital from one area to the other, and some wish to make gifts (the latter including governments, emigrants, and charitable foundations).

In any organized market there must be intermediaries who are prepared to "quote a price," in this case a rate of exchange between two currencies. These intermediaries must move the price quoted in such a way to permit them to make the supply of each currency equal to the demand for it and thus to balance their books. In an important foreign-exchange market the price quoted is constantly on the move.

A foreign-exchange market usually (but not always) differs from other organized markets—*e.g.*, those for commodities or securities, in that there is a standard, government-determined price at which one currency exchanges for another, called the "parity." There is usually no parity price for a commodity such as cotton unless some special arrangement has been made. The actual price quoted in a foreign-exchange market normally deviates from the parity price within moderate limits.

As between two countries (or currency areas, when several countries use the same currency), both on the gold standard, the parity is determined by the official gold content of the respective currencies. For many centuries there was also what almost amounted to a parity between gold-standard and silver-standard currencies, because of the fact that a number of countries operated what was called a bimetallic standard, under which the value of gold was fixed by law in terms of silver. The parity between a gold-standard currency and a silver-standard currency had a slightly blurred character because of the fact that not all the bimetallic countries had identical laws in regard to the silver value of gold. Though it may be paradoxical, these laws were effective for many centuries in fixing the silver value of gold in the free markets of the world. The bimetallic system was given up by those still adhering to it (the U.S., France, Italy, Switzerland, Holland, and Belgium) in 1873. Thereafter there was no parity of exchange between countries on the gold standard and countries on the silver standard.

#### EQUILIBRATING MOVEMENTS

If the demand by those holding a particular currency, say sterling, for another currency, say the dollar, exceeds the demand of dollar holders for sterling, the dollar will tend to rise in the foreign-exchange market. Under the gold-standard system there was a limit to the amount by which it could rise or fall. If a sterling holder wanted to make a payment in dollars, the most convenient way for him to procure the dollars would be in the foreign-exchange market. But under the gold standard he had another option; *i.e.*, he had a legal right to obtain gold from the authorities in exchange for paper currency at the established par value of that currency and remit the gold to the other country, where he would have a legal

right to obtain its currency in exchange for bars of gold at the official valuation. Thus it would not be advantageous for a sterling holder to obtain dollars in the foreign-exchange market if the quotation for a dollar there exceeded parity by more than the cost of remitting gold. The foreign-exchange quotation at which it became cheaper to remit gold rather than use the foreign-exchange market was known as the "gold-export point." There was also a "gold-import point" determined on similar lines.

**Arbitrage.** Most of those seeking dollars did not undertake to remit gold even if the dollar quotation was at the gold-export point. The remission of gold was handled by arbitrageurs, who engaged in buying and selling currencies simultaneously on different exchanges in order to profit by small differences in the quoted rates. Their action would reduce the supply of sterling, since they would be selling sterling for gold to the British authorities, and increase the supply of dollars, since they would acquire dollars in exchange for gold from the U.S. authorities. The arbitrageurs would carry out these operations to the extent needed to prevent the scarcity of the dollar from raising its sterling price above the gold-export point for the U.K., and conversely. At the same time, the gold reserve of the British authorities would be diminished, and the gold reserve of the U.S. authorities increased.

Before 1931 the majority of countries were on the gold standard. In 1931 Great Britain departed from it, as did some other countries, including those of the British Commonwealth, the Scandinavian countries, and a number of others. These were countries maintaining a fixed parity of exchange with sterling.

After World War II most countries returned to what may be called a modified form of the gold standard. It resembles the gold standard in that each country establishes a legal gold valuation for its currency. This valuation is registered with the United Nations' International Monetary Fund (see below). The gold valuations serve to determine parities of exchange between the different currencies. It is also possible, as under the old gold standard, for the actual exchange quotation to deviate somewhat on either side of the official parity. There is agreement with the International Monetary Fund about the range, on either side of parity, within which a currency is to be allowed to fluctuate.

But there is a difference in the technical mode of operation. The service of the arbitrageurs in remitting physical gold from country to country as needed has been dispensed with. Instead the authorities are under an obligation to ensure that the actual exchange rates quoted within their own territories do not go outside the limits agreed upon with the International Monetary Fund. This they do by intervening in the markets of their own territories. If, for instance, the dollar is in short supply in London, the British authorities are bound to supply dollars to the market to whatever extent is needed to keep the sterling price of the dollar from rising above the agreed-upon limit. The same is true with the other currencies of the members of the International Monetary Fund who are discharging their obligations. Thus the obligation of the monetary authorities to supply the currency of any Fund member at a rate of exchange that is not above the agreed-upon limit has taken the place of the obligation under the old gold standard to give actual gold in exchange for notes.

It would be inconvenient for the monetary authorities of a country to be continually watching the exchange rates in its market of all the different currencies. Most authorities have confined themselves to watching the rate of their own currency against the dollar and supplying from time to time whatever quantity of dollars may be required. At this point the arbitrageurs come into service again. They can be relied upon to operate in such a way that the exchange rates between the various currencies in the various foreign-exchange markets are kept mutually consistent. This use of the dollar by many monetary authorities has caused it to be called the currency of "intervention."

The  
modified  
gold  
standard

The official fixing of exchange rates as limits on either side of parity, outside of which exchange-rate quotations are not allowed to fluctuate, bears a family resemblance to the gold points of the old gold-standard system. The question naturally arises why, in devising a somewhat different system, it was considered desirable to keep this range of fluctuation. In the old system it arose necessarily out of the cost of remitting gold. Since there is no corresponding cost in the new system, why did the authorities decide not to have a fixed parity of exchange from which no deviation would be allowed? The answer is that there is convenience in having a range within which fluctuation is allowed. Supply and demand between each pair of currencies will not be precisely equal every day. There will always be fluctuations, and if there were one rigidly fixed rate of exchange the authorities would have to supply from their reserves various currencies to meet them. In addition to being inconvenient, this would require each country to maintain much larger reserves than would otherwise be necessary.

**Short-term movements.** Commercial banks and other corporations involved in dealings across currency frontiers are usually able to see some (but not necessarily all) of their needs in advance. Their foreign-exchange experts will watch the course of the exchanges closely and, if a currency is weak (*i.e.*, below parity), will advise their firms to take the opportunity of buying it, even if somewhat in advance of need. Conversely, if the currency is above parity but not expected to remain so indefinitely, they may recommend postponing purchases until a more favourable opportunity offers. These adjustments under the influence of common sense and self-interest have an equilibrating influence in foreign-exchange markets. If a currency is temporarily weak, it is presumably because of seasonal, cyclical, or other factors. If on such an occasion private enterprise takes the opportunity to buy the currency while it is cheap, that tends to bring demand up to equality with supply and relieves the authorities from the need to intervene in order to prevent their currency from falling below the lower point whenever there is a temporary deficit in the balance of payments. The usefulness of such private movements of funds assumes complete confidence in the currency. (The question of deep-seated imbalances not due merely to temporary causes is deferred to a later section.)

Another equilibrating influence arises from the movements of short-term interest rates. When the authorities have to supply foreign currencies in exchange for the domestic currency, this causes a decline in the money supply in domestic circulation—unless the authorities deliberately take offsetting action. This decline in the money supply tends to raise short-term interest rates in the domestic money market. This will bring an inflow of money from abroad to take advantage of the higher rates or, what amounts to the same thing, discourage foreigners from borrowing in that country's money market since borrowing will have become more expensive. Thus, the interest-rate differential will cause a net movement of short-term funds in the direction required to offset the temporary deficit or, in the opposite case, to reduce a temporary surplus that is embarrassing to others. It must be stressed again that this interest-rate mechanism implies complete confidence that the parity will not be altered in the near future.

The helpful movement of interest rates may be reinforced by action of the monetary authorities, who by appropriate open-market operations may cause short-term interest rates to rise above the level that they would have attained under market forces and thus increase the equilibrating movement of short-term funds. The Bank of England provided the most notable example of the smooth and successful operation of this policy during many decades before World War I.

**Forward exchange.** The transactions in which one currency is exchanged directly for another are known as "spot" transactions. There can also be "forward" transactions, consisting of contracts to exchange one currency for another at a future date (*e.g.*, three months ahead)

but at a rate fixed on now. For instance, a German firm may have a commitment to pay a U.S. firm in dollars in three months' time. It may not want to take the risk that the dollar will rise relatively to the mark during the three months, so that it would have to surrender more marks in order to honour its commitment. It could of course buy the dollars right away and thus obviate this risk, but it may not have any spare cash and borrowing may be inconvenient. The firm has the alternative of buying dollars at a rate agreed upon now for which it does not have to surrender marks until three months have passed. Some firms have a regular routine procedure for covering all future commitments to be paid for in a foreign currency as soon as these are entered into. Of course, even a firm that does this may combine its routine procedure with a little judgment (*e.g.*, if there are good reasons for believing that the foreign currency will become cheaper during the relevant period). And firms with multinational commitments will vary the distribution of their assets among different currencies in accordance with changing conditions. The forward-exchange rate will, like the spot rate, be continually varying. It is not usually identical with the spot rate but in normal times has a regular relation to it. This relation is determined as follows.

Dealers in forward exchange usually balance their commitments; *e.g.*, a contract to deliver forward marks can be offset against one to deliver forward dollars, and nothing more has to be done about it. If a particular dealer cannot manage this he will be in communication with another who may be in the opposite position. It may not, however, always be possible to offset every transaction. If this is not done, the dealer must make a spot purchase of the currency—say marks—in excess demand in the forward market. If he did not do this he would risk an exchange loss on some of his forward transactions. For the purpose of evaluating the forward-exchange rate to be asked in a particular deal, it is always correct to suppose that the deal is one that cannot be offset. If the dealer has to purchase marks on the spot, he can earn the rate of interest prevailing in Frankfurt until the time comes when he has to deliver the marks. Whether this is advantageous or not depends on whether the rate of interest in Frankfurt is higher or lower than that in New York. If it is higher in Frankfurt the dealer will normally quote a rate per forward mark that is lower than the spot rate; but if the rate of interest in Frankfurt is lower, then the forward mark will normally stand above the spot mark to compensate the dealer for having to employ his liquid funds in a less remunerative market. When the relation of the forward rate to the spot rate is determined by a comparison of the short-term interest rates in the two centres in the manner just described, the forward rate is said to be at "interest parity."

The question arises as to what particular interest rates are used to calculate the interest parity. There is a variety of practice. In previous times the rate of interest on U.S. Treasury bills and the rate of interest on British Treasury bills were used to determine the interest parity of the sterling price for forward dollars. More recently the interest rates on Eurodollars and Eurosterling have been used—*i.e.*, the interest on dollar and sterling accounts held by European banks (see below).

In normal times arbitrage may be expected to hold forward rates to their interest parities. There have been times, and even rather prolonged periods, in which the forward rate for a currency has fallen below (or risen above) its interest parity. This may happen when there is a large one-way movement of funds (*e.g.*, when there is a lack of confidence in a particular currency). In some cases, such as a simultaneous multiple swapping of currencies, the arbitrager does not have to commit any funds, but in forward arbitrage funds have to be committed for a period of three months. It is true that an arbitrager who had bought three months' sterling could resell the sterling before the three months had elapsed, but if he did so he might have to accept a loss. If the one-way movement is very heavy there may be a shortage of funds available for forward arbitrage. Nonetheless the demand for for-

ward sterling has to be kept equal to the supply of it, and if there is insufficient arbitrage for this purpose then a positive profit has to appear on the purchase of forward sterling—i.e., its price has to fall below the interest parity.

If dealers in a forward currency cannot offset contracts for sale with contracts for purchase and find an excess of customers wishing to sell, the excess supply causes immediate pressure on the spot market, since arbitrageurs and others who supplement the forward demand for the weak currency must cover their positions by selling an equivalent amount spot. The only way in which the authorities can prevent an excess offer of their currency forward from causing an immediate drain on their reserves is by offering to buy it forward themselves, without simultaneously selling it spot. British authorities engaged in such operations during the period when sterling was weak, and similar operations have been conducted by other central banks in connection with the swap agreements for mutual accommodation to be described below.

The foregoing descriptions of the equilibrating movements of short-term funds do not apply when there is a serious lack of confidence that a given parity will be maintained. Occasions of lack of confidence have occurred much more frequently under the modified gold standard (International Monetary Fund) than they did under the old gold standard. The reason for this is simple. Under the old gold standard it was not expected that a country of good standing would alter the gold valuation of its currency (although in much earlier days "debasement" was common enough). A devaluation of the official gold content was regarded as not far removed from a declaration of bankruptcy, and it was assumed that a country would avoid it at all costs and in all times short of a major war or revolution. Under the International Monetary Fund this position has been altered quite deliberately. When a country's payments are in "fundamental disequilibrium," it may propose a change of parity. The reason why this remedy was proposed at the Bretton Woods Conference (1944), which set up the International Monetary Fund, was that it was thought to be better than alternative remedies, such as domestic deflation.

#### DIS-EQUILIBRATING MOVEMENTS

Whatever the merits from a long-term point of view, the idea that it is quite respectable for a country to alter the par value of its currency in certain circumstances has had disturbing effects on the movements of short-term funds—effects that may not have been clearly foreseen at the time of Bretton Woods. Such movements of funds have sometimes been very large indeed. These movements are not equilibrating, like those described in relation to a parity in which there is confidence; on the contrary, they are disequilibrating. If a currency becomes weak—i.e., if the demand for it falls below the supply—this may give rise to the idea that the authorities having the weak currency may in due course decide to devalue it, as they are perfectly entitled, under International Monetary Fund principles, to do.

**Covering.** Foreign-exchange advisers to corporations have to watch for such possibilities and should propose a readjustment of assets entailing a movement out of the weak currency. It is not necessary that there should be, on an objective assessment, a probability that the currency in question will be devalued—i.e., that there should be more than a 50 percent chance that it will be devalued. To provoke a disequilibrating movement of funds it is enough that there should be a small chance only—i.e., much less than 50 percent—that it will be devalued. In strict theory, funds should be moved out of a given currency whenever the probability that it will be devalued outweighs the cost of moving the funds (e.g., the cost of selling the suspect currency forward at a discount).

If a firm or its affiliate has foreseeable commitments to make payments in a currency other than that of the area in which it operates, it may think it wise to "cover" its position by buying the currency at once, in either the spot

or the forward market. Covering may take other forms also. If a contract to pay abroad is in the currency of the home country—i.e., the paying country—then the prospective foreign receiver of these funds will have to consider whether he should not cover his own position by selling the currency of the paying country forward. Payments in the opposite direction have also to be considered. If these are in the currency of the home country, the foreigner due to make the payment will consider whether he should cover his position by buying the currency of the home country forward. If the payment is in the foreign currency, then the firm in the home country due to receive it will consider whether to cover itself by selling the foreign currency forward. Thus, there are four main classes of covering. In normal times it is probable that not all positions are covered in these four ways, although it is not impossible that they should be.

If a suspicion arises that a particular currency, say that of the "home" country, may be devalued, then the position is radically changed. The following arguments apply in reverse to the case when it is believed that a particular currency may be valued upward. It is necessary to go through the four classes of cases. Members of the home country who normally cover their commitments to make payments in a foreign currency would clearly continue to do so. And those, if any, who do not habitually do so would be strongly advised to do so when there is a possibility that the home currency may be devalued. To take the second case—that of outward payments to be made in the home currency—the same applies: foreigners who normally sell it forward should continue to do so, and those who do not normally sell it forward would be strongly advised to do so lest the currency be devalued before the payment is made. Coming to the payments due in to the home country, in the case of those to be made in the home currency, the foreigners who normally cover themselves by buying forward or spot should be advised to cease doing so immediately, since they may get the currency cheaper before the payment has to be made. Thus in this case the fear of devaluation causes those concerned to stop covering their positions. The same applies to inward payments to be made in foreign currencies; residents of the home country would be advised to cease from such covering, since in the interval their currency may be devalued, and therefore it would be foolish to sell the foreign currency due to come in advance of payment.

Thus the prospect of devaluation may cause both additional covering and uncovering. Both types of change are adverse to the currency under suspicion. It is notable that the total value of the appropriate covering plus that of the uncovering when a currency becomes suspect is independent of the proportion of positions that are normally covered. If all positions are normally covered then the adverse effect will consist of an uncovering of about half of all positions. If all positions are not normally covered, then the adverse effect will be equal to the sum of the amount of extra covering and the amount of uncovering. The movement of funds under these heads can be very large in relation to a country's normal balance of incoming and outgoing payments. It makes no difference whether the changed action by the firms relates to the spot or to the forward markets. This is because, when there is a big one-way movement in the forward market, the whole of it is thrown, through the actions of the dealers, arbitrageurs, etc., onto the spot market.

**Hedging.** Whereas the word covering relates to payments foreseen or possible, the term hedging is used for operations related not to prospective payments but to existing assets. Thus, a non-British firm may need to have a sterling balance for an indefinite period ahead. It may think it desirable in this case to protect its position against the possibility of sterling being devalued in the near future by selling sterling forward at the existing quoted rate. If sterling is devalued before the forward contract matures, the operator will get a foreign currency—say the franc—at the old rate and can rebuy sterling at a cheaper rate. The profit that he makes recoups him for

Effect of possible devaluation

Four classes of covering

the loss in the franc value of his sterling due to the devaluation. If there is no devaluation he can renew his hedge at the date due, if sterling is still suspect, or he can terminate it without loss except for the actual cost of the hedging transaction.

An even more important use of hedging is to protect the international value of real assets such as securities, real estate, industrial buildings and plants, etc. If a non-British person conducts business and has assets in Britain, he may think it wise to protect the international value of these assets by selling a certain amount of sterling forward. A devaluation, if it occurs, will reduce the foreign-exchange value of the sterling assets; but the profit that the owner makes from selling sterling forward and buying it back at a cheaper rate will be an offset to this loss.

**Speculation.** The movements so far considered are of a precautionary nature. It is sometimes suggested, when there is a big movement of funds out of a currency, that those prompting it are actuated by some motive hostile to the suspect currency. This is usually quite wrong. Such large movements of funds are often referred to incorrectly as "speculative." This gives a false impression of what is happening. Speculation can, and often does, occur when a currency becomes suspect; but the word speculative should be confined to movements of funds made not to protect positions but purely in the hope of gain. A person may believe that the Deutsche Mark is likely to be valued upward and decide to buy Deutsche Marks, not because he has any commitments denominated in Deutsche Marks but because he wants to resell them afterward at a profit. He will probably buy the Deutsche Marks forward. Such speculation plays only a minor role in the big movements of funds in anticipation of a change of parity. It may, however, mount up very strongly in the last stages when an upward or downward revaluation has become almost certain.

A big outward movement of funds may precipitate a change of parity, desirable or undesirable in itself, simply because there are not enough reserves to finance the withdrawals. Even if the country in trouble is assisted by international credits (see below), in certain cases these may not be large enough to avert the need for devaluation. A great movement of funds from a particular country may occur because it is thought likely that it will have to devalue. There may also be a great movement into a country thought likely to value upward. The latter kind of movement will cause difficulties for other countries, since the funds must come from somewhere. This adverse effect may be concentrated on one other currency, as in the classic crisis centred on a possible upward valuation of the Deutsche Mark in November 1968, where the drain was mainly from the French franc; or it may be more widely diffused, as in the crisis of the mark in September 1969.

#### PROPOSALS FOR MORE FLEXIBLE RATES

When the inconveniences of the International Monetary Fund system, by which exchange rates can be adjusted from time to time, began to become evident, proposals were made to obtain the same result in a different way by having continuously flexible exchange rates.

If exchange rates were continually on the move, instead of being changed only on comparatively rare occasions, the movements would not provoke the large anticipatory shiftings of funds that have proved so inconvenient.

**Freely floating rates.** One proposal was to abolish any fixed parity, even a temporary one, and let rates move under the free-market influence of supply and demand, just as the prices of commodities do in an organized market. Such a system would relieve the authorities of all responsibility for interfering in the process of exchange-rate fixing and leave the whole business to market forces.

Critics argue that the system would have serious disadvantages. At any time there are likely to be discrepancies in the balance between supply and demand owing to seasonal, cyclical, and random causes. Under any system of (permanently or temporarily) fixed rates in which there is complete confidence, very small movements in a rate

cause helpful movements of funds of an equilibrating kind. On the other hand, when there is no fixed rate and no bottom limit, a small movement in the rate will not attract as large an equilibrating movement of funds. But, if there is a temporary deficit of a certain amount, as a result of the seasonal, cyclical, or random causes, some equilibrating movement is needed. To secure this under floating rates a larger downward movement will be required in order to attract the funds. Thus this system entails a larger oscillation in the actual market rate than would occur under the system in which there are fixed limits. Even if foreign-exchange advisers are able to form an objective and accurate judgment of what the long-run equilibrium rate is, an excessive oscillation will still be needed to induce the movement of funds. But such oscillations are detrimental to international trade and international investment.

Some carry the argument further. They hold that foreign-exchange advisers have shown themselves to be unduly influenced by irrelevant events and somewhat erratic in their judgment. To the extent that this might be so, still larger oscillations would be required in the actual rates to get the necessary movement of funds.

**Flexible rates with official intervention.** The idea of freely floating rates implies that the authorities will not meddle in the market. But most authorities will want to secure as much stability as possible. If there should be a downward movement that the authorities know to have been caused by some random event beyond the ken of the foreign-exchange advisers to corporations, the authorities will not want to let the foreign-exchange rate fall when they know quite well that the cause of weakness is temporary. They will naturally want to intervene to offset the special factor and to keep the exchange rate steady. If flexible rates are ever established as a regular system, it is almost certain that the authorities will insist on having the freedom to intervene when in their judgment intervention is expedient. Most experts hope that with better statistical analysis of the trends of the various magnitudes in the external balance, governments will be able to confine their interventions to offsetting temporary items and will not interfere with long-run trends as determined by underlying forces.

A notable experiment with such a system was made by the United Kingdom between 1931 and 1939. There was a high degree of official intervention. The rules of the game were that the authorities would intervene to offset imbalances due to temporary causes and also to offset movements of what came to be called "hot money," while allowing the rate to move toward its long-run natural level as determined by market forces. The experiment was too short-lived to yield many valuable lessons. The system was modified somewhat by the Tripartite Agreement in 1936 between the United States, the United Kingdom, and France, joined also by other countries, under which each authority was expected to do more to keep the rate stable than it might have been disposed to do if it had only its own interest to consider.

A flexible system on a wider international scale would require a consensus among the countries concerned as to the principles underlying the interventions and on how to diagnose an existing situation. For instance, if sterling were weak, British authorities might hold that the weakness was not due merely to temporary causes but to an underlying disequilibrium and that accordingly they should not intervene to prevent the exchange rate from going down. At the same time, Americans might take an opposite view, holding that sterling was not at present overvalued in relation to the dollar and that accordingly the British should support sterling and not let it drift downward. It would be still more difficult to get consensus among several powers; the change in the rate between two powers would affect the rates of all the others as well. While this may not be an objection in principle it would certainly be a very serious one in practice.

In the briefer period of the British experiment (1931-36), no consensus was required. The currencies of the world were then divided into two groups, those linked to

sterling and those linked to gold. There were changes in the gold value of the dollar, but these amounted to changes in parity and not to a flexible rate system. Intervention in the exchange rate between the sterling area and the gold-attached currencies was executed by the Bank of England only; the Federal Reserve System did not intervene. This was a very special system with its consequent absence of a need for consensus and is not likely to occur again. So the problem of how to obtain consensus remains.

**Crawling peg.** Members of the International Monetary Fund have a right to adjust their rates of exchange (more strictly, to adjust the gold parity of their currencies) from time to time in the event of a "fundamental disequilibrium." This is often called the adjustable peg system. The expression crawling peg has been invented to describe another possible system. With the crawling peg there would still be a parity of exchange, but the parity itself would be allowed to move from day to day, the idea being that it should not move by a large amount, possibly not by more than 2 percent a year. There would have to be an initial consensus about this figure when the system was set up, but no further consensus would be required for any change of parity within the limit. The parity on each day (or for each week) would be fixed by reference to the average market rates of a preceding period, say a year. The authorities would cease to have power over the parity but would still have the duty to intervene in such a way as to prevent the actual market rates going outside the limits on either side of the changing parity. In connection with this proposal, it has also been suggested that the band on either side of parity between the upper and lower limits should be broadened so as to give the market forces a little more scope.

Two major advantages are suggested for the crawling-peg system. First, it is maintained that the prospect of a rate change of not more than, say, 2 percent in the course of a year would obviate those massive movements of precautionary funds that have been such an inconvenience under the adjustable-peg system. Second, the authorities would be relieved of deciding about the parity and could let market forces determine the direction and, within the prescribed limits, the amount of the exchange-rate movement.

There are difficulties in this. If reliance is placed on small exchange-rate movements to get adjustment from a position of fundamental disequilibrium, the remedy will be slow working. Accordingly, monetary authorities in every country will need larger reserves than under a system with a quicker adjustment mechanism. The question also arises whether 2 percent a year is enough. Another difficulty is that a country may suddenly encounter unusual disturbances in its domestic monetary system. Financial advisers will then raise the question whether this country will not be forced by the circumstances to abandon its loyalty to the crawling-peg system and have a larger devaluation. Then all the old troubles will begin again.

A modification of the strict scheme outlined above has also been suggested, whereby the authorities would agree to a maximum rate of change in parity of, say, 2 percent a year and would agree to space out that change so as not to provoke precautionary movements of funds; but the direction and the amount of that change, subject to the limits, would be determined by the authorities and not by market forces. This would entail losing what, in the opinion of some, is a valuable feature of the strict scheme.

Whatever changes may be made in the future, there is not likely to be a return to rigidly fixed and permanent exchange rates as under the old gold standard. There are some in central banking circles who would like rates under the existing system to be moved only very occasionally and as a measure of last resort. That is a rather different concept from the one that actuated the founders of the International Monetary Fund at Bretton Woods, who thought of exchange-rate change as a measure of adjustment to be used from time to time whenever circumstances seemed to require it. The reason for not going

back to an absolutely rigid fixed-rate system is that a movement of the exchange rate, whether from time to time or continuously, is thought to be a valuable weapon of adjustment; in particular, it may prevent the need for a domestic deflation that would create a socially unacceptable level of unemployment in order to correct a deficit.

## II. Balance of payments accounting

### THE CURRENT ACCOUNT

When using balance of payments statistics it is important to understand their basic concepts. The balance of payments includes, among other things, payments for goods and services; these are often referred to as the balance of trade, but the expression has been used in a variety of ways. In order to be more specific, some authorities have taken to using the expression "merchandise balance," which unmistakably relates to trade in goods and excludes services and other occasions of international payment.

Figures for the merchandise balance often quote exports valued on a FOB basis (free on board) and imports valued on a CIF basis (including cost, insurance, and freight to point of destination). This swells the import figures relatively to the export figures by the amount of the insurance and freight included. The reason for this practice has been that in many countries the trade statistics have been based on customs house data, which naturally include insurance and freight costs for imports but not for exports. The authorities have more recently made a point of providing estimates of imports valued on an FOB basis.

Another expression, "balance of goods and services," is often used. The British, however, continue to use the term invisibles for current services entering into international transactions. For many years the "visible" balance was taken to be equivalent to exports quoted FOB and imports CIF as explained above. The British authorities have more recently instituted another linguistic usage by which the "visible" balance is equivalent to the true merchandise balance. The old usage still lingers on in the less expert literature.

And so the total current account is the balance of goods (merchandise) and services. The U.K. includes unilateral transfers among "invisibles" and in the current account. The U.S. statistics, more correctly, show them under a separate heading.

Services include such items as payments for shipping and civil aviation, travel, expenditures (including military) by the home government abroad and expenditures by foreign governments at home, interest and profits and dividends on investments, payments in respect of insurance, earnings of banking, merchanting, brokerage, telecommunications and postal services, films and television, royalties payable by branches, subsidiaries and associated companies, agency expenses in regard to advertising and other commercial services, expenditures by journalists and students, construction work abroad for which local payment is made and conversely, earnings of temporary workers such as entertainers and domestic workers, and professional consultants' fees. This list contains the more important items but is not comprehensive.

Among unilateral transfers the more important are outright aid by governments, subscriptions to international agencies, grants by charitable foundations, and remittances by immigrants to their former home countries.

### THE CAPITAL ACCOUNT

There is also the capital account, which includes both long-term and short-term capital movements.

**Long-term flows.** Long-term capital movement divides into direct investments (in plant and equipment) and portfolio investments (in securities). In the 19th century direct investment in plant and equipment preponderated. The U.K. was much the most important contributor to direct investment overseas. In the early part of the century it even contributed to the industrial development of the U.S.; later its attention shifted to South

The various kinds of payments

America, Russia, other European countries, and India. Investment in what came to be called the "Commonwealth" and "Empire," not prominent at that time, became very important in the 20th century. The other countries of western Europe also made important contributions to direct investment overseas.

The most important items of direct investment were railways and other basic installations. In early stages direct investment may help developing countries to balance their payments, but in later stages there will have to be a flow of interest and profit in the opposite direction back to the investing country. The U.K. is frequently cited as the country whose overseas investments were most helpful for developing countries because her rapidly growing population and small cultivable land area permitted her to develop large net imports of food and to run corresponding deficits on her merchandise account. The complementary surplus this generated in the developing countries from which the imports came enabled them to pay the interest and profit on British capital without straining their balances of payments.

Between World War I and World War II the U.S. began to take a more active interest in overseas investment, but this was not always well advised. After the great world slump, which started in 1929, international investment almost ceased for lack of profit opportunities.

The  
international  
capital  
market

After World War II the U.S. began to build up a leading position as overseas investor. The process accelerated in 1956 and afterward, both on direct investment and on portfolio investment accounts. This may have been partly due to the desire of U.S. firms to have plants inside the European Common Market. Other countries also found more opportunities for capital export than there had been in the interwar period. The U.K. gave special attention to the British Commonwealth.

**Short-term flows.** In this context a very important distinction must be drawn between the short-term capital that flows in the normal course of industrial and commercial development and that which flows because of exchange-rate movements. The first class of short-term capital may be thought of as going in the train of direct long-term investment. A parent company may desire from time to time to supply its branch or affiliate with working capital. There may also be repayments from time to time. The second type of short-term capital flow was described in the section on foreign exchange. When there is confidence in a parity, these flows are normally equilibrating—i.e., they tend to offset a surplus or deficit on other accounts. But when there is lack of confidence in the maintenance of a parity large disequilibrating flows occur, as has already been described.

**Eurocurrency markets.** An international capital market developed in the 1960s dealing in what are known as Eurocurrencies, of which much the most important is the Eurodollar. The prefix Euro is used because initially the market largely centred on the countries of Europe, but it has by no means been confined to them. Japan and the Middle Eastern oil states have been important dealers. While these short-term lendings normally move across national frontiers, they do not enter directly into balances of payments as they do not directly involve foreign exchange transactions. They may, however, indirectly cause such transactions to take place.

The nature of the market is as follows: In the ordinary course of affairs, an Italian, for example, acquiring dollars—say from exports or from a legacy—would sell these dollars for his own currency. But he may decide to deposit the dollars at his bank instead, with an instruction not to sell them for cash but to repay him in dollars at a later date. Thus the bank has dollars in hand and a commitment to pay them out in, say, three months. It may then proceed to lend these dollars to another bank, anywhere in the world. Since the lending and borrowing is done in dollars, no foreign exchange transaction is directly involved. The sum total of all operations of this sort is the Eurodollar market. It is not centred on any particular place and has no formal rules of procedure or constitution. It consists of a network of deals conducted

by telephone and telex around the world. U.S. residents themselves lend to and borrow from this market.

One may ask why lenders and borrowers use this market in preference to more conventional methods of lending and borrowing. Ordinarily the answer is because they can get more favourable terms, since the market works on very narrow margins between lending and borrowing rates. This involves expertise; London has played the most important part in the creation of the market. The lender hopes to get a better rate of interest than he would on a time deposit in the U.S. (restrictions limiting interest payable on U.S. time deposits are said to have been a contributing cause of the growth of the market). At the same time, normally, the borrower will find that he has to pay a lower rate than he would on a loan from a commercial bank in the U.S.

This has not always been the case. In 1969 Eurodollar interest rates went to very high levels. One reason for this was the set of restrictions imposed by the U.S. on its commercial banks lending abroad. The second was that although the prime lending rates of the principal U.S. banks might be below Eurodollar rates, many individuals, including U.S. citizens, found that they could not get loans from their banks because of the "credit squeeze."

Because this form of international lending does not involve the sale of one currency for another, it does not enter into balances of payments accounts. Nonetheless it may have a causal effect on the course of the exchanges. For instance, the Italian cited above might have chosen to sell his dollars had he not been tempted by the more attractive Eurodollar rate of interest. In this case, the market causes dollars not to be sold that otherwise would have been. Others who have liquid cash at their disposal for a time may even *buy* dollars in order to invest them in the market at short term. That would be helpful to the dollar. There are countercases. An individual who has to make a payment in dollars but lacks cash may borrow the dollars in the Eurodollar market, when otherwise he would have got credit in his own country and used that to buy dollars; in this case the market is hurtful to the dollar because its existence prevents someone from buying dollars in the regular way.

#### ASSESSING THE BALANCE

To summarize, the overall balance of payments comprises the current account (merchandise and services), unilateral transfers (gifts, grants, remittances, etc.), and the capital account (long-term and short-term capital movements). If payments due in exceed those due out, a country is said to be in overall surplus; and when payments due out exceed payments due in, it is in overall deficit. The surplus or deficit must be balanced by a monetary movement in the opposite direction, and consequently the overall balance including monetary movements must always be equal.

In practice, great difficulties have been found in assessing whether a country is in deficit or in surplus. It is often important to establish this with a view to possible corrective measures. The U.K. lays chief stress on the combined balance of current and long-term capital account—i.e., excluding short-term capital. This may be the best plan. Such a balance, however, omits short-term movements that occur in the ordinary course of business, which may be called "normal" and which ought in principle to be included. On the other hand it is not desirable to include equilibrating or disequilibrating capital movements of the kind referred to above. These occur in consequence of a deficit (or surplus), actual or anticipated. But there may be great statistical difficulty in distinguishing between the normal short-term capital flows and those that are consequential on a surplus or deficit.

It has been noted that the overall balance, including monetary movements, must be equal, but it usually happens that the figures do not quite balance. United States statisticians call the residual figure that has to be inserted to square the account "errors and omissions." If the average value of this figure over a substantial period,

Deficit  
or surplus

such as ten years—an even longer period may have to be taken if a country is in persistent surplus or deficit—has a positive or negative value of substantial amount, then it may be taken to constitute genuine items that have escaped the statistical net. These may legitimately be included in assessing whether a country is in genuine surplus or deficit and whether corrective measures are needed.

The “errors and omissions” item is extremely volatile from year to year and often very large. Such movements up and down are probably caused by precautionary short-term capital movements. There have been periods when a minus item in the U.S. account was rather strikingly associated with a plus item in the U.K. account, and conversely. Accordingly, in the short term, the “errors and omissions” item should not be included in assessing whether a country is in surplus or deficit.

It has been noted that the U.K. lays chief stress on the balance of current and long-term capital accounts (which include unilateral transfers). The U.S. position is less clear. The official balance, published every quarter by the Department of Commerce, is called the “Commerce Balance” or the “Liquidity Balance.” Recently stress has also been laid on what is called the “Official Settlements Balance.”

In distinguishing between monetary and nonmonetary items, the Commerce Balance includes any increase in the holding of short-term dollar securities abroad as part of the U.S. deficit during the period; but it does not include as counterweight any increase in short-term foreign claims held by U.S. resident banks or others (apart from official holdings). Thus in this respect the treatment is asymmetrical. The rationale for this is precautionary. The argument is that short-term dollar assets held abroad outside the central banks may at any time be sold in the market or turned in to the central banks of the respective countries and thus constitute a drain, or the threat of a drain, on the U.S. reserves. On the other hand the corresponding foreign short-term assets held by U.S. resident banks or others are not readily mobilizable by the U.S. authorities for making payments. Thus by this reckoning, if during a period non-central-bank foreign holdings of short-term dollar securities and resident non-central-bank U.S. holdings of short-term foreign securities went up by an equal amount, the situation would be shown as having deteriorated, since the former class (liabilities) are a threat to the U.S. reserve, while the latter class (assets) cannot be mobilized by the U.S. authorities to meet such a threat. Thus, though the motive for this asymmetrical treatment may be understandable, it is statistically unsatisfactory and also unsatisfactory as a guide to corrective action.

The U.S. Official Settlements Balance reckons an increase in non-central-bank foreign holdings of short-term dollar assets as an inflow of short-term capital into the U.S.; similarly an increase in U.S. resident holdings of short-term foreign assets is an outflow of short-term capital. This is a logical treatment. But the balance thus defined proved in the 1960s to be extremely volatile. This was due to large movements of funds between foreign central banks and non-central-bank foreign holders, associated with the rise of the Eurodollar market. Oscillations of this kind do not represent changes in the fundamental balance that are needed in order to determine whether corrective measures are required. It may well be that the British method of omitting short-term capital movements altogether in the assessment of surplus or deficit is, although imperfect, the most practical available.

### III. Adjusting for fundamental disequilibrium

Reference has been made to the Articles of Agreement of the International Monetary Fund, which permit a nation in “fundamental disequilibrium” to alter its exchange parity. A “fundamental disequilibrium” exists when outward payments have a continuing tendency not to balance inward payments. The sum total of payments going each way depends on such matters as the competitive-

ness of the country's prices for tradable goods, profit prospects abroad (encouraging capital to flow outward) and profit prospects at home (which may attract foreign capital), past events such as international investments on which interest and profit and perhaps repayments are continuing to accrue, the provision by the home country of services abroad and by foreign countries of services at home, the flow of gifts, etc.

Taking equilibrium as a starting point, a disequilibrium may occur for various reasons. Some may be grouped under the head of structural change (resulting from changes in tastes, habits, institutions, technology, etc.). Or a fundamental imbalance may occur if wages and other costs rise faster in relation to productivity in one country than they do in others. Imbalance may also result when aggregate demand runs above the supply potential of a country, forcing prices up or raising imports. A war may have a profoundly disturbing effect on a country's economy.

#### THE CLASSICAL VIEW

In the traditional “classical” view no intervention by the authorities was necessary to maintain external equilibrium, except for their readiness to convert currency into gold (or silver) upon demand. The system was supposed to work automatically. If a country had a deficit, gold would flow out, and the consequent reduction in the domestic money supply would cause prices to move downward. This would stimulate exports and tend to reduce imports. The process would continue until the deficit was eliminated. Classical doctrine did not embody a clear-cut theory about international capital movements. It was usually assumed that the trade balance (more strictly, balance on goods and services) would be tailored to accommodate any capital movement that occurred. Thus, if the country was exporting capital, gold flows would cause prices to move to such a level that exports minus imports would be equal to the capital flow; equilibrium in the overall balance was automatically secured.

In due course the classical scheme of thought came under criticism. Would an outflow or inflow of specie necessarily have a sufficient effect on the price level to ensure an equal balance of payments eventually? More important, might not a reduction in the money supply have a side effect on the level of economic activity? A critic might go further and argue that this side effect would be stronger than the effect on prices to such a degree as to cause unemployment to rise to an undesirable level. The criticism was carried still further by the argument that the whole system was undesirable if in its necessary working it caused bouts of severe unemployment from time to time. The last-mentioned point is especially associated with the name of Keynes, whose writings helped to shake the almost universal belief that an automatic gold standard was the ideal system.

#### CONTEMPORARY VIEWS

**Monetary and fiscal measures.** The belief grew that positive action by governments might be required as well. The doctrine was first related to monetary policy in particular. The idea was that interest-rate adjustments should be combined with open-market operations by a central bank to ensure that the domestic money supply and borrowing facilities were conducive to external long-period equilibrium. After World War II the idea came to be widely held that government budget policy (usually called fiscal policy) should be brought in to assist monetary policy. For instance, if aggregate domestic demand was running so high as to cause rising prices, this should be reduced both by having a tight monetary policy and by increasing taxation more than expenditure or reducing expenditure without reducing taxation. The correct apportionment of this task between the monetary and fiscal arms is still a subject of discussion.

Nor is there yet agreement about the scope of these policies or their ability to secure fundamental equilibrium in all cases. There is probably agreement that when overall demand is running in excess of the supply potential of

From  
laissez-  
faire to  
intervention

the economy, it should be reduced by monetary and fiscal policies. There is difference of opinion as to whether the reduction of aggregate demand will bring external payments into balance in all cases. For instance, a country may have a deficit owing to some underlying economic change (such as a shift in the pattern of world trade), even if domestic demand is not above the supply potential and prices are not rising. In this case, policies designed to reduce domestic demand (commonly called deflationary policies) would cause unemployment. Some hold that, if there is an external deficit, deflationary policies should be pursued to whatever extent may be needed to eliminate that deficit. Others hold that such a policy is socially unacceptable.

The varieties of governmental action

Opinions differ also about how deflationary measures work to improve the external balance. Some hold that they work mainly by reducing domestic activity and thereby the amount of imported materials that a country needs and the amount of income that people can afford to spend on imported goods. If this were the whole effect of a deflationary policy, it would improve the external balance only in proportion to the amount by which it increased unemployment. Those who hold that this is the only manner in which deflation affects the external balance are especially opposed to relying on deflationary policies alone to eliminate a deficit in conditions in which aggregate domestic demand is not running above the supply potential. Some hold that a reduction of home demand also helps because it makes producers look around more eagerly for export markets (and increase their selling efforts in the home market). This appears to be doubtful. There is further disagreement on the extent to which deflationary policies influence the course of prices. If aggregate demand is running above the supply potential of the economy, it is highly probable that deflationary policies will slow the increase of prices and thus make a country more competitive with foreign suppliers. There is not the same agreement about the effects when demand is initially running below the supply potential of the economy. Some hold that a deflationary policy, if pushed hard enough, will infallibly slow up price increases and so help the country's external balance. Others hold that it will not, and some even argue that higher interest rates and higher taxes (weapons of deflation) could cause prices to rise. Thus it is not absolutely clear that monetary and fiscal policies will in all cases suffice to cure an external deficit, at least without socially unacceptable results.

There is also the opposite case of countries with a trade surplus. It is clear that these countries will be unwilling to encourage policies that cause domestic prices to rise. Price inflation is a social evil and politically unpopular.

In the case of surplus countries, the same distinction must be made between the situation in which aggregate demand is fully up to or above the supply potential of the economy and that in which it is not. In the former case a further increase in demand would almost certainly have an inflationary effect; accordingly, surplus countries in this condition will be unwilling to use monetary and fiscal policies to eliminate their external surpluses. On the other hand, if aggregate demand is running below supply potential, then a surplus country might reasonably be asked to increase aggregate demand by monetary and fiscal policies on the view that the increase will not cause inflation but will tend to remove the external surplus by inducing more imports and possibly causing producers to be less active in their selling efforts abroad.

**Incomes policy.** Prices may be rising in a country even when aggregate demand is not in excess of the supply potential. This may be due to increases of wages and other factor incomes in excess of productivity increases. Some hold that this could be dealt with by monetary and fiscal policies designed to increase unemployment. Alternatively, efforts have been made to discourage excessive wage increases by a direct approach. This may consist of a campaign of education and propaganda on the evil effects of wage-price inflation, together with what are called "guideposts" or "guidelines" as to the maximum average rates of wage increases consistent with

price stability. The matter can be carried further with legal sanctions against excessive wage increases. The attempt to deal with the problem directly in this way is generally known as "incomes policy." Efforts made in this direction so far have not had very marked results.

**Devaluation and revaluation.** Exchange-rate movements have already been discussed. For this purpose they might be effectuated either by a more frequent use of the "adjustable peg," as now allowed in the constitution of the International Monetary Fund, or by the adoption of flexible exchange rates. The weapon would work by making the products of a deficit country more price competitive or those of a surplus country less price competitive.

Any program (including an incomes policy) that seeks to rectify an imbalance by changing the level of prices will be effective only if demand is "price elastic." In other words, if the offer of an article at a lower price did not cause an increase in demand for it more than in proportion to the fall in price, the proceeds from its export would fall rather than increase. Economists believe that price elasticities are sufficiently great for most goods so that price reductions will increase revenues in the long run. The outcome is not quite so certain in the short run.

A much faster means of changing relative price levels is devaluation, which is likely to have a quick effect on the prices of imported goods. This will raise the cost of living and may thereby accelerate demands for higher wages. If granted, these would probably cause rises in the prices of domestically produced goods. A "wage-price spiral" might follow. If this went too quickly it might frustrate the intended effect of the devaluation, namely that of enabling the country to offer its goods at lower prices in terms of foreign currency. This means that if the beneficial effects of a devaluation are not gathered in quickly, there may be no beneficial effect at all.

The authorities of a country that has just devalued will therefore be especially active in preventing or moderating domestic price increases. They will need to use the other policy measures already discussed. Devaluation (or the downward movement of a flexible rate) is thus not a remedy that makes other forms of official policy unnecessary. Some have argued that if exchange rates were allowed to float, nothing further would have to be done officially to bring the external balance into equilibrium. This is a minority view.

One further point must be made regarding the exchange-rate weapon. It has been found in practice that governments resist upward valuation more than they do devaluation. Devaluations have in fact been larger and more frequent than upward valuations. This has an unfortunate consequence. It means that the aggregate amount of price inflation in deficit countries resorting to devaluation as a remedy will not be offset by equivalent price decreases in the surplus countries. Therefore this system, if more strongly resorted to, would have a bias toward worldwide inflation.

An exception to this must be made for the "crawling peg." Logically that system would produce in the world as much upward valuation as downward valuation and therefore as much tendency for prices to fall as for prices to rise, at least to the extent that price movements are affected by exchange-rate movements.

**Trade restrictions.** Since World War II the major industrial countries have attempted to reduce interferences with the free flow of international trade. This policy, by extending the international division of labour, should increase world economic welfare. An exception has had to be allowed in favour of the less developed countries. In the early stages of the development of a country, the effectiveness and feasibility of the three types of adjustment mechanism already discussed, particularly the all-important monetary and fiscal policies, may be much less than in the more advanced countries. The less developed countries may therefore be driven to protection or the control of imports, for lack of any other weapon, if they are to stay solvent. It has already been noted that, even in the case of a more advanced country, the effectiveness and appropriateness of the above-men-

tioned adjustment mechanisms are not always certain. Thus, there is no certainty that some limitation on foreign trade and on the international division of labour may not be a lesser evil than the consequences that might follow from a vigorous use of the other adjustment mechanisms, such as unemployment.

**Restrictions on capital exports.** Interference with capital movements is generally considered a lesser evil than interference with the free flow of trade. Thus in 1964 the U.S. imposed an "Interest Equalization Tax" (on investment in foreign portfolio securities) and restraints on direct capital investment abroad. The theory of the optimum international movement of capital has not yet been thoroughly developed, but there may be a presumption in favour of absolutely free movement. The matter is not quite certain; for instance, it might be desirable from the point of view of the world optimum to channel the outflow of capital from a high-saving country into the less developed countries, although the level of profit obtainable in other high-saving countries might be greater. Or it might be expedient to restrain wealthy individuals in less-developed countries, where domestic saving was in notably short supply, from sending their funds to high-saving countries.

While there may be good reasons for interfering with the absolutely free international flow of capital in certain cases, it is not obvious that the outflow of capital from, or inflow of capital into, a country should be tailored to surpluses or deficits in current external accounts. It may be that in some cases the sound remedy for a deficit (or surplus) is to adopt adjustment measures such as those referred to above, bearing upon current items, rather than taking the easier way of adjusting capital movements to the de facto balance on current account.

#### IV. International cooperation

##### THE INTERNATIONAL MONETARY FUND

The International Monetary Fund, founded at the Bretton Woods Conference in 1944, is the official organization for securing international monetary cooperation. It has done most useful work in various fields, such as research and the publication of statistics and the tendering of monetary advice to less developed countries. It has also conducted valuable consultations with the more developed countries, and it has helped to introduce more order into currency movements and exchange relations than obtained, for instance, after World War I.

**Drawing rights.** Of particular interest to this discussion is the Fund's system of Drawing Rights, which permits countries in temporary deficit to draw supplies of foreign currency according to predetermined quotas. These extra supplies of currency give a country more time in which to adjust its balance of payments and so avoid taking unsound or unneighbourly measures like import restrictions for lack of enough reserves to tide it over a difficulty. The mechanism is as follows. Members of the Fund—now numbering over 100—are required to make initial deposits according to their quotas, 25 percent in gold and 75 percent in their own currencies. The Fund makes its stock of members' currencies available to member countries that wish to draw upon their quotas. When creditor countries are presented with their own currencies previously deposited by them with the Fund, they are obliged to take them in final discharge of debts owed by other member countries. Since they previously deposited these currencies themselves they are in effect getting nothing from the debtor countries in respect of the debts owed to them, and their willingness to accept payment in this way is their contribution to the overall liquidity of the world system. Later the creditor countries may themselves become debtors and partake of the benefits. The debtors, who in a sense are getting something for nothing, have to repay the Fund usually in three to five years.

The exercise of Drawing Rights is subject to discussion and sometimes to conditions, except for drawings on what are called the gold tranches—i.e., sums equal to the members' original deposits of gold—which are given "the overwhelming benefit of the doubt." Countries are also

free to draw without discussion up to the net amount to which they have previously been drawn upon by other countries.

The International Monetary Fund as it finally emerged from the wartime discussions was a much more modest undertaking than had originally been conceived by the British. An early British proposal would have required creditor countries to receive payment in paper money up to the total amount of all the quotas of all the debtor countries. This seemed to many to be more than it was fair to ask creditors to do. The U.S. claimed that for a number of years after the war it was likely to be in credit against the whole of the rest of the world, and so it was. Under the British plan they would have had to give an unconscionably large amount of credit, with no certainty of repayment. At that time it did not seem at all likely that the U.S. would ever go into deficit at a later date, which, of course, it did.

**The scarce currency problem.** The arrangement was bound to create difficulties should the debtor-creditor position among member countries be lopsided. The sum total of the quotas of the countries in debit might exceed the sum total of the quotas of the countries in credit. The debtor countries, having paid gold into the Fund and undertaken certain obligations, would naturally have the right, subject to discussions and to convincing the Fund that they would in due course put their houses in order, to draw the whole amount of their quotas as needed. But if the position was lopsided—e.g., if the sole creditor country was the U.S.—the Fund would not have enough dollars to satisfy the Drawing Rights of all the debtor countries. To meet this difficulty the "scarce currency" clause (article 7) was devised. If any country should become an overwhelming creditor, so that the supply of its currency available to the Fund became exhausted, this currency would be declared "scarce." The debtor countries would then have the right to discriminate in their monetary and commercial policies against the country in question. Thus the debtor countries would be able to maintain full trading relations with each other, while confining their restrictions to dealings with the creditor. This seemed a sensible arrangement.

But the scarce currency provision has not been applied. In the early postwar years the U.S. met the situation by giving "Marshall Plan Aid" on a generous scale and thereby relieving the world dollar shortage. Later, toward the close of the 1950s, the position was reversed and some countries of continental Europe became heavy creditors. But by this time the scarce currency clause had become ideologically unacceptable. Great efforts had been made to get rid of all forms of discrimination in international dealings, and it would have been thought objectionable to revive discrimination under this clause. Furthermore, many nations had in the meanwhile dismantled the administrative machinery needed for such discrimination. The difficulty would have to be met in another way.

##### OTHER EFFORTS AT FINANCIAL COOPERATION

**The Group of Ten.** During 1961 there were signs of a crisis. The U.S. had been running a heavy deficit since 1958, and the U.K. plunged into one in 1960. It looked as if these two countries might need to draw upon continental European currencies in excess of the amounts available. Per Jacobsson, then managing director of the International Monetary Fund, persuaded a group of countries to provide standby credits amounting to \$6,000,000,000 in all, so that supplementary supplies of their currencies would be available. The plan was not confined to the countries that happened to be in credit at that time but was extended to other important countries, the currencies of which might run short at some future time. This plan was known as the "General Arrangements to Borrow." The adhering countries were ten in number: the U.S., the U.K., Canada, France, Germany, Italy, The Netherlands, Belgium, Sweden, and Japan. They became known as the "Group of Ten."

The arrangement was subject to the agreement that

The  
heritage of  
Bretton  
Woods

Problems  
of the  
1960s

countries actually supplying additional currency would have the right to take cognizance of how the Fund used it. This put them in a power position as against the International Monetary Fund itself. Since then the Group of Ten has worked together in deliberating on international monetary problems.

At the meeting of the International Monetary Fund in 1963 the idea was put forward that some reform would be needed in the international monetary system, especially by way of increasing liquidity, and the Group of Ten was asked to give this consideration. It was felt that before any new plan was proposed, prior agreement of the Group of Ten would be essential. After four years of discussion, the Group of Ten devised the "Special Drawing Rights" proposal adopted by the International Monetary Fund at the Rio de Janeiro meeting in 1967 (see below).

The dominant position gained by the Group of Ten has been due not only to their provision of standby credit but also to the manner in which they do their business. The ultimate authority of the Group resides in the finance ministers of the countries concerned, who meet from time to time. Their deputies meet more frequently for detailed work on particular problems. These deputies consist of high-ranking persons in their respective treasuries and central banks; they are resident in their own countries and have day-to-day knowledge of their problems and of what is politically feasible. In this respect they are in a much more advantageous position than the executive directors of the International Monetary Fund, who live in Washington, D.C., and have less contact with their home governments; they also tend to be persons of higher standing and authority.

**The Basel Group.** In 1930, a Bank for International Settlements was established at Basel; its main duty was to supervise and organize the transfer of German reparations to the recipient countries. This "transfer problem" had caused much trouble during the 1920s. There may also have been a hope in the minds of some that this institution might one day develop into something like a world central bank.

Not long after it was set up the Germans gained a moratorium on their reparations payments. By then, however, the Bank for International Settlements had become a convenient place for the heads of the European central banks to meet together and discuss current problems. This practice was resumed after the war, and the U.S., although not a member, was invited to join in the deliberations.

When Marshall Plan Aid was furnished by the U.S. to help European countries in their postwar reconstruction, a European Payments Union was established to facilitate multilateral trade and settlements in advance of the time when it might be possible to re-establish full multilateralism on a world scale. The war had left a jumble of trade restrictions that could not be quickly abolished. The European Payments Union also contained a plan for the provision of credit to European debtors. The U.K. was a member, and with it was associated the whole sterling area. Responsibility for working the machinery of the European Payments Union was assigned to the Bank for International Settlements. The European Payments Union was ultimately wound up after the countries of Europe were able to eliminate the last restrictions and make their currencies fully convertible in 1958.

In January and February 1961 there was a serious sterling crisis, due partly to the British deficit of 1960 and partly to a large movement of funds in anticipation of an upward valuation of the German mark, which happened, and thereafter in anticipation of a second upward valuation, which did not happen at that time. To help the British, the Basel Group of central banks provided substantial credits. These were liquidated when the U.K. transferred its indebtedness to the International Monetary Fund the following July. The Basel Group has provided further credits from time to time. The problems involved have continued to be discussed at the monthly meetings.

Special mention should be made of an arrangement for the support of the sterling area in 1968. After the devaluation of sterling in 1967 it was feared that the monetary

authorities of the countries composing the sterling area might wish to reduce their holdings of sterling. As there was a continuing problem of world liquidity and sterling played an important part as a reserve currency, the international consensus was that any substantial reduction in the holding of sterling as a reserve currency would be damaging to the international monetary system. Under the arrangement made in 1968 the U.K. on its side agreed to give a dollar guarantee to the value of the greater part of the sterling-area reserves; there were slightly different arrangements with each monetary authority. On its side the Bank for International Settlements agreed to organize credits to finance payments deficits for some countries of the sterling area, should these occur at times when the U.K. might find it difficult to handle them.

**The OECD.** A body known as the Organization for European Economic Co-operation was set up in 1948 to make arrangements for the distribution of Marshall Aid among the countries of Europe. When its tasks in this connection were accomplished, it remained in existence, was broadened to include the U.S., Canada, and Japan, and was renamed the Organization for Economic Co-operation and Development. It has a permanent staff and headquarters in Paris. It undertakes research on a substantial scale and affords a forum for the discussion of international economic problems. Special mention should be made of Working Party No. 3 of its Economic Committee, which is concerned with problems of money and exchange; at times the personnel of the Working Party has been much the same as that of the deputies of the Group of Ten. It issued a very important report on balance of payments adjustment problems in 1966. The Organization for Economic Co-operation and Development has also set up an organization called the Development Assistance Committee, concerned with problems of assistance to the developing countries.

**Swap agreements.** The informal system of swap agreements provides a mutual arrangement between central banks for standby credits designed to see countries through difficulties on the occasions of large movements of funds. These are intended only to offset private international flows of capital on precautionary or speculative account, not to finance even temporary deficits in countries' balance of payments. Arranged ad hoc and informally, they depend on the mutual goodwill and trust of the central banks involved. The system of credits, although informal, must be reckoned as important, since they are of large amount. For instance, in 1973 the U.S. had swap credits amounting to \$18,000,000,000.

Events may move in the future in one of two different ways. Some hold that the mutual swap system should be formalized and rendered permanent. In this form it would constitute an international arrangement of even greater importance than the International Monetary Fund itself. But it has to do only with large-scale precautionary and speculative movements of short-term private capital. And so the problem resolves itself into the question whether these large private movements must be expected to be a permanent feature of the international monetary world. If skillful craftsmanship (e.g., the substitution of a more flexible official exchange-rate system for the "adjustable peg") can produce a state of affairs in which large flows cease to occur, then the provision of mutual standby swap credits will no longer be needed.

(R.F.H.)

## V. International reserves

### GOLD AND RESERVE CURRENCIES

Gold remained the most important medium available to the monetary authorities for international settlements in the 1960s, but the quantity of gold available declined as a proportion of international reserves. The founders of the International Monetary Fund had intended that the currencies of members should have a fixed value in gold to be altered only on occasions of official change of parity. The provisions of the International Monetary Fund, however, were not sufficient to secure this. It was necessary for governments with reserves of gold to intervene in the market to maintain the gold value of major

Working  
Party  
No. 3

Inter-  
vention  
to maintain  
gold value

currencies at par. In the 1950s the British did this through the London gold bullion market. In the autumn of 1960, lack of confidence in the dollar developed, and financial advisers recommended the conversion of dollars into gold on a rather substantial scale. The result was a supernormal demand for gold in the London market, and the British had to turn to the U.S. for assurance that they would be reimbursed in gold for the dollars acquired in the process of holding down the gold price. The result of this was burdensome to the U.S., since dollars were by no means the only currency converted into gold. The British authorities acquired dollars because the dollar was the "currency of intervention." It seemed unfair that the U.S. should lose gold in respect of the total flight out of currencies, dollars or others. Accordingly, an arrangement was made for setting up what became known as the gold pool. It was agreed that when the British, to hold the price of gold down, had to sell it in the London market, the members of the gold pool would reimburse them for the gold lost. For several years this prevented a rise in the price.

In March 1968 there was a loss of confidence in the dollar of even larger dimensions. This was attributable partly to the continuing U.S. trade deficit and partly to doubts arising from the devaluation of sterling in the preceding November. The demand for gold became so great that the authorities decided to close the gold bullion market in London; when it reopened, no further attempt was made to hold down the price of gold. The gold pool arrangement came to an end. At the same time the former members of the gold pool agreed that their central banks would continue to exchange gold against currencies held by other central banks at the official rate. The result was the "two-tier system," in which gold circulated among central banks against currencies at the official valuation but usually circulated in free markets at a higher valuation. It lasted until November 1973, when the countries that had established it agreed to terminate it.

#### SPECIAL DRAWING RIGHTS

By the 1960s the limitations of the world's reserves of gold, sterling, and dollars had become painfully apparent. To resolve this difficulty, a new kind of reserve called Special Drawing Rights (SDR's) was devised by the International Monetary Fund. Members of the fund were to be allocated SDR's, year by year, in prearranged quantities, to be used for the discharge of international indebtedness. At the IMF meeting in 1969, agreement was reached for an issue extending over three years. These Special Drawing Rights differed from ordinary Drawing Rights in three important respects: (1) The use of Special Drawing Rights was not to be subject to negotiations or conditions. (2) There was to be only a very much modified form of repayment obligation. A member who used more than 70 percent of all the Special Drawing Rights allotted to him in a given period had to repay to the extent needed to reduce his average use of the rights during that period to 70 percent of the total. Thus 70 percent of all Special Drawing Rights issued could be thought of as reserves in the fullest sense, since a member who limited his use to this amount would have no repayment obligation. (3) In the case of Drawing Rights, the fund uses currencies as subscribed by members to provide the medium of payment. By contrast, the Special Drawing Rights were to be accepted in final discharge of debt without being translated into any particular currency. This should obviate the need for anything like the General Arrangements to Borrow. Though currencies would have to be subscribed by members receiving Special Drawing Rights, these would be in the background and would not be used, except in the case of a member in net credit on Special Drawing Rights account who wished to withdraw from the scheme.

#### **VI. The system of floating rates**

##### THE CRISIS OF THE DOLLAR

The international monetary system established at the Bretton Woods Conference in 1944 underwent profound

changes in the 1970s. This system had assumed that the dollar was the strongest currency in the world because the United States was the strongest economic power. Other countries were expected to have difficulty from time to time in stabilizing their exchange rates and would need assistance in the form of credits from the International Monetary Fund, but the dollar was expected to remain stable enough to function as a substitute for gold in international transactions. In the second half of the 1960s these assumptions came into question. The war in Vietnam led to an inflation that produced enormous deficits in the U.S. balance of payments and ultimately forced devaluation of the dollar. In 1970 the U.S. balance of payments deficit was almost \$10,000,000,000. The flood of dollars into other countries caused difficulty for the European central banks, which were forced to increase their dollar holdings in order to maintain their currencies at the established exchange rates. As the flood continued in 1971, the West German and Dutch governments decided to let their currencies float—that is, to let their exchange rates fluctuate beyond their assigned parities. Austria and Switzerland revalued their currencies upward in relation to the dollar. These measures helped for a time, but in August the outflow of dollars resumed, and on August 15 Pres. Richard M. Nixon formally suspended what remained of the U.S. commitment made in 1934 to convert dollars into gold. This ended the postwar monetary system established at the Bretton Woods Conference. Most of the major trading countries decided to abandon fixed exchange rates and let their currencies find their own values in relation to the dollar.

End of  
Bretton  
Woods  
system

##### THE SMITHSONIAN AGREEMENT AND AFTER

On December 17 and 18, 1971, representatives of the Group of Ten met at the Smithsonian Institution in Washington and agreed on a realignment of currencies. The dollar was devalued in terms of gold, while other currencies were appreciated in terms of the dollar. On the whole, the dollar was devalued by nearly 10 percent in relation to the other Group of Ten currencies (those of the U.K., Canada, France, West Germany, Italy, The Netherlands, Belgium, Sweden, and Japan).

Several months after the Smithsonian Agreement, the six members of the European Economic Community (EEC) agreed to maintain their exchange rates within a range of 2.25 percent of parity with each other, by means of purchases and sales of each other's currencies. This arrangement came to be known as "the snake in the tunnel"—the tunnel being the wider range of 4.5 percent permitted under the rules of the International Monetary Fund.

The Smithsonian Agreement proved to be only a temporary solution to the international currency crisis. A second devaluation of the dollar (by 10 percent) was announced in February 1973, and not long afterward Japan and the EEC countries decided to let their currencies float. At the time, these were thought of as temporary measures to cope with speculation and to prevent great shifts of capital from one currency to another. In fact, however, it was the end of the system of established par values. Throughout the rest of the decade the major currencies continued to float, their exchange rates being determined by the course of events from day to day or year to year. The quadrupling of the price of petroleum at the end of 1973, followed by the deepest recession since the 1930s together with a prolonged inflation, made a return to fixed par values impossible. Instead, the finance ministries and central banks began to seek ways of making the system of floating rates manageable.

Much of the work involved in learning to live with the system of floating rates was carried on by financial specialists meeting in various national capitals. The most important group was the Committee of Twenty, set up by the International Monetary Fund, which held its first meeting in September 1972 and concluded in June 1974 with an Outline of Reform. It proposed a system of "stable but adjustable par values," with occa-

Drawing  
Rights

sional use of floating rates. The Special Drawing Rights would become the principal reserve asset, while gold and the dollar would play a reduced role.

In November 1975 the heads of government of France, West Germany, Italy, Japan, the U.K., and the U.S. met at the Château de Rambouillet near Paris to discuss monetary and economic questions. The meeting represented a compromise between French and American views on the exchange rate mechanism. The French had favoured an early return to stable par values, while the Americans had wanted to preserve the right of countries to let their currencies float. The two countries agreed to add to the Articles of Agreement of the IMF a provision that would permit currencies to float if the situation required it. The turbulent character of the exchange markets in ensuing years made a return to stable par values seem remote.

## Excretion, Human

Excretion, the elimination of the waste products of metabolism and the removal of surplus substances from the tissues of the body, is performed by several organs. The lungs excrete carbon dioxide and water. The skin gives off water, salts, and a little urea. The intestines excrete some water along with the dietary residues and bacteria (see EXCRETION AND EXCRETORY SYSTEMS; SKIN, HUMAN; RESPIRATION, HUMAN). Most of the remaining excretion is through the urine, the product of the excretory system, consisting of the kidneys, the ureters, the bladder, and the urethra. The present article is concerned with the functioning of this system.

The ureters, urethra, bladder, and the collecting tubules

and renal pelvis of the kidney function primarily as passageways or storage units for the urine that is produced by the nephrons, the 1,000,000-1,250,000 functioning units of each kidney. Each nephron consists of a glomerulus—a tuft or coil of the smallest of the blood vessels, the capillaries—and a long narrow tube, or tubule. The closed end of the tubule is widened and folded back to form a double-walled cup, called Bowman's capsule, which enfolds the glomerulus. The three main segments of the rest of the tubule, the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule, vary in diameter and structure and have specialized functions (see EXCRETORY SYSTEM, HUMAN).

The kidney has evolved so as to enable man as a complex organism to exist on dry land where water and salts must be conserved, wastes excreted in concentrated form, and the blood and the tissue fluids strictly regulated as to volume, chemical composition, and osmotic pressure. Under the drive of arterial pressure, water and salts are filtered from the blood through the capillaries of the glomerulus into the lumen, or passageway, of the nephron, and then most of the water and the substances it contains that are essential to the body are reabsorbed into the blood. The rest of the filtrate is drained off as urine. The kidneys, thus, help maintain a constant internal environment despite a wide range of changes in the external environment.

The kidneys regulate three essential and interrelated properties of the tissues—water content, acid-base balance, and osmotic pressure—in such a way as to maintain electrolyte and water equilibrium—that is, to maintain a balance between quantities of water and the quantities of such chemicals as calcium, potassium, sodium, phosphorus, and sulfate in solution. Unless the concentrations of mineral ions such as sodium, crystalloids such as glucose, and wastes such as urea are maintained within narrow limits, bodily malfunction rapidly develops leading to sickness or death.

The removal of both kidneys leads to an accumulation of urinary constituents in the blood (uremia) with death in 14-21 days. Whenever the blood contains an abnormal constituent in solution or an excess of normal constituents including water and salts, the kidneys excrete these until normal composition is restored. The kidneys are the only means for eliminating the wastes that are the end products of protein metabolism. They do not themselves modify the waste products that they excrete, but transfer them to the urine in the form in which they are produced in other parts of the body. The only exception to this is their ability to manufacture ammonia and hippuric acid. Both ammonia and hippuric acid are also products of metabolism, waste products excreted in the urine. The kidneys also eliminate drugs and toxic agents. Thus the kidneys eliminate the unwanted end products of metabolism, such as urea, while limiting the loss of valuable substances such as glucose. In maintaining the acid-base equilibrium, the kidneys remove the excess of hydrogen ions produced from the normally acid-forming diet and manufacture ammonium radicals to remove these ions as ammonium salts.

To carry on its functions the kidney is endowed with a relatively huge blood supply. The blood processed in the kidneys amounts to some 1,250 millilitres a minute, or 1,800 litres (about 475 gallons) a day, which is 400 times the total blood volume and roughly one-fourth the volume pumped each day by the heart. Every 24 hours 170-180 litres (45-47.5 gallons) of water are filtered from the bloodstream into the renal tubules; and by far the greater part of this—some 168.5 litres of water together with salts dissolved in it—is reabsorbed by the cells lining the tubules and returned to the blood. The total glomerular filtrate in 24 hours is no less than 50-60 times the volume of blood plasma (the blood minus its cells) in the entire body. Only 1.5 litres of water, containing the waste products of metabolism, are passed out as urine in 24 hours, a fair daily average for an adult man on an ordinary mixed diet in temperate climates; but the actual volume varies with fluid intake and occupational and environmental factors. With vigorous sweating it may fall to 500 milli-

urine  
processed  
by kidneys

litres (about a pint) a day; with a large water intake it may rise to three litres, or six times as much. The kidney can vary its reabsorption of water to compensate for changes in plasma volume resulting from dehydration or overhydration.

The kidneys also perform certain nonexcretory functions. They secrete substances that enter the blood. These are of two kinds: renin, which is concerned indirectly with the control of electrolyte balance and blood pressure; and erythropoietin, which is important for the formation of hemoglobin and red blood cells, especially in response to anemia or deficiency of oxygen reaching the body tissues. Finally, the kidneys are subject to both nervous and humoral (hormonal) control; but they do possess a considerable degree of autonomy; *i.e.*, function continues in the organ isolated from the nervous system but kept alive with circulating fluid. Indeed, if this were not so kidney transplantation would be impossible.

#### VASCULAR CONSIDERATIONS

The two kidneys are bean-shaped organs, more or less upright, with the convex side away from the centre of the body, and with the concave side toward it. Within each kidney are cone-shaped masses, called pyramids, each with its base toward the convex side of the kidney, and with the apex (papilla) protruding into the cavity, or pelvis, at the concave side of the kidney. A layer of tissue between the bases of the pyramids and the outside of the kidney is called the cortex; projections of the cortex extend down between the pyramids. The pyramids, collectively, are called the renal medulla. Each pyramid and its surrounding tissue is called a lobe. The point on the concave side of the kidney where blood vessels, nerves, and the ureter enter is called the renal hilum.

The main renal (kidney) artery divides in the renal hilum into five or six branches, which run outward through the medulla between the pyramids. At the junction of medulla and cortex, the branches give rise to the arcuate arteries, which turn at right angles to run over the bases of the pyramids between cortex and medulla parallel to the kidney surface. These arteries in turn give rise to the interlobular vessels, which branch off at right angles and enter the cortex. Each interlobular vessel is an end artery; that is, it does not join with its fellows. It gives off on all sides short wide branches, called afferent arterioles, thick muscular walled vessels that lead to the glomeruli. The afferent arterioles split up into the glomerular capillaries, forming a tuft or network enclosed in Bowman's capsule.

The glomerulus consists of this capillary bundle folded into the capsule of the nephron. The vessel, called an efferent arteriole, that carries blood from the capsule is half the diameter of the afferent vessel but of similar bore because its muscle coat is thinner; the efferent arteriole breaks up into a second set of capillaries that branch out around the proximal and distal convoluted tubules of the same and of neighbouring nephrons. From this capillary complex around the tubules the blood is collected into veins that drain via interlobular trunks to join the renal vein at the hilum. The afferent and efferent arterioles of the nephron can contract and dilate so as to condition the glomerular pressure over a wide range. The tubules receive only blood that has first passed through a glomerulus. They have little or no direct arterial supply.

The blood supply of the medulla is different from that of the cortex. The efferent arterioles from adjacent glomeruli send out straight branches, called vasa recta, that descend into the pyramids parallel to the Henle loops. They conform to the curve of the loops and return after branching as the ascending vasa recta to join the interlobular veins. The vasa recta form close functional units with the Henle loops and the collecting ducts in the medulla.

The renal arteries are short and spring directly from the abdominal aorta, so that arterial blood is delivered to the kidneys at maximum available pressure. The rate of flow in the cortex is many times greater than that in the medulla because of the rich network of vessels around the

nephrons in the cortex. The blood pressure in the glomerular capillaries is higher than that in other parts of the body. Within the kidney there are no interconnections between the branches of the renal artery, but there are many between the intertubular capillaries and there are wide arteriovenous shunts (bypasses between arteries and veins) in the arcuate zone, the border area between cortex and medulla. These are unimportant under normal conditions, because they remain closed in order to direct all available blood to the cortex; but in certain circumstances, such as surgical shock, the shunts may divert blood rapidly from the arterial to the venous side of the circulation and bypass the cortex.

The shunt mechanism, together with arteriolar control of the afferent-efferent glomerular complex, affords a wide range of variability in blood supply to different parts of the kidney. The muscular coats of the arterioles are well supplied with sympathetic vasoconstrictor fibres (nerve fibres that induce narrowing of the blood vessels), and there is also a small parasympathetic supply from the vagus and splanchnic nerves that induces dilatation of the vessels. Sympathetic stimulation causes vasoconstriction and reduces urinary output, but severing of the nerves is without much effect. The vessel walls are also sensitive to circulating epinephrine and norepinephrine hormones, small amounts of which constrict the efferent arterioles, and large amounts of which constrict all the vessels; and to angiotensin, which is a constrictor agent closely related to renin.

Because of these factors, the kidney has a remarkable capacity to regulate its internal circulation regardless of the systemic blood pressure, provided the latter is not extremely high or extremely low. The forces involved in circulation of the blood in the kidneys must remain constant if the monitoring of the water and electrolyte composition of the blood is to proceed undisturbed; and this autoregulation is preserved even in the kidney cut off from the nervous system and, to a lesser extent, in the isolated perfused organ (*i.e.*, in an organ removed from the body and kept viable by having salt solutions of physiologically suitable concentrations circulated through it). The exact mechanism by which the kidney regulates its own circulation is not certainly known, but various theories have been proposed: (1) If systemic blood pressure rises, the renal blood flow remains constant because of the increased viscosity of the blood. Normally, the interlobular arteries have an axial (central) stream of red cells with an outer layer of plasma so that the afferent arterioles skim off more plasma than cells. If the blood pressure rises, the skimming effect increases, and the more densely packed axial flow of cells in the vessels offers increasing resistance to the pressure, which has to overcome this heightened viscosity. Thus the overall renal blood flow changes little. Up to a point, similar considerations in reverse apply to the effects of reduced systemic pressure. (2) Changes in the arterial pressure modify the pressure exerted by the interstitial (tissue) fluid of the kidney on capillaries and veins so that increased pressure raises, and decreased pressure lowers, resistance to blood flow. (3) If the renal blood flow tends to rise, there is a higher sodium content in the fluid in the distal tubules because of the increased filtration rate. This content stimulates the formation of renin, which causes constriction of the vessels and reduction of flow.

The effective renal flow of whole blood is about  $1\frac{1}{4}$ – $1\frac{1}{2}$  quarts (1,200–1,300 millilitres) per minute, equivalent to a quarter of the resting cardiac output, or 400 millilitres per 100 grams of kidney substance per minute. Women have smaller kidneys than men, and the corresponding flow figures are 15 percent less for the same standard body surface. The plasma flow per minute is some 600–700 millilitres, but only five-sixths of this, the effective plasma flow, is actually available for glomerular filtration, because some blood passes through inert connective tissue. The flow is greater when one is lying down than when standing; it is higher in fever; and it is reduced by prolonged vigorous exertion, pain, anxiety, and other emotions that constrict the arterioles and divert blood to other organs. It is also reduced by depletion of water

Factors that affect renal flow

Depen-  
dence of  
filtration  
rate on  
glomerular  
pressure

and salts and, markedly, in shock, including operative shock, hemorrhage, and asphyxia. A profound fall in systemic blood pressure, as after severe hemorrhage, may so reduce renal blood flow that no urine at all is formed for a time. Death may occur from suppression of glomerular function if dehydration causes a fall in pressure. Simple fainting causes vasoconstriction and reduced urine output. Urinary secretion is also stopped by obstruction of the ureter when back pressure reaches a critical point.

The importance of these vascular factors lies in the fact that the basic process occurring in the glomerulus is one of filtration, the energy for which is furnished by the blood pressure within the glomerular capillaries; and the higher this pressure, the greater the filtration rate. Indeed, the volume of urine formed depends more on the blood pressure than on the actual volume of blood flow. Glomerular pressure is a function of the systemic pressure as modified by the tonus (state of constriction or dilation) of the afferent and efferent arterioles, as these open or close spontaneously or in response to nervous or hormonal control. Constriction of the afferent vessels reduces blood flow, glomerular pressure, and filtration rate. Efferent constriction also causes reduced flow, but raises glomerular pressure and filtration. The arteriovenous shunt system comes into play only exceptionally, as after severe crushing injuries, when it may divert the blood flow massively from cortex to medulla and so cause a fatal destruction of cortical substance.

#### THE FORMATION OF URINE

The urine leaving the kidney shows great differences in composition from the plasma entering it (Table 1). The study of renal function must account for these differences; *e.g.*, the absence of protein and glucose from the urine and the very high levels of ammonia and creatinine in the urine, while sodium and calcium remain at similar low levels in both urine and plasma.

	plasma g/100 ml	urine g/100 ml	concentration in urine
Water	90-93	95	—
Proteins and other colloids	7-8.5	—	—
Urea	0.03	2	× 60
Uric acid	0.002	0.03	× 15
Glucose	0.1	—	—
Creatinine	0.001	0.1	× 100
Sodium	0.32	0.6	× 2
Potassium	0.02	0.15	× 7
Calcium	0.01	0.015	× 1.5
Magnesium	0.0025	0.01	× 4
Chloride	0.37	0.6	× 2
Phosphate	0.003	0.12	× 40
Sulfate	0.003	0.18	× 60
Ammonia	0.0001	0.05	× 500

The modern view of the formation of urine is briefly as follows: a large volume of ultrafiltrate—a liquid from which the blood cells and the blood proteins have been filtered out—is produced by the glomerulus into the capsule. As this liquid traverses the proximal convoluted tubule, most of its water and salts are reabsorbed, some of the solutes completely and others partially; *i.e.*, there is a separation of substances that must be retained from those due for rejection. Subsequently the loop of Henle, distal convoluted tubule, and collecting ducts are mainly concerned with the fine control of water and electrolyte balance.

**Glomerular filtration.** Urine formation begins as a process of ultrafiltration of a large volume of blood plasma from the glomerular capillaries into the capsular space, colloids such as proteins being held back while crystalloids (substances in true solution) pass through. About 20 percent of the water in the plasma, together with its dissolved crystalloids, traverses the glomerular membrane, leaving the protein constituents behind. The

actual filtration membrane consists of the wall of the capillaries, which is largely endothelium, or lining, and the wall of the capsule, the permeability of which is such as to suggest that it acts as a porous membrane and that the diameter of its pores determines the size of the molecules filtered. The pore size is just small enough to retain the plasma proteins. The smallest protein molecule—serum albumin, of molecular weight 72,000—is detained, whereas free hemoglobin (68,000) and gelatin (35,000) pass freely. An alternative theory is that plasma solutes diffuse across the basement membrane. But glomerular function accords with the known characteristics of artificial porous membranes in that larger particles pass as rapidly as smaller ones and all molecules smaller than the filter pores are transmitted. The only difference between plasma and filtrate is the absence from the latter of molecules above a certain borderline size. Since the capsular filtrate is a true ultrafiltrate, a rise in arterial pressure increases its volume and a rise in ureteric back pressure decreases it. Normally no protein passes the filter, but normal filtration depends on proper nutrition and oxygenation of glomeruli and capsules, and if these are damaged by lack of oxygen or by disease they become more permeable, and plasma proteins enter the urine. It should be added that certain quite healthy individuals, mostly young, have albuminuria (plasma protein albumin in the urine) when they are standing but not when they are recumbent, and that there is often temporary albuminuria during pregnancy, from pressure on the renal veins.

Thus the initial filtrate is produced by entirely physical means. It contains all the substances present in blood, and in the same concentration as in the blood, except the colloids and fats. It is virtually protein-free, it is isotonic (in balance) with plasma, and contains glucose, urea, creatinine, uric acid, and blood electrolytes. Animal experiments confirm that fluid collected directly from Bowman's capsule is identical in composition with plasma, minus only the protein of the latter.

The driving force in filtration is the blood pressure in the glomerular capillaries, some 70 millimetres of mercury (mm Hg). (The average pressure in the arteries varies from about 80 to about 120 mm Hg.) But the effective filtration pressure is less than this because the osmotic pressure of the plasma proteins tends to retain water in the plasma and because of resistance within the capsule and from surrounding tissues. Pressure in the veins, in the ureters, and outside the kidneys also has to be overcome. Glomerular pressure must be greater than that in the capsule and capsular pressure must exceed the pressure in the ureter if urine is to flow normally. In practice, the effective glomerular pressure must always exceed at least 45 mm Hg, and probably 60 mm.

**Tubule function.** The role of the tubules may be assessed by comparing the amounts of various substances in the filtrate and in the final urine (Table 2).

Driving  
force in  
filtration

Table 2: Effect of Tubular Reabsorption on Urine (24-hour figures)

	glomerular filtrate	urine	tubular reabsorption (percent)
Water	170 l	1.5 l	99.1
Glucose	170 g	—	100
Sodium	560 g	5 g	99.1
Chloride	620 g	9 g	98.5
Phosphate	5.1 g	1.2 g	76.5
Calcium	17 g	0.2 g	98.8
Urea	51 g	30 g	41.4
Sulfate	3.4 g	2.7 g	20.6

It is apparent that the filtrate must be modified in the tubules to account for the differing compositions of filtrate and final urine; *e.g.*, to allow for the total absence of glucose in the latter, the much smaller volume of urine than filtrate, and also for the acidity of urine compared

General  
function of  
tubules

with the neutrality of the filtrate. It is also clear that the composition of the fluid reabsorbed within the proximal tubule must be similar to filtrate, but not identical with it. It has less urea and sulfate and no creatinine, for these are wastes.

As the filtrate passes along the proximal tubule, most of its water and salts are reabsorbed into the blood of the network of capillaries around the tubules. Of other substances, some are reabsorbed completely, others in part, because this portion of the nephron separates substances that must be retained in the body from those destined for excretion in the urine. The function of the proximal tubule is essentially reabsorption of filtrate in accordance with the needs of homeostasis (equilibrium), whereas the distal part of the nephron and collecting duct are mainly concerned with the detailed regulation of water, electrolyte, and hydrogen-ion balance. All these tubular processes are both chemical and physical and are under hormonal control. Although the urine differs so markedly from filtrate, if tubule function is experimentally reduced by cooling or poisoning, the urine will come increasingly to resemble the filtrate. Also, the more rapidly filtration occurs, the less time there is for the urine to be modified during its passage through the tubules.

That tubular reabsorption occurs is established by animal experiments showing that filtrate withdrawn directly from the capsules contains substances, such as chlorides, that are much reduced or absent in fluid collected from the tubules. Absorption affects all the glucose of the filtrate, 80 percent of its water (the remainder is absorbed in the distal tubule), most of the sodium, potassium, and chloride ions, some of the uric acid, and little or none of the urea and sulfate. Of the total solids 75 percent are reabsorbed in the proximal tubule, leaving a fluid isotonic with the plasma of arterial blood. The first part of the tubule absorbs amino acids, glucose, and phosphate; the whole convolution absorbs sodium, potassium, calcium, chloride, and bicarbonate and acidifies the fluid slightly. Potassium is absorbed in the proximal tubule and secreted back into the urine in the distal tubule.

The tubule has only a certain capacity for reabsorption. Thus, normally all the glucose arriving in the filtrate is absorbed; but if plasma glucose is raised high enough, the glucose arrives at the tubule cells faster than they can absorb it—a condition that occurs in diabetes; in other words, there is a critical rate of delivery determined by plasma concentration and filtration rate, and a maximum reabsorptive capacity for each substance in the filtrate. The rate of tubular reabsorption has an upper maximum value that is constant for any given substance. Consequently, if the plasma level rises sufficiently, all surplus of the substance will pass out in the urine; this is true even for glucose, which is totally reabsorbed under normal conditions. On the other hand, the upper maximum value is much lower for phosphates, so there is normally always some phosphate in the urine. The amino acids also have their own maximum tubular reabsorption value, but this is high enough to ensure that they are entirely reabsorbed under normal conditions; in certain rare inherited disorders such as cystinuria, in which there is excessive excretion of cystine, their reabsorption is reduced.

Such little secretion as does occur in the kidney takes place in the proximal tubule, save for the secretion of potassium and some uric acid in the distal tubule. Secretion occurs both passively and also actively against the electrochemical gradient (passive secretion is movement of dissolved substances from a stronger to a weaker solution; active secretion, so called because it requires expenditure of energy, is from a weaker to a stronger solution). These actively secreted substances are mainly a few metabolic products; such as creatinine, histamine, and choline, as well as some drugs, such as penicillin. (The therapeutic level of penicillin in the plasma can be enhanced and prolonged by administering agents that block tubular secretion.) But any substance for which renal clearance exceeds filtration rate must be to some extent secreted.

Of the water in the filtrate 80–85 percent is reabsorbed as a passive accompaniment to the active reabsorption of

80–85 percent of the sodium ions in the filtrate. The energy required for absorption of this sodium uses 80 percent of the oxygen consumed by the kidney, and represents one-eighth of the oxygen consumption of a resting man. The water is absorbed because of the osmotic needs of the passage of sodium and chloride ions out of the tubular fluid, and water must accompany these ions as a vehicle to prevent a rising osmotic gradient (*i.e.*, to prevent a rising difference in the concentration of the sodium solution inside and outside the tubule). The sodium ions move passively from fluid to cells and are then actively expelled into the blood against a gradient at the cell membranes. The transfer of chloride ions is also a passive obligatory transfer to complement the sodium ions.

The overall effect is to keep the osmotic pressure of the fluid roughly identical with that of the filtrate throughout the proximal tubule, so that fluid entering the distal nephron, though much less in volume, is still in balance with plasma. The mechanism by which the degree of acidity or alkalinity of the fluid is stabilized in the tubule is the bicarbonate cycle.

The proximal tubule cell synthesizes carbonic acid from carbon dioxide and water under the influence of carbonic anhydrase. The carbonic acid then dissociates, and bicarbonate ions with reabsorbed sodium ions enter the tubular fluid and then enter the blood and the extracellular fluid. Hydrogen ions enter the tubular fluid and most combine with bicarbonate to form carbonic acid. The partial pressure of carbon dioxide in the tubule fluid rises and the gas diffuses back into the tubule cell. Thus the bicarbonate actually reabsorbed is not that of the filtrate, but the net effect is the same as if this were the case.

The proximal tubular reabsorption of phosphate is complex and is affected by the phosphate content of the filtrate and plasma, the diet, and the hormone of the parathyroid glands. Phosphate competes with glucose for reabsorption, and its reabsorption is reduced by parathyroid hormone and by vitamin D and increased by a high dietetic intake.

The loop of Henle begins as a descending limb running towards the medulla from the proximal tubule; it then turns back in a hairpin bend to become the ascending limb running in a parallel course back to the distal convoluted tubule. Most of the loops originate from peripheral glomeruli in the cortex and are restricted to the cortex; but about a tenth arise from glomeruli near the medulla in the deeper layers of the cortex and extend well down in the pyramids toward their tips. These long loops and their accompanying vasa recta are important in concentrating the urine.

The fluid entering the loops from the glomeruli is in balance with plasma, and one function of the loops is to produce and maintain a state of increased concentration in the fluid occupying the bends of the loops; *i.e.*, in the deeper cortical and medullary parts of the kidney. It is now assumed that this increased concentration is achieved by what is known as countercurrent multiplication. The principle of this mechanism is analogous to the physical principle applied in the conduction of hot exhaust gases past cold incoming gas so as to warm it and conserve heat. That exchange is a passive one; but in the kidney the countercurrent multiplier system uses energy in transferring substances independent of concentration gradients to produce hypertonicity (high concentrations) at the bends of the loops and in the tissue fluid in the adjacent medulla.

The process may continue until the urine acquires an osmotic concentration many times that of plasma, and this tonicity is shared by the interstitial tissues and tissue fluid of the medulla, which is hypertonic compared with the cortex. The substances active in maintaining this high osmotic concentration are urea and sodium. There is more sodium at the bends of the loops, where the fluid is more concentrated. In the ascending limb sodium is absorbed more rapidly than water, so that the fluid leaving the system and arriving at the distal convoluted tubule is more dilute than that entering.

The functions of the distal tubule are: (1) urinary dilu-

tubules

Functions  
of distal  
tubule

tion, (2) final regulation of the amount of ammonium in the urine, (3) final regulation of the amounts of sodium, potassium, and hydrogen ions in the urine, (4) acidification of the urine, (5) transport of potassium and chloride ions, and (6) calcium excretion.

The fluid from the proximal tubule is isotonic with filtrate and plasma, but it is so altered in the loop of Henle that it arrives diluted at the distal tubule. The formation of a dilute urine is a function of the distal tubule, this part of the nephron being normally rather impermeable to water. The tubule also produces a fine and final adjustment of acid-base balance in the blood-urine system. There is a "sodium pump" in the tubule, activated by a hormone of the cortex of the adrenal gland, which pumps sodium out of the tubule into the tubule cells and extracellular fluid in exchange for potassium and hydrogen ions. The "pump" is very effective; and if the diet is salt-free the urine will contain little or no sodium.

Most of the urinary ammonia is formed in the distal tubules from glutamine (an amino acid). The more acid the urine is, the greater is its content of ammonium ions, which unite with obligatorily excreted surplus anions (negative ions) such as chloride, sulfate, and phosphate, thus sparing other cations (positive ions) such as sodium and potassium. The excretion of calcium and phosphate runs in parallel; most of the calcium is excreted as phosphate.

The collecting ducts receive dilute fluid, and concentrate it by means of reabsorption of water and salts as a fine adjustment to bodily needs under the ultimate control of a hormone that reduces urine output secreted by the posterior lobe of the pituitary gland—*i.e.*, ADH, or vasopressin. Basically, the final volume of urine excreted is determined, first, by the amount of osmotically active solutes filtered at the glomeruli and, second, by the amount of circulating ADH. The first amount is a function of the effective filtration pressure. Some 130 millilitres of filtrate are formed every minute, and of this perhaps 16 millilitres reaches the distal tubules. As the rate of urine formation is only one millilitre per minute, the reabsorption of fluid within the collecting ducts must be 15 millilitres per minute; *i.e.*, some 12 percent of all water reabsorption in the kidney occurs in the ducts, and this reabsorption results in progressive concentration of the urine. It is reconcentrated in the ducts to the osmotic pressure—the concentration—of the fluid in the bends of the loops of Henle. The concentrating power has its limits, the limit being reached when the osmotic pressure of the urine (due mainly to its urea and salt content) becomes high enough to balance the resorptive power of the duct cells.

Influence  
of  
vasopressin  
on water  
reabsorp-  
tion

The variable amount of water reabsorption in the duct is determined under the direct influence of vasopressin (ADH), which increases the permeability of the duct lining to water. The secretion of this hormone by the pituitary is part of a feedback mechanism responsive to the tonicity of plasma and extracellular fluid. This interrelation between plasma osmotic pressure and ADH output is mediated by specific and very sensitive receptors in the base of the brain. These receptors are particularly sensitive to sodium and chloride ions. At normal blood tonicity there is a steady receptor discharge and a steady stimulation of ADH output. If the plasma becomes hypertonic—has greater osmotic pressure than normal—from the ingestion of crystalloids such as sodium chloride, receptor discharge increases, ADH output goes up, and more water is absorbed from the ducts. If the osmotic pressure of the plasma becomes low, the reverse is the case. On the other hand, water ingestion dilutes the body fluids and reduces or abolishes ADH secretion, resulting in a water diuresis (excretion) so that larger amounts of tubular fluid enter the urine.

The situation is complex because there are also receptors in the atria of the heart and in the great blood vessels sensitive to changes in blood volume; and these receptors too, can reflexly inhibit ADH output if there is any tendency to excessive blood volume. Exercise increases ADH output and reduces urinary flow. The same result may

follow emotional disturbance, fainting, injury, or the use of certain drugs. Diuresis is an increased flow of urine produced as the result of fluid intake, hormone activity, or the taking of certain drugs. Urea and salts are diuretics because they have the power of retaining water within the tubules. If ADH secretion is inhibited by drinking excess water, or by disease or tumour affecting the base of the brain, water diuresis results; and the rate of urine formation will approach the figure of 16 millilitres per minute filtered at the glomeruli. In certain pituitary disorders—diabetes insipidus—there may be a fixed and irreversible output of a large quantity of dilute urine.

In general, the fluid entering the collecting ducts is either in balance with plasma or more dilute than plasma; the duct wall remains permeable under the influence of a steady output of ADH; more water than solute is reabsorbed, and the urine becomes concentrated, basically because of the osmotic gradient between the dilute fluid in the ducts and the highly concentrated interstitial fluid in the renal medulla produced by countercurrent processes in Henle's loops. In this final process of concentration, the collecting ducts and their accompanying vasa recta act as powerful exchange units in relation to the medulla.

#### TESTS OF RENAL FUNCTION

**Quantitative tests.** Tests of kidney function include renal (kidney) clearance, filtration fraction and glomerular filtration rate, excretion rate, and reabsorption of glucose. The results of each test are measured against standard or normal values to assess degree of abnormality.

The renal clearance of any substance is the volume of plasma containing that amount of the substance that is removed by the kidney in one minute. The basic formula is as follows: the clearance for the substance, in millilitres per minute, equals the concentration of the substance in the urine multiplied by the volume of urine excreted per minute and divided by the plasma concentration of the substance ( $C = U \times V/P$ ). It is obvious that clearance is really an artificial concept, since no portion of the plasma is ever really cleared. Taking urea, for instance, if the plasma concentration is 30 milligrams (mg) per 100 millilitres and the amount of urea excreted by the kidneys in one minute is 20 milligrams, then 67 millilitres of plasma contains the amount of urea excreted in a minute. In fact, the plasma flow through both kidneys is some 700 ml per minute containing 210 grams urea; of this, 120 ml containing 36 mg urea is filtered through the glomeruli per minute, and of this urea 20 mg escapes in the urine, some being reabsorbed in the tubules. Thus the clearance value for urea is an abstraction, but is useful in assessing kidney function.

The filtration fraction (FF) represents the proportion of the plasma passing through the glomeruli that is actually filtered off. As can be seen from the example given, this fraction is some 15–20 percent (120 out of 700 ml). It is that percentage of the renal plasma flow that is actually turned into glomerular filtrate, since the fraction is equal to the glomerular filtrate divided by the renal plasma flow.

Filtration  
fraction  
and  
glomerular  
filtration  
rate

The glomerular filtration rate (GFR) is the volume of filtrate formed in unit time. It can be readily measured by injecting into the bloodstream some nontoxic agent, soluble in plasma, not metabolized, freely filtered at the glomerulus, neither secreted nor reabsorbed by the tubules, and capable of accurate estimation in blood and urine. In these circumstances the filtrate will contain the substance in the same concentration as in the plasma, and all of it will be recoverable from the urine. In these conditions the clearance value and the glomerular filtration rate will be identical. Such a substance is the carbohydrate inulin. If this is given intravenously at such a rate as to maintain a constant plasma concentration of inulin, then the product of the concentrations of inulin in the urine and the volume of urine passed per minute, divided by the plasma concentration of inulin, is equal to the volume of filtrate per minute, and also to the volume of plasma completely freed of inulin per minute.

This procedure gives a simple measure of the actual glomerular filtration rate, which is independent of any actual constituent of blood or urine. In the normal adult the glomerular filtration rate is 125 ml per minute per 1.73 square metres of body surface. In the glomeruli of both kidneys together some 125 ml of fluid is filtered off each minute from the blood through the walls of the glomerular capillaries into the capsules of the nephrons, a filtrate, as has been seen, identical with plasma except that it contains no colloids. Female values are about 85 percent of these for the same standard area of body surface.

It follows from the above that for a substance partly reabsorbed from the filtrate when it reaches the tubules, the clearance value will be less than the glomerular filtration rate; while, for a substance that is additionally excreted into the tubules, the clearance value will exceed the glomerular filtration rate. Experimentally, the clearance values for inulin, creatinine, and sodium ferricyanide are identical, which suggests that all must be dealt with by physical filtration at the glomeruli and that the tubules exert no influence on their further excretion.

Clearance value is not the same as excretion rate. For inulin and some other compounds, the clearance value is not altered by changing the amount of inulin in the plasma, because the amount of urine completely cleared of the agent remains the same. But the excretion rate equals total quantity excreted per millilitre of filtrate per minute, and this value increases in linear relation with the plasma concentration.

So far, clearance and other factors in terms of substances filtered at the glomerulus have been measured. But there are certain substances, such as *p*-aminohippuric acid (PAH) and iodopyracet, which are vigorously and totally excreted by the tubules after some glomerular filtration and are completely removed from the blood traversing the kidney if their plasma level is small. In such cases the clearance rate equals the renal blood flow. Thus, if plasma iodopyracet is one milligram per 100 millilitres, and the glomerular filtration rate (GFR) is 120 millilitres per minute, then this glomerular filtration rate is equivalent to a urinary content of 1.2 milligrams iodopyracet. Five hundred and eighty millilitres of plasma reach the tubules each minute. If the plasma contains one milligram of iodopyracet per 100 ml, it contains 580 mg iodopyracet, and the tubules actively secrete the whole of this from the blood so that all the original iodopyracet in the blood is excreted.

The maximum rate of reabsorption of glucose by the proximal tubule and the maximum rate of secretion of *p*-aminohippuric acid by the tubule are both indices of the maximum functioning ability of the proximal portion of the renal tubules. To arrive at this value for a particular substance, it is necessary first to assess the proportion of the substance excreted through the tubule rather than elsewhere (e.g., at the glomeruli).

The urea clearance, another effective test of renal function, is determined from the urea content of the urine and the urea content of the blood, measured at fixed intervals for two or three hours after drinking water to induce diuresis. The dilution test measures the kidney's response to a water load, as shown by the excretion of appropriately dilute urines. The level of blood urea is itself a useful index of renal function. But if protein intake is very low, the blood urea may be a less sensitive index of renal function than the blood creatinine, since the latter is much less affected by the nature of the diet.

**Qualitative tests of renal function.** It is often desirable to establish that a particular kidney is present and functioning—that there is a healthy kidney present on one side before an organ on the other side is removed or before the opposite kidney is transplanted. The simplest method is to give an intravenous injection of some dye such as methylene blue and to inspect the ureter openings through a cystoscope (an instrument for viewing the inside of the bladder) to note the jets of coloured urine. In intravenous pyelography (IVP) the kidneys are observed in X-rays by intravenous injection of a radio-opaque-iodine-containing contrast medium that they se-

lectively excrete. A series of X-rays then indicates when the contrast first appears and brings out the dense shadows of the renal structures; they also indicate the position of the organ; finally the dye collects in the bladder; it is then possible to see whether there is rupture or tumour in this structure. This test also gives a rough comparison of function in the two kidneys.

Retrograde pyelography is more an anatomical than a functional test. In the procedure, a fine catheter is passed into a ureter opening and up one ureter, and radio-opaque dye is injected to outline the ureter, renal pelvis, and calices. The test may be useful in showing that an organ that fails to perform in an IVP is nevertheless present. The radioactive renogram is obtained by injecting an agent tagged with a radioactive form of iodine. The radiation is detected with counters placed over the kidneys, and the counts can be transcribed on moving graph paper, yielding typical time curves for normal and disordered function. Finally, there is the scintillogram, obtained by injection of gamma-ray-emitting substances that are concentrated and persist in the kidneys. An agent such as an isotope of mercury can be used to render the kidney capable of producing exposure of an X-ray plate in the vicinity; that is, an autoradiogram to indicate the site, size, and shape of the organ and the presence of defects suggestive of cysts or tumours.

raphy

THE URINE

The volume and composition of normal urine vary widely from day to day even in health, as a result of food and fluid intake and of fluid loss through other channels as affected by environmental conditions and exercise. The daily volume averages 1.5 litres (about 1.6 quarts) with a range of 1–2.5 litres, but after copious sweating it may fall as low as 500 millilitres, and after excess fluid intake it may reach 3 litres or more. There is also a 24-hour variation. Excretion is minimal in the early hours, maximal during the first few hours after rising, with peaks after meals and during the early stages of exertion. The urine produced between morning and evening is two to four times the night volume. The excessive secretion of urine (polyuria) of chronic renal disease is typically nocturnal.

The volume of urine is regulated to keep plasma osmotic concentration constant, to control the total water content of the tissues, and to provide a vehicle for the transfer to the exterior of some 50 grams (g) of solids, mostly urea and sodium chloride, in a day. In a man who ingests 100 g of protein and 10 g of salt daily, the urine will contain 30 g of urea and 10 g of salt; there are many other possible constituents, but they amount to less than 10 g overall.

Some urinary constituents (Table 3), the products of metabolism of nitrogenous substances obtained from food, vary widely in relation to the composition of the diet; thus the excretion of urea and sulfate is dependent on the diet-protein content. A high-protein diet may yield a 24-hour output of 17 g of nitrogen, a low-protein diet of the same calorific value only 3–4 g.

The urine is normally clear. It may be turbid from calcium phosphate, which clears if acetic acid is added.

Volume  
and con-  
stituents  
of urine

Table 3: Urine Constituents (g/24 hours)

Urea	25–30
Uric acid	.6–0.7
Creatinine	1.0–1.2
Hippuric acid	0.7
Ammonia	0.7
Amino acids	3.0
Sodium	1–5 (NaCl 15.0)
Potassium	2–4
Calcium	0.2–0.3
Magnesium	0.1
Chloride	7
Phosphate	1.7–2.5
Sulfate	1.8–2.5
Iron	0.003

Excretion  
rate and  
renal  
blood  
flow (RBF)

Certain deposits may settle on standing: mucus from the lining of the urinary tract; a brick-red amorphous deposit of urates as the urine cools, redissolving on warming; crystals of calcium oxalate, triple phosphate, or calcium biphosphate in acid urine. Microscopic deposits include occasional casts, vaguely resembling in form the renal tubules from whose lining they have been shed.

The urine froths when shaken because of the presence of bile salts. Its colour depends on the concentration, but is normally a bright clear yellow from the pigment urochrome, an end product of protein metabolism. There are also traces of other pigments: urobilin and uroerythrin. The content of protein or amino acids is normally very small, less than 100 milligrams in a 24-hour period.

The specific gravity of urine may vary between 1.001 and 1.04, but is usually 1.01–1.025. Such variation is normal, and a fixed low specific gravity is an indication of chronic renal disease. If fluid intake is stopped for 24 hours, even a normal kidney will secrete urine with a specific gravity of at least 1.025. There is a limit to the concentrating powers of the kidney, so that the urine is rarely more than four times as concentrated as plasma. Since the protein and salt of the diet must be excreted, they need a minimum water output of 850 ml as a vehicle. If this is not available from intake it has to be withdrawn from the tissues, causing dehydration; but the usual intake is well above the minimum and the urine is rarely at its maximum possible concentration. Osmotic pressure runs roughly parallel to specific gravity.

The reaction of the urine is usually acid, with an overall range of pH 4 to 8 (lemon pie has a pH of 2.3; the value 8 is slightly alkaline, about equal to the pH of a 1 percent solution of sodium bicarbonate). The acidity is due to the excreted acid products of metabolism, the conversion of the sulfur and phosphorus of ingested proteins to sulfuric and phosphoric acid, buffered by potassium and ammonium. There is normally an excess of hydrogen over hydroxyl (OH) ions. This condition assumes a mixed diet containing some meat. If the diet is predominantly vegetarian or fruitarian, it contains sodium and potassium salts of organic acids, and the latter are metabolized leaving alkaline residues in the urine. Medicinal consumption of bicarbonate also gives an alkaline urine.

Of the anions, the chlorides are derived from the food and vary with intake; they may disappear on a salt-free diet or after major surgical operations. Sulfates result from oxidation of the sulfur in protein and are excreted as sulfates of calcium, potassium, sodium, magnesium, and ammonium. There is some sulfur passed as thiocyanate, cysteine, and mercaptan. Phosphate comes in part from the food, in part from oxidation of organic phosphates in food and tissue lecithins and nucleins. It can leave the body in either the feces or the urine; if there is much calcium or magnesium in the food, there will be more phosphate in the feces and less in the urine. Phosphates are present in the urine in forms which, if the urine is neutral or alkaline, may precipitate as a deposit. The phosphate formed by putrefaction of normal urine, ammonium phosphomagnesiates, yields crystalline deposits.

Of the cations, potassium varies with the diet, being increased by a high meat consumption; sodium also varies with intake. Calcium and magnesium are always present but in small amounts. There is always some ammonia, secreted in the distal tubules as a complement to acids derived from the food.

Organic components are nitrogenous or non-nitrogenous. As stated, the loss of nitrogen is dependent on diet. Urea accounts for up to 90 percent, ammonia 2 to 4 percent, creatinine 3 percent, uric acid 1 to 3 percent. There is also nitrogen in hippuric acid and in the various pigments. The urea content is an important index of the state of protein metabolism. There is an excess of urinary (and plasma) uric acid in gout. There are also traces of purine bases: xanthine, hypoxanthine, and adenine; tea and coffee drinking yield caffeine, theobromine, and derivatives. The hippuric acid is synthesized in the liver and

increases on a vegetarian diet. The non-nitrogenous organic constituents include oxalic acid from the food (*e.g.*, rhubarb), lactic acid (increased by exertion), derivatives of the water-soluble vitamins and sex hormones, with many different intermediate metabolites at various times.

Foreign proteins of molecular weight less than 68,000 are excreted in the urine, while those of the plasma are retained in the body. If, however, the kidneys are damaged by disease or toxins, the glomeruli will transmit some of the normal serum albumin and globulin and the urine will coagulate on warming. Normally, the urine contains only very small amounts of protein: after exercise, in pregnancy, and in some persons when standing (orthostatic albuminuria). The protein loss may be greatly increased in certain chronic renal diseases; in nephrosis it may even reach 50 milligrams in a 24-hour period. Certain specific and easily identifiable proteins appear in the urine in diseases of the bone marrow.

Glucose is found in the urine in diabetes mellitus; but there may also be an abnormal amount of glucose in the urine because of a low threshold for tubular reabsorption, without any disturbance of glucose metabolism. Glucuronic acid is an oxidation product of glucose and is a detoxicating agent, combining with poisons in the liver to form glucuronides, which are excreted. Lactosuria (abnormal amount of lactose in the urine) may occur in nursing mothers. Ketone bodies (acetone, acetoacetic acid) are present in traces in normal urine but in quantity in severe untreated diabetes and in relative or actual carbohydrate starvation; *e.g.*, in a person on a high-fat diet.

The urine may contain hemoglobin or its derivatives after hemolysis (liberation of hemoglobin from red blood cells), after incompatible blood transfusion, and in malignant malaria (blackwater fever). Fresh blood may derive from bleeding in the urinary tract. Bile salts and pigments are increased in jaundice, particularly the obstructive variety; urobilin is greatly increased in certain diseases such as cirrhosis of the liver.

Porphyryns are normally present only in minute amounts but may be increased in congenital porphyria, marked by sensitivity to sunlight or by insanity, or after poisoning with the drug sulfonmethane, when there is purple urine.

Finally, the normally extremely small quantities of amino acids in the urine may be much increased in hepatitis, in failure of tubular reabsorption and in certain diseases due to inborn errors of protein metabolism. Phenylketonuria, a disease identified by the presence of phenylpyruvic acid in the urine, is due to lack of the enzyme phenylalanine hydroxylase, so that phenylalanine is converted not to tyrosine but to phenylpyruvic acid. This is excreted and its presence in blood and tissues causes mental retardation; if the urine of every newborn infant is tested, restriction of phenylalanine in the diet in such cases may be beneficial. Alkaptonuria, a disease identified by the presence of homogentisic acid in the urine, is due to lack of the enzyme that catalyzes the oxidation of homogentisic acid. Free homogentisic acid in the urine darkens on standing, and deposits of the acid in the tissues may cause chronic arthritis or spinal disease. Other such disorders are cystinuria, the presence of the amino acid cystine in the urine, when the bladder may contain cystine stones; and maple syrup disease, another disorder involving abnormal levels of amino acid in the urine and blood plasma.

#### URINE COLLECTION AND EMISSION

From the nephrons the urine enters the final 15 or 20 collecting tubules that open on to each papilla of the renal medulla, projecting into a minor calyx. There are some five to ten of these cuplike recesses, opening into two or three major calices, and these in turn open into the renal pelvis, the upper expanded portion of the ureter. The pelvis and calices together make up the renal sinus, which has been mentioned earlier. The ureter is a narrow thick-walled muscular tube that begins at its junction with the pelvis of the kidney, descends on the posterior abdominal wall behind the lining of the abdominal cavity (peritoneum), and opens into the base of

Abnormal constituents of urine

Components of urine

Passage of urine from nephron to bladder

the bladder. The ureters pass very obliquely through the thick musculature of the bladder wall, so that their orifices are virtually valvular, and this situation ensures that there is normally no reflux, or backflow, of urine when the bladder contracts during micturition (passage of urine).

Urine is passed down the channel of the renal pelvis and ureter by a succession of peristaltic waves of contraction that begin in the muscle fibres of the minor calices, travel out to the major calices and then along the ureter every 10–15 seconds. Each wave sends urine through the ureteric orifice into the bladder in discontinuous spurts; these can be seen through a cystoscope if a dye is injected into the bloodstream. Gravity aids this downward flow, which is faster when one is standing erect. Though the overall picture suggests that there is a pacemaker near the pelviureteric junction, this has never been satisfactorily demonstrated in the tissue. The pressure in the renal pelvis is normally low, but the smooth muscle coat of the ureter is a powerful one and the pressure above an obstructed ureter may rise as high as 50 millimetres of mercury. The ureters are doubly innervated from the splanchnic nerves above and the hypogastric network below.

**The bladder.** The bladder is a hollow three-layered organ of variable capacity, with a powerful intermediate muscle coat that empties the organ when it contracts, and two muscular sphincters that keep the exit closed at all other times. This smooth muscle coat constitutes the powerful detrusor muscle. At the base of the bladder the region of the bladder neck, or trigone, is demarcated by the two ureteric orifices and the internal opening of the urethra, the channel that runs from the bladder to external urinary meatus. Muscle fibres loop around the urethral opening to form the internal sphincter, which is under involuntary unconscious control. The external sphincter consists of two striated (striped) muscles under voluntary control: the compressor urethrae, which surrounds the membranous urethra, and the pair of bulbocavernosus muscles.

The mucous membrane lining the bladder is distensible; it is ridged in the empty organ and smoothed out in distension. In micturition the longitudinal muscle of the bladder shortens to widen the bladder neck and allow urine to enter the urethra. The urethra normally contains no urine except during the act of micturition, its walls remaining apposed by muscle tone. In the male, but not in the female, the external sphincter can maintain continence even if the internal sphincter is not functioning.

The innervation of the bladder and urethra is complex and important. Essentially, there are three groups of nerves: (1) The parasympathetic nerves constitute the main motor supply to the detrusor; they make it contract, raise pressure within the bladder, relax the internal sphincter, and cause emptying. Afferent parasympathetic channels convey impulses from stretch receptors in the bladder wall to higher centres, permitting cognizance of the state of distension of the organ and stimulating the desire to micturate. (2) The sympathetic nerves stimulate closure of the ureteric and internal urethral orifices and contraction of the internal sphincter, and their action on the detrusor is inhibitory; *i.e.*, the effect is to prevent bladder outflow. Thus the sympathetic serves to control the situation in the distending bladder up to the point when evacuation can be deferred no longer. Afferent paths in the sympathetic convey sensations of pain, overdistension, and temperature from the mucosa of the bladder and the urethra. (3) The somatic nerves cause contraction of the external sphincter; their sensory fibres relay information as to the state of distension of the posterior urethra.

**Bladder function in micturition.** Certain reflexes combine to ensure both maintenance of a steady holding state for urine and normal progressive micturition with complete emptying. When the internal pressure of the bladder rises, it contracts; and it also contracts when urine enters the urethra; the urethra relaxes when urine enters it; it also relaxes when the bladder contracts.

Both bladder sphincters are normally closed. As the

organ fills with urine, the contractile response of the muscle wall causes a rise in internal pressure. Relaxation then occurs as an active process of adjustment so that the organ may hold its contents at a lower pressure. As urine continues to enter the bladder, this rise and fall of pressure continues in steplike fashion, with the final pressure always gradually rising.

The repeated transient contraction waves at first are small and are not consciously felt; later, stimuli reach the brain and cause pain and a sharp rise of pressure. These later major contractions can be inhibited voluntarily. The desire to micturate begins at around a content of 400 millilitres, but it can be voluntarily overridden until the content reaches 600–800 ml, equivalent to a pressure of 100 ml water. Until this point the sphincters remain contracted to keep the urethral exit closed, but eventually the desire to micturate becomes urgent and irrepressible. Until this time, if it is socially inconvenient to urinate, voluntary inhibition of the detrusor and contraction of the perineal muscles keep the internal pressure as low as possible and prevent efflux. The threshold is dependent to some extent on the rate of filling and is higher when filling is slow; and training affects the amount the bladder can retain. In young children the situation is less controllable, and even small amounts of urine may excite reflex evacuation. Emotional influences are important. Anxiety inhibits the capacity of the bladder to relax on filling, so that under conditions of stress—*e.g.*, on the battlefield—there may be frequent involuntary passage of small quantities of urine.

**Micturition.** Micturition is a complex activity, partly reflex and unconscious and mediated by the lower spinal cord centres, partly under conscious control by the higher centres of the brain. Voluntary micturition begins with willed messages from the brain that reach the bladder via the motor fibres of the pelvic nerves to stimulate the detrusor, at the same time actively relaxing both urethral sphincters. But the reflexes already mentioned ensure that, once the process has begun and urine has entered the urethra, the contraction of the detrusor will continue and the sphincters will remain relaxed until evacuation is complete and the bladder empty. Evacuation is aided by voluntary contraction of a wide range of accessory muscles. The muscles of the abdominal wall contract to increase pressure on the bladder from without; the diaphragm descends and the breath is held; at the same time there is relaxation of the muscles of the perineal floor. Thus voluntary initiation and control of micturition is effected partly by an active process of stimulating parasympathetic sacral nerve outflow, partly by removing the normal inhibition exerted by the higher centres on the reflex centres in the spinal cord. Once begun, micturition is carried through to completion by lower and higher centres acting in concert; sensory messages from the urine-distended urethra also play a part. It follows that even if a bladder is not particularly distended and if reflex emptying is not urgent, the bladder can nevertheless be evacuated by voluntary contraction of the abdominal wall, so initiating the reflex process that, once begun, takes over.

Because the bladder is a hollow organ with a powerful muscular coat, some function persists, however disordered, even if nervous control is damaged or abolished. Even the completely denervated organ retains some automatic emptying, if only from its own elasticity. Certain typical clinical situations may be differentiated, corresponding to different modes of disordered function:

1. Lack of conscious inhibition of micturition because of damage to the cerebral cortex or, more usually, from psychological causes results in a desire to micturate that cannot be suppressed although bladder volumes may be quite small; micturition is precipitate and continues till the bladder is empty.

2. Transverse lesions or other damage to the spinal cord above the reflex centres that also cause paralysis of the lower half of the body produce an "automatic" bladder. There is persistent unconscious control, but this is established only after an interval. At first the bladder is atonic (lacking in physiologic tone) and becomes greatly

Normal  
micturition

Abnormal  
micturition

Innervation of  
bladder  
and  
urethra

distended; the detrusor relaxes and reflex micturition is abolished. Pressure finally rises sufficiently to overcome the spasm of the sphincters and urine is voided in small amounts. Further accumulation and partial voiding recur; that is, there is retention of urine with overflow incontinence. Under these conditions inflammation of the bladder readily develops, which may cause disability or death from chronic ascending urinary infection. If overdistension is prevented by regular catheterization, or by manual expression by firm pressure on the lower abdominal wall, an "automatic" bladder develops after some months. This is a small capacity organ with frequent emptying at a content of around 150 millilitres; there is reflex control mediated through the sacral segments of the spinal cord, the higher centres do not restrain the detrusor, and the internal sphincter relaxes more readily. Voluntary assistance from the abdominal muscles is a help in this situation, if these too have not been paralyzed; but there is always some residual urine from incomplete emptying and there is a risk of infection.

3. In contrast, there is the isolated, or "autonomous," bladder resulting from damage to the central nervous system below the sacral cord reflex centres. The bladder responds to distension like any hollow organ with a smooth muscle coat. It becomes tense but contracts only weakly so that, while small amounts of urine are voided, the residual urine may be as high as 200–300 millilitres. This condition is known as active incontinence as opposed to the overflow incontinence of the automatic bladder. Here again, active support from the abdominal muscles is helpful.

Finally, the effects of chronic obstruction to bladder outflow, as from narrowing of the urethra or compression of the urethra by an enlarged prostate, must be noted. There is chronic retention, the pressure within the bladder rises, but for a time hypertrophy of the muscle wall maintains normal micturition and overcomes the obstruction. Eventually severe chronic overdistension results with paralysis of the bladder wall and retention with passive overflow, dribbling of urine. In such circumstances, if surgical aid is not available, ascending infection of the urinary tract is inevitable.

#### HORMONES AND THE KIDNEY

Certain hormones are intimately related to renal function. The role of the antidiuretic hormone (ADH, or vasopressin) of the posterior lobe of the pituitary in controlling diuresis has already been discussed. Vasopressin regulates water excretion by increasing membrane permeability to water and by accelerating water and ion transfer in a direction determined by the osmotic gradient. The receptors of the base of the brain form part of the feedback mechanism that stimulates ADH output if the osmotic concentration of extracellular fluid (ECF) is high so as to concentrate the urine, and that reduces ADH output and so dilutes the urine if osmotic concentration of ECF and of plasma falls.

The hormones of the adrenal cortex are also important in influencing renal function, directly or indirectly. In stress situations, as after an injury or a surgical operation, the output of hydrocortisone and other corticosteroids is increased because the adrenals are stimulated by ACTH, the adrenocorticotrophic secretion of the pituitary. Hydrocortisone increases protein breakdown, and consequently the output of nitrogen in the urine, and affects water metabolism; lack of hydrocortisone reduces the power of the kidney to deal with normal water loads. The hormone also promotes sodium retention and loss of potassium and hydrogen ions by the kidney. Aldosterone influences electrolyte metabolism by facilitating the reabsorption of sodium ions at the distal tubules, also at the expense of hydrogen and potassium excretion. The action of aldosterone has been described as priming the sodium reabsorption pump; it is probably the adrenal hormone most important to tubular function. Metabolites of corticosteroids devoid of activity are rapidly excreted in the urine, where they can be estimated to assess adrenocortical function.

The action of the parathyroid glands is to increase

blood calcium by mobilizing calcium from the bones and other sources; if this hormone functions to excess, as in tumours of the glands, the urinary loss of calcium is much increased and calcium stones tend to form in the kidneys and the bladder. The pituitary growth hormone facilitates protein synthesis and decreases the urinary loss of nitrogen. The sex hormones estrogen and progesterone exert an ill-defined activity as regards salt and water metabolism.

The juxtaglomerular apparatus (JGA), consisting of an asymmetrical cuff of large granular cells in the wall of the afferent arteriole near its entry into the capsule of the nephron, contains renin in the granules in the cells. Renin is a true internal secretion of the kidney. Entering the plasma, it acts as an enzyme that induces one of the plasma globulins to yield angiotensin I, which is inactive, and which gives rise in turn to angiotensin II, the most potent agent for constricting the blood vessels and raising the blood pressure. The formation of renin at the JGA is induced by a fall in blood pressure and inhibited by a rise. When the pressure falls, the output of angiotensin II raises the pressure and also excites the release of aldosterone from the adrenal cortex. This process is another example of a feedback mechanism analogous to that controlling the output of ADH.

#### BIOLOGICAL CONSIDERATIONS

During the greater part of pregnancy the glomerular filtration rate (GFR) is increased by as much as 50 percent, corresponding to an increase in renal blood flow of up to 25 percent in the middle three months of pregnancy. Glycosuria is frequent due to increased glucose loading of the filtrate, there is some sodium retention with a tendency to abnormal accumulation of serous fluid (edema), and some protein may appear in the urine.

The kidneys of the fetus begin to function well before birth, as indicated by a steady rise in the urea and uric acid content of the amniotic fluid in which the fetus exists; the fetus probably swallows fluid and voids it as urine. But even at birth, half the work of excretion is still being carried out via the placental circulation and the maternal kidneys, and this dependence is abruptly curtailed. Kidney function is far from fully developed in the newborn infant. The glomerular filtration rate is only some 30 millilitres per minute per square metre of body surface, compared to 75 in the adult, and tubular function does not attain adult performance until the end of the first year. The 24-hour output of urine is only some 20 millilitres; the output of water and the renal clearance of sodium, potassium, and phosphate is low; the urine is dilute and often contains protein. Because the kidney has such a poor capacity to excrete solids, the infant is exposed to the dehydrating effect of vomiting and diarrhea, which readily induce renal failure.

There is an increased urine output at the commencement of muscular exercise, due to the general stimulation of circulation, but a later falling off with the fatigue and sweating caused by severe prolonged exertion. The 24-hour rhythm in output has been mentioned. The small output in the early morning hours is a practical convenience to prevent disturbance of sleep. If the natural sleep rhythm is inverted, as by working on night shift, electrolyte and water output follow suit. The urine is acid at night and becomes less so, or alkaline, on rising. Output is maximal during the first waking hours and rises after meals. Because of all this variation in water and solute output, any analytic study of urine components must be conducted on 24-hour specimens.

Hydrogen-ion concentration in the urine may vary from pH 4 to 8; i.e., from many hundred times that of the plasma to a fraction; hence the ability of the kidneys to regulate acid-base balance in body fluids. Essentially, they do so by controlling the rate of reabsorption of bicarbonate from the filtrate, and by excreting hydrogen ions with regeneration of bicarbonate. The mechanism is one of ion exchange, mediated through the reversible chemical reaction between water and carbon dioxide: water plus carbon dioxide yields carbonic acid, which yields hydrogen ions and carbonate ions ( $\text{H}_2\text{O} + \text{CO}_2$

$\rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$ ), so that hydrogen ion ( $\text{H}^+$ ) in the tubule cells is exchanged for sodium ion ( $\text{Na}^+$ ) in the filtrate. Only minor changes in pH occur in the proximal tubules, rather more in the distal tubules, where the fluid becomes slightly acid, but a major change toward acidity occurs in the distal collecting ducts. For every molecule of acid excreted in the urine, one molecule of sodium bicarbonate ( $\text{NaHCO}_3$ ) is regenerated and returned to the blood in the vessels surrounding the tubules.

#### Regulation of body fluids

Constant composition of blood and body fluids is basically dependent on regulation of the volume, osmotic pressure, and constituents of the extracellular fluid (ECF). This fluid forms the internal environment of the tissues, and invariance is essential to life. It is an important part of homeostasis to keep the volume of ECF constant by adaptive changes in sodium and water output. Such maintenance is effected by the circulation, respiration, and ingestion, and also by selective renal excretion. Like the lungs, bowel, and skin, the kidney is an organ for exchanges between the ECF and the external environment; and these are large exchanges, the kidneys producing 170 litres of glomerular filtrate in 24 hours and reabsorbing all but 1.5 litres. The amount of water lost through the kidneys, however, corresponds closely to the body's current needs, whereas loss by skin and lungs is largely controlled by environmental factors such as humidity and temperature. Again, the bowel absorbs almost all ingested water as a load on the circulation, without relation to bodily needs. Thus it is the kidneys that are the fine regulators of water and solute content of the ECF. They adjust the volume and composition of blood and ECF within narrow bounds, but there are limits to this control. The kidneys cannot concentrate the urine to more than 1,400 milliosmoles per kilogram, equivalent to a specific gravity of 1.035. There is an obligatory excretion of excess electrolytes and end-products of protein metabolism such as urea, so that there is an obligatory output of urine as determined by solute and protein ingestion and rate of urea formation. If there is not enough water available for this vehicle, the blood urea rises; and if the protein intake is excessive more urine is needed to prevent such a rise. It is easier, in this context, for the kidney to produce a dilute rather than a concentrated urine; osmolality may fall as low as 30 milliosmoles per kilogram; the function of ADH in part is to prevent such overdilution.

At least 90 percent of the osmotic pressure of ECF and of plasma is due to sodium chloride, the content of which is regulated by renal water excretion and reabsorption under the delicate control of the hypothalamic osmoreceptors and ADH. The volume of ECF depends largely on its sodium content, and so on the rate of renal excretion of sodium, which is very sensitive, adjusting even to minor changes of posture. Of the filtered sodium, 85 percent is reabsorbed obligatorily as sodium chloride in the proximal tubules without much regard for current needs. But in the distal tubules there is a fine facultative reabsorption in exchange for potassium and hydrogen ions, and this exchange is closely related to the body situation as regards mineral metabolism; it is effected under the control of the adrenal cortical hormones, particularly aldosterone, and also of the humoral renin-angiotensin system. Thus, if the body loses sodium, the concentration of sodium ions in the ECF falls, but normal osmolality is restored by an increased water output; if the sodium content of the ECF rises, as in dehydration, water loss is reduced.

The control of potassium transfer is largely independent of the factors governing movements of sodium. A moderate potassium load is usually accurately excreted in the urine within an hour or two. What is important is not so much the preservation of a constant potassium level in plasma or ECF as its maintenance within individual cells. The kidney cannot conserve potassium as well as it does sodium, and potassium depletion may readily occur in severe vomiting or diarrhea. The rate of potassium excretion in the distal tubule is mainly determined by the amount of sodium ions available for exchange and by the influence of aldosterone on this exchange.

When water is drunk it is nearly all rapidly absorbed from the bowel into the bloodstream, slightly increasing the volume of the plasma and decreasing its osmotic pressure by dilution. There is an interchange with the ECF and the cells, with some excess water leaving the plasma and entering the ECF and then the cells, and with electrolytes leaving the cells and entering first the ECF and then the plasma.

The kidneys respond to the challenge after a latent period of about half an hour; urine output rises to a peak within 90 minutes and then declines slowly until the diuresis is all over, within a few hours. This response is selective to water intake, a great increase in water output in a dilute urine with little or no associated loss of solids. There is no accompanying increase in renal blood flow or glomerular filtration rate, but simply an inhibition of the ADH output so as to reduce water reabsorption in the distal part of the nephron.

Retention of excess water in the body, causing visible swelling of the subcutaneous tissues, or edema, may result from a number of factors: abnormal blood vessel permeability, a low level of plasma proteins, and failure of the right side of the heart, but a common cause is renal failure. Thus in acute nephritis there is a diminished urine output and much retention of fluid. Severe water intoxication, or "water poisoning," is the extreme condition, due to excessive intake, or to kidney disease or an abnormally large output of ADH; it produces headache, nausea, convulsions, coma, and even death.

Water deprivation leads to a fall in ECF volume and a consequent rise in its crystalloid osmotic pressure. Water enters the fluid from the cells, metabolism is disturbed, and there is a loss of potassium and protein. Urine output falls under the control of ADH and electrolyte excretion is increased. With continued deprivation of water even the plasma volume will eventually fall and urine concentration will lead to renal failure with gross nitrogen retention (uremia). Thirst is the biological response to such a situation, but it is emotionally as well as biologically conditioned; there may be thirst when the situation does not warrant it and an absence of thirst just when drinking is urgently required.

An excess of salt intake, as from drinking seawater, or a relative excess of salt content, as in dehydration, increases the crystalloid content and osmotic pressure throughout the body fluids and the volume of the ECF at the expense of cellular fluid. The kidneys cannot concentrate the urine to the osmotic pressure required; this failure leads to cellular dehydration and death.

Salt loss is usually due to sweating, as in stokers and miners, and forms part of the heat-exhaustion syndrome. It is only occasionally due to dietetic deficiency. It does not normally produce much thirst, though fluid and salt replenishment is urgent. The sodium content of the ECF and plasma falls, as does the volume of these fluids, leading to a reduced cardiac output, circulatory failure, impaired renal tubular function, and a rising level of urea in the blood. If water, but not salt, is supplied, the sodium deficiency will increase still further, causing cramps, collapse, rapid pulse, shock, and renal failure. There will be no chloride in the urine. The correct management consists of the administration of dilute saline solution by mouth or intravenously.

**BIBLIOGRAPHY.** The following works all provide detailed and well-written surveys of the whole field of kidney function in a form suitable for medical students and others with a good scientific grounding: E.J.M. CAMPBELL, C.J. DICKINSON, and J.D.H. SLATER (eds.), *Clinical Physiology*, 3rd ed., pp. 149-197 (1968); C.H. BEST and N.B. Water excess and deprivation

## Excretion and Excretory Systems

Every organism, from the smallest protist to the largest mammal, must rid itself of the potentially harmful by-

products of its own vital activities. The physiological process by which the organism disposes of its nitrogenous by-products is called excretion. The mechanisms for that process constitute the excretory systems, particularly such organs of vertebrate animals as elaborate and complicated as the kidney and its associated urinary ducts.

#### GENERAL FEATURES

**Definitions and distinctions.** The meaning of excretion is most easily understood in the context of vertebrate physiology. The animal swallows food (ingestion). In the stomach and intestine some of the food is broken down into soluble products (digestion) that are absorbed into the body (assimilation). In the body these soluble products undergo further chemical change (metabolism); some are used by the body for growth, but most provide energy for the various activities of the body. Metabolism involves the uptake of oxygen and the elimination of carbon dioxide in the lungs (respiration). Besides carbon dioxide, compounds of nitrogen arise from metabolism and are eliminated, chiefly by the kidney, in the urine (excretion). Food not digested is eliminated through the anus (defecation).

These processes are characteristic of animals in general, but not of plants. A green plant takes in carbon dioxide from the atmosphere and nitrogen (as nitrate) from the soil. It uses the energy of sunlight to build these nutrients into the materials required for growth and in the process gives out oxygen (see PHOTOSYNTHESIS). The processes of ingestion, excretion, and defecation have no obvious parallels in plants, but see ELIMINATION.

In a broad sense animals live on plants, and the by-products of animals are the raw materials on which plants grow. These mutually supporting activities of plants and animals are kept precisely in balance by the activities of bacteria. Bacteria convert the urine and feces of animals (and also the dead bodies of both plants and animals) to carbon dioxide and nitrate. In the living world as a whole, carbon and nitrogen are in continuous circulation, driven by the energy of sunlight (see BIOSPHERE). Over most of the earth, for most of time, no by-products accumulate. Occasionally the cycles get out of balance, as they must have done during the prehistoric period when coal was being formed in the earth as a consequence of the failure of bacteria to decompose all the remains of plants (see COALS).

**Products of excretion.** Although every type of organism takes in some materials and eliminates others, excretion in the strict sense is a process found only in animals. For the purposes of this article excretion will be taken to mean the elimination of nitrogenous by-products and the regulation of the composition of the body fluids (see also HOMEOSTASIS).

The primary excretory product arising naturally in the animal body is ammonia, derived almost entirely from the proteins of the ingested food. In the process of digestion proteins are broken down into their constituent amino acids. Some of the amino acid pool is then used by the animal to build up its own proteins, but a great deal is used as a source of energy to drive other vital processes. The first step in the mobilization of amino acids for energy production is deamination, the splitting off of ammonia from the amino acid molecule. The remainder is oxidized to carbon dioxide and water, with the concomitant production of the energy-rich molecules of adenosine triphosphate (ATP; see METABOLISM).

Since ammonia is highly toxic to most animals, it must be effectively eliminated. This is no problem in small aquatic animals because ammonia rapidly diffuses, is highly soluble in water, and escapes easily into the external medium before its concentration in the body fluids can reach a dangerous level. But in terrestrial animals, and in some of the larger aquatic animals, ammonia is converted into some less harmful compounds (detoxication). In mammals, including man, it is detoxified to urea, which may be considered as being formed by the condensation of one molecule of carbon dioxide with two molecules of ammonia (though the biochemistry of the process is more complex than that). Urea is highly soluble

in water but cannot be excreted in a highly concentrated solution because of the osmotic pressure (see below) it would exert. Conservation of water being a pressing need for most terrestrial animals, it is not surprising that many of them have evolved more economical methods for disposing of nitrogenous by-products. Birds, reptiles, and terrestrial insects excrete nitrogen in the form of uric acid, which is highly insoluble in water and can be removed from the body as a thick suspension or even as a dry powder.

#### EXCRETORY MECHANISMS

**Osmotic pressure.** In order to understand the advantages of the excretion of uric acid over urea it is necessary to know something about the behaviour of molecules in solution. Molecules of a solute (e.g. salt, sugar) in water tend to move by diffusion from a region where they are in high concentration to one where they are in low concentration, and molecules of water tend to move in the opposite direction. If a porous membrane is interposed between these regions, the movements of molecules may be variously restricted depending upon their size in relation to the size of the submicroscopic pores in the membrane. The passage of water molecules from pure water through such a membrane into a solution containing molecules that are too large to pass is called osmosis, a process that takes place spontaneously and does not require energy. This process can be reversed by applying hydrostatic pressure to the solution, a process that does require energy. The level of hydrostatic pressure at which there is no net movement of water in either direction across the membrane is called the osmotic pressure of that particular solution; the greater the concentration of dissolved molecules in the solution the greater is its osmotic pressure and the greater the force needed to remove water from it.

Applying these principles to excretion, it can be seen why more energy is required to remove water from urine containing urea than from urine containing the same weight of uric acid. The molecule of urea is smaller than that of uric acid, so there are more molecules of urea to exert osmotic pressure. But an even more important difference is that whereas urea is highly soluble in water, uric acid is not. As water is progressively removed from a solution of urea, the osmotic pressure opposing further removal progressively increases. For the uric acid solution, however, as water is removed, the uric acid comes out of solution, or precipitates, when the solution is at a lower concentration, and, therefore, at a lower osmotic pressure, which does not increase further.

**Regulation of water-salt balance.** The mechanisms of detoxication that animals use are obviously related to their modes of life. This is true, with greater force, of the mechanisms of homeostasis, the ability of organisms to maintain internal stability. A desert-living mammal constantly faces the problem of water conservation; but a freshwater fish faces the problem of getting rid of the water that enters its body by osmosis through the skin. At the level of the individual cell, whether it be the cell of a unicellular organism or a cell in the body of a multicellular organism, the problems of homeostasis present themselves in similar ways.

For the continuation of its intracellular processes the cell must maintain an intracellular chemical environment in which the concentrations of various ions (see below) are kept constant in the face of changing concentrations in the medium surrounding the cell. This is the task of the cell membrane. In the higher animals the task is easier since cells in the interior of their bodies are bathed in an internal medium—the blood—whose composition is regulated so as to minimize the effects of changes in the external medium. This regulatory function is undertaken by specialized cells or organs such as the kidney, thereby lessening the regulatory burden of the other cells of the body.

The biological necessity for homeostatic mechanisms is particularly urgent for controlling the inorganic components of cells and body fluids. Inorganic salts can exert even greater osmotic pressure against membranes im-

The osmotic process

Elimination and regulation

permeable to them than urea. This is so because, under the conditions in the body, they are almost completely dissociated into their component ions. For example, a molecule of common salt (sodium chloride) is dissociated into a positively charged sodium ion and a negatively charged chloride ion, both of which can exert osmotic pressure.

Besides their osmotic effects, inorganic ions have profound effects upon metabolic processes, which in general will take place only in the presence of appropriate concentrations of these ions. The most important inorganic ions in organisms are the positively charged hydrogen, sodium, potassium, calcium, and magnesium ions, and the negatively charged chloride, phosphate, and bicarbonate ions. The membranes of cells are not completely impermeable to these ions and are in fact endowed with the ability to transport ions from one side to the other, whereby they control the concentrations of ions within the cells; when such transport is in the direction that requires a supply of energy, it is called active transport (see MEMBRANE, BIOLOGICAL).

Osmotic regulation is the maintenance of the normal concentration of the body fluids; *i.e.*, the total concentration of all dissolved substances (solutes) that would exert osmotic pressure against a membrane impermeable to them. Osmotic regulation controls the amount of water in the body fluids relative to the amount of osmotically active solutes. Ionic regulation is the maintenance of the concentrations of the various ions in the body fluids relative to one another. There is no hard and fast distinction between the two processes; organs that participate in one process at the same time participate in the other.

**Principal excretory structures.** Whereas the kidney is undoubtedly the principal organ subserving both nitrogenous excretion and osmotic and ionic regulation in the mammalian body, these functions are not always performed by a single organ in other animals. As indicated earlier, primitive aquatic animals do not require any special provision for nitrogenous excretion. But by reason of their permeable skins they may have serious problems of osmotic and ionic regulation, especially in freshwater, where cells covering the surface of the body have the ability actively to transport salts into or out of the animal. In some cases these nonkidney regulatory activities are performed by certain recognizably specialized cells; *e.g.*, in the gills of fishes (see below). In other cases, specialized cells are assembled into organs of salt uptake or salt elimination; *e.g.*, the salt glands of birds (see below).

This dispersal of the regulatory function may be the primitive condition, for it is only in the more highly evolved terrestrial animals that the regulatory function is restricted to an excretory system proper. This is readily understandable in view of the need of terrestrial animals to conserve water. This evolutionary development toward one system reaches its climax in the birds, reptiles, and terrestrial insects, in which all the processes of elimination that might involve loss of water—defecation, nitrogenous excretion, and ionic regulation—converge upon the same final channel.

For the excretory organs of a wide variety of vertebrate and invertebrate animals, there is evidence that the primary process of urine production is nonselective, in that in those animals all substances dissolved in their body fluids, with the possible exception of proteins, are found in the primary urine. In many animals the primary urine is produced by filtration from the blood. At a later stage, substances in the primary urine that are useful to the body are selectively reabsorbed. In addition, a few substances are known to be actively transported (secreted) into the urine.

The nonselective formation of primary urine serves another aspect of excretion: the elimination of foreign substances. Mechanisms of active transport are highly specific to the substances transported. All dissolved constituents of the body fluids pass freely into the primary urine and then specific reabsorptive mechanisms gather up the "wanted" substances. In this way a natural economy automatically eliminates "unwanted" substances simply by not providing mechanisms for their reabsorption.

## INVERTEBRATE EXCRETORY SYSTEMS

In their detoxication mechanisms, so far as they have been investigated, the invertebrates in general conform to the principles applying to all animals, namely, that aquatic forms get rid of ammonia by diffusion through the surface of the body; terrestrial forms convert ammonia to uric acid. This implies that in aquatic forms the excretory organ is principally of importance for the composition of their body fluids. Normally, the body fluids of marine invertebrates have the same concentration as seawater; they usually differ, however, in the proportions of ions, with relatively more potassium and less magnesium than seawater. Furthermore, their urine normally has the same concentration as seawater, but correspondingly it contains less potassium and more magnesium. In freshwater invertebrates the urine is commonly, though not invariably, more dilute than the body fluids. By producing dilute urine a freshwater invertebrate conserves the salt content of its body while eliminating the water that enters its body by osmosis through its water-permeable surface.

Regulation  
of body  
fluids

Figure 1: Invertebrate excretory systems. (A) Contractile vacuole of an amoeboid protozoan. (B) Protonephridial system of a flatworm, with enlargement of a single-celled flame bulb that terminates the tubules of excretory canals. (C) Metanephridial system of an earthworm, with paired nephridia in one segment. (D) Renal organ of a clam, cut away to show glandular region. (E) Renal system of a crayfish, exposed through cut-away shell. (F) Excretory system of a mosquito.

Some invertebrates, notably echinoderms, coelenterates, and sponges, have no organs to which an excretory function can be confidently ascribed. Since all of these animals are aquatic, it is reasonable to suppose that they excrete nitrogen (as ammonia) by simple diffusion. Their

Active  
transport  
of ions

body fluids (where present) are closely similar to seawater in composition, and it may be presumed that regulation operates only at the cellular level.

The excretory organs of other invertebrates are of diverse evolutionary origin. This is not to say, however, that each invertebrate phylum has evolved its own particular type of excretory organ; rather, there appear to be five main types of invertebrate excretory organ: contractile vacuole, nephridium, renal gland, coxal gland, and malpighian tubule.

**The contractile vacuoles of protozoans.** Some protozoan animals possess an organelle having the form of an internal sac, or vacuole, which enlarges by the accumulation of a clear fluid and then discharges its contents to the exterior. The cycle of filling and emptying may be repeated as frequently as every half minute. The chief role of the contractile vacuole appears to be in osmotic regulation, not in nitrogen excretion.

Contractile vacuoles occur more frequently and are more active in freshwater species than in closely related marine species. In freshwater, the concentration of dissolved substances in the cell is greater than in the external medium, and the cell takes in water by osmosis. If the contractile vacuole is put out of action, the cell increases in volume. If the concentration of salts in the medium increases—which would have the effect of decreasing the rate of osmosis—the rate of output by the contractile vacuole diminishes. The fluid eliminated by the vacuole is more dilute than the cytoplasm.

**The nephridia of annelids, nemertines, flatworms, and rotifers.** The word nephridium applies in its strict sense only to the excretory organs of annelids, but it may usefully be extended to include the excretory organs of other phyla having similar characteristics. Annelids are segmented animals that typically contain a pair of nephridia on each segment. Each nephridium has the form of a very fine tubule, often of considerable length; one end usually opens into the body cavity and the other to the exterior. In some annelids, however, the tubule does not open into the body cavity but ends internally in a cluster of cells of a special type known as solenocytes, or flame cells. The possession of solenocytes by some annelids is one of the characters that allies them with other nonsegmented phyla that have no true body cavity. They also have a system of tubules opening at the surface and ending internally in flame cells embedded among the other cells of the body. In most cases, there is no regular arrangement of the various parts of the system.

Animals belonging to all of these phyla are primarily aquatic, and, in the few cases known, the main excretory product is ammonia. How much of it leaves the body by the nephridia and how much through the body surface is unknown.

Very few physiological studies have been made on nephridia other than those of the earthworm. Although the earthworm is considered a terrestrial animal, its relationships with its environment are characteristically those of a freshwater animal. The nephridium of the earthworm is longer and more complex than that of marine annelids, four regions being distinguishable. Body fluid enters the nephridium via an internal opening called the nephridiostome. As the fluid passes along the tubule, probably driven by cilia, its composition is modified. In the two lower regions of the tubule the fluid becomes progressively more dilute, presumably as a result of the reabsorption of salts. Finally, a very dilute urine passes into the bladder (an enlarged portion of the tubule) and then to the exterior through the external opening, or nephridiopore. The rate of urine flow for an earthworm may be as much as 60 percent of its body weight in a period of 24 hours.

**The renal glands of mollusks.** The anatomical form of the renal gland varies from one class of mollusks to another, but a common plan is clearly evident. The renal gland is a relatively wide tube opening from a sac (the pericardium) surrounding the heart, at one end and to the mantle cavity (effectively to the exterior) at the other. There is a single pair of renal glands; in some forms one member of the pair may be reduced or absent. Clams

have the simplest arrangement; the region nearest to the pericardium has glandular walls and gives way to a non-glandular, wider tube that extends to the urinary opening.

The vast majority of mollusks are aquatic, and, as would be expected, excrete nitrogen in the form of ammonia. In octopuses, however, nitrogen is excreted as ammonium chloride, which is quite strongly concentrated in the urine. Terrestrial snails and slugs excrete uric acid but may also excrete ammonia when living in moist surroundings.

In all mollusks so far investigated the primary process in urine production appears to be filtration of the blood. This may take place through the wall of the heart into the pericardium, or from blood vessels that supply the glandular part of the renal gland. The composition of the primary urine may be altered by reabsorption or secretion, or both. In freshwater mollusks salts are reabsorbed in the glandular tube and in the wide tubule, and the final urine is more dilute than the blood. The rate of urine flow is high, up to 45 percent of the body weight per day in the freshwater mussel. In marine mollusks the urine has the same concentration as the blood, as would be expected, but (in the few cases examined) its ionic composition is different.

**The coxal glands of aquatic arthropods.** Coxal glands are tubular organs, each opening on the basal region (coxa) of a limb. Since arthropods are segmented animals, it is reasonable to suppose that the ancestral arthropod had a pair of such glands in every segment of the body. In crustaceans now living there is, as a rule, only a single pair of glands, and in higher crustaceans these open at the bases of the antennae. Each antennal gland is a compact organ formed of a single tubule folded upon itself. When unravelled the tubule is seen to comprise three or four easily recognizable regions. The tubule arises internally as a small sac, the coelomic sac, which opens into a wider region, the labyrinth, having complex infoldings of its walls. The labyrinth opens either directly into the bladder, as in marine lobsters and crabs, or into a narrow part of the tubule, the canal, which in turn opens into the bladder, as in freshwater crayfishes.

The coelomic sac, well-supplied with blood vessels, gives evidence that the primary process in urine production is filtration of the blood through the wall of the coelomosac in a manner analogous to filtration in the glomerulus and Bowman's capsule of the vertebrate kidney (see below). In lobsters and marine crabs the urine in all parts of the organ has the same ion concentration as the blood. In freshwater crayfishes the urine has the same concentration as far as the end of the labyrinth; from there on reabsorption takes place in the canal and the urine leaves the body as a very dilute solution. The addition of the canal to the system demonstrates one way crustaceans have adapted to life in freshwater. But this is not the only way in which the regulatory problem is solved in freshwater crustaceans. In freshwater crabs, for example, there is a great decrease in the water permeability of the surface (principally the gills) so that water enters by osmosis quite slowly. In contrast to the rate of urine flow in a freshwater crayfish (about 5 percent of the body weight per day), that of the freshwater crab is 100 times less (about 0.05 percent). In the crab the urine has the same concentration as the blood, but because the flow is so small the salt loss via the urine is negligible. A few semiterrestrial crabs are known to produce urine more concentrated than the blood.

In all crustaceans for which analyses are available the concentrations of ions in blood and urine differ. At a urine flow of 5 percent of the body weight per day the activities of the antennal glands are certainly capable of effecting changes in the composition of the blood. These activities are somehow coordinated with salt uptake by the cells of the body surface so as to subserve homeostasis. The role of the antennal glands in nitrogenous excretion seems to be unimportant.

**The malpighian tubules of insects.** Although some terrestrial arthropods (e.g., land crabs, ticks) retain the coxal glands of their aquatic ancestors, others, the insects,

Ion concentration in urine

The common plan of the renal gland

have evolved an entirely different type of excretory system. The malpighian tubules, which vary in number from two in some species to over 100 in others, end blindly in the body cavity (which is a blood space) and open not directly to the exterior but to the alimentary canal at the junction between midgut and hindgut. The primary urine issuing from the malpighian tubules has to pass through the rectum before it leaves the insect's body, and in the rectum its composition is profoundly changed. The insect excretory system therefore comprises the malpighian tubules and the rectum acting together.

The malpighian tubules are bathed in the insect's blood, but since they are not rigid it is impossible for any hydrostatic pressure to be developed across their walls, such as could bring about filtration. The primary urine is formed by a process of secretion in the following way: Potassium ions are actively transported from the blood into the cavity of the tubule and are necessarily followed by negatively charged ions so as to maintain electroneutrality. In turn, water follows the ions, probably by osmosis, and various other substances—sugars, amino acids, and urate ions—also enter the primary urine by diffusion from the blood.

The primary urine, together with soluble products of digestion and insoluble indigestible matter from the midgut, then passes to the rectum. Here (or in some insects at an earlier stage) the urine is acidified and the soluble urate is thereby converted to insoluble uric acid, which comes out of solution. Water is then reabsorbed together with the soluble products of digestion and other useful substances, including the bulk of the ions that entered the primary urine. In insects that live in dry surroundings the rectum has remarkable powers of reabsorption, its contents finally being voided as hard, dry pellets containing solid uric acid.

The activity of the excretory system in insects is under hormonal control. This has been most clearly demonstrated in the case of *Rhodnius*, a bloodsucking bug. Immediately after the ingestion of a blood meal there is a rapid flow of urine whereby most of the water taken in with the blood meal is eliminated. The distension of the body after ingestion is the stimulus that causes certain cells in the central nervous system to release a hormone that acts upon the malpighian tubules to promote a brisk flow of primary urine.

#### VERTEBRATE EXCRETORY SYSTEMS

The kidney and its associated ducts are the excretory system of the mammal, and, as already noted, most of the nitrogenous waste arising in the mammalian body is excreted as urea. Other nitrogenous compounds regularly present in the urine in smaller amounts are uric acid (or the closely related compound allantoin) and creatinine; both of these arise mainly as by-products of the renewal and repair of tissues.

In birds, reptiles and amphibians the kidneys are compact organs as they are in mammals, but in fishes they are narrow bands of tissue running the length of the body (see below under *Evolution*). In amphibians, as in mammals, the main excretory product is urea. In birds and reptiles it is uric acid. In most fishes the main excretory product is ammonia.

**Structure and function.** In mammals. The mammalian kidney (Figure 2) is a compact organ with two distinct regions: cortex and medulla. The functional unit of the kidney is the nephron, of which there are about 1,000,000 in each kidney of man, tightly packed together. Each nephron (Figure 2) is a tubular structure consisting of four regions. It arises in the cortex as (1) a small vesicle about one-fifth of a millimetre in diameter, known as Bowman's capsule, into which projects a tuft of capillary blood vessels, the glomerulus. Bowman's capsule is continuous with (2) the proximal convoluted tubule, which also lies in the cortex. Following the proximal convoluted tubule is (3) the loop of Henle, which descends into the medulla and then runs straight up again to the cortex where it continues as (4) the distal convoluted tubule. A collecting tubule, into which several nephrons open, courses through the medulla to open a wide cavity, the

Figure 2: The mammalian kidney. (Left) The kidney proper, with a single nephron (of thousands present) in white and somewhat larger proportionately. (Right) Nephron enlarged to show component parts.

pelvis of the kidney. From the pelvis the ureter leads to the bladder, and from the bladder the urethra leads out of the body. (See also EXCRETORY SYSTEM, HUMAN.)

The mechanism of urine formation involves three processes: filtration, reabsorption, and secretion. Primary urine is formed by filtration from the blood. From this primary urine certain substances are reabsorbed into the blood and other substances are secreted into the primary urine from the blood. The word secretion is used by renal physiologists to imply transport, other than by filtration, from the blood to urine. Filtration implies that all molecules below a certain size are allowed to pass nonselectively into the primary urine; reabsorption and secretion imply the existence of specific mechanisms for the transport of specific substances.

The membrane covering the glomerulus is permeable to water and to all the constituents of the blood plasma except proteins. The glomerular capillaries are intercalated in the course of an artery, with the consequence that the pressure of the blood in these capillaries is higher than in the capillaries in other parts of the kidney. Opposed to the blood pressure are the pressure of the fluid within Bowman's capsule and the osmotic pressure exerted by the proteins of the blood plasma; but the blood pressure is sufficiently in excess of the sum of these to ensure a rapid flow of fluid, the glomerular filtrate or primary urine, into Bowman's capsule. The glomerular filtrate contains the nitrogenous compounds ultimately to be excreted in the urine. As the glomerular filtrate passes through the proximal tubule, 80 percent of the water, and many substances of value to the body (e.g., glucose), are reabsorbed into the blood capillaries surrounding the tubule. This reabsorptive process is accomplished without any change in the concentration of the tubular fluid, which remains the same as that of the blood plasma.

After traversing the loop of Henle, the remaining 20 percent of the glomerular filtrate passes into the distal tubule, where further reabsorption, notably of salts, takes place. If this is accompanied by a proportionate reabsorption of water, the tubular fluid remains at the same concentration as the blood plasma, but if the reabsorption of water is restricted, as it may be in certain circumstances (see below), the tubular fluid becomes more dilute than the blood plasma. Under normal physiological conditions some 15 percent of the glomerular filtrate is reabsorbed in the distal tubule. Most of the remaining 5 percent is reabsorbed in the collecting tubule. The amount of fluid, at this point called urine, that reaches the pelvis of the kidney is only 1 percent of the volume originally filtered at the glomerulus; but it contains nearly all the nitrogenous waste of the filtrate in concentrated solution. A few substances are also secreted from the blood through the walls of the tubule into the tubular fluid.

The action of the loop of Henle is more difficult to describe. The descending and ascending limbs lie close together, and there is secretion of a small amount of salt from the ascending limb into the descending limb

Mechanism of urine formation in mammals

Action of the loop of Henle

Primary urine formation in insects

throughout the length of the loop. At any level the fluid in the descending limb is slightly more concentrated than the fluid in the ascending limb. As the fluid passes down the descending limb it becomes progressively more concentrated; as it passes up the ascending limb it becomes more dilute and leaves the loop more or less at the same concentration as the blood plasma. The net result of this activity on the part of all the loops in the kidney is to create at the inner margin of the medulla a region where all the fluids are more strongly concentrated than the normal blood plasma. The collecting tubules run through this region before opening into the pelvis; and since their walls are ordinarily permeable to water, water is removed from them by osmosis so that the final urine is more concentrated than the blood.

Desert-living mammals produce highly concentrated urine and their kidneys have a greater thickness of medulla because of the greater development of the loops of Henle. This mechanism is in full operation in an animal suffering from thirst; the water content of its body is conserved by the excretion of a small volume of concentrated urine. If the body has excess water, the mechanism becomes inoperative; instead, the reabsorption of salts (without a proportionate amount of water) in the distal tubule results in the production of a large volume of dilute urine (diuresis).

Although the kidney has a nerve supply, its activities are regulated by hormones in accordance with the body's needs. The pituitary gland at the base of the brain releases an antidiuretic hormone (ADH) into the blood. The ADH increases the permeability of the distal and collecting tubules to water, thereby facilitating the reabsorption of water. A slight increase in the concentration of the blood, such as would occur in the event of water deficiency, causes an increased secretion of ADH and the excretion of a small volume of concentrated urine. Conversely, dilution of the blood cuts off the release of ADH, decreasing the permeability of the tubules and causing diuresis. Another hormone, aldosterone, produced by the cortex of the adrenal gland, favours the excretion of potassium ions in preference to sodium ions.

Characteristics of the uric acid of birds and reptiles

*In birds and reptiles.* The main excretory product of birds and reptiles is uric acid. Since their glomeruli are relatively small, so also is their daily volume of urine. Not highly concentrated by mammalian standards—although it may be turbid with crystals of uric acid—the urine of birds and reptiles is conducted not to a urinary bladder but to the terminal portion of the alimentary canal, the cloaca; from the cloaca it is voided with the feces. Like mammals, and unlike the lower vertebrates, birds and reptiles have skins impermeable to water, and thus are well adapted to terrestrial life. The relative inability of the kidney to produce concentrated urine is compensated for in birds that possess salt glands, which remove excess salt from their bodies. These organs are modified tear glands that discharge a concentrated solution of sodium chloride through the nostrils. Salt glands enable marine birds to drink seawater with no ill effects.

*In amphibians.* The kidneys of amphibians have been much studied by renal physiologists, and the direct evidence for the occurrence of filtration at the glomerulus was first provided by experiments on the amphibian kidney.

Although amphibians are formally given the status of terrestrial animals, they are poorly adapted to life on land. They excrete nitrogen in the form of urea and cannot produce urine more concentrated than the blood. Their skins are permeable to water. On land amphibians are liable to lose water very rapidly by evaporation. In freshwater they suffer entry of water by osmosis, which is counteracted by the excretion of a large volume of dilute urine. The urine is stored in a large bladder before being voided, providing a reserve of water the animal can use when it comes on land.

When an amphibian leaves the water, a number of physiological adjustments are made that have the effect of conserving water. The rate of glomerular filtration is reduced by restriction of the blood supply, and this together with an increased release of antidiuretic hormone

results in the production of a small volume of urine of the same concentration as the blood. The antidiuretic hormone also increases the permeability of the bladder to water and allows the stored urine to be reabsorbed into the body.

*Fishes.* The homeostasis problem is the same for freshwater fishes as for other freshwater animals. Water enters the body by osmosis and salts leach out. To compensate, the kidney (which has large glomeruli) produces a relatively large amount (about 20 percent of the body weight per day) of dilute urine. This serves to remove the water but by itself is insufficient to prevent gradual loss of salts. Extremely diluted salts are taken up from the freshwater and transported directly into the blood by certain specialized cells in the gills. Nitrogenous excretion is no problem: some ammonia is carried away in the large volume of dilute urine, but most of it simply escapes to the external medium by diffusing through the gills.

By contrast, the homeostasis problem of marine fishes is unlike that of most marine animals. The salt content of the blood of marine fishes is less than half that of seawater (see below under *Evolution*), with the consequence that the marine fish tends to lose water and gain salt. This, it would seem, could be compensated most easily by the excretion of urine more concentrated than the blood, but the kidneys of fishes are not able to do this. In marine bony fishes the kidney has small glomeruli and produces only a small amount (about 4 percent of the body weight per day) of urine, which is of the same concentration as the blood. The fish replaces its lost water by continually swallowing seawater, and the special cells of the gills, working in reverse, reject salt to the external medium. Nitrogen is excreted mostly as ammonia but also as another detoxication product, trimethylamine oxide.

In sharks and rays ammonia is converted to urea, and urea plays an important role in homeostasis. Surprisingly, urea is retained in the blood to such an extent that the blood is slightly more concentrated than seawater. Thus loss of water by osmosis is prevented and these fish have no need to swallow seawater. Any excess of salt in their bodies is removed via the rectal gland, functionally analogous to the salt gland of birds.

Osmotic and ionic regulation in fishes is under hormonal control. This has been studied particularly in fishes such as eels and salmon, which are able to move between freshwater and seawater.

#### EVOLUTION OF THE VERTEBRATE EXCRETORY SYSTEM

Studies of the embryonic development of primitive vertebrates, such as the dogfish shark, clearly show that the excretory system arises from a series of tubules, one pair in every segment of the body between the heart and the tail. This continuous series of tubules constitutes the archinephros, the name implying that the kidney of the ancestral vertebrate had some such form as this. Each tubule opens internally to the body cavity and may, in the remote past, have opened separately to the exterior; but in all living vertebrates the tubules open on each side into a longitudinal duct, the archinephric duct. At the posterior end of the body cavity the two archinephric ducts unite before opening to the exterior. Later in development, Bowman's capsule arises as a diverticulum of each tubule, subsequently becoming indented by the glomerulus. Eventually, the tubules usually lose their internal openings to the body cavity. The most anterior tubules of the archinephros (pronephros) usually degenerate in the adult.

These ducts and tubules also subserve the reproductive function, and for this reason zoologists are accustomed to speak of them as the urinogenital system. The extent to which the ducts and tubules are shared is greater in the male than in the female. In the male the spermatic tubules of the testis connect with the kidney tubules in the middle region of the archinephros (mesonephros), and in some vertebrates (e.g., the frog) where there is no development of the posterior region (metanephros), the tubules of the mesonephros serve to convey both urine

Excretion in marine fishes

Relationship between excretory and reproductive systems

and sperm. In the reptiles, birds, and mammals there is greater separation of function, the mesonephros being exclusively genital and the metanephros being exclusively urinary (see Figure 3).

Figure 3: Evolution of the urogenital system in male vertebrates. The ancestral archinephric condition has evolved in different patterns for the amphibians, reptiles, and mammals (birds have a pattern similar to reptiles). The broken lines indicate the change in ancestral plan in each of the major vertebrate classes.

In the female, even in the lower vertebrates, the two systems are confluent only at the posterior end. It has been held that the oviduct is a derivative of the archinephric duct, but the evidence for this is not compelling.

In primitive marine animals the blood is almost identical with seawater in composition; in typical freshwater animals the concentration of the blood is about half that of seawater. Many originally marine animals have evolved the ability to live in freshwater; relatively few animals, after having evolved into freshwater, have returned to the sea, and in none of them has the blood returned to its original "seawater" concentration. The earliest fossil vertebrates are found in marine deposits, but the fossil record shows clearly that the early evolution of fishes took place in freshwater. It is assumed that the blood of early freshwater fishes, like that of other freshwater animals, was osmotically equivalent to half-strength seawater. The sharks and rays returned to the sea during the Carboniferous Period, and no doubt at that time they evolved the device of urea retention. The bony fishes returned to the sea later, in the Mesozoic Era, and solved their problem by swallowing seawater and rejecting excess salt at the gills.

**BIBLIOGRAPHY.** H.W. SMITH, *From Fish to Philosopher* (1953), is a popular introduction to vertebrate evolution in

terms of kidney evolution. Among the general sources of information on the comparative structure and function of excretory systems are: E. FLOREY, *An Introduction to General and Comparative Animal Physiology*, ch. 5, 13 (1966); E.S. GOODRICH, *Studies on the Structure and Development of Vertebrates* (1930), an older work of unchallenged authority on morphological and evolutionary aspects of all vertebrate systems, including the urinogenital; A.S. ROMER, *The Vertebrate Body*, 3rd ed., ch. 13 (1962), on excretory and reproductive systems; M.S. GORDON *et al.*, *Animal Function: Principles and Adaptations*, ch. 7 (1968), on the regulation of water and salts in animals; W.S. HOAR, *General and Comparative Physiology*, ch. 8, 11 (1966); J. FIELD (ed.), *Handbook of Physiology*, sect. 4, *Adaptation to the Environment*, ch. 13-14 (1964), on the excretory function; presumes a greater background knowledge than do the works of Hoar, Florey, or Romer listed above.

More advanced books, covering parts of the subject, include: E.S. GOODRICH, "The Study of Nephridia and Genital Ducts since 1895," *Quart. J. Micro. Soc.*, 86:113-392 (1945), a review of research on the urinogenital systems up to the mid-1940s; W.T.W. POTTS and G. PARRY, *Osmotic and Ionic Regulation in Animals* (1963); and K. SCHMIDT-NIELSEN, *Desert Animals* (1964), with particular regard for the problems of water conservation in animals.

## Excretory System, Human

The excretory system, also called the urinary system, normally consists of two kidneys, which remove dissolved waste and excess substances from the blood and form urine; the bladder, where the urine is stored; the two ureters, which convey urine from the kidneys to the bladder; and the urethra, the passageway by which urine leaves the body (the development of this system is detailed in EMBRYOLOGY, HUMAN; its functioning, in EXCRETION, HUMAN). For a general treatment, see EXCRETION AND EXCRETORY SYSTEMS. This article is focussed on the structure of the system, including only such details of the functioning as are necessary to illuminate the structure.

### THE KIDNEYS

**General description and location.** Resembling kidney beans in shape and colour, the kidneys are reddish-brown, and are concave on one long side, convex on the opposite. They are normally high in the abdominal cavity and against its back wall, lying on either side of the vertebral column between the levels of the twelfth thoracic and third lumbar vertebrae, and outside the peritoneum, the membrane that lines the abdomen.

The location of the kidneys varies with changes in posture; they ascend somewhat when the body is recumbent and descend when it is erect. Their location is also influenced by movements of the diaphragm, the muscular partition between the chest and the abdomen that moves up and down as part of the processes of breathing. The right kidney is usually located about 1.5 centimetres (about 0.6 inch) lower than the left, as it is displaced downward by the greater bulk of the liver on the right side.

The long axis of the kidneys corresponds roughly with that of the body, except for a slight tilt that brings the upper ends closer to the backbone. Centred in the medial side of each kidney (the concave side toward the backbone) is a deep vertical cleft, the hilus, which leads into a cavity in the kidney known as the renal (kidney) sinus. The hilus is the point of entrance or emergence for the renal arteries, veins, lymphatic vessels, and nerves, and it includes the renal pelvis, the expanded upper end of the ureter.

The size of the kidneys varies. In adults their average length is 12 centimetres, their width seven centimetres, and their thickness 2.5 centimetres (in inches, about 4.7, 2.8, and one, respectively). Their average weight in men is about 145 grams (about five ounces); in women, about ten grams (0.4 ounce) less.

The kidneys are close to many other structures, separated from them only by the renal fascia (a sheet of connective tissue) or by fat. The relationships of the two kidneys differ.

In front, the right kidney is close to the liver, the right adrenal (suprarenal) gland, the descending part of the duodenum (the first portion of the small intestine), and

Size, colour, and shape of kidneys

the right colic flexure of the large intestine—the angle between the vertical section of the colon on the right (ascending colon) and the horizontal portion (transverse colon).

Almost the entire area near the liver, like the part near the small intestine, is covered by peritoneum, which the other areas lack. The upper front surface of the left kidney is near the left adrenal gland, the stomach, and the spleen; the narrow portion of the pancreas called its tail runs across the middle of the kidney, and coils of the small intestine cover its lower half.

Behind, both kidneys lie on a bed of fatty tissue. They are close to the diaphragm and two of its ligaments; to two muscles at the back of the abdominal cavity, the psoas major and the quadratus lumborum; and to the tendon of another muscle, the transversus abdominis.

Enclosing each kidney is the renal capsule, a smooth, tough covering. This covering is continuous with the lining of the renal sinus and with the connective tissue framework of the kidney.

The fat-laden retroperitoneal tissues, especially plentiful behind and to the outer side of each kidney, make up what is called the adipose renal capsule. Within the fatty tissue is a fibrous sheet, the renal fascia, that encloses—and forms a partial partition between—each kidney and its corresponding adrenal gland. The compartment formed by the renal fascia is relatively open below, so that any blood, urine, or pus that collects around a kidney as a result of injury or infection tends to spread downward along a ureter rather than to either side. In consequence, abscesses or collections of blood (hematomas) affecting either kidney rarely involve the opposite kidney or the space around it.

Renal capsule and adipose renal capsule

Figure 1: Human renal excretory system.

**Renal vessels and nerves.** The renal arteries are large and arise, one on each side, from the abdominal aorta, at a point opposite the upper border of the second lumbar vertebra (*i.e.*, a little above the small of the back). Because of the position of the aorta, ordinarily a little to the left of the midline, the right renal artery is longer than the left. Each artery, at places close to the renal hilus, gives off small branches to the adrenal gland and ureter and branches into anterior and posterior divisions. Each division then divides further to supply the various parts of the kidney.

The large veins carrying blood from the kidneys usually lie in front of the corresponding arteries and join the inferior vena cava almost at right angles. The left vein is about 7.5 centimetres (about three inches) long. The right vein is about 2.5 centimetres (about one inch) long, because the inferior vena cava lies closer to the right kidney.

The kidneys are supplied from both the sympathetic and the parasympathetic components of the autonomic nervous system, and the renal nerves contain both afferent and efferent fibres (afferent fibres carry nerve impulses to the central nervous system; efferent fibres, from it).

**Internal configuration.** A cross section of a kidney reveals the renal sinus—the large cavity that has already been mentioned—and areas of kidney tissue usually distinguishable by their colour. The paler tissue, called the renal medulla, is roughly in the form of cones, called renal pyramids, with bases outward and apexes projecting, either singly or in groups, into the renal sinus. The bases of the pyramids are irregular, with slender projections, called rays, extending toward the kidney surface. The darker tissue is the cortex. It arches over the bases of the pyramids and has extensions, called renal columns, that fill gaps between the pyramids.

Each projection of one or more pyramid apexes into the sinus is known as a renal papilla, and each group of pyramids that project into a papilla, together with the portion of cortex that arches over the group, is a renal lobe.

The renal sinus includes the renal pelvis, a funnel-shaped expansion of the upper end of the ureter, and, reaching into the kidney substance from the wide end of the funnel, two or three extensions of the cavity called the major calyces. The major calyces are divided in turn into six to twelve smaller cavities, the minor calyces, into which the renal papillae project. The renal pelvis serves as the initial reservoir for urine, which flows into the sinus through the urinary collecting tubules, small tubes that open into the sinus at the papillae.

**Minute structure.** The functioning units of the kidneys, the structures that actually produce urine in the process of removing waste and excess substances from the blood, are the nephrons, of which there are approximately 1,000,000 in each kidney. Each nephron is a long tubule, or extremely fine tube, at one end closed, expanded, and folded into a double-walled cuplike structure. This structure, called the renal corpuscular capsule or Bowman's capsule, encloses a cluster of microscopic blood vessels—capillaries—called the glomerulus. The capsule and glomerulus together constitute the renal corpuscle. Blood flows into and away from the glomerulus through tiny arteries called arterioles, which reach and leave the glomerulus through the open end of the capsule. This opening is called the vascular pole of the corpuscle.

In the renal corpuscle, fluid filters out of the blood in the glomerulus through the inner wall of the capsule and into the nephron tubule. As this filtrate passes through the tubule, its composition is altered by secretion of certain substances into it and by selective reabsorption of water and other constituents from it. The final product is urine, which is conveyed through the collecting tubules into the renal pelvis.

The tubules of the nephrons are 30–55 millimetres (1.2–2.2 inches) long. The corpuscle and the initial portion of each tubule, called the proximal convoluted tubule, lie in the renal cortex. The tubule then descends into a renal pyramid, makes a U-shaped turn, and comes back to the cortex at a point near its point of entry into the medulla. This section of the tubule, consisting of the two parallel lengths and the bend between them, is called Henle's loop

The nephrons

Figure 2: Stylized drawing of nephron, glomerulus, and collecting tubule.

From *Stedman's Medical Dictionary*; 21st ed. (1966); The Williams & Wilkins Co., Baltimore

or the nephronic loop. After its re-entrance into the cortex, the tubule returns to the vascular pole (the opening in the cuplike structure of the capsule) of its own nephron. The final portion of the tubule, the distal convoluted tubule, leads from the vascular pole of the corpuscle to a collecting tubule, by way of a short junctional tubule. Several of the collecting tubules join together to form a somewhat wider tubule, which carries the urine to a renal papilla and the renal pelvis.

The successive sections of the nephron tubule vary in shape and calibre (e.g., one portion of Henle's loop is considerably narrower), and these differences, together with differences in the cells that line the sections, are associated with specific functions in the production of urine.

**Intrarenal network of blood vessels.** The intrarenal network of blood vessels merits particular attention, since it forms part of the blood-processing apparatus of the kidneys. The anterior and posterior divisions of each renal artery, mentioned earlier, divide into lobar arteries, each of which enters the kidney substance through or near a renal papilla. Each lobar artery gives off two or three branches, called interlobar arteries, which run outward between adjacent renal pyramids. When these reach the boundary between the cortex and the medulla they split almost at right angles into branches called arcuate arteries that curve along between the cortex and the medulla parallel to the surface of the kidney. Many arteries, called interlobular arteries, branch off from the arcuate arteries and radiate out through the cortex to end in networks of capillaries in the region just inside the capsule. En route they give off numerous branchlets, the arterioles that carry blood to the glomeruli and break up to form the capillaries of each glomerulus. They are then reconstituted to become the arterioles carrying blood away from the glomeruli. The arterioles bringing blood to the glomeruli are called afferent; those carrying blood away, efferent.

Throughout most of the cortex the efferent arterioles redivide into a second set of capillaries located between the nephron tubules; these capillaries participate with the nephron tubules in the complex process that begins with the glomerular filtrate and ends with urine.

The afferent arterioles are almost twice as thick as the efferent arterioles because they have thicker muscular coats, but their channels are almost equal.

In the cortical region near the medulla, the area called the juxtamedullary zone, the efferent glomerular arterioles divide into vessels supplying the contiguous tubules and others that enter the bases of the renal pyramids.

Known as the arteriolae rectae spuriae, these vessels run toward the apexes of the pyramids. Ultimately uniting to form vessels called venae rectae, they drain into the arcuate veins that parallel the arcuate arteries. Some arterioles that arise in the cortex, in the juxtamedullary zone, run directly into the pyramids without breaking up into glomeruli. Since they become increasingly common with age, these arterioles are probably accounted for by the degeneration of glomeruli to which they were originally afferent.

Normally the blood circulating in the cortex is more abundant than that in the medulla, but in certain conditions such as those associated with severe trauma—e.g., crushing of the limbs—most cortical vessels may become constricted and the juxtamedullary vessels dilated. In consequence much or even most of the renal blood flow may bypass the cortex and run through the relatively few but larger juxtamedullary glomeruli and arterioles. This is known as the renal shunt mechanism; because of the short-circuiting of most of the cortical glomeruli and tubules, the flow of urine is diminished, and in extreme cases may cease.

The renal venules (small veins) and veins accompany the arterioles and arteries closely and are referred to by similar names. The venules just beneath the renal capsule, called stellate venules because of their radial arrangement, drain into interlobular venules. In turn these combine to form the tributaries of the arcuate, interlobar, and lobar veins. Blood from the renal pyramids passes into vessels called venae rectae that join the arcuate veins. In the renal sinus the lobar veins unite to form veins corresponding to the main divisions of the renal arteries, and they normally fuse to constitute a single renal vein in or near the renal hilus.

The branches of the renal arteries interconnect only through capillaries. Such interconnections cannot provide adequate supplies of blood for an active organ; if, therefore, one of the main renal arterial branches is blocked as a consequence of disease or injury the area is largely deprived of blood and dies. The intrarenal veins and venules interconnect (anastomose) more freely than the arteries, so that venous disease or injuries produce less serious effects.

The stellate venules just inside the capsules interconnect with veins in the adipose capsule of the kidney, and the latter with veins serving the adrenal glands, the ureters, the sex glands, and the loins. These interconnections are normally insignificant, but in disease, particularly when it causes slow blockage of the renal veins, the interconnections may enlarge and provide an adequate venous drainage for the kidneys.

Lymphatic capillaries are in a network just inside the renal capsule, and there is a deeper network between and around the renal blood vessels. There are few lymphatic capillaries in the actual renal substance, and those present are evidently associated with the connective tissue framework, while the glomeruli contain no lymphatics. The lymphatic networks inside the capsule and around the renal blood vessels drain into lymphatic channels accompanying the interlobular and arcuate blood vessels. The main lymph channels run alongside the main renal arteries and veins to end in lymph nodes beside the aorta and near the sites of origin of the renal arteries. Some lymphatics from the upper part of the kidney and from the adrenal gland pass upward through the diaphragm to end in lymph nodes in the thorax.

Lymphatic networks

#### THE URETERS

**General characteristics.** The ureters are thick-walled ducts, about 25–30 centimetres (9.8–11.8 inches) in length and from four to five millimetres (0.16–0.2 inch) in diameter, that transport the urine from the kidneys to the urinary bladder. Throughout their course they lie behind the peritoneum, the lining of the abdomen and pelvis, and are attached to it by connective tissue. The abdominal and pelvic portions of the ureters are almost equal in length.

In both sexes the ureters enter the bladder wall about five centimetres (two inches) apart, although this distance

Arterioles in juxtamedullary zone

is increased when the bladder is distended with urine. The ureters run obliquely through the muscular wall of the bladder for nearly two centimetres (0.8 inch) before opening into the bladder cavity through narrow apertures. This oblique course provides a kind of valvular mechanism; when the bladder becomes distended it presses against the part of each ureter that is in the muscular wall of the bladder, and this helps to prevent the flow of urine back into the ureters from the bladder.

**Structure of the ureteric wall.** The wall has three layers, the adventitia, or outer layer; the intermediate, muscular layer; and the lining, made up of mucous membrane. The adventitia consists of fibroelastic connective tissue that merges with the connective tissue behind the peritoneum. The muscular coat is composed of smooth muscle fibres and, in the upper two-thirds of the ureter, has two strata—an inner layer of fibres arranged longitudinally and an outer layer disposed circularly. In the lower third of the ureter an additional longitudinal layer appears on the outside of the vessel. As each ureter extends into the bladder wall its circular fibres disappear, but its longitudinal fibres extend almost as far as the mucous membrane lining the bladder.

The effect of gravity on the passage of urine from the kidney to the bladder is minimal. The chief propelling force is produced by peristaltic (wavelike) movements in the ureter muscles. These movements may be initiated by pacemakers of specialized muscle cells located in the renal pelvis or its calices. The mucous membrane lining increases in thickness from the renal pelvis downward. Thus in the pelvis and the calices of the kidney the lining is two to three cells deep; in the ureter, four to five cells thick; and in the bladder, six to eight cells. The mucous membrane of the ureters is arranged in longitudinal folds, permitting considerable dilation of the channel. There are no true glands in the mucous membrane of the ureter or of the renal pelvis.

#### THE URINARY BLADDER

Shape and  
location of  
bladder

**General description.** The urinary bladder is a hollow muscular organ forming the main urinary reservoir. It rests on the anterior part of the pelvic floor (see below), behind the symphysis pubis and below the peritoneum. (The symphysis pubis is the joint in the hip bones in the front midline of the body and at its base.) The shape and size of the bladder vary according to the amount of urine that it contains. When empty it is tetrahedral in form and lies within the pelvis; when distended it becomes ovoid and expands into the lower abdomen. It is described as having a body, with a fundus, or base; a neck; an apex; and a superior (upper) and two inferolateral (below and to the side) surfaces, although these features are not clearly evident except when the bladder is empty or only slightly distended.

The fundus or base is triangular and faces backward and downward. In the male its lower part is close to the rectum. Its upper part is separated from the rectum by a pouch of peritoneum. In the female the bladder is close to the cervix and the anterior wall of the vagina and is connected to both by loose connective tissue. In both sexes the ureters enter the bladder through the superolateral angles (the angles above and to the side) of the base, while the urethra leaves it through the third or inferior angle.

The neck of the bladder is the area immediately surrounding the urethral opening; it is the lowest and most fixed part of the organ. In the male it is firmly attached to the base of the prostate, a gland which encircles the urethra. In the female there is no prostate, or only rudimentary glands representing it, and the bladder neck is continuous with the first part of the urethra.

The apex of the bladder points forward in both sexes toward the upper part of the symphysis pubis and the apex is attached to a ligament, the median umbilical ligament, that extends upward on the inside of the anterior abdominal wall to the umbilicus. When the bladder is distended the apex rises above the symphysis.

The superior surface of the bladder is triangular and is covered with peritoneum. The bladder is supported on

the levator ani muscles, which constitute the major part of the floor of the pelvic cavity. The bladder is covered, and to a certain extent supported, by the visceral layer of the pelvic fascia. This fascial layer is a sheet of connective tissue that sheaths the organs, blood vessels, and nerves of the pelvic cavity. The fascia forms, in front and to the side, ligaments, called pubovesical ligaments, that act as a kind of hammock under the inferolateral surfaces and neck of the bladder.

**Blood and nerve supplies.** The blood supply of the bladder is derived from the superior, middle, and inferior vesical (bladder) arteries. The superior vesical artery supplies the dome of the bladder, and one of its branches (in some instances) gives off the artery to the ductus deferens, a part of the passageway for sperms. The middle vesical artery supplies the base of the bladder. The inferior vesical artery supplies the inferolateral surfaces of the bladder and assists in supplying the base of the bladder, the lower end of the ureter, and other adjacent structures. Small branches from other arteries often reach the bladder—in the female, branches from the uterine and vaginal arteries.

The nerves to the urinary bladder belong to the sympathetic and the parasympathetic divisions of the autonomic nervous system. The sympathetic nerve fibres carry to the central nervous system the sensations associated with distention of the bladder, are concerned with vasomotor functions (*i.e.*, with the constriction of the smooth muscle in the blood-vessel walls), and are believed by a majority of research workers to be involved in relaxation of the muscular layer of the vesical wall and with contraction of the sphincter mechanism that closes the opening into the urethra. The parasympathetic nerves are concerned with contraction of the muscular walls of the bladder and with relaxation of its sphincter. Consequently they are actively involved in urination (also called micturition) and are sometimes referred to as the emptying or detrusor nerves.

The nerves  
to the  
bladder

**Structure of the bladder wall.** The bladder wall has a serous coat over its upper surface. This covering is a continuation of the peritoneum that lines the abdominal cavity; it is called serous because it exudes a slight amount of lubricating fluid called serum. The other layers of the bladder wall are the fascial, muscular, submucous, and mucous coats.

The fascial coat is a layer of connective tissue, such as that which covers muscles. The muscular coat consists of coarse fascicles, or bundles, of smooth muscle fibres arranged in three strata, with fibres of the outer and inner layers running lengthwise, and with fibres of the intermediate layer running circularly; there is considerable intermingling of fibres between the layers.

In males the fibres of the outer layer pass into the prostate anterior and posterior to the urethra, while others blend with rectal muscular fibres to form the rectovesical muscle. (The prostate is a gland through which the urethra passes as it leaves the bladder. The rectovesical muscle is so called because it is shared by the rectum and the bladder.)

In females the outer layer is continuous with the musculature in the walls of the urethra and the vagina. Other fibre bundles in both sexes run into the pubovesical ligaments, mentioned previously as furnishing a support for the bladder.

The circular or intermediate muscular stratum of the vesical wall is thicker than the other layers. Its fibres, although running in a generally circular direction, do interlace.

The internal muscular stratum is an indefinite layer of fibres that are mostly directed longitudinally.

The submucous coat consists of loose connective tissue containing many elastic fibres. It is absent in the trigone, a triangular area whose angles are at the two openings for the ureters and the single internal urethral opening. Slim bands of muscle run between each ureteric opening and the internal urethral orifice; these are thought to maintain the oblique direction of the ureters during contraction of the bladder. Another bundle of muscle fibres connects the two ureteric openings and produces a slightly downwardly curved fold of mucous membrane

The  
mucous  
coat of the  
bladder

between the openings. Behind the internal urethral orifice in males there is sometimes a slight bulge caused by the projection of the median lobe of the prostate. This bulge, called the *uvula vesicae*, may become much more prominent in older men with enlargement of the prostate.

The mucous coat, the innermost lining of the bladder, is an elastic layer impervious to urine. Over the trigone it is firmly adherent to the muscular coat and is always smooth and pink whether the bladder is contracted or distended. Elsewhere, if the bladder is contracted, the mucous coat shows multiple folds and has a red, velvety appearance. When the bladder is distended, the folds are obliterated, but the difference in colour between the paler trigonal area and the other areas of the mucous membrane persists. The mucous membrane lining the bladder is continuous with that lining the ureters and the urethra.

#### THE URETHRA

**General description.** The urethra is the channel that conveys the urine from the bladder to the exterior. In the male it is about 20 centimetres (about 7.9 inches) long and carries not only the urine, but also the semen and the secretions of the prostatic, bulbo-urethral, and urethral glands. During urination and orgasm it opens up, and its diameter then varies from 0.5 to 0.8 centimetre (0.2 to 0.3 inch) along its length, but at other times its walls touch and its lining is raised into longitudinal folds. The male urethra has three distinguishable parts, the prostatic, the membranous, and the spongy, each part being named from the structures through which it passes rather than from any inherent characteristics.

The prostatic section of the male urethra commences at the internal urethral orifice and descends almost vertically through the prostate, from the base of the gland to the apex, describing a slight curve with its concavity forward. It is about 2.5 to three centimetres (one to 1.2 inches) long and is spindle-shaped; its middle portion is the widest and most dilatable part of the urethra. The posterior wall of the prostatic section shows a longitudinal elevation, the urethral crest, and the shallow furrows on each side of the crest are the prostatic sinuses into which the numerous prostatic glands open through tiny pores. The crest becomes slightly more prominent at about its midpoint to form a further elevation called the seminal colliculus. The colliculus has three openings on its surfaces. On either side of the central opening, which leads to a short cul-de-sac, are the openings through which the right and left ejaculatory ducts discharge seminal fluid into the urethra.

The membranous part of the male urethra is so called because it is in the area between the two layers of a membrane, called the urogenital diaphragm. The urethra is narrower here than at any other point except at its external opening and is encircled by a muscle, the sphincter urethrae. The two small bulbo-urethral glands are on either side of it. The membranous urethra is not firmly attached to the layers of the urogenital diaphragm.

The spongy part of the male urethra is that part of the urethra that traverses the penis. It derives its name from the fact that it passes through the corpus spongiosum of the penis. The shape and calibre of this section of the urethra vary. As in other parts of the urethra, the walls are normally touching except during micturition and orgasm.

The ducts of the bulbo-urethral glands enter the spongy urethra about 2.5 centimetres (one inch) below the lower layer of the urogenital membrane; except near its outer end, many mucous glands also open into it.

The female urethra is much shorter (three to 4.5 centimetres, or 1.2 to 1.8 inches), and more distensible than the corresponding channel in men and carries only urine and the secretions of mucous glands. It begins at the internal opening of the urethra into the bladder and curves gently downward and forward through the urogenital diaphragm, where it is surrounded, as in the male, by the sphincter urethrae. It lies behind and below the symphysis pubis. Except for its uppermost part, the urethra is embedded in the anterior wall of the vagina. The external urethral orifice is immediately in front of the vaginal

opening, about 2.5 centimetres (about one inch) behind the clitoris, and between the labia minora, the inner folds at the outer opening of the vagina.

The lining is raised in longitudinal folds and, except during micturition, the walls of the urethra touch. Near the lower end of the urethra a number of mucous glands drain into the urethra through two short ducts opening on either side of the external urethral orifice.

**Structure of urethral wall.** The male urethra is a tube of mucous membrane supported on a submucous layer and an incomplete muscular coat. The membrane forms longitudinal folds when the tube is empty; these folds are more obvious in the membranous and spongy parts. There are many glands in the mucous membrane, more common in the posterior wall of the spongy part. The submucous layer is composed of fibroelastic connective tissue containing numerous small blood vessels, including more venules than arterioles.

The thin muscular coat consists of smooth muscle fibres. Around the prostatic and, to a lesser extent, around the membranous parts of the urethra, this coat can be differentiated into inner longitudinal and outer circular layers. Scanty bundles of smooth muscle fibres, disposed mainly in a circular or oblique fashion, surround the spongy part of the urethra.

The female urethra has mucous, submucous, and muscular coats. As in the male, the lining of the empty channel is raised into longitudinal folds. It also shows mucous glands, mentioned in the preceding paragraphs as existing in the male urethra.

The submucous coat resembles that in the male, except that the venules are even more prominent. In both sexes, but especially in females, this layer appears to be a variety of erectile tissue.

The muscular coat extends along the entire length of the female urethra and is continuous above with the musculature of the bladder. It consists of inner longitudinal and outer circular layers, and fibres from the latter intermix with those in the anterior wall of the vagina, in which the urethra is embedded.

## Excretory System Diseases

The term excretory system, a convenient label with which to cover the kidneys and the urinary tract in one system, describes with accuracy an important part of renal (kidney) function, that part which concerns the disposal of waste products; *i.e.*, compounds such as urea that are formed in the breakdown of food and tissue but that must be eliminated from the body because they cannot normally be used to supply either energy or structural material. Some such wastes are disposed of by the lungs, skin, and bowel; but the kidneys are the most specialized excretory organ.

The functioning unit of the kidney is the nephron, consisting of (1) a cluster of minute blood vessels or capillaries called the glomerulus; (2) a double-walled capsule, enclosing the glomerulus; and (3) continuous with the

The female  
urethra

capsule a long, winding, narrow tube of varying diameter and wall thickness. Fluid filters from the blood through the walls of the glomerulus. The fluid normally differs from the blood in its lack of cells and proteins. The capsule and tubules reabsorb substances, including water, from the filtrate, and excrete into the filtrate substances that are waste products or in excessive supply.

If the task of excretion does not occur solely in the kidneys, neither does "excretion" fully describe everything that these organs do. Importantly, they also regulate the amount and composition of the body fluid, which accounts for well over half of the total mass of the body. This regulatory or homeostatic function of the kidneys has to be kept in mind if the mechanisms that underlie the varied manifestations of renal disorders are to be understood. The excretory and regulatory functions of the kidneys together constitute their most notable role in the body's economy; but the kidneys are also a source of important hormones, renin and erythropoietin. The impact of excretory system diseases on the two major aspects of renal performance—the elimination of wastes and the conservation of an appropriate amount and quality of body fluid—is the primary concern in this article. Many of the manifestations of renal disease can be accounted for in terms of disturbance of these two functions, and the alleviation of varieties of renal disease that cannot yet be cured is dependent on man's knowledge of these two functions.

The matter does not, of course, end with the formation of urine, a quite unconscious process; the urine has to pass down the ureters to the bladder, be stored there, and voided when convenient, under voluntary control. The whole mechanism can be deranged by structural changes in the lower urinary tract, by infection, or by neurological disorders that lead to abnormal emptying of the bladder. Disturbance of the lower urinary tract is an important cause of pain and distress, notably during pregnancy and in the elderly; and it can lead to serious and progressive damage to the kidneys, either by interfering with the drainage of urine or by allowing bacterial infection to have access to the kidney.

#### FUNCTIONAL ASPECTS OF EXCRETORY SYSTEM DISEASES

Diseases often manifest themselves as patterns of disordered function. In excretory system disease, the amount and composition of the urine may become grossly inappropriate to the needs of the body, with consequent distortions of body fluids as outlined in this section. Disturbances of urine flow are also considered, but abnormalities in the urine itself are dealt with in the article EXCRETION, HUMAN.

**Effects of abnormal renal function on body fluid.** The major constituents of body fluid are protein, water, and electrolytes—the dissociated salts of sodium and potassium. Renal disease in its diverse forms can lead to bodily deficits or excesses of water, sodium, and potassium, and also to protein deficits occasioned by great losses of protein in the urine. Inability of the kidney to function normally may lead to retention in the blood of the waste products of protein metabolism such as urea and uric acid, and of other nitrogenous compounds such as creatinine. There may be abnormally high levels of phosphates in the blood, which in turn can lead (for reasons about which there is still some disagreement) to low blood levels of calcium. The calcium deficiency can cause tetany, a condition marked by muscular spasms and pain, and calcium may be lost from the bones in the process of restoring normal calcium levels in the blood and tissue fluid. For descriptive purposes, changes in volume, changes in composition, and protein depletion of renal origin will be discussed separately, but these disturbances can and often do coexist.

Though body fluid is apparent only in the bloodstream, it is present, and in larger amounts, in the tissues, both between the cells (extracellular fluid) and within them (intracellular fluid). Extracellular fluids, including blood plasma, amount to 25 percent of body weight, and contain sodium as their predominant cation (positive ion; metals and hydrogen in solution are cations). Intracellu-

lar fluids, amounting to 33 percent of body weight, have potassium as their predominant cation. These various "compartments" of body fluid are in osmotic equilibrium, so that if solute (*e.g.*, sodium chloride) is added to the extracellular compartment so as to increase the concentration of the extracellular solution, water will join it to reduce the concentration, and that compartment will increase. An increase in extracellular fluid, if it is considerable, may be clinically apparent as edema, a swelling of the tissues by fluid, which can usually be displaced by firm pressure. Edema is present in acute inflammation of the kidney (nephritis), in protein deficiency of renal origin, and in chronic nephritis complicated by heart failure associated with abnormally high blood pressure; a factor common to all these states is failure of the kidneys to excrete sodium in adequate amount. (If sodium were excreted, water would be also in order for the osmotic equilibrium to be maintained.) Importantly, the kidneys in such edematous states need not themselves be diseased; normal kidneys, in a patient with heart failure, may retain sodium when handicapped in their function by poor circulation and by abnormal amounts of sodium-retaining hormones, such as aldosterone. Increase in extracellular fluids is the only volume change that is both common and easily discernible in renal disease. The opposite condition, sodium depletion or clinical dehydration, occurs rarely, when the kidneys fail to conserve sodium properly; this can happen in intrinsic renal disease, but sodium depletion is more commonly the result of vomiting and diarrhea when they are complications of terminal renal disease. Dehydration can be recognized by a lack of elasticity in the superficial tissues, and by poor filling of the blood vessels, as well as by signs of impaired circulation, including a fall in blood pressure. Though changes in intracellular fluid volume occur in some diseases, especially when the potassium content of the body is affected, there is no easy way of detecting them.

Because of the importance of osmotic forces in determining fluid distribution within the body, an important attribute of body fluid is its overall osmotic concentration, or osmolality. This depends on the concentration of solutes; while all solutes contribute to it, small particles such as sodium or chloride ions are influential out of all proportion to their weight, and indeed account for over 90 percent of the osmolality of plasma. In the context of renal disease, changes in osmolality depend largely on how the kidney handles water. When the kidney either is incapable of conserving water or is not stimulated by the antidiuretic hormone of the pituitary to reabsorb water, water is lost from the body, and a state of water depletion develops, characterized by increasing osmolality of body fluid. At other times, the kidneys may retain too much water, especially when too much hormone is present; in this case, water excess results, giving a clinical state of water intoxication, with decreased osmolality of body fluids.

Besides osmolality, another very important general property of body fluid is its degree of acidity or alkalinity. This is largely regulated by the discharge of carbon dioxide in expired air, but the kidneys are involved in the excretion of nonvolatile acids, such as sulfate and phosphate. Imperfect function leads to retention of both organic and inorganic acid radicals, the state of so-called renal acidosis. (Acid radicals are the negative ions of acids, corresponding to hydrogen, the positive ion.) This may occur as part of generalized renal failure or as a specific disease of the renal tubules, one of whose functions is to convert the slightly alkaline glomerular filtrate into the (usually) acid urine. To do this, the tubules both secrete hydrogen ions and synthesize ammonia; both or either of these processes may be deficient.

Apart from these general changes in body fluid, the pattern of individual constituents can be profoundly distorted in renal disease. For many substances, the problem is one of failure of excretion, with consequent increased concentration in body fluids. In so far as excretion is achieved by filtration, the rise in concentration may assist excretion, permitting prolonged states of balance, at the cost of increased, but often tolerable, levels

The two major aspects of renal performance

Edema and dehydration

Change in hydrogen-ion concentration

of concentration. For example, a man in renal failure must put out as much urea as a healthy man taking the same diet; but he can only do so at a blood-urea concentration of 100 milligrams per 100 millilitres, instead of a normal blood-urea of 25 milligrams per 100 millilitres. Substances whose concentration increases in this way include urea, creatinine, uric acid, phosphate and sulfate, urochrome, and indeed all the usual constituents of urine apart from those that are "regulated" rather than simply "excreted." Potassium requires special mention because of the special danger associated with retention of this substance, which can lead to fatal irregularity of cardiac action. This is a recognized danger of acute renal failure, now commonly prevented by use of the artificial kidney and its semipermeable membranes, and sometimes by the use of resins that will take up potassium in the alimentary tract.

Normal urine contains traces of protein, and in many forms of renal disease there is an increased excretion of protein in the urine, usually representing an increased permeability of the tuft of capillaries forming the glomerulus. This increased proteinuria (often, but less correctly, known as albuminuria) generally amounts to 0.5 gram per day or more. When it exceeds five grams per day, and persists at this level, the loss of protein in the urine exceeds the capacity of the liver to produce new protein from the available materials; the concentration of protein in the blood decreases, and this leads to an increasing outflow of fluid from the bloodstream into the tissues (there is normally an equilibrium between the physical pressure in the capillaries, which tends to force fluids out, and the osmotic pressure of plasma proteins, the effect of which is to hold fluid in). This balance of forces is upset by a deficit of plasma proteins. The general loss of fluid into the tissues leads to massive edema, to which the kidneys contribute further by retaining salt and water. The combination of high levels of protein in the urine, low protein levels in the blood, and consequent edema is known as the nephrotic syndrome. This is a good example of a syndrome, defined as a recognizable pattern of manifestations that has not one but a number of possible causes. Other examples of syndromes in renal disease are acute renal failure and chronic renal failure.

**Disorders of urine flow.** If little or no urine appears, it may be because the kidneys are forming little urine (oliguria) or none (anuria); or it may represent a holdup in the bladder or urethra affecting the outflow from both kidneys. About one person in 500 is born with only one kidney, and loss of a kidney from disease or accident is not rare. In such cases, patients with complete obstruction to the remaining ureter will experience the same effect as in obstruction of the entire lower urinary tract. Partial or complete failure to form urine is treated in the section on acute renal failure, obstructive conditions in the section on diseases of the urinary tract, below. Bladder emptying also depends on an intact nerve supply. The sensation of a full bladder is carried in the pelvic nerves to the sacral region of the spinal cord; this desire to micturate—urinate—may be inhibited by the higher centres in the nervous system. In the lack of inhibition, and indeed with voluntary initiation, micturition is effected by parasympathetic nerve impulses, again in the pelvic nerves. Spinal disease and injury, and general diseases of the central nervous system, can lead either to incontinence or to difficulty in emptying the bladder. The distended bladder may later overflow, when pressure within it builds up to overrule the failure of relaxation of the urethral sphincters—the phenomenon of overflow incontinence.

Pain associated with urination can arise from bladder distension, which is then relieved by effective micturition; from inflammation of the lower urinary tract, commonly due to infection but rarely caused by chemical irritants in the urine; and from mechanical irritation by tumour or during the passage of stones. The term dysuria is applied to pain that accompanies, or closely follows, the passage of urine. It is commonly, but not necessarily, associated with frequency of urination. This in turn may

represent either an irritable or contracted bladder; or the actual amount of urine formed may be unusually large (polyuria), in which case voiding is likely to be painless. Sometimes polyuria may not be noticed by day, but may manifest itself in the need to micturate on several occasions during the night (nocturia). The acute onset of dysuria and frequency suggests urinary infection; sustained polyuria is more likely to be due to renal failure (defective concentrating power) or to diabetes. In those who drink beverages into the night, nocturia is physiological.

Incontinence, the involuntary passage of urine (or feces), may be due to a faulty nerve supply, which either leaves the sphincters relaxed or allows them to be overcome by distension of the bladder. Comatose and disturbed patients, especially among the elderly, are commonly incontinent. Apart from nerve lesions, the sphincters that normally prevent the escape of urine may be damaged by repeated childbirth, by the growth of the prostate, or by other distortions of the bladder neck. Procedures have been devised to stimulate the sphincters electrically, when their nerve supply is damaged; or to stimulate the bladder to empty itself at set times. For the problem of chronic incontinence, however, devices to catch the urine and prevent soiling of clothing are the most practical.

Incontinence of urine

#### DISEASES OF THE KIDNEY

In this section, attention is directed not only to specific diseases of the kidney but also to the syndromes of acute and chronic renal failure, which have multiple causes. Infective disorders of the kidney are dealt with later, as part of the general problem of infection of the urinary tract.

**Acute renal failure.** Acute renal failure occurs when renal function suddenly declines to very low levels, so that little or no urine is formed, and the substances, including even water, that the kidney normally eliminates are retained in the body. There are two main mechanisms that can produce acute renal failure. When the cardiac output—the amount of blood pumped into the general circulation by the heart—is depressed by hemorrhage or by medical or surgical shock, the renal circulation is depressed to an even greater extent. This leads directly to inefficient excretion, but, more importantly still, the kidney tissue cannot withstand prolonged impairment of its blood supply and undergoes either patchy or massive necrosis (tissue death). Given time, the kidney tissue may regenerate, and it is on this hope that the treatment of acute renal failure is based. The form of acute renal failure that is due to a poor supply of blood (ischemia) has many causes, the commonest and most important being multiple injuries, abortion with abnormal or excessive bleeding from the female genital tract, internal hemorrhage, transfusion reactions, and severe heart attacks; an interesting special case is the transplanted kidney, which commonly goes through a phase of acute renal failure that is independent of possible rejection. The second common mechanism of acute renal failure is toxic. Many poisons are excreted by the kidney, and in the process just like other urinary constituents they become concentrated and, in this way, reach levels in the tubular fluid that damage the lining cells of the tubules. Though the tubular cells die, and are shed in the urine, regeneration can take place, and the patient survive, if he can be maintained during the period of depressed renal function and is not killed by other effects of the poison. Poisons that can affect the kidney in this way are numerous, but the main groups are heavy metals (mercury, arsenic, uranium); organic solvents (carbon tetrachloride, methanol); other organic substances (glycols, aniline, phenindione, insecticides); and antibacterial agents (sulfonamides, kanamycin, amphotericin). In addition to the ischemic and toxic causes of acute renal failure, mention must be made of fulminating varieties of acute renal illnesses that are generally mild (e.g., acute glomerulonephritis—see below), and of the acute form of immunologic rejection that can destroy a kidney irrevocably within minutes of transplantation.

The clinical course of acute renal failure can usefully

Renal failure due to poisons

Stoppage of urine flow

**Renal failure: second phase of clinical course**

be divided into an onset phase, a phase of established acute renal failure, and a recovery phase. In general, but not invariably, the second of these phases is characterized by a low output of urine—oliguria—and the third by an increasing urine output (polyuria). The onset phase is dominated by general illness, in which the episode of acute renal failure arises; at this stage there may be evidence of threatened renal damage such as blood in the urine or pain in the loins. At this early stage, renal damage may be reversible by prompt treatment of circulatory failure or by infusion of diuretics, substances that increase urine flow. Once the onset phase has passed, and acute renal failure becomes established, diuretics are ineffective and may cause damage.

In the second phase, small amounts of urine, often containing red blood cells, or hemoglobin, are passed; complete absence of urine is not common and suggests that an obstruction is preventing urine from being passed. In quantitative terms, a urine volume of less than 500 millilitres (about a pint) per day constitutes significant oliguria; this is the least amount in which the excretory demand imposed by an ordinary diet can be met. In the actual situation of acute renal failure, the excretory demands may in fact be much greater, since many of the causes of acute renal failure also are causes of increased breakdown of the tissues in general. The nonprotein nitrogen of the blood increases, the rate of increase being conditioned both by the degree of renal failure and by the amount of tissue breakdown. Besides nitrogen, the kidney can no longer excrete adequate amounts of water, sodium, and potassium. These various inadequacies point the way to the necessary management of acute renal failure—the elimination from intake of any dangerous substance that the kidney can no longer handle. The diet must either be free of protein or contain small amounts of high-quality protein to lessen tissue breakdown. It must also be free from sodium and potassium: many persons with renal failure have died from pulmonary edema, a correlate of sodium retention, and others from the acute toxic effects on the heart of a raised level of potassium in the blood. Water cannot be excluded from the intake but must be limited. The concentration of sodium in the blood is a good guide to the adequacy of water restriction, and a progressive fall in serum sodium implies that too much water is being taken in. Kidney function may recover, often in seven to ten days. The use of dialysis, the removal of waste products by straining the blood through semipermeable membranes, gives further time for renal recovery. Potassium can be removed from the body by resins, but this is less often required if dialysis is available.

Although by comparison with the oliguric phase the recovery phase presents fewer problems, the convalescent kidney takes time to recover its full regulatory function, and unusual losses of electrolytes may occur at this stage. Careful observation and measurements of non-protein nitrogen and electrolytes are still required. Many make a complete recovery from acute renal failure, but in some persons residual renal damage persists. In a few, this is so severe as to bring them effectively into the category of chronic renal failure.

**Chronic renal failure.** The term uremia, though it is sometimes used as if it were interchangeable with chronic renal failure, really means an increase in the concentration of urea in the blood. This can arise in many acute illnesses in which the kidney is not primarily affected, and also in the condition of acute renal failure described above. Uremia ought to represent a purely chemical statement, but it is sometimes used to denote a clinical picture, that of severe renal insufficiency.

As with acute renal failure, there are many conditions that can lead to chronic renal failure. The two commonest causes are pyelonephritis and glomerulonephritis (kidney inflammation involving the structures around the renal pelvis or the glomeruli), and other common causes are renal damage from the effects of high blood pressure and renal damage from obstructive conditions of the lower urinary tract. All of these primary disorders are described below. What they have in common is a

progressive destruction of nephrons (the functional units in the kidneys), of which there are normally some 2,000,000, but which may be reduced to less than a twentieth of that number in disease. The quantitative loss of nephrons can account for the majority of the changes observed in chronic renal failure; the failure in excretion is due directly to loss of glomerular filters, and other features such as the large quantities of dilute urine represent a change in tubular function that could be accounted for by the increased load that each remaining nephron has to carry. There are many other causes of chronic renal failure besides the four common ones. They include congenital anomalies and hereditary disorders; diseases of collagen (the fibrous protein found in connective tissue); tuberculosis; the effects of diabetes and other metabolic disorders; and a number of primary disorders of the kidney tubules. Of the many causes, there are some that have importance out of proportion to their frequency, by virtue of their reversibility; these include renal amyloidosis (abnormal deposits in the kidney of a complex protein substance called amyloid), whose causes may be treatable; damage to the kidney from excessive calcium or deficiency of potassium; uric acid deposition in gout; the effects of analgesic agents—substances taken to alleviate pain—and other toxic substances.

The person suffering from renal failure may have no symptoms other than a feeling of thirst and a tendency (shared with many normal people) to pass urine at frequent intervals and through the night; or he may be in a coma, with occasional convulsions.

The general appearance of the sufferer may be sallow and “earthy,” because of a combination of anemia and the retention of urinary pigment. Even if not in actual coma, the affected person may be withdrawn; muscle twitchings and more general convulsions may occur. The coma is thought to represent poisoning, and convulsions are often related to the severity of the high blood pressure that commonly complicates advanced renal failure. Blurred vision is also a manifestation associated with high blood pressure. Bruising and hemorrhages may be noticeable.

Although the toxin (or toxins) of uremia has yet to be identified, the rapid improvement that follows dialysis points strongly to a toxic component. Urea itself is not notably toxic. Not all the chemical alterations in uremia are simple retentions. There is acidosis—a fall in the alkalinity of the blood and tissue fluids—reflected clinically in deep respiration as the lungs strive to eliminate carbon dioxide. The capacity of the kidney to adjust to variation in intake of salt, potassium, and water becomes progressively impaired, so that electrolyte disturbances are common. Poor appetite, vomiting, and diarrhea are common in uremic patients, and these in turn add another component to the chemical disturbance. Phosphate is retained in the blood and is thus associated with low blood levels of calcium; the parathyroids are overactive in renal failure, and vitamin D is less than normally effective. (Parathyroid hormone causes release of calcium from the bones, and vitamin D promotes absorption of calcium from the intestines.) These changes can lead to severe bone disease in persons suffering from renal failure, because bone calcium is depleted and the calcium stores are not adequately replenished.

In chronic renal failure, excessive production of renin by the kidney can lead to severe high blood pressure, (hypertension); and the effects of this may even dominate the clinical picture. In addition to damage to the brain and the retina, the high blood pressure may lead directly to heart failure. Hypertension can also accelerate the progress of renal damage by its impact on the renal blood vessels themselves, setting up a cycle that can be hard to break.

The patient in advanced renal failure is vulnerable to infection and other complications, such as vomiting or diarrhea, which need special care. When symptoms of advanced renal failure appear, deterioration can be delayed by a strict low-protein diet, 18–20 grams of high-quality protein each day. In terminal renal failure, the affected person can be rescued only by some form of

**Effects of chronic renal failure**

**Chronic renal failure: four common causes**

dialysis and then maintained by dialysis or transplantation.

**Glomerulonephritis.** Glomerulonephritis is the disorder commonly known as nephritis, or Bright's disease. The primary impact of the disease is on the vessels of the glomerular tuft, the cluster of capillaries in the nephron. The suffix "-itis" suggests an inflammatory lesion, and glomerulonephritis is indeed associated with infection, in the limited sense that it may begin soon after a streptococcal infection and may be aggravated in its later course by infections of various kinds. Nevertheless, there is convincing evidence that glomerulonephritis does not represent a direct attack on the kidney by an infective agent but is, rather, an "allergic" disorder, in the sense of the formation of antibodies that react against kidney tissue, or of antigen-antibody complexes that lodge in the glomerular tuft, with subsequent damage. This view of glomerulonephritis is based partly on analogy with the renal damage that can be induced in animals by allergic mechanisms, and partly on finding that a protein component of the allergic reaction is deposited in the diseased glomerulus. Within the general concept of an allergic disorder, there is ample room for a variety of primary stimuli and of later disease-causing mechanisms. Such a diversity is strongly suggested not only by the variations in the glomerular tissues observed both with the ordinary and with the electron microscope but also by the varying manifestations of the disease observed in the affected person.

**Acute glomerulonephritis.** Typically, acute glomerulonephritis appears one to two weeks after a sore throat, or—less commonly—after a streptococcal infection of the skin has been present for some time.

The affected person notices puffiness of the face and ankles, and at the same time the urine becomes scanty and noticeably blood-stained. On examination, loose tissues show edema, and the fluid is easily displaced by light pressure; both the blood pressure and the blood levels of urea are slightly or moderately increased. If fluids are not restricted at this stage, or if the blood pressure rises further, the person may experience severe breathlessness (due to accumulation of fluid in the lungs) or convulsions. A week or so later, there is often an increase in urine volume, there is no longer any blood in the urine, and the blood pressure is back to normal. Protein is still present in the urine, and this abnormality may persist for some weeks or months, even in persons who ultimately recover. The whole illness is an alarming one, but the fact is that the acute attack of glomerulonephritis needs no particular treatment other than some restriction of fluid and protein, and that nine out of ten affected persons recover completely. Exceptional outbreaks, with a higher mortality, have sometimes been observed.

As just indicated, the usual sequel is complete recovery. A very few patients may die in the acute attack, however, or in a few months' time, when the impact of the disease has been unusually severe. Another possibility is that the affected person may appear to have recovered completely, having lost all symptoms; but the disease process remains active, and there is progressive loss of nephrons, leading ultimately to chronic renal failure. This process may take 20 years, for many of which the person has no definite symptoms except that the urine contains protein and small numbers of red blood cells. This is the picture of latent nephritis, though it need not be assumed that the finding of protein in the urine (proteinuria) in the absence of symptoms means automatically that the patient has kidney disease; symptomless proteinuria has many causes and may indeed be found in young people who never develop any later evidence of renal disease. In summary, acute glomerulonephritis can lead to renal failure within a few months or even weeks, after many years of symptom-free proteinuria, or after a period of massive proteinuria, which causes the nephrotic syndrome. All of these manifestations may be seen although the affected person has never had, or cannot recall, an acute attack. Persons with acute glomerulonephritis who do badly are far outnumbered by persons who sustain an acute attack but thereafter do well.

**Vascular disease.** In the discussion of chronic renal failure, attention was drawn to the cycle in which high blood pressure secondary to renal disease can produce further damage to the kidneys. Clearly, primary vascular disease—disease affecting the blood vessels—could equally well be a cause of renal damage.

The most dramatic instance of this is the condition known as "malignant hypertension," or accelerated hypertension, which arises when the blood pressure attains really high levels, the diastolic figure (the blood pressure between heart contractions) being 140 millimetres of mercury or higher (the normal being around 80). Sustained levels of this magnitude cause serious damage to the arterioles, the smallest of the arteries; this damage is widespread, but as it affects the kidneys it produces rapid destruction of renal substance, with a scarred kidney. Unless the blood pressure is controlled, malignant hypertension can cause death in a few months; since treatment at an early stage is notably effective, the condition represents an important medical emergency. Since the retinas are damaged as rapidly as the kidneys, the affected person may first notice blurring or loss of vision.

More modest, but still elevated, levels of blood pressure can cause more gradual renal damage in elderly people or in those made prematurely aged by widespread arteriosclerosis ("hardening of the arteries"). Here, the damage is in the larger arteries rather than in the arterioles, and the condition is one of slowly progressive scarring. Renal damage can also arise, by various mechanisms, in a large number of diseases that impair the blood vessels, such as diabetes mellitus, the collagen disorders, bacterial inflammation of the heart lining, and many more.

**Tumours.** Tumours in general are covered in the article CANCER. Here those tumours peculiar to the excretory system, and their local effects, are briefly discussed. In the case of benign tumours, these effects include pressure on local structures and obstruction to hollow organs; with malignant tumours, one must add the possibilities of local invasion and of spread by the bloodstream or lymphatics to other organs (metastasis).

**Carcinoma.** The commonest tumour of the renal substance is a carcinoma (formerly called a hypernephroma), a malignant tumour, arising from epithelial cells (the cells of the bodily coverings and linings). One to two percent of all tumours are renal carcinomas, and most affected persons are aged from 40 to 60. The tumour may be symptomless or may first be apparent from the occurrence of metastases in the lungs, causing spitting up of blood; or in the bones, causing pathological fracture.

Much more commonly, the first evidence of the tumour is blood in the urine, which may be painless, or may cause colic of the ureter, if clots are being passed. There may also be a dull pain in the loins, from stretching of the kidney capsule. The tumour may be directly palpable, or it may be revealed by X-rays. The silhouette of the kidney, revealed by X-rays, may be distorted by a rounded swelling; or the renal pelvis, made visible by the injection of a contrast medium, may be displaced or distorted. Less common first indications of renal carcinoma are an obscure fever, or polycythemia (excess of red cells in the blood). Direct visual examination of the urinary tract with an instrument called a cystoscope may demonstrate the side that is affected, blood coming from one ureteric opening only. Since this could equally arise from a tumour of the renal pelvis, X-ray examination of the renal pelvis is usually called for. An exploratory operation may sometimes be needed; if carcinoma is found to be present, the kidney must be removed. There is some evidence that the results of surgery may be somewhat improved by radiation therapy. The overall outlook is poor, with a five-year survival rate no better than 50 percent. This is, however, one of the forms of malignant tumour in which arrest or even regression has been described.

**Nephroblastoma (Wilms' tumour).** Nephroblastoma is a less common, but nevertheless an important, tumour in childhood, in which other forms of cancer are less common. About half the cases occur at ages two to four, but

Glomerulonephritis: allergic disorder

Signs and symptoms of carcinoma

the tumour may be present even at birth. The tumour, a mixture of various tissues of embryonic origin, rapidly attains a large size, so that a mass in the child's abdomen is commonly the first abnormality noticed. Pain and blood in the urine are much less common than in renal carcinoma, affecting perhaps a fifth of patients. Spread of tumour to the renal veins, with subsequent spread to other structures, is common. The condition usually calls for removal of the kidney, and the outlook is poor; both kidneys may be affected, a situation that has on occasion been dealt with by removal of both, followed by transplant of a healthy kidney.

**Other tumours.** In addition to tumours of the renal substance, the renal pelvis may be affected by fernlike growths of the epithelium (papillomas).

Similar tumours affect the lower urinary tract, and the whole group is discussed later in this article. Benign tumours of the kidney substance occur, but rarely; on the other hand, cysts (abnormal sacs filled with liquid or semisolid substance) of the kidney are relatively common, but are not tumours in any strict sense, being rather malformations brought about by failure of the embryonic tubules to achieve a proper outlet. Several forms of renal cystic disease, most of them fatal, occur in infancy. In the "sponge kidney" (medullary cystic disease) the outlook is good. Various forms of solitary cyst occur, which may need local surgical treatment if they cause symptoms. The form of polycystic (multiple-cyst) renal disease that allows survival into adult life is a familial condition, in which several members of the family have little trouble until middle life but then are progressively affected by kidney malfunction. Episodes of blood in the urine and urinary infection are common, and the kidneys are large and irregular. Cysts of other organs—e.g., the liver—may be present. X-rays show irregularity of the renal pelvis, through pressure from the cysts. Puncture of the cysts is possible, but the results are not encouraging; the general treatment is that of chronic renal failure, which may now include removal of the kidney and transplantation.

#### OBSTRUCTION TO THE FLOW OF URINE

The causes of obstruction to the flow of urine lie in the lower urinary tract and are dealt with in a later section; here it is appropriate to consider the effects of urinary obstruction on the kidney (obstructive nephropathy). It should first be noted, however, that obstructions may arise at the junction of the renal pelvis and the ureter, either from faulty action of smooth muscle or from the pressure of an abnormal blood vessel crossing the pelvis; such cases can benefit from a plastic operation on the renal pelvis or from division of the abnormal vessel. Whether the obstruction arises in this way, or lower down, it can lead to renal pain; to the passage of irregular amounts of urine when obstruction is intermittent; and to a mass in the kidney when obstruction persists. As the renal pelvis swells, the renal tissue shrinks, leading to the condition called hydronephrosis, in which a greatly swollen sac is surrounded by a mere rind of atrophied renal tissue. A massive hydronephrosis, with negligible renal substance remaining, may suggest removal of the kidney.

**Trauma.** The kidney may be wounded in military operations or in motor accidents, usually along with other viscera. It may be bruised or even ruptured in closed injuries, including those from explosions, on the football field, or by a foul blow in the boxing ring. Since the kidney receives about a fifth of the heart output, bleeding can be spectacular, both into the urine and into the tissues and the kidney, forming a large mass of blood, called a hematoma, and leading to surgical shock. Some bleeding may follow the procedure of renal biopsy—taking a specimen of kidney tissue for examination—but with proper precautions this is not severe. In the past, massive irradiation to the kidney region led to chronic renal damage (radiation nephritis); but with adequate precautions, this should now be of historical interest only.

The usual signs of traumatic injury to the kidney are blood in the urine and the development of a tender mass

in the loin, with progressive signs of shock (pallor, sweating, fall in blood pressure). Such signs call for resuscitation, and for surgical exploration if the bleeding continues. The surgical treatment may be carried out to arrest the bleeding by closing the tear. Surgical removal of the kidney may be done if it cannot be saved. Abnormal solitary kidneys are not unknown, and such kidneys are more exposed to trauma by their size or position. Removal of such a kidney can lead only to death or emergency transplantation.

**Dialysis and transplantation.** The failure of a vital function normally, and by definition, leads to death; but in the case of the kidneys there are two methods of substituting for renal function. In principle the simpler of these two is to transplant a kidney from a donor, ideally an identical twin. The immunological and surgical problems of transplantation are dealt with in the article TRANSPLANTS, ORGAN AND TISSUE. Here only the part played by renal transplantation in the total care of renal disease is considered. The question of a transplant does not arise in most cases of acute renal failure when the loss of function is largely recoverable; and in chronic renal failure it arises only when the residual renal function is barely adequate to support life. Transplantation and dialysis are complementary rather than rival methods. Dialysis is used while a patient is awaiting transplant and during episodes of oliguria or of threatened rejection, while, on the other hand, patients who find dialysis a psychological burden can be offered a transplant. In addition to its complementary role in a transplant program, dialysis can be used independently in the maintenance of patients with chronic renal failure; and it can be used to preserve life in acute renal failure and in acute poisoning, to allow more time for recovery.

There are two main techniques of dialysis in current use. In peritoneal dialysis, the patient's own abdominal cavity is used as the container of fluid; the fluid is run in, allowed to reach equilibrium, and removed, taking with it urea and other wastes. The process is tedious and cannot be repeated over many occasions. But it has proved suitable for the short-term treatment of acute renal failure. Hemodialysis (filtration of the blood through semi-permeable membranes) has also been used in the treatment of acute renal failure, since the method—the artificial kidney—was devised, in the 1940s; but, for chronic use, the problem was one of repeated access to the arterial bloodstream. This was largely solved by the introduction of a permanent shunt between an artery and a vein, which could be diverted through the "artificial kidney" when required. In the original artificial kidney, the patient's blood was pumped through cellophane tubing immersed in a large bath of physiological fluid (solution of the same osmotic pressure as blood); in some later models, streams of blood and of dialyzing fluid are made to flow in opposite directions, separated by plastic sheets. This introduction of the "countercurrent" principle has allowed the apparatus to be smaller, and disposable versions of both patterns are now available. Some patients on intermittent hemodialysis have been kept alive for nearly ten years now. Most continued hemodialysis is still done in hospitals or special centres; but some patients using automatic equipment have been successfully trained to carry out the procedure in their own home.

#### DISEASES OF URINARY TRACT

**Obstruction.** While it is possible for the urinary tract to be obstructed by a large mass (tumour, stone, or foreign body) lying in the bladder, the tubular portions of the tract (urethra and ureters) are much more vulnerable to obstruction. The urethra may be obstructed by the lodging therein of stones (calculi) formed in the bladder or kidneys; by fibrous contraction of the urethral wall (urethral stricture); and by congenital valve or diaphragm (membranous obstruction). Although not strictly a part of the excretory tract, the prostate lies inconveniently close to the bladder neck, and in older men it is an important cause of obstruction; fibrous disease of the bladder neck can also cause obstruction. The ureters can likewise be obstructed by calculi and stricture (narrow-

dialysis

Effect of  
urinary  
obstruction on  
kidney

Characteristics of urinary calculi

ing); by fibrosis—scarring—of surrounding tissue (retroperitoneal fibrosis); and by tumour, though this is more likely to cause blood in the urine.

Urinary calculi vary greatly in size and composition, but mostly they contain calcium, together with phosphate or oxalate. Stones of organic matter (uric acid, cystine) are also found. Predisposing factors include infection, a high rate of calcium excretion, a low rate of urine formation (e.g., in tropical countries, because of fluid loss through sweating), and various metabolic disorders, notably gout. They may cause trouble by their size; or by entering the ureter or urethra, giving rise to colic, to hematuria—blood in the urine—and, in the event of impaction, to obstructive kidney disease. The direct treatment of calculi is surgical. The sufferer needs general investigation for any underlying cause; e.g., a functioning parathyroid tumour that causes excessive excretion of calcium.

In the past at least, a common cause of urethral stricture was gonorrhea, in which inflammation of the urethra is followed by scarring and stricture. Bruising of the urethra by instruments during treatment can also occur. The affected person has increasing difficulty in passing urine, and the bladder becomes distended. Treatment may be either by repeated dilation of the stricture or by surgery.

**Trauma.** Apart from the urethra, the urinary tract is likely to be injured only in massive general injury or by accidental ligation (tying) of the ureters in a pelvic operation. The urethra can, however, be ruptured by a blow or fall on the perineum (crotch) if it is trapped between the external mass and the pelvic bone. If there is no external wound, the damage is indicated by the appearance of a swelling containing blood and urine, by the failure of any attempt to pass urine, and by bleeding from the urethra. The patient becomes shocked, and a surgical operation is urgently needed to repair the urethra and drain the potentially infected swelling.

**Tumour.** The occurrence of papillomatous tumours, initially benign but often becoming malignant, has already been mentioned in relation to the renal pelvis. Similar tumours can occur in the lower urinary tract, and these also give rise to painless hematuria. Workers with the chemicals naphthylamine and benzidine have been shown to have a high incidence of bladder tumours, often multiple and recurrent. Clinically, blood in the urine is the most frequent symptom, but irritation of the bladder with difficulty in urination appears later. Removal when practicable or destruction by diathermy are normal treatments.

**Infection of urinary tract.** Infection of the urinary tract is a common and important cause of both minor and major illness. At one extreme, an attack of cystitis—inflammation of the bladder—may cause only trivial discomfort; on the other hand, infection once established may cause lifelong discomfort, may be largely unresponsive to treatment, and may greatly shorten life itself. Infection may be with a great variety of organisms, but the commonest are those that inhabit the bowel, where they are relatively harmless, becoming a cause of disease only when they gain entrance to vulnerable tissue. Because of the short female urethra, urinary infections are more common in women than in men and occur especially during pregnancies, when there may be partial stagnation of the urine from pressure on the urinary tract. In later life, as prostatic disease enters the picture, urinary infection becomes more of a problem in men. Another vulnerable period is infancy, when the use of diapers probably facilitates entry of organisms into the urethra. The introduction of a catheter into the bladder may be necessary to relieve urethral obstruction, but since the procedure always carries a risk of introducing infection, it is not lightly undertaken.

In all forms of urinary infection the urine may be cloudy and may contain more ammonia than usual. Urination tends to be painful if the urethra is inflamed, and both painful and frequent if inflammation involves the bladder. Bladder infection may also cause fever, dull pain in the lower part of the abdomen, and vomiting. If the in-

fection reaches the kidneys, symptoms are even more severe, and there is pain in the loins, on one or both sides.

Urinary infection is diagnosed from the symptoms and from laboratory examination of the urine. Treatment is with sulfenamides or with broad-spectrum antibiotics.

Like other tissues, the excretory system can be involved in tuberculous infection. This is now relatively uncommon and, when it occurs, can often be managed by the general chemotherapy appropriate to tuberculous infection. Advanced renal tuberculosis requiring removal of the kidney rarely occurs.

**BIBLIOGRAPHY.** For further information, the following may be consulted in their latest available edition: H.E. DE WARDENER, *The Kidney*, 3rd ed. (1967), a clearly written short textbook; M.B. STRAUSS and L.G. WELT (eds.), *Diseases of the Kidney*, 2nd ed. (1971), a comprehensive textbook at an advanced level; D.A.K. BLACK (ed.), *Renal Disease*, 3rd ed. (1972), a multiple-author book, which concentrates on selected areas of current development.

## Exegesis and Hermeneutics, Biblical

Exegesis, or critical interpretation, and hermeneutics, or the science of interpretive principles, of the Bible have been used by both Jews and Christians throughout their histories for various purposes. The most common purpose has been that of discovering the truths and values of the Old and New Testaments by means of various techniques and principles, though very often, due to the exigencies of certain historical conditions, polemical or apologetical situations anticipate the truth or value to be discovered and thus dictate the type of exegesis or hermeneutic to be used. The primary goal, however, is to arrive at biblical truths and values by an unbiased use of exegesis and hermeneutics.

### NATURE AND SIGNIFICANCE

Biblical exegesis and hermeneutics play a basic role in Jewish and Christian theology, since both Jews and Christians are traditionally "people of the book." The major part of that book, the Hebrew Bible in the original text or in one of its non-Hebrew versions, is common to Jews and Christians. To it Christians add the New Testament, and some Christians also include in their Bible the writings called the Apocrypha (from the Greek "hidden away"), most of which, while not forming part of the Hebrew Bible, were included in the Greek version of the Old Testament (the Septuagint), rendered by Hellenistic Jews c. 2nd century BC, which constituted the "authorized version" of the early church.

Biblical exegesis is the actual interpretation of the sacred book, the bringing out of its meaning; hermeneutics is the study and establishment of the principles by which it is to be interpreted. Where the biblical writings are interpreted on a historical perspective, just as with philological and other ancient documents, there is little call for a special discipline of biblical hermeneutics. But it has been widely held that the factors of divine revelation and inspiration in the Bible, which, according to Jewish and Christian belief, set it apart from other literature, impose their appropriate hermeneutical principles, although there has been divergence of opinion on what these principles are. Again, because of the place that the biblical writings have occupied in synagogue and church, their exploitation for apologetical or polemical ends, their employment as a source for dogma or as a means of grace, fostering individual and community devotion, and the use of certain parts (especially the psalms) in the congregational liturgy, the science of hermeneutics has been studiously cultivated as a theological discipline. To treat the Bible like any other book (even in order to discover that it is not like any other book) has been condemned by believers as an unworthy, not to say impious, attitude.

At times the languages in which the biblical texts were originally composed have for that reason been treated as sacred languages. Hebrew may be to the philologist a Canaanite dialect, not substantially different from Phoenician, or Moabite, or other Semitic languages, but for

The role of biblical exegesis and hermeneutics in Jewish and Christian theology

Situations leading to urinary infection

Varying standards and presuppositions

some people even today this language is invested with an aura of sacredness. As for the language of the New Testament, in the days before its place within the general development of Hellenistic Greek was properly appreciated, it could be called a "language of the Holy Ghost," as it was by the German Lutheran theologian Richard Rothe (1799–1867). And even scholars who know very well the true character of the biblical languages are tempted at times to make the Old and New Testament vocabularies, down to the very prepositions, bear a greater weight of theological significance than sound linguistic practice permits. Where in other Greek literature the context would be allowed to determine the precise force of this or that synonym, there is a tendency to approach the New Testament with definitions ready made and to impose them on the text: to give one example, of two common Greek words meaning "new," it is sometimes laid down in advance that *kainos* denotes new in character and *neos* new in time ("young"). Often such distinctions are valid, but their validity must be established by the context; where the context discourages such precise differentiations, they must not be forced upon it.

Again, it is a truism in linguistic study that the meaning of a word depends on its usage, not on its derivation. It may be of interest to know that the Hebrew word for "burnt offering" (*ola*) etymologically means "ascending" (cf. the verb *'ala*, "ascend"), and to trace the stages by which it attained its biblical meaning, but this knowledge is almost wholly irrelevant to the understanding of the word in the Old Testament ritual vocabulary, and any attempt to link it, say, with the ascension of Jesus in the New Testament, as has been done, can lead only to confusion.

Similarly there has been a tendency to place the history contained in the biblical writings on a different level from "ordinary" history. Here the increasing knowledge of the historical setting of the biblical narrative, especially in the Old Testament, has helped to remove the impression that the persons and peoples portrayed in this narrative are not quite "real"; it has integrated them with contemporary life and promoted a better understanding of what they had in common with their neighbours and what their distinctive qualities were.

#### BIBLICAL CRITICISM

A prerequisite for the exegetical study of the biblical writings, and even for the establishment of hermeneutical principles, is their critical examination. Most forms of biblical criticism are relevant to many other bodies of literature.

**Textual criticism.** Textual criticism is concerned with the basic task of establishing, as far as possible, the original text of the documents on the basis of the available materials. For the Old Testament, until 1947, these materials consisted principally of: (1) Hebrew manuscripts dated from the 9th century AD onward, the Masoretic text, the traditional Jewish text with its vocalization and punctuation marks as recorded by the editors called Masoretes (Hebrew *masora*, "tradition") from the 6th century to the end of the 10th; (2) Hebrew manuscripts of medieval date preserving the Samaritan edition of the Pentateuch (first five books of the Bible); (3) Greek manuscripts, mainly from the 3rd and 4th centuries AD onward, preserving the text of the pre-Christian Greek version of the Hebrew Bible together with most of the apocryphal books (the Septuagint); (4) manuscripts of the Syriac (Peshitta) and Latin (Vulgate) versions, both of which were based directly on the Hebrew. Since 1947 the discovery of Hebrew biblical texts at Qumrān (then Jordan) and other places west of the Dead Sea has made it possible to trace the history of the Hebrew Bible back to the 2nd century BC and to recognize, among the manuscripts circulating in the closing generations of the Second Jewish Commonwealth (c. 450 BC–c. AD 135), at least three types of Hebrew text: (1) the ancestor of the Masoretic text, (2) the Hebrew basis of the Septuagint version, and (3) a popular text of the Pentateuch akin to the Samaritan edition. A comparative examination of these three indicates that the ancestor of the Masoretic text is

in the main the most reliable; the translators of the Revised Standard Version (1952) and New English Bible (1970) have continued to use the Masoretic text as their Old Testament basis.

For the New Testament the chief text-critical materials are (1) manuscripts of the Greek text, from the 2nd to the 15th centuries, of which some 5,000 are known, exhibiting the New Testament text in whole or in part; (2) ancient versions in Syriac, Coptic, Latin, Armenian, Georgian, Ethiopic, and other languages; and (3) citations in early Christian writers. A comparative study of this material enables scholars to get behind the Byzantine type of text, (the types that first diffused from Constantinople from the 4th century onward, gained currency throughout Greek-speaking Christendom and formed the basis of the earliest printed editions of the Greek testament) to a variety of types current in various localities in the generations immediately preceding; but the more recent discovery of manuscripts (mainly on papyrus) of the 3rd and even 2nd centuries, which cannot be neatly assigned to one or another of these types, makes the earlier history of the text more problematic, and the Revised Standard Version and New English Bible are both based on an eclectic text (in which, where the witnesses show variant readings, the reading preferred is that which best suits the context and the author's known style).

**Philological criticism.** Philological criticism consists mainly in the study of the biblical languages in their widest scope, so that the vocabulary, grammar, and style of the biblical writings can be understood as accurately as possible with the aid not only of other biblical writings but of other writings in the same or cognate languages. New Testament Greek, for example, is a representative of Hellenistic Greek written in the 1st century AD, ranging from the literary Hellenistic of Hebrews, I Peter, and portions of Luke–Acts, to the colloquial or vernacular idiom of some other books (e.g., the conversations in the Gospels). Some Aramaic influences have been discerned in parts of the New Testament that have a Palestinian setting, but not to a point where scholars are obliged to conclude that some books, or parts of books, were originally composed in Aramaic. Moreover, the Septuagint version exercised on some New Testament writers the kind of influence that the King James Version has exercised on many English writers, especially in the provision of a theological vocabulary in areas such as law, ethics, atonement, and sacrifice. The study of Old Testament Hebrew has been enriched by the study of other Semitic languages—Akkadian and Ugaritic among the ancient languages, and Arabic, which preserves many archaic features. Such comparative study has led to the suggestion of new meanings for a considerable number of biblical Hebrew words—a tendency that is amply illustrated by the New English Bible—but this department of philological criticism requires much more carefully defined guiding lines than have hitherto been laid down.

**Literary criticism.** Literary criticism endeavours to establish the literary genres (types or categories) of the various documents and to reach conclusions about their structure, date, and authorship. These conclusions are based as far as possible on internal evidence, but external evidence is also very helpful, especially where date is concerned. If the document under consideration is unmistakably quoted in another composition, for example, that quotation forms a *terminus ante quem* (later limiting point in time) for dating purposes. If, on the other hand, the document is clearly dependent on another document that can be dated on independent grounds, the date of the earlier document provides a *terminus post quem* (earlier limiting point in time).

Proved dependence on such an earlier document may also throw light on the structure of the work being studied. But much of the evidence for the history of its structure is internal. The evaluation of such evidence is the province of what used to be called the higher criticism, a term first employed with a biblical reference by the German biblical scholar and orientalist Johann Gottfried Eichhorn (1752–1827):

I have been obliged to bestow the greatest amount of labour

New  
Testament  
textual  
problems

Importance of  
literary  
genres

Biblical  
manuscript  
texts and  
editions

on a hitherto entirely unworked field, the investigation of the inner constitution of the separate books of the Old Testament by the aid of the higher criticism (a new name to no humanist).

Eichhorn paid special attention to the Pentateuch; his work marks an important step forward in Pentateuchal criticism. The chronological arrangement of the successive law codes contained in the Pentateuch, or of the successive editions of one fundamental law code, has been related to the history of Israelite culture and religion recorded in the other Old Testament books—histories, prophecies, and psalms—with the mounting aid supplied by contemporary non-Israelite documents. The development of some Old Testament books is indicated expressly in their contents: one can note the composition of the first and second editions of the Book of Jeremiah in Jer. 36:4, 32; and scholars can reach some conclusions about later editions by a comparison of the longer edition in the Masoretic text with the shorter edition in the Septuagint (now also attested in a fragmentary Hebrew text from Qumrān). In the absence of such explicit evidence, conclusions about the structure of other prophetic books, such as Isaiah and Ezekiel, must be more tentative.

In the New Testament, literary criticism has centred principally on the Gospels. In the Synoptic Gospels (that is, those having a common source; *i.e.*, Matthew, Mark, and Luke) indicators as to source and composition are provided by the presence of so much material common to two or to all three of them. The majority opinion for well over a century has been that Mark served as a source for Matthew and Luke, and that the two latter had a further common source, generally labelled Q (for *Quelle*, the German term for “source”), comprising mainly sayings of Jesus. Aspects of the Gospel problem that literary criticism leaves unsolved are more likely to be illuminated by other critical approaches. The Fourth Gospel (John) having much less in common with the Synoptic Gospels than the latter three have among themselves, it presents an independent line of transmission, and a comparative study of those areas where the Johannine and Synoptic traditions touch each other yields valuable conclusions for the beginnings of the gospel story.

**Tradition criticism.** Tradition criticism takes up where literary criticism leaves off; it goes behind the written sources to trace the development of oral tradition, where there is reason to believe that this preceded the earliest documentary stages, and attempts to trace the development of the tradition, phase by phase, from its primary life setting to its literary presentation. The development of the tradition might cover a lengthy period, as in the Old Testament narratives of the patriarchs—Abraham, Isaac, and Jacob—and the judges, such as Deborah and Samuel, many of which were originally attached to particular sanctuaries. The recognition of the life setting of each successive phase is necessary to the interpretation of the material received and delivered by one generation after another.

In the New Testament, too, special attention has been paid to the oral stage of the Gospel tradition, though here the preliterary period is measured in decades, not (as in the Old Testament) in generations and centuries. Not only the record of the ministry of Jesus but the development of Christian theology in the short preliterary stage has formed the subject matter of this study.

**Form criticism.** Form criticism has become one of the most valuable tools for the reconstruction of the preliterary tradition. This discipline classifies the literary material according to the principal “forms”—such as legal, poetic, and other forms—represented in its contents, and examines these in order to discover how they were handed down and what their successive life settings were until they assumed their present shape and position. In their various ways laws, narratives, psalms, and prophecies are amenable to this approach. By this means some scholars have undertaken to recover the *ipsissima verba* (“very own words”) of Jesus by removing the accretions attached to them in the course of transmission. The exegetical task assumes a threefold shape as scholars work back from (1) interpretation of the present Gospels

through (2) interpretation of the tradition lying behind them to (3) reconstruction of the proclamation of Jesus.

Scholars are not left completely to speculation as they attempt to reconstruct the stages by which the Gospel tradition attained its final form: here and there in the New Testament letters, and in some of the speeches included in Acts (which convey the general sense of what was said and should not be regarded as the author's free creations), there are fragments and outlines of the story of Jesus and of his teaching. Sometimes the characteristic terminology of tradition (“I received . . . I delivered”) is used when such fragments are introduced, a decade or so before the composition of the earliest Gospel (*cf.* I Cor. 11:23; 15:3).

**Other types of exegetical critical techniques.** *Redaction criticism.* Redaction criticism concentrates on the end product, studying the way in which the final authors or editors used the traditional material that they received and the special purpose that each had in view in incorporating this material into his literary composition. It has led of late to important conclusions about the respective outlooks and aims of the four evangelists, Matthew, Mark, Luke, and John.

*Historical criticism.* Historical criticism places the documents in their historical setting and promotes their interpretation in the light of their contemporary environment. This is necessary for their understanding, whether they are historical in character or belong to another literary genre. If they are historical in character it is important to establish how faithfully they reflect their dramatic date—the date of the events they record (as distinct from the date of final composition). This test has been applied with singularly positive results to Luke–Acts, especially in relation to Roman law and institutions; and in general the biblical outline of events from the middle Bronze Age (c. 21st–c. mid-16th centuries BC) to the 1st century AD fits remarkably well into its Near Eastern context as recovered by archaeological research.

*“History of religions” criticism.* “History of religions” criticism, to use an ungainly expression, relates Old and New Testament religion to the religious situation of the contemporary world of the writings and tries to explain biblical religion as far as possible in terms of current religious attitudes and practices. This is helpful to a point, insofar as it throws into relief those features of Hebrew and Christian faith that are distinctive; it is carried to excess when it attempts to deprive those features of their unique qualities and to account completely for them in religious–historical terms. When the cult of Israel was practically indistinguishable from that of the Canaanites, the protests of the 8th-century BC Hebrew prophets Amos or Hosea stand out over against popular Yahweh worship (Hebrew) and Baal worship (Canaanite) alike. Another attempt has been made by historians of religion to recreate for the 1st century AD a pre-Christian Gnostic myth—referring to an esoteric dualism in which matter is viewed as evil and spirit good—of the primal or heavenly man who comes from the realm of light to liberate particles of a heavenly essence that are imprisoned on earth in material bodies and to impart the true knowledge. By men's acceptance of this secret salvatory knowledge (gnosis), the heavenly essence within man is released from its thralldom and reascends to its native abode. Fragments of this myth have been recognized in several books of the New Testament. But the attempt has not been successful: according to many recent (latter half of the 20th century) New Testament scholars and historians of the early church, it is probable that the concepts of primal man and redeemer-revealer were not brought together in Gnosticism *except* under the influence of the Christian apostolic teaching, in which Jesus fills the role of Son of man (or Second Adam) together with that of Saviour and Revealer.

On the other hand, the Iranian religious influence, primarily that of Zoroastrianism (see also ZOROASTRIANISM AND PARSIISM), on the angelology and eschatology (concepts of the last times) of Judaism in the last two centuries BC is unmistakable, especially among the Pharisees (a liberal Jewish sect emphasizing piety) and the Qumrān

Biblical texts in relation to their historical milieu

Tracing the oral tradition

community (presumably the Essenes) near the Dead Sea. In the latter, indeed, Zoroastrian dualism finds clear expression, such as in the concept of a war between the sons of light and the sons of darkness, although it is subordinated to the sovereignty of the one God of Israel.

The value of these critical methods of Bible study lies in their enabling the reader to interpret the writings as accurately as possible. By their aid he can ascertain better what the writers meant by the language they used at the time they wrote and how their first readers would have understood their language. If the understanding of readers today is to have any validity, it must bear a close relation to what the original readers were intended to understand.

#### TYPES OF BIBLICAL HERMENEUTICS

As has been said, the importance of biblical hermeneutics has lain in the Bible's status as a sacred book in Judaism and Christianity, recording a divine revelation or reproducing divine oracles. The "oracles" are primarily prophetic utterances, but often their narrative setting has also come to acquire oracular status. Quite different hermeneutical principles, however, have been inferred from this axiom of biblical inspiration: whereas some have argued that the interpretation must always be literal, or as literal as possible (since "God always means what he says"), others have treated it as self-evident that words of divine origin must always have some profounder "spiritual" meaning than that which lies on the surface, and this meaning will yield itself up only to those who apply the appropriate rules of figurative exegesis. Or again, it may be insisted that certain parts must be treated literally and others figuratively; thus some expositors who regard the allegorical (symbolic) interpretation of the Old Testament histories as the only interpretation that has any religious value maintain that in the apocalyptic writings that interpretation which is most literal is most reliable.

**Literal interpretation.** Literal interpretation is often, but not necessarily, associated with the belief in verbal or plenary inspiration, according to which not only the biblical message but also the individual words in which that message was delivered or written down were divinely chosen. In an extreme form this would imply that God dictated the message to the speakers or writers word by word, but most proponents of verbal inspiration repudiate such a view on the reasonable ground that this would leave no room for the evident individuality of style and vocabulary found in the various authors. Verbal inspiration received classic expression by the 19th-century English biblical scholar John William Burgon:

The Bible is none other than *the voice of Him that sitteth upon the Throne!* Every Book of it, every Chapter of it, every Verse of it, every word of it, every syllable of it, (*where are we to stop?*) every letter of it, is the direct utterance of the Most High! (*From Inspiration and Interpretation*, 1861).

This explains Burgon's severe judgment that the revisers of the English New Testament (1881), in excluding what they believed to be scribal or editorial additions to the original text, "stand convicted of having deliberately rejected the words of Inspiration in every page" (*The Revision Revised*, p. vii, London, 1883). Such a high view of inspiration has commonly been based on the statement in II Tim. 3:16 that "all [Old Testament] scripture is God-breathed" (Greek *theopneustos*, which means "inspired by God") or Paul's claim in I Cor. 2:13 to impart the gospel "in words not taught by human wisdom but taught by the Spirit, interpreting spiritual truths in spiritual language." On this latter passage the English bishop and biblical scholar Joseph Barber Lightfoot (1828–89) remarked:

The notion of a verbal inspiration in a certain sense is involved in the very conception of an inspiration at all, because words are at once the instruments of carrying on and the means of expressing ideas, so that the words must both lead and follow the thought. But the passage gives no countenance to the popular doctrine of verbal inspiration, whether right or wrong (*From Notes on Epistles of St. Paul from Unpublished Commentaries*, 1895).

The detailed attention that Lightfoot and his Cambridge University colleagues, Brooke Foss Westcott (1825–1901), successor of Lightfoot as bishop of Durham, and Fenton John Anthony Hort (1828–92), paid in their exegesis to the vocabulary and grammatical construction of the biblical documents, together with their concern for the historical context, sprang from no dogmatic attachment to any theory of inspiration but represented the literal method of interpretation at its best. Such grammatico-historical exegesis can be practiced by anyone with the necessary linguistic tools and accuracy of mind, irrespective of confessional commitment, and is likely to have more permanent value than exegesis that reflects passing fashions of philosophical thought. Biblical theology itself is more securely based when it rests upon such exegesis than when it forms a hermeneutical presupposition.

**Moral interpretation.** Moral interpretation is necessitated by the belief that the Bible is the rule not only of faith but also of conduct. The Jewish teachers of the late pre-Christian and early Christian Era, who found "in the law the embodiment of knowledge and truth" (Rom. 2:20), were faced with the necessity of adapting the requirements of the Pentateuchal codes to the changed social conditions of the Hellenistic Age (3rd century BC–3rd century AD). This they did by means of a body of oral interpretation, which enabled the conscientious Jew to know his duty in the manifold circumstances of daily life. If, for example, he wished to know whether this or that activity constituted "work" that was forbidden on the sabbath, the influential school of legal interpretation headed by the rabbi Hillel (late 1st century BC to early 1st century AD) supplied a list of 39 categories of activity that fell under the ban.

The Christian Church rejected the Jewish "tradition of the elders" but for the most part continued to regard the Ten Commandments as ethically binding and devised new codes of practice, largely forgetting Paul's appeal to the liberty of the Spirit, or viewing it as an invitation to indulge in allegory. In order to deduce moral lessons from the Bible, allegorization was resorted to, as when the *Letter of Barnabas* (c. AD 100) interprets the Levitical food laws prescribed in the book of Leviticus as forbidding not the flesh of certain animals but the vices imaginatively associated with the animals. To set up principles of exegesis by which ethical lessons may be drawn from all parts of the Bible is not easy, since many of the commandments enjoined upon the Israelites in the Pentateuch no longer have any obvious relevance, such as the ban on boiling a kid in its mother's milk (Ex. 23:19b, etc.), or on wearing a mixed woollen and linen garment (Deut. 22:11); and much of the teaching of Jesus in the Sermon on the Mount is widely regarded as a counsel of perfection, impracticable for the average man, even when he professes the Christian faith. Even summaries of the biblical ethic, such as the golden rule (Matt. 7:12; cf. Tob. 4:15) or the twofold law of love to God and love to one's neighbour (Deut. 6:5; Lev. 19:18), in which the Decalogue (Ten Commandments) is comprehended (Mark 12:29–31; cf. Rom. 13:8–10), involve casuistic interpretation (fitting general principles to particular cases) when they are applied to the complicated relations of present-day life. The difficulties of applying biblical ethics to modern situations do not mean that the task of application should be abandoned but that it should not be undertaken as though it provided an easy shortcut to moral solutions.

**Allegorical interpretation.** Allegorical interpretation places on biblical literature a meaning that, with rare exceptions, it was never intended to convey. Yet at times this interpretation seemed imperative. If the literal sense, on which heretics, such as the 2nd-century biblical critic Marcion, and anti-Christian polemicists, such as the 2nd-century philosopher Celsus, insisted, was unacceptable, then allegorization was the only procedure compatible with a belief in the Bible as a divine oracle. Law, history, prophecy, poetry, and even Jesus' parables yielded new meanings when allegorized. The surface sensuous meaning of the Canticles (the Song of Solomon) was gladly forgotten when its mutual endearments were understood

Interpretation of biblical inspiration

The Bible as a guide to conduct

to express the communion between God and the soul, or between Christ and the church. There are still readers who can reconcile themselves to the presence of a book such as Joshua in the canon only if its battles can be understood as pointing to the warfare of Christians "against the spiritual hosts of wickedness in the heavenly places" (Eph. 6:12). As for the Gospel parables, when in the story of the good Samaritan (Luke 10:30-37) an allegorical meaning is sought for the thieves, the Samaritan's beast, the inn, the innkeeper, and the two pence, the result too often is that the explicit point of the story, "Go and do likewise," is blunted.

Typo-  
logical  
interpreta-  
tion

Closely allied to allegorical interpretation, if not indeed a species of it, is typological interpretation, in which certain persons, objects, or events in the Old Testament are seen to set forth at a deeper level persons, objects, or events in the New. In such interpretations, Noah's ark (Gen. 6:14-22) is interpreted to typify the church, outside which there is no salvation; Isaac carrying the wood for the sacrifice (Gen. 22:6) typifies Jesus carrying the cross; Rahab's scarlet cord in the window (Jos. 2:18-21) prefigures the blood of Christ; and so on. These are not merely sermon illustrations but rather aspects of a hermeneutical theory that maintains that this further significance was designed (by God) from the beginning. Traces of typology appear in the New Testament, as when Paul in Rom. 5:14 calls Adam a "type" of the coming Christ (as the head of the old creation involved its members in the results of his disobedience, so the head of the new creation shares with its members the fruit of his obedience), or when in I Cor. 10:11 he says that the Israelites' experiences in the wilderness wanderings befell them "typically," so as to warn his own converts of the peril of rebelling against God. The fourth evangelist stresses the analogy between the sacrificial Passover lamb of the Hebrews and Christ in his death (John 19). The writer of the Hebrews treats the priest-king of Salem, Melchizedek, who was involved with Abraham as a type of Christ (Heb. 7)—without using the word "type"—and the Levitical ritual of the Day of Atonement as a model (though an imperfect one) of Christ's sacrificial ministry (Heb. 9).

**Other hermeneutical principles.** *Anagogical interpretation.* Anagogical (mystical or spiritual) interpretation seeks to explain biblical events or matters of this world so that they relate to the life to come. Jordan is thus interpreted as the river of death; by crossing it one enters into the heavenly Canaan, the better land, the "rest that remains for the people of God." "The Jerusalem that now is" points to the new Jerusalem that is above. In Judaism of the closing centuries BC, the Eden of Genesis, the earthly paradise, lent its name to the heavenly paradise mentioned occasionally in the New Testament (Luke 23:43; II Cor. 12:3; Rev. 2:7).

Another form of mystical interpretation is the Mariological (referring to Mary, the mother of Jesus) application of scriptures that have another contextual sense. Thus Mary is the second Eve, whose offspring bruises the serpent's head (Gen. 3:15); Mary is the star-crowned woman of Rev. 12, whose son is caught up to the throne of God, and in more popular piety the dark-faced Madonna of the monastery at Montserrat, near Barcelona, Spain, can be identified with the "black but comely" bride of the Song of Solomon.

*Parallelism.* Parallelism, the interpretation of Scripture by means of Scripture, is a corollary of the belief in the unity of Scripture. But as a hermeneutical principle it must be employed sparingly, since the unity of Scripture should be based on comprehensive exegetical study, rather than itself provide a basis. Where one or two biblical documents (e.g., the letters to the Romans and to the Galatians) are treated as the norm of biblical doctrine, there is a danger that other parts of the volume (e.g., the Letter to the Hebrews) will be forced to yield the same sense as the "normative" documents; the distinctiveness of certain biblical authors will then be blurred. One naive form of parallelism is the "concordant" method, in which it is axiomatic that a Hebrew or Greek word will always (or nearly always) have the same force wherever it occurs in the Bible, no matter who uses

it. There is, again, a harmonistic tradition that smooths out disparities in the biblical text (e.g., as between the gospel narratives or the parallel records of Kings and Chronicles) in a manner that imposes a greater strain on faith than do the disparities themselves.

One exegetical device of the Jewish rabbis (teachers, biblical commentators, and religious leaders) was that of *gezera shawa*, "equal category," according to which an obscure passage might be illuminated by reference to another containing the same key term. There are several examples in Paul's Old Testament exegesis, one of the best known being in Gal. 3:10-14, where the mystery of Christ's dying the death that incurred the divine curse (Deut. 21:23) is explained by his bearing vicariously the curse incurred by the lawbreaker (Deut. 27:26). One may compare the explanation in Heb. 4:3-9 of God's "rest" mentioned in Ps. 95:11 by reference to his resting on the seventh day after creation's work (Gen. 2:3)—an explanation dependent on the Septuagint, not the Hebrew.

*Analogical interpretation.* Analogical interpretation traditionally includes not only interpretation according to the analogy of Scripture (parallelism, in other words) but also interpretation according to the "analogy of faith"—an expression that misapplies the language of Rom. 12:6 in the King James Version of 1611. It has at times been pressed to mean that no biblical interpretation is valid unless it conforms to the established teaching of a religious community, to the verdict of tradition, or to the "unanimous consensus of the fathers." Where the established teaching is based, in intention, on Scripture, then an interpretation of Scripture that conflicts with it naturally calls for further scrutiny, but such conflict does not rule out the interpretation beforehand; if the conflict is confirmed, it is the established teaching that requires revision.

*Other types.* There is an unconscious tendency to conform hermeneutical principles to the climate of opinion in and around the community concerned, and to change the hermeneutic pattern as the climate of opinion changes. It is not surprising that in the circles where Pseudo-Dionysius (early-6th-century writings attributed to Dionysius, a convert of St. Paul) was revered as a teacher, Scripture was interpreted in Neoplatonic (idealistic and mystical) categories, and if in the latter half of the 20th century there is an influential and persuasive school of existential hermeneutics, this may be as much due to a widespread contemporary outlook on life as was the liberal hermeneutic of the preceding generations.

At a far different level contemporary movements continue to influence biblical interpretation. The interpretation of prophecy and apocalyptic in terms of events of the interpreter's day, which has ancient precedent, is still avidly pursued. Just as in the 16th century the apocalyptic beast of Revelation was interpreted to be the papacy or Martin Luther (in accordance with the interpreter's viewpoint), so also today in some nonacademic circles the ten kings denoted by the beast's horns in Revelation are identified with the European Economic Community in its ultimate development, or the threat to "destroy the tongue of the sea of Egypt" (Isa. 11:15) is believed to be fulfilled in the condition of the Suez Canal in the years following 1967. Whatever critical exegetes think of such aberrations, historians of exegesis will take note of them and recognize the doctrine of Scripture that underlies them.

Existential  
interpretations

#### THE DEVELOPMENT OF BIBLICAL EXEGESIS AND HERMENEUTICS IN JUDAISM

**Early stages.** The beginnings of biblical exegesis are found in the Old Testament itself, where earlier documents are interpreted in later documents, as in the recasting of earlier laws in later codes, or the Chronicler's reworking of material in Samuel and Kings. In addition, even before the Babylonian Exile (586 BC) there is evidence of the kind of midrashic exposition (nonliteral interpretations) familiar in the rabbinical period (c. 300 BC-c. AD 500) and after.

In Isa. 40 and following, the restoration of Israel after the return from exile is portrayed as a new creation: the

Concor-  
dant and  
harmon-  
istic  
methods

characteristic verbs of the Genesis creation narrative—"create" (*bara*), "make" (*asa*) and "form" (*yatzar*)—are used of this new act of God (e.g., Isa. 43:7). Even more clearly are the same events portrayed as a new Exodus: on their journey back from Babylon, as earlier through the wilderness, the God of Israel makes a way for his people; he protects them before and behind; he champions them "with a mighty hand and an outstretched arm," he brings water from the rock for their sustenance (Isa. 43:2, 16, 19; 48:21; 52:12; Ezek. 20:33).

A pattern of divine action in mercy and judgment is discernible as one moves from the earlier prophets to the later prophets and apocalyptists (those concerned with the intervention of God in history). Yahweh's "strange work" in bringing the Assyrians against Israel in the 8th century BC (Isa. 28:21; 29:14) is repeated a century later when he raises up the Chaldeans (Babylonians) to execute his judgment (Hab. 1:5 fol.). Ezekiel's visionary figure Gog is the invader whose aggression was foretold in earlier days by Yahweh through his "servants the prophets" (Ezek. 38:17), and one may recognize in him a revival not only of Isaiah's Assyrian (Isa. 10:4 fol.) but also of Jeremiah's destroyer from the north (Jer. 1:14 fol.; 4:6 fol.). The same figure reappears in the last "king of the north" in Dan. 11:40 fol.; he too is diverted from his path by "tidings from the east and the north" (cf. Isa. 37:7) and "shall come to his end, with none to help him" (cf. Isa. 31:8).

In some degree these later predictions are interpretations, or reinterpretations, of the earlier ones, as when the non-Israelite prophet Balaam's "ships . . . from Kittim" (Num. 24:24) are interpreted in Dan. 11:30 as the Roman vessels off Alexandria in 168 BC that frustrated the Syrian king Antiochus IV Epiphanes (c. 215–164/163 BC) in his attempt to annex Egypt.

Ezra (c. 400 BC), whose role as the archetypal "scribe" is magnified by tradition, is said in the canonical literature to have brought the law of God from Babylonia to Jerusalem (Ezra 7:14), where it was read aloud to a large assembly by relays of readers "with interpretation"—and "they gave the sense, so that the people understood the reading" (Neh. 8:8). This may be the first recorded use of an Aramaic Targum—a paraphrase of the Hebrew that included interpretation as well as translation.

In the scribal and rabbinic tradition, two forms of exposition were early distinguished—*peshat*, "plain meaning" and *derash*, "interpretation," by which religious or social morals were derived, often artificially, from the text. There was, however, no sense of conflict between the two.

**The Hellenistic period.** The translation of the Hebrew Bible into Greek by Alexandrian Jews in the 2nd and 3rd centuries BC provided opportunities for recording interpretations that were probably current in Hellenistic Judaism. Literal translations might be misleading to Greek readers; metaphors natural in Hebrew were rendered into less figurative Greek. "Walking with God" or "walking before God" was rendered as "pleasing God." Such renderings are scarcely to be called anti-anthropomorphisms (that is, against depicting God in human terms or forms). In certain books there are some renderings that might be so described: in Ex. 24:10, for example, "they saw the God of Israel" becomes "they saw the place where the God of Israel stood"; but an examination of the Hebrew context suggests that this is precisely what was seen.

There was a tendency to universalize certain particularist statements of the Hebrew: in Amos 9:11 fol. the prophecy that David's dynasty will repossess the residue of Edom becomes a promise that the residue of men (the Gentiles) will seek the true God—a promise that is quoted in the New Testament as a "testimony" to the Christian Gentile mission.

The other main contribution to biblical exegesis in Alexandria was made by the Jewish philosopher Philo (c. 30/ c. 20 BC–after AD 40), whose interpretation of the Pentateuch in terms of Platonic idealism and Stoic ethics had more influence on Christian than on Jewish hermeneutics.

In Palestinian Judaism the most distinctive exegetical

work in the Hellenistic period was that of the Qumrān community (c. 130 BC–AD 70). The community, believing itself raised up to prepare for the new age of everlasting righteousness, interpreted Scripture so as to find there the divine purpose about on the point of fulfillment, together with its own duty in the impending crisis. Biblical prophecies in the Qumrān commentaries refer to persons and events of the recent past, the present, or the imminent future. The time of their fulfillment was concealed from the prophets; only when this was revealed to the Teacher of Righteousness, the organizer of the community, could their intent be grasped.

Rabbinic exegesis was present in all the varieties of rabbinic literature but is found especially in the Targumim and Midrashim (plural of Targum and Midrash). Among the former, special interest attaches to the early Palestinian Pentateuch Targum; it preserves, for example, messianic (referring to the expected anointed deliverer) exegesis of certain passages to which later rabbis gave a different interpretation because of the Christians' appeal to them. The earlier Midrashim—those whose contents are not later than AD 200—expound Exodus, Leviticus, Numbers, and Deuteronomy and are almost entirely Halakhic—i.e., recording legal interpretations from various schools. The later Midrashim are more homiletic and include a considerable element of Haggada; i.e., illustrative material drawn from all sources (see also TALMUD AND MIDRASH).

Rabbinic exegesis was not haphazard; it observed certain rules, which were variously formulated in the schools. The name of the famous interpreter Hillel is linked with seven *middot* or norms: (1) inference from less important to more important and vice versa, (2) inference by analogy, (3) the grouping of related passages under an interpretative principle that primarily applies to one of them, (4) similar grouping where the principle primarily applies to two passages, (5) inference from particular to general and vice versa, (6) exposition by means of a similar passage, (7) inference from the context. By the time of Rabbi Ishmael (c. AD 100) these rules were expanded to 13, and Eliezer ben Yose the Galilaean (c. AD 150) formulated 32 rules, reflecting rational principles of exegesis, which remained normative into the Middle Ages.

**The medieval period.** By the beginning of the Middle Ages the Masoretes of Babylonia and Palestine (6th–10th century) had fixed in writing, by points and annotation, the traditional pronunciation, punctuation, and (to some extent) interpretation of the biblical text. The rise of the Karaites, who rejected rabbinic tradition and appealed to Scripture alone (8th century onward) stimulated exegetical study in their own sect and in Judaism generally: in reaction against them Sa'adia ben Joseph (882–942), *gaon* (head) of the Sura academy in Babylonia, did some of his most important work. He adopted as one basic principle that biblical interpretation must not contradict reason. He translated most of the Bible into Arabic and composed an Arabic commentary on the text.

The French Jewish biblical and talmudic scholar Rashi (R. Solomon Yīshāqi of Troyes, 1040–1105), the most popular of all Jewish commentators, paid careful heed to the language and rejected those midrashic traditions that were inconsistent with the plain meaning of the text. Abraham ibn Ezra, of Spanish birth (1092/93–1167), in some respects anticipated the Pentateuchal literary criticism of later centuries. Other important names are Joseph Qimḥi of Narbonne and his sons Moses and David, the last of whom (c. 1160–1235) commented on the prophets and psalms; his psalms commentary took issue especially with Christian exegesis.

The great philosopher and codifier Maimonides (Moses ben Maimon, 1135–1204) composed, among many other works, his *Guide For the Perplexed* to help readers who were bewildered by apparent contradictions between the biblical text and the findings of reason. Like his younger contemporary David Qimḥi, he classified some biblical narratives as visionary accounts.

Far removed from the rational exegesis of these scholars was the mystical tradition, or Kabbala, which com-

Later events as recapitulations of earlier events

Metaphorical and philosophical interpretations

Norms of interpretation

Mystical interpretation

bined with an earlier mysticism—involving reflection on Ezekiel's inaugural chariot vision—the Neoplatonic doctrine of emanations. Adherents of this mystical exegesis of Scripture found some encouragement in the Pentateuch commentary of the Spanish Talmudist, Kabbalist, and biblical commentator Moses ben Nahman (c. 1195–1270). The tracing of mystical significance in the numerical values of Hebrew letters and words (*gematria*) made a distinctive contribution to mystical exegesis. The chief monument of mystical exegesis is the *Zohar* (“brightness”), in form a midrashic commentary on the Pentateuch, produced in Spain in the 13th century. In the *Zohar* the *peshaṭ* (literal) and *derash* (nonliteral meanings) types of interpretation are accompanied by those called *remez* (“allusion”), including typology and allegory, and *sod* (“secret”), the mystical sense. The initials of the four were so arranged as to yield the word PaRDeS (“Paradise”), a designation for the fourfold meaning. The highest meaning led by knowledge through love to ecstasy and the beatific vision (see also JEWISH MYSTICISM).

**The modern period.** Following a line marked out earlier by the Spanish philosopher and poet Moses ibn Ezra (1060–1139), Benedict de Spinoza (1632–77) put forward a thoroughgoing reappraisal of the traditional account of the origin of the Pentateuch in his *Tractatus Theologico-Politicus* (1679). In the following century the Jewish Enlightenment (*Haskala*) brought a fresh appreciation of the Bible as literature. The pioneer of the Enlightenment, Moses Mendelssohn (1729–86), prepared a German translation of the Pentateuch, which he furnished (along with Solomon Dubno and others) with a commentary; he also translated the psalms and the Song of Solomon.

The tradition of orthodox Jewish exegesis has been maintained to the present day. In the 19th century the Russian rabbi Meir ben Yehiel Michael, “Malbim,” (1809–79) wrote commentaries on the prophets and the writings, making a special point of explaining differences between synonyms. In the 20th century the traditional values of Judaism were popularly expounded in Joseph Herman Hertz's commentary on *The Pentateuch and Haftorahs* (1929–36) and in the Soncino *Books of the Bible* (1946–51). Martin Buber (1878–1965), the great modern Jewish philosopher, imparted to his many studies in biblical literature and religion—including his revolutionary German translation of the Bible (1926 and following), partly executed in association with the religious philosopher Franz Rosenzweig (1886–1926)—the qualities of his personal genius that was influenced by Hasidic (18th-century mystical) piety and an existential interpretation of life.

In recent decades the most valuable Jewish exegesis has been in association with the wider world of biblical scholarship. Journals such as the *Jewish Quarterly Review* and the *Hebrew Union College Annual* welcome contributions from non-Jewish scholars; in interconfessional projects such as the Anchor Bible, Jewish scholars cooperate in the Old and New Testament alike.

The whole field of biblical study, including exegesis, is cultivated most intensively in Israel. Yehezkel Kaufmann (1890–1963) produced the encyclopaedic *History of Israelite Religion from its Beginnings to the End of the Second Temple* (8 vols., 1937–56) in Hebrew that pursues a path involving a radical revision of current biblical criticism and interpretation. Moshe Zevi Hirsh Segal (died 1968) dealt with a wide area of biblical and related literature, maintaining the essential Mosaic authorship of the Pentateuch (supplemented by later editors who worked in Moses' spirit). The most ambitious enterprise in this field is the “Bible Project” of the Hebrew University of Jerusalem, which aims to produce a critical edition of the Hebrew Bible but also fosters a number of ancillary studies in biblical text and interpretation, mostly published in its annual report *Textus*, in which non-Jewish as well as Jewish scholars participate.

#### THE DEVELOPMENT OF BIBLICAL EXEGESIS AND HERMENEUTICS IN CHRISTIANITY

**Early stages.** The earliest Christian exegesis of the Old Testament is found in the New Testament, not in the

written texts only but in the oral tradition lying behind them. Some lines of exegesis are present in so many separate strands of primitive Christian teaching that they are most reasonably assigned to Jesus, who began his Galilaean ministry with the announcement that the time appointed for the fulfillment of prophecy, and the Kingdom of God that was its main theme, had arrived. If the accomplishment of his ministry involved his death, that was accepted in the same spirit; he submitted to his captors with the words: “. . . Let the scriptures be fulfilled” (Mark 14:49). The church began with the conviction that Jesus, crucified and risen, was the one of whom the prophets spoke. He was the prophet like Moses, prince of the house of David, priest of the order of Melchizedek, servant of the Lord, Son of man, and exalted Lord. If the prophets themselves were uncertain about the person or time indicated by their oracles, the early Christians were certain: the person was Jesus, the time was now. The New Testament writers shared a creative and flexible principle of exegesis that has regard for the literary and historical context and traces a consistent pattern of divine action in judgment and mercy, reproduced repeatedly in the history of Israel and manifested definitively in Christ. This exegesis is elaborated at times by means of typology and allegory, as when Paul illustrates the relationship between law and gospel by the story of Hagar and Sarah, the concubine and wife of Abraham, respectively (Gal. 4:21–31), or when Israel's tabernacle in the wilderness becomes the material counterpart to the heavenly sanctuary in which believers of the new age offer spiritual worship to God (Heb. 8:2 fol.). The writer to the Hebrews, indeed, occasionally relates the old order to the new order platonically in terms of the earthly copy of an eternal archetype.

At an early date Christians developed a line of Old Testament exegesis designed to show that they, not the Jews, stand in the true succession of the original people of God. This line is seen in the *Letter of Barnabas*, the apologist Justin's (c. 100–c. 165) *Dialogue with Trypho*, and the 3rd-century *Against the Jews* ascribed to the North African bishop Cyprian (c. 200–258).

**The patristic period.** Alexandria had long boasted a school of classical study that practiced the allegorical interpretation of the Homeric epics and the Greek myths. This method of exegesis was taken over by Philo and from him by Christian scholars of Alexandria in the 2nd and 3rd centuries. Clement of Alexandria (c. 150–c. 215) and Origen (c. 185–c. 254) did not completely rule out the literal sense of Scripture—Origen's *Hexapla*, a six column edition of various biblical versions, was a monument to his painstaking study of the text for its own sake—but claimed that the most meaningful aspects of divine revelation could be extracted only by allegorization. Clement stated that the Fourth Gospel was a “spiritual gospel” because it unfolds the deeper truth concealed in the matter-of-fact narratives of the other three. Origen treated literal statements of Scripture as “earthen vessels” preserving divine treasure; their literal sense is the body as compared with the moral sense (the soul) and the spiritual sense (the spirit). The true exegete, he claimed, pursues the threefold sense and recognizes the spiritual (allegorical) as the highest.

Later, the Antiochene fathers, represented especially by Theodore of Mopsuestia (c. 350–428/429) and John Chrysostom (c. 347–407), patriarch of Constantinople, developed an exegesis that took more account of literal meaning and historical context. But the allegorizers could claim that their method yielded lessons that (while arbitrary) were more relevant and interesting to ordinary Christians.

In the West, the Alexandrian methods were adopted by Ambrose (c. 339–397), bishop of Milan, and Augustine (354–430), bishop of Hippo, especially as formulated in the seven “rules” of Tyconius (c. 380), a Donatist heretic (one who denied the efficacy of sacraments administered by an allegedly unworthy priest), which classified allegorical interpretation in relation to: (1) the Lord and his church, (2) true and false believers, (3) promise and law, (4) genus and species, (5) numerical sig-

20th-century commentators

Alexandrian allegorization

nificance, (6) "recapitulation," and (7) the devil and his followers. There were other Latin exegetes, like Ambrosiaster (commentaries ascribed to Ambrose) and, supremely, Jerome (c. 347–419/420), the learned Latin Father, who paid close attention to the grammatical sense. In the Old Testament Jerome appealed from the Greek version to the "Hebraic verity" and in such a work as his commentary on Daniel provided some fine examples of historical exegesis. Augustine, though not primarily an exegete, composed both literal and allegorical commentaries and expository homilies on many parts of Scripture, and his grasp of divine love as the essential element in revelation supplied a unifying hermeneutical principle that compensates for technical deficiencies.

**The medieval period.** As the patristic age gave way to the scholastic age, the English monk Bede of Jarrow (died 735) wrote commentaries designed to perpetuate patristic exegesis, mainly allegorical: thus Elkanah with his two wives (1 Sam. 1:2) is interpreted as referring to Christ with the synagogue and the church.

In the early Middle Ages the fourfold sense of Scripture—developed from Origen's threefold sense by subdividing the spiritual sense into the allegorical (setting forth the doctrine) and the anagogical (relating to the coming world)—was increasingly expounded and received its final authority from Thomas Aquinas (1225/26–74). For Thomas, the literal sense, expressing the author's intention, was a fit object of scientific study; the figurative senses unfolded the divine intention.

Medieval exegesis was greatly influenced by the *Glossa Ordinaria*, a digest of the views of the leading fathers and early medieval doctors (teachers) on biblical interpretation. This compilation owed much in its initial stages to Anselm of Laon (died 1117); it had reached its definitive form by the middle of the 12th century and provided the exegetical norm of the *Summa theologiae* ("Summation of Theology") of Thomas Aquinas and others.

For all the interest in allegory, literal interpretation was cultivated in many centres in the West, often with the aid of Hebrew, knowledge of which was obtainable from Jewish rabbis. One such centre was the Abbey of Saint-Victor at Paris, where Hugh (died 1141) compiled biblical commentaries that fill three volumes of J.-P. Migne's (1800–75) *Patrologiae Cursus Completus* (Series Latina) and indicate the commentator's dependence on Rashi as well as on his Christian predecessors. Of Hugh's disciples, Andrew, abbot of Wigmore (died 1175), carried on his master's tradition of literal scholarship, and Richard, the Scottish-born prior of Saint-Victor (died 1173) pursued a line more congenial to his mystical temperament. Herbert of Bosham (c. 1180) produced a commentary on Jerome's Hebrew Psalter. Robert Grosseteste, bishop of Lincoln (died 1253), wrote commentaries on the days of creation and the Psalter that both drew on the Greek fathers and profited by his direct study of the Hebrew text. Nicholas of Lyra (c. 1265–c. 1349), the greatest Christian Hebraist and expositor of the later Middle Ages, compiled *postillae*, or commentaries, both literal and figurative, on the whole Bible; he insisted that only the literal sense could establish proof. Luther ranked him among the best exegetes: "a fine soul, a good Hebraist and a true Christian."

**The Reformation period.** The English theologian John Colet (c. 1466–1519) broke with medieval scholasticism when he returned from the Continent to Oxford in 1496 and lectured on the Pauline letters, expounding the text in terms of its plain meaning as seen in its historical context. The humanist Erasmus (c. 1466–1536) owed to him much of his insight into biblical exegesis. By the successive printed editions of his Greek New Testament (1516 and following), Erasmus made his principal, but not his only, contribution to biblical studies.

Martin Luther (1483–1546) was a voluminous expositor, insisting on the primacy of the literal sense and dismissing allegory as so much rubbish—although he indulged in it himself on occasion. The core of Scripture was to him its proclamation of Christ as the one in whom alone lay man's justification before God. John Calvin (1509–64), a more systematic expositor, served his apprentice-

ship by writing a youthful commentary on the Roman statesman and philosopher Seneca the Younger's (c. 4 BC–AD 65) *De clementia* ("Concerning Mercy"); systematic theologian though he was, he did not allow his theological system to distort the plain meaning of Scripture, and his philological–historical interpretation is consulted with profit even today.

Scientific exegesis was pursued on the Catholic side by scholars such as F. de Ribera (1591) and L. Alcasar (1614) who showed the way to a more satisfactory understanding of the Revelation. On the Reformed side, the *Annotationes in Libros Evangeliorum* (1641–50) by the jurist Hugo Grotius (1583–1645) were so objective that some criticized them for rationalism.

**The modern period.** The modern period is marked by advances in textual criticism and in the study of biblical languages and history, all of which contribute to the interpretation of the Bible. The German theologian J.A. Bengel's (1687–1752) edition of the Greek text of the New Testament with critical apparatus (1734), in which he framed the canon that "the more difficult reading is to be preferred," was followed by his exegetical *Gnomon Novi Testamenti* ("Introduction to the New Testament," 1742): "apply thyself wholly to the text," he directed; "apply the text wholly to thyself." The English bishop Robert Lowth's (1710–87) Oxford lectures on *The Sacred Poetry of the Hebrews*, published in Latin in 1753, greatly promoted the understanding of the poetry of the Old Testament by expounding the laws of its parallelistic structure. The German philologist Karl Lachmann (1793–1851) applied his expertise in classical criticism to editing the text of the New Testament; to him also belongs the credit of arguing that Mark was the earliest of the Gospels and a main source of Matthew and Luke (1835). The problem of the source analysis of the Pentateuch was given what for long appeared to be its final solution by Julius Wellhausen (1844–1918), who related the successive law codes to the development of the Israelite cultus. For the period preceding the 9th century BC, however, he operated in a historical vacuum that Near Eastern archaeology was in his day only beginning to fill; its subsequent findings have dictated radical modifications in his reconstruction of Israel's religious history. In the middle half of the 19th century, New Testament exegesis was overshadowed by the school of Ferdinand Christian Baur (1792–1860), which envisaged a sharply opposed Petrine (Peter) and Pauline (Paul) antithesis in the primitive church, followed in the 2nd century by a synthesis that is reflected in most of the New Testament writings. In France, Ernest Renan's (1823–92) works on early Christianity were helpful philological and historical studies; the most popular volume, his *Vie de Jésus* (1863), was the least valuable. In England, where the poet and educator Matthew Arnold (1822–88) endeavoured to find an impregnable moral foundation for biblical authority, New Testament exegesis received contributions of unsurpassed worth between 1865 and the end of the century from J.B. Lightfoot, B.F. Westcott, and F.J.A. Hort.

At the beginning of the 20th century a new direction was given to Gospel interpretation by the German scholar William Wrede (*Das Messiasgeheimnis in den Evangelien*, 1901) and the medical missionary theologian Albert Schweitzer (*The Quest of the Historical Jesus*, Eng. trans., 1910), who so emphasized the eschatological orientation of Jesus' mind and message that New Testament scholarship can never be the same again. The writings of the biblical scholar C.H. Dodd (*The Parables of the Kingdom*, 1935; *The Apostolic Preaching and its Developments*, 1936) stressed realized eschatology—that the standards of the last times were realized by Jesus and his disciples—in the preaching of Jesus and of the primitive church; he has been a leading pioneer of the "biblical theology" movement. Karl Barth's (1886–1968) commentary on Romans (1919) launched an existential interpretation of the New Testament, which has been pursued more radically by Rudolf Bultmann (1884–), under the influence of Wilhelm Dilthey (1833–1911), according to whom the interpreter must project

himself into the author's experience so as to relive it, and of Martin Heidegger (1889– ), whose conception of the truly authentic man as capable of freedom because he has faced reality provides the "pre-understanding" for Bultmann's existential theology. Bultmann's disciple Ernst Fuchs (1903– ) considers the hermeneutical task to be the creation of a "language event" in which the authentic language of Scripture encounters one now, challenging decision, awakening faith, and accomplishing salvation. The chief rival to existential exegesis is the "salvation-history" hermeneutic espoused by Oscar Cullmann (1902– ).

Rudolf Bultmann and Martin Dibelius (1883–1947) pioneered the modern form-critical study of the Gospels. The form-critical method was fruitfully applied to the Old Testament by Hermann Gunkel (1862–1932) and Sigmund Mowinckel (1884–1965). Among Catholic scholars, exegetical studies are vigorously promoted by Jean Daniélou (with his researches into early Jewish Christianity), the Dominicans of the École Biblique et Archéologique (The School of the Bible and Archeology) in Jerusalem (to whom one must credit the Jerusalem Bible), and the Jesuits of the Pontifical Biblical Institute and others.

#### CONCLUSION

The encouragement given by the second Vatican Council (1962–65) of the Roman Catholic Church to biblical scholarship, to be cultivated in association with "separated brethren" and with consideration for the requirements of non-Christians, is one symptom of a new day in biblical exegesis, when this study is no longer pursued to vindicate sectional traditions but rather as a cooperative enterprise aiming at making widely available the permanent value of the Bible.

**BIBLIOGRAPHY.** *The Cambridge History of the Bible*, 3 vol. (1963–70), includes contributions by specialists on biblical interpretation from pre-Christian times to the present day. J. BARR, *Old and New in Interpretation* (1966), discusses the relation between the Old and New Testaments and examines critically some of the interpretative principles favoured by exegetes and theologians; another work on this subject is E.C. BLACKMAN, *Biblical Interpretation* (1957). C.E. BRAATEN, *History and Hermeneutics* (1966), discusses the relevance of the historical-critical method to theological study and the idea of revelation through history; F.F. BRUCE, *Biblical Exegesis in the Qumran Texts* (1959), examines the interpretative principles followed by biblical commentaries and other documents among the Dead Sea Scrolls. The major work on the theme of salvation-history in the Bible is O. CULLMANN, *Salvation in History* (1967). C.H. DODD, *According to the Scriptures* (1952), shows the various ways in which the Christian interpretation of important areas of the Old Testament provided the substructure of New Testament theology. F.W. FARRAR, *History of Interpretation* (1886, reprinted 1961), provides a classical survey of biblical exegesis from the early rabbinical period to the 19th century, although now outdated; R.M. GRANT, *A Short History of the Interpretation of the Bible*, rev. ed. (1963), is probably the best work of its kind. B. LINDARS, *New Testament Apologetic* (1962), studies the Old Testament quotations in the New Testament as evidence, in their text and interpretation, for the developing life and thought of the primitive church. J.M. ROBINSON and J.B. COBB (eds.), *The New Hermeneutic* (1964), expounds the modern hermeneutical concern to make the word of God existentially relevant to the present situation. B. SMALLEY, *The Study of the Bible in the Middle Ages*, 2nd rev. ed. (1952), remains the standard work on early medieval exegesis. G. VERMES, *Scripture and Tradition in Judaism* (1961), gives an account of the interaction of the written text and oral tradition in Jewish exegesis of the pre-Christian and early rabbinical age. An outline of the history of biblical interpretation and of the main exegetical trends of the mid-20th century is presented in J.D. WOOD, *The Interpretation of the Bible* (1958); A. RICHARDSON and W. SCHWEITZER (eds.), *Biblical Authority for Today* (1951), discusses the difficulties of applying biblical ethics to some of the most urgent concerns of the modern world.

(F.F.B.)

### Exercise and Physical Conditioning

Exercise, within the context of this article, is the physical training of the body in order to improve its function. Active exercise is physical exertion as a voluntary effort;

passive exercise is exercise involving a machine or the hands of another person. Physical conditioning is the enhancement of physical fitness through the proper employment of exercise.

After a consideration of other relevant terms, this article will discuss the contemporary need for exercise to compensate for sedentary or for physically specialized ways of living; the effect on the body of physical inactivity, and of physical inactivity coupled with a plentiful supply of food; the effect on obesity of exercise alone, and of exercise combined with a suitable diet; the physiological response to exercise of various degrees of intensity; the effects of physical conditioning; the development of physical behavioral patterns; and the types of exercise suited to specific needs.

#### GENERAL CONSIDERATIONS

**Fatigue and exhaustion.** Fatigue, defined with respect to the effect of exercise, is the diminution in subsequent performance following physical activity. Fatigue may be psychological (see FATIGUE) and be due to boredom, or ennui, or it may be physiological, and be due to exhaustion of the substances required for muscular contractions or to the accumulation of toxins that depress nervous system activity. Exhaustion is the extreme state of fatigue in which no further units of the physical activity can be performed—"I cannot climb another step."

**Types of physical fitness.** General physical fitness is the capacity of the body to perform work, to resist disease and infection, and to resist the physical stresses imposed by such things as heat, cold, atmospheric pressure changes at altitude or under water, and accelerative forces of jolts and vibrations. General physical fitness is, thus, the capability of the individual to dominate his usual environment, and the degree of fitness that one requires is related to the degree of stress that he must be able to overcome. The Samoan who lives peacefully in a warm climate with abundant food at arm's reach survives well with a low degree of general fitness. If the Samoan were to be transported suddenly to the frozen north, he would be unfit for the rigours of trapping. To become fit as a northern trapper, the Samoan would need to acquire specific physical fitness; that is, the special body structures and functions required to perform under the new set of unusually demanding conditions. Specific physical fitness, then, is a readiness of each system of the body to meet special demands. If unusually heavy loads must be moved, strength fitness must be acquired. Muscles must be strengthened and nerve-muscle coordination improved. If work is continuous, endurance fitness is needed. Short efforts of maximum intensity lasting less than ten seconds require anaerobic fitness, the ability of the body to work without oxygen. Exhaustive efforts of longer duration require aerobic fitness, the ability to consume oxygen efficiently. The ability to make sudden changes in posture requires orthostatic fitness. Orthostatic fitness is dependent on how well the blood circulation can adjust to a quick change of posture such as standing up after lying down.

Rapidity of movement, accuracy, and agility require speed fitness, an attribute of the brain and the sensory and motor nervous systems. Limiting rapidity of movement is relaxation fitness, the ability to elongate muscles quickly. Relaxation fitness includes ability voluntarily to reduce excess tension in the nerve-muscle system.

**Types of physical conditioning.** Physical conditioning commences the moment that physical effort exceeds the effort required by ordinary daily activity. The degree of physical conditioning that has occurred thereby is manifested by the improvement in performance that follows after recovery from the fatigue of the effort. Frequent and regular practice bouts of a new kind of activity induce lasting changes in body structure and function that help to make it fit for that activity. This adaptation to the new activity is termed general physical conditioning. After a few weeks, no further improvement occurs, and, in fact, a deterioration in fitness may be expected if the intensity of the activity is not continually increased. Continued improvement in fitness is achieved by specific

physical conditioning, which consists of progressive overloads of the activity or its components to stimulate improvement in the structure and function of those body systems that support the new activity. This specific physical conditioning is accomplished by strength training, involving the daily lifting of progressively heavier weights; endurance training, both anaerobic (sprints) and aerobic (prolonged efforts); speed training (short bursts of activity at maximal rapidity); and relaxation training (letting go after deliberate overtensing of muscles) if these are components of fitness for the activity.

**Health and fitness, and fitness and skill.** In a discussion of the effects of exercise and physical conditioning, it is necessary to differentiate between health and fitness, and between fitness and skill. Health, in its narrowest definition, is the absence of disease; more broadly, it is the capacity of all body organs and systems for high-level function. Fitness relates to performance and survival. Usually, but not always, good fitness requires good health. Many exceptions are seen in sports competition. Sick athletes often win contests and sometimes break world records. Olympic contestants suffering from infections, dysentery, influenza, fever, and broken bones often turn in superior performances. Conversely, very healthy people who are not conditioned are unfit for strenuous occupations.

Again, skilled performance usually implies good fitness—and good health—but there are too many exceptions to make the generalization acceptable. The superbly skilled basketball player who has less strength and endurance than his opponents can sometimes handily outscore them. The drama of the sick, wounded, and nearly exhausted star football player who re-enters the game during the dying minutes and scores the winning points is played out regularly. This is not to say that the highly skilled player would not do better if he were more healthy and more fit; it is only to indicate that skill is a separate attribute.

#### THE MODERN NEED FOR EXERCISE

The  
sedentary  
person  
and  
exercise

It is easy to accept the fact that physical conditioning is necessary to achieve and maintain high levels of physical performance. The need for physical fitness among competitive athletes is clear. There is no question that explorers, soldiers, and firemen need to exercise regularly to be physically prepared for emergencies. Why a sedentary person in industrialized society needs exercise may not be so clear. What does physical fitness mean to the man or woman who needs only to push a button?

One who chooses ease and comfort and enjoys the soft life would be content to leave exercise to the athlete whom he watches on television or the fireman whom he can call in case of need. To some extent he can sit back, but if his exercise intensity falls below a certain level he will begin to suffer.

Each individual probably has a minimum level of physical activity below which serious deterioration occurs. The human body, like any living organism, must be used or it will lose its structure and function. The loss of structure and function that occurs when a broken arm is immobilized in a plaster cast clearly demonstrates the atrophy of disuse.

Fortunately for the person who is not predisposed to exert himself if he does not have to, only a small amount of exercise is necessary to preserve low-level, but normal, structure and function. This significant observation was made during studies to determine how much exercise man in space might need to counteract the state of weightlessness.

**Bodily effect of physical inactivity.** It appears that man in affluent cultures has progressed so rapidly from a hard, primitive life to a soft, modern one that he has retained the same energy mechanisms that enabled him to consume vast quantities of food and burn it all up in a day of vigorous physical activity. He has retained his potential capacity for hard physical work. All he needs to restore the potential capacity to actual capacity after long periods of physical idleness is a month or two of daily physical training. When his near-maximum physical ca-

pability is achieved, he can maintain it by exercising hard on alternate days. After he stops training, his physical capabilities drop to the pretraining level in a month or two. Thus, fitness for hard physical work can be seen to be a temporary condition. It can be gained and lost at will.

Coupled with a changing capability for work with increasing and decreasing exercise are changing utilization of energy and an accompanying change in requirement for food. The problem is that, as physical activity is decreased, there is no concomitant decrease in appetite. In fact, the opposite occurs; physical inactivity leads to increased food intake. Cattle raisers know this and pen their stock. The result of the inactivity and increased appetite can be predicted; a rapid gain in body fat and a softening of muscle tissue.

Although it seems an enviable situation when millions of people are supplied with an overabundance of food and at the same time have no hard physical work to do, for the majority the situation is disastrous because overfeeding and underexercise lead to death-dealing obesity and degenerative diseases of the heart and blood vessels.

**Effect of exercise on obesity.** Exercise requires energy, and energy is derived from foodstuffs stored in the body as fats, proteins, and carbohydrates. The nutritional unit of energy is the calorie, defined as the amount of heat required to raise the temperature of one kilogram of water 1° C. Exercise draws on the food reserves of the body for its energy requirements. If foodstuffs are not replaced in equal amount (*i.e.*, if one calorie is not supplied for every calorie consumed), the body becomes thinner. Fats, especially, are reduced, as these represent long-term stores of energy provided for just this kind of prolonged food shortage.

At the outset of physical training after a long period of idleness, the body becomes thinner and harder, but, because of increased muscle mass, there may be no loss of body weight. Muscle tissue is heavier than fat tissue, and muscles are enlarged when they are used repeatedly under moderately heavy loads.

After a few months of training, muscle enlargement tapers off, and the balance between food intake and energy output of physical activity is accurately revealed by changes in body weight. If food intake exceeds energy output, fat is stored and weight increases. A slight deficit in food intake results in fat and weight loss. It may seem easier to combat obesity by slight starvation rather than by forced exercise because of the large amount of exercise needed to consume an ounce of fat—about one mile of walking, jogging, or running (the speed makes little difference in the energy cost of traversing a mile in distance); weight control by diet alone, however, requires such severe restriction of food intake that it is difficult to obtain the required nutrients—proteins, vitamins, and minerals—and the sparse intake does not satisfy hunger. This is why reducing diets often fail.

With added exercise, one does not need to reduce food intake in order to lose fat, lose weight, and become thinner. Moreover, since exercise, especially before mealtime, lessens the appetite, it is easier to attain a lean body by a combination of increased physical activity and diet restriction.

**Physiological responses to exercise.** As was mentioned above, the cost of completing a mile, whether walking, jogging, or running, is about the same as far as energy is concerned. This says nothing, however, about the severity of exercise; the stress effect of exercise on the heart, lungs, and other structures of the body.

**Light exercise.** Walking is light exercise. It can be continued for hours. As is indicated in Table 1, the heart rate seldom exceeds 110 beats per minute and the rate of breathing is usually less than 17 per minute. The chemical changes brought about by muscular contractions proceed apace, and the blood constituents are undisturbed. Other light physical activities include bowling, archery, baseball, woodworking, auto repair, and housekeeping. Other exercise equivalents are shown in Table 2.

**Moderate exercise.** Jogging—easy running on level surfaces—is moderate exercise. A few minutes of con-

Diet and  
exercise

Table 1: Physiological Responses to Exercise*							
intensity of exercise	heart rate beat /min)	blood pressure (mm Hg)		respiration (breaths/min)	ventilation volume (litres/min)	oxygen consumption (litres/min)	energy input (calories/hr)
		systolic	diastolic				
Maximum	200	200	85	50	120	5.0	1,440
Very heavy	150	180	80	30	70	3.5	1,008
Heavy	140	170	79	25	60	3.0	864
Fairly heavy	130	160	78	20	50	2.5	720
Moderate	120	150	77	18	40	2.0	576
Light	110	140	76	16	30	1.5	432
Very light	100	130	75	14	20	1.0	288
Resting	70	120	72	10	10	0.33	100
*These data are typical of college men and are variable according to age, body composition, physical condition, and environment.							

Table 2: Exercise Equivalents to Other Activities*						
intensity of exercise	equivalents					
	work output (calories /hr)	walk, jog, run (miles/hr)	climbing grades (%)	cycling (miles/hr)	sports	occupations
Maximum	300	13.0	12	20	running	digging
Very heavy	200	6.0	6	14	mountain- eering	chopping wood
Heavy	170	5.5	5	12	tennis	pick and shovel
Fairly heavy	140	5.0	4	10	volleyball	gardening
Moderate	110	4.5	3	9	golf	house painting
Light	80	4.0	2	8	table tennis	housekeeping
Very light	50	3.5	Level	7	bowling	shopping
*These values are representative only and subject to the variables mentioned in Table 1.						

tinuous jogging is tiring unless the performer is well conditioned. During moderate exercise the heart rate is around 120 beats per minute and breathing rate is about 18 per minute. Blood changes are slight or nonexistent. Equivalent activities include golf (carrying clubs and walking 18 holes), basketball, football, downhill skiing, skating, and canoeing. (Some of these, such as basketball and football, include bursts of strenuous exercise.)

*Strenuous exercise.* Running at near-maximum speeds is strenuous exercise. It can be endured only for a few seconds. Heart rate exceeds 130 per minute; respirations are faster than 20 per minute. The chemical residues of muscle activity accumulate as acids in the blood. Within five minutes the nonathlete is exhausted. Similar strenuous activities are wrestling, fast rowing, speed swimming, sprint skating, gymnastics, and shovelling snow fast.

*Static exercise.* Gymnastics, weight lifting, and other strenuous activities involving static endurance (*i.e.*, holding a stressful position, as when one links the fingers of the two hands and pulls outward) are in a separate category, since their fatigue is confined to the involved musculature. Nevertheless, when such static exercise is continued beyond one minute, the heart, lungs, and chemical processes are severely stressed.

**Effects of physical conditioning.** *Muscular development.* A bout of exercise leaves on almost every organ and system of the body an imprint that persists for several days. This is manifested by improvements shown in subsequent performances and by increased efficiency—need for less effort to produce the same work. The body quickly becomes “conditioned” to new physical work, mainly by improved skill, and by fewer wasted motions and less tenseness during the effort. There are other effects more important to general fitness.

The most obvious change in the body due to physical training is an increase in the strength, size, and hardness of the muscles used in exercise. Increase in muscular strength is derived in part from the increase in muscle mass—a bigger engine—but in greater part from the better organization of nerve impulses that reach the working muscles at a faster rate and draw them into a stronger contraction. There are nervous systems that inhibit the degree of contraction, probably as safety mechanisms. With training, inhibitions are lessened, allowing the mus-

cles to contract more nearly to their capacity. Weak muscles can be doubled in strength in two months or less by near-maximal loading every other day. It is not the number of times muscles are contracted but the degree of tension under which they are placed that dictates the strengthening effect of training. One strong contraction has far more effect toward development of strength than a thousand weak ones.

Increase in muscle size is, for some unknown reason, due to moderately heavy contractions repeated 15 to 20 times in a pumping motion. Single repetitions of near-maximal effort will increase the strength, but not the size of muscle. This fact is important to persons whose activities require speed and agility and to whom bulky, heavy muscle would be a disadvantage.

In situations in which mass is desired, as in shot putting or for the person who desires bulging muscles for vanity, the pumping form of weight training is effective.

Increased hardness of muscle is due to the greater degree of contraction that can be achieved by bringing more muscle fibres into action. In the relaxed state, the trained muscle is firm but supple, possibly because of its increased ratio of muscle fibres to fat.

*Effects on circulatory and respiratory systems.* The response of heart muscle to exercise training is similar to that of skeletal muscle. After such training the heart can contract more strongly and in a better coordinated way so as to wring out more blood with each contraction. In endurance training, the heart musculature becomes larger, adding to the potential power of each stroke. The heart rate becomes slower at rest; intensive endurance training can slow the resting rate ten beats per minute.

The heart muscles’ private blood supply, the coronary circulation, increases as the result of exercise training. This increase in coronary vessels increases the endurance of the heart and may aid in surviving a heart attack.

In exercise training, new blood vessels appear in all active tissue, aiding in the delivery of supplies and the removal of waste. There is practically no increase in the volume of blood to fill these new vessels, but an improved control of pressures provides for a better diversion of blood to active muscles and away from tissues such as the kidneys, which tend to shut down during heavy exercise. Marathon runners who empty their blad-

Increase in muscular strength

Benefit to coronary circulation

ders before the race have no need to urinate during the two and one-half hour run.

The lungs are little affected by exercise since their capacity to ventilate air is not taxed even during maximum effort. The muscles of breathing, the diaphragm and the rib musculature, however, are worked hard during strenuous exercise, and their fatigue can limit work.

The familiar "stitch-in-the-side" during continuous exercise is probably due to muscle cramp in a portion of the diaphragm. A phenomenon known as "second wind" appears when the respiratory system and other systems of the body adjust to the intensity of the effort.

Overanticipation of exercise

*Effects on the nervous system.* It is the nervous system that is most affected by exercise training. In those untrained in exercise mere anticipation of exercise triggers an overwhelming response. As one becomes accustomed to exercise, however, the body seems to have the ability to size up the exact amount of effort the exercise would require and then to adjust all systems of the body to a proper setting to accommodate it.

The nervous control of body systems from the perception of the task to the setting of the levels of response improves in accuracy with training. The improvement is due to a shift from volitional control, with all the imaginative inputs, to more of an involuntary control by conditioned reflexes. Overactive mental processes in the voluntary control of movement cause "paralysis by analysis." It is not until a task can be performed almost unconsciously that it can be accomplished with the greatest skill. This accounts for the apparent ease and casualness with which champions achieve record performances.

Learning new skills

Learning a new skill is accomplished most quickly and perfection is achieved most rapidly if the skill is practiced in the manner that most closely approximates the final performance. "Walking through" a movement is a good way to be introduced to a new skill, such as a dance step. As soon as possible, the tempo should be advanced to the proper rate. Every element—tempo, stride, force—should match in practice that of the hoped-for performance. This is because training is specific to the point that slow running does not improve sprinting; badminton play does not enhance tennis ability. Each pattern of movement has its own characteristic postures, interplays between opposing muscles, and sequences in which motion is started, stopped, speeded, and slowed. Through training these patterns are imprinted in the nervous system and are "replayed" automatically on signal, as when the music begins or the starting pistol is fired.

#### DEVELOPMENT OF MOVEMENT BEHAVIOUR

*The baby.* Habits of exercise probably start before birth. Later, this inherent behaviour is modified by the environment as the baby is encouraged either to move or to be still. The size of the baby's bed and playpen, and the kinetic nature of his toys influence his use of space.

*The child.* The child's movement behaviour is further modified by either rough-and-tumble or hands-off attitudes of parents and playmates. Constraint of physical activity may create emotional problems such as anxiety and fear of exploration.

*Characteristic styles of movement.* In preschool years the child develops characteristic styles of movement that tend to persist—characteristic ways of running, jumping, and climbing, for example.

When the child tries on a pair of roller skates for the first time, he does not learn the motions from scratch. He builds the new skills upon his old ones, starting with walking motions and converting them into gliding ones. Sometimes old habits of movement interfere with the acquisition of a skill and must be inhibited. The old habits may be modified, but they are never entirely broken. Early success in a new skill is achieved by permitting old habits of movement to be employed in the new pattern.

In teaching a new skill, such as striking a ball, one does not start with a model of a perfect stroke and expect every pupil to conform exactly to that model. Instead, the starting point is with each pupil's own way of stroking; one then gradually improves his technique.

Eye movement and hand movement patterns developed

in active play are utilized when the child begins to read and write. A sense of direction, for example, comes from thinking about pushing a toy car from left to right along a "road." Stacking blocks and hammering pegs orient the child's cognitive and muscles sense to up and down, and top and bottom—all important in forming letters. Some reading and writing difficulties are corrected by constructive play in which such pattern clues are used.

A school program of physical education usually commences in the early grades with activities included to develop social behaviour, the ability to identify one's self as a functional member of a group, to discover one's own strengths and weaknesses, and to adjust behaviour accordingly. The child explores the whole spectrum of movement and learns what it means to lie perfectly still, to huddle, to stretch, to tense, to relax and let go, and to leap.

*The youth.* The youth in school is introduced to competitive sport and to the testing of his physical fitness. He learns the rules and the techniques of many sports and experiences the culture of each. He selects a team or a club and joins in its etiquette and its spirit.

*The adult.* After school years the adult is usually left to his own devices for exercise. The interests that he has developed in school may persist, and this is fortunate if the interests are sports such as golf or tennis, for places to play and partners are easily found.

Sports available to the adult

It is the player of varsity basketball, football, or other team sports who has difficulty when he graduates. Non-strenuous team sports such as cricket can be played by older adults, but the more strenuous team sports are potentially dangerous for men in middle age.

Most people who remain active in sports throughout life reach an age when a less demanding type of sport is substituted for their previous activity. The handballer, for example, turns to bowling or golf as his vision declines and his reflexes slow.

#### EXERCISE NEEDS

*Heart health regimen.* Modern sedentary man past 30 begins to think of fitness for his survival as he sees his companions in their 40s die of heart attacks. This usually calls for exercise of a different nature from sport, unless he is a runner, an oarsman, a swimmer, or a cyclist and is continuing that activity.

It is estimated that maintenance of a physically active status decreases the chance of coronary heart disease by about a third. Exercise also aids in eliminating other conditions such as obesity and high blood pressure that are among the causes of heart disease.

In order to confer these benefits, exercise should require the expenditure of at least 300 Calories per day and should increase the heart rate above 120 beats per minute for at least three continuous minutes. Such exercise benefits metabolic and cardiovascular functions.

Exercises that require the expenditure of 300 Calories include walking, jogging, or running four miles; playing 18 holes of golf (walking); or an hour of bowling, canoeing, or ballroom dancing. The four miles need not be walked all at once; some busy housewives walk a total of six miles in an ordinary day.

None of the Calorie-burning activities mentioned except jogging, running, and possibly canoeing is vigorous enough to elevate the heart rate above 120 beats per minute. Hence the preventive program must include either these or other heart stimulators such as stair climbing—at least three floors, or 50 steps. To be sure the heart rate exceeds 120 beats per minute, the pulse can be counted. A six-second counting technique is easy; by simply adding a zero to the six-second total, the pulse for 60 seconds is obtained. Example: 12 beats in six seconds is a 120 heart rate.

The man who has been idle for years does not benefit from a "crash" attempt to make up for lost years of exercise by an exhaustive regimen. This can do more harm than good. After a long layoff, before exercise is undertaken a medical examination that includes an evaluation of response to exercise is prudent. According to specialists in sports medicine, it is more important for a person

Preliminaries to a program of exercise

to seek medical advice before deciding to become inactive; the risks to health are greater than deciding to step up the level of exercise.

Unless exercise is contraindicated, a reconditioning regimen that commences at an easy level (walking) for brief periods (five minutes) will produce cardiovascular, neuromuscular, and metabolic benefits at any age and for persons in the poorest starting physical condition. In severely deconditioned individuals, the exercise heart rate during the first month of training should not exceed 100 per minute. During the month, the duration of daily exercise can be extended from five to ten minutes.

The second month, the exercise heart rate can be advanced to 110 per minute if no discomfort appears. Unusual responses such as pains of any kind call for medical review before exercise is resumed. Again, the duration of the exercise at the elevated heart rate progresses during the month from five to ten minutes. The third month, the exercise heart rate and duration are advanced as before, this time to a heart rate of 120. On days when the exercise does not feel comfortable, it should be stopped and the same program repeated the following day. It is not absolutely necessary to exercise every day, especially on days when ordinary life activities are moderately vigorous.

Exercise benefits do not persist more than a month following cessation of training. The beneficial effects of exercise, like those of food, cannot be stored but must be renewed almost daily.

As age advances, the capacity for strenuous exercise decreases. Maximum heart rate declines with age; an estimate for an adult can be calculated by subtracting his age in years from 220. Example: at age 48 the maximum heart rate is approximately 220 minus 48, or 172.

A safe level of unsupervised exercise in a healthy adult is about 20 beats per minute less than the maximum heart rate. The man aged 48, for example, has an estimated safe limit for unsupervised exercise of 152—172 less 20. Thus it can be seen that for this 48-year-old man the exercise heart rate should be not less than 120 per minute to constitute an effective training stimulus, and not more than 152 to remain within safe limits.

**Fat reduction.** Protection of the heart is the adult's main goal of exercise, but there are three other goals. The second, already mentioned, is the role 300 Calories' worth of exercise plays in the prevention of obesity. Three hundred Calories per day is approximately the expenditure level that allows a nutritious food intake without storage of fat.

**Muscle strengthening.** The third adult exercise need is for a loading of muscles above 50 percent of their maximum strength. Such muscle loading can be brief; as little as five seconds just once a day. Lifting an active child or carrying a heavy sack of groceries will prevent loss of muscle tissue and strength.

**Circulatory adjustment.** The fourth need is to stand up for a total of at least two hours every day. This meets a twofold objective, to maintain bone structure and to preserve orthostatic tone—the adjustment of blood pressure to postural changes that prevents fainting on sudden standing after reclining.

**Avoidance of exercise injuries.** Injuries that occur during physical activities are usually the result of forces from outside the body. It is doubtful that a muscle can tear itself by the force of its own contraction. When momentum or resistance is applied suddenly, however, the external force may be added to the internal force of contraction and cause damage. In running it is the swing of the leg against partially contracted hamstring muscles that causes the "pulled" muscle.

Most exercise injuries involve connective tissue. Muscle "pulls" usually include injury of the sheets of connective tissue, the fascial tissues, that enclose the muscles. Sore heels and "shin splints" are due to traumatic inflammation of the periosteum, the membrane that encloses each bone. Foot and knee pains are frequently ligamentous in origin. Many of the above listed problems can easily be avoided by progressing gradually from extremely light to heavy training and by using footwear or ground surfaces

that absorb the shock of foot strike in jogging or running.

Although the heart muscle is no exception to the rule that a muscle cannot damage itself by exercise, vascular, metabolic, or other disease, if present, may be exacerbated by heavy activity. On the other hand, controlled exercise plays an important role in recovery following coronary heart disease, commencing with extremely light movement after healing of the injured tissue is complete. Through programs of exercise, postcoronary patients may regain full working capacity.

Enlargement of the heart muscle occurs as the result of prolonged periods of continuous heavy exercise. This normal hypertrophy characterizes "athlete's heart" and is a healthy enlargement of the heart muscle resulting from the increased work of the heart to meet the circulatory demands of heavy exercise.

**Exhaustion.** Exhaustion after many minutes of heavy exercise can be caused by excessive heat storage, "hyperthermia," leading to heat stroke.

When one is near exhaustion, hallucination may occur, leading to aberrant behaviour. Endurance athletes performing at high altitude or in hot weather frequently perceive sights and sounds that are not actually present.

The combined effects of extremely hot or cold baths and fatigue from exercise are potentially dangerous. After exercise the water temperature should be luke warm, 5° (F) or less above body temperature.

The phenomenon of "staleness" or overtraining in athletes is only imperfectly understood. The symptoms are lassitude and poor performance, the latter possibly due to a lessening of the training intensity. There are circulatory and respiratory overreactions to exercise, as in the untrained. A period of rest, a change of activity, or a win following a losing streak often acts to reverse the condition, suggesting that psychosomatic factors may be operating.

**Assessment of exercise adequacy.** If an adult is moderately active during the day, all of the needs for exercise may be met without the addition of formal exercise. Walking to work, or to shopping, doing manual chores while standing, and hurrying up a hill or up stairs while carrying a fairly heavy load once a day will meet all of an adult's needs for exercise.

There are two ways to see if exercise or other physical activity is adequate. One is by making a daily check of all four exercise needs. The other is to assess physical status along the following guidelines: ability to endure a busier than usual day without fatigue; ability to walk briskly for ten continuous minutes without discomfort; ability to climb three continuous flights of stairs without running out of breath; ability to lift and carry fairly heavy loads without strain; when the abdomen is held taut, the belly feels muscular, not fat; ability to get out of bed quickly without feeling dizzy or faint; bones are not easily broken; participation in an active hobby not less than twice a week; the daily activity level can be classified above the sedentary level, with some physical activity at least ten minutes of every hour all day, or with continuous, intensive exercise an average of not less than five minutes per day. If all of these conditions are met, the individual can be said to be well exercised and in good physical condition.

## Existentialism

The various philosophies (dating from about 1930) that have been referred to by the term Existentialism have in common an interpretation of human existence in the world that stresses its concreteness and its problematic character.

### NATURE OF EXISTENTIALIST THOUGHT AND MANNER

According to Existentialism: (1) Existence is always particular and individual—always *my* existence, *your* existence, *his* existence. (2) Existence is primarily the problem of existence (*i.e.*, of its mode of being); it is, therefore, also the investigation of the meaning of Being. (3) This investigation is continually faced with diverse possibilities, from among which the existent (*i.e.*, man) must make a selection, to which he must then commit himself. (4) Because these possibilities are constituted by man's relationships with things and with other men, existence is always a being-in-the-world—*i.e.*, in a concrete and historically determinate situation that limits or conditions choice. Man is therefore called *Dasein* ("there being") because he is defined by the fact that he exists, or is in the world and inhabits it.

Contrasts  
and  
directions  
of thought

With respect to the first point, that existence is particular, Existentialism is opposed to any doctrine that views man as the manifestation of an absolute or of an infinite substance. It is thus opposed to most forms of Idealism, such as those that stress Consciousness, Spirit, Reason, Idea, or Oversoul. Secondly, it is opposed to any doctrine that sees in man some given and complete reality that must be resolved into its elements in order to be known or contemplated. It is thus opposed to any form of objectivism or scientism since these stress the crass reality of external fact. Thirdly, Existentialism is opposed to any form of necessitarianism; for existence is constituted by possibilities from among which man may choose and through which he can project himself. And, finally, with respect to the fourth point, Existentialism is opposed to any solipsism (holding that I alone exist) or any epistemological Idealism (holding that the objects of knowledge are mental), because existence, which is the relationship with other beings, always extends beyond itself, toward the being of these entities; it is, so to speak, transcendence.

Starting from these bases, Existentialism can take diverse and contrasting directions. It can insist on the transcendence of Being with respect to existence, and, by holding this transcendence to be the origin or foundation of existence, it can thus assume a theistic form. On the other hand, it can hold that human existence, posing itself as a problem, projects itself with absolute freedom, creating itself by itself, thus assuming to itself the function of God. As such, Existentialism presents itself as a radical atheism. Or it may insist on the finitude of human existence—*i.e.*, on the limits inherent in its possibilities of projection and choice. As such, Existentialism presents itself as a humanism.

Diversity  
of interests  
and  
sources

From 1940 on, with the diffusion of Existentialism through continental Europe, its directions have developed in terms of the diversity of the interests to which they are subject: the religious interest, the metaphysical (or nature of Being) interest, the moral and political interest. This diversity of interests is rooted, at least in part, in the diversity of sources on which Existentialism has drawn. One such source has been the subjectivism of the 4th–5th-century theologian, St. Augustine, who exhorted man not to go outside himself in the quest for truth, for it is within him that truth abides. "If you find that you are by nature mutable," he wrote, "transcend yourself." Another source has been the Dionysian Romanticism of Nietzsche, who exalted life in its most irrational and cruel features and made this exaltation the proper task of the "higher man," who exists beyond good and evil. Still another source has been the nihilism of Dostoyevsky, who, in his novels, presented man as continually defeated as a result of his choices and as continually placed by them before the insoluble enigma of himself. As a consequence of the diversity of these

sources, Existentialist doctrines have focussed on several aspects of existence.

They have focussed, first, on the problematic character of the human situation, through which man is continually confronted with diverse possibilities or alternatives, among which he may choose and on the basis of which he can project his life.

Second, the doctrines have focussed on the phenomena of this situation and especially on those that are negative or baffling, such as the concern or preoccupation that dominates man because of the dependence of all his possibilities upon his relationships with things and with other men; the dread of death or of the failure of his projects; the "shipwreck" upon insurmountable "limit situations" (death, the struggle and suffering inherent in every form of life, the situation in which everyone daily finds himself); the guilt inherent in the limitation of choices and in the responsibilities that derive from making them; the boredom from the repetition of situations; the absurdity of man's dangling between the infinity of his aspirations and the finitude of his possibilities.

Third, the doctrines have focussed on the intersubjectivity that is inherent in existence and is understood either as a personal relationship between two individuals, I and thou, such that the thou may be another man or God, or as an impersonal relationship between the anonymous mass and the individual self deprived of any authentic communication with others.

Fourth, Existentialism focusses on ontology, on some doctrine of the general meaning of Being, which can be approached in any of a number of ways: through the analysis of the temporal structure of existence; through the etymologies of the most common words—on the supposition that in ordinary language Being itself is disclosed, at least partly (and thus is also hidden); through the rational clarification of existence by which it is possible to catch a glimpse, through ciphers or symbols, of the Being of the world, of the soul, and of God; through existential psychoanalysis that makes conscious the fundamental "project" in which existence consists; or, finally, through the analysis of the fundamental modality to which all the aspects of existence conform—*i.e.*, through the analysis of possibility.

There is, in the fifth place, the therapeutic value of existential analysis that permits, on the one hand, the liberating of human existence from the beguilements or debasements to which it is subject in daily life and, on the other, the directing of human existence toward its authenticity; *i.e.*, toward a relationship that is well-grounded on itself, and with other men, with the world, and with God.

The various forms of Existentialism may also be distinguished on the basis of language, which is an indication of the cultural traditions to which they belong and which often explains the differences in terminology among the various authors. The principal representatives of German Existentialism are Martin Heidegger and Karl Jaspers; those of French personalistic Existentialism are Gabriel Marcel and Jean-Paul Sartre; that of French Phenomenology is Maurice Merleau-Ponty; that of Spanish Existentialism is José Ortega y Gasset; that of Russian Idealistic Existentialism is Nikolay Berdyayev (who, however, lived half of his adult life in France); and that of Italian Existentialism is Nicola Abbagnano. The linguistic differences, however, are not decisive for a determination of philosophical affinities. For example, Marcel and Sartre are farther apart than Heidegger and Sartre; and there is greater affinity between Abbagnano and Merleau-Ponty than between Merleau-Ponty and Marcel.

### HISTORICAL SURVEY OF EXISTENTIALISM

Many of the theses that Existentialists defend or illustrate in their analyses are drawn from the wider philosophical tradition.

**Precursors of Existentialism.** The problem of what man is in himself can be discerned in the Socratic imperative "know thyself," as well as in the work of Montaigne and Pascal, a religious philosopher and mathema-

Approaches  
to the  
general  
meaning  
of Being

Socrates,  
Montaigne,  
and Pascal

tician. Montaigne had said: "If my mind could gain a foothold, I would not write essays, I would make decisions; but it is always in apprenticeship and on trial." And Pascal had insisted on the precarious position of man situated between Being and Nothingness: "We burn with the desire to find solid ground and an ultimate sure foundation whereon to build a tower reaching to the Infinite. But our whole groundwork cracks, and the earth opens to abysses."

The stance of the internal tribunal—of man's withdrawal into his own spiritual interior—which reappears in some Existentialists (in Marcel and Sartre, for example) already belonged, as earlier noted, to St. Augustine. In early-19th-century French philosophy, it was defended by a reformed *Idéologue*, Marie Maine de Biran, who wrote: "Even from infancy I remember that I marvelled at the sense of my existence. I was already led by instinct to look within myself in order to know how it was possible that I could be alive and be myself." From then on, this posture inspired a considerable part of French philosophy.

The theme of the irreducibility of existence to reason, common to many Existentialists, was also defended by a leading German Idealist, F.W.J. von Schelling, as he argued against Hegel in the last phase of his philosophy, and Schelling's polemic, in turn, inspired the scholar usually cited as the father of Existentialism, the religious Dane Søren Kierkegaard.

The requirement to know man in his particularity and, therefore, in terms of a procedure different from those used by science to obtain knowledge of natural objects was confronted by Wilhelm Dilthey, an expounder of historical reason, who viewed "understanding" as the procedure and thus as the proper method of the human sciences. Understanding, according to Dilthey, consists in the reliving and reproducing of the experience of others. Hence it is also a feeling together with others and a sympathetic participation in their emotions. Understanding, therefore, accomplishes a unity between the knowing object and the object known.

**The immediate background and founding fathers.** The theses of Existentialism found a particular relevance during World War II, when Europe found itself threatened alternately by material and spiritual destruction. Under those circumstances of uncertainty, the optimism of Romantic inspiration, by which the destiny of man is infallibly guaranteed by an infinite force (such as Reason, the Absolute, or Mind) and propelled by it toward an ineluctable progress, appeared to be untenable. Existentialism was moved to insist on the instability and the risk of all human reality, to acknowledge that man is "thrown into the world"—i.e., abandoned to a determinism that could render his initiatives impossible—and to hold that his very freedom is conditioned and hampered by limitations that could at any moment render it empty. The negative aspects of existence, such as pain, frustration, sickness, and death—which 19th-century optimism refused to take seriously because they do not touch the infinite principle that these optimists believed to be manifest in man—become for Existentialism the essential features of human reality.

The thinkers who, by virtue of the negative character of their philosophy, constituted the exception to 19th-century Romanticism thus became the acknowledged masters of the Existentialists. Against Hegelian necessitarianism, Kierkegaard interpreted existence in terms of possibility: dread—which dominates existence through and through—is "the sentiment of the possible." It is the feeling of what can happen to a man even when he has made all of his calculations and taken every precaution. Despair, on the other hand, discovers in possibility its only remedy, for "If man remains without possibilities, it is as if he lacked air." Karl Marx, in holding that man is constituted essentially by the "relationships of work and production" that tie him to things and other men, had insisted on the alienating character that these relationships assume in capitalistic society, where private property transforms man from an end to a means, from a person to the instrument of an impersonal process that

subjugates him without regard for his needs and his desires. Nietzsche had viewed the *amor fati* ("love of fate") as the "formula for man's greatness." Freedom consists in desiring what is and what has been and in choosing it and loving it as if nothing better could be desired.

**Emergence as a movement.** Contemporary Existentialism reproduces these ideas and combines them in more or less coherent ways. Human existence is, for all the forms of Existentialism, the projection of the future on the basis of the possibilities that constitute it. For some Existentialists (the Germans Heidegger and Jaspers, for example), the existential possibilities, inasmuch as they are rooted in the past, merely lead every project for the future back to the past, so that only what has already been chosen can be chosen (Nietzsche's *amor fati*). For others (such as Sartre), the possibilities that are offered to existential choice are infinite and equivalent, such that the choice between them is indifferent; and for still others (Abbagnano and Merleau-Ponty), the existential possibilities are limited by the situation, but they neither determine the choice nor render it indifferent. The issue is one of individuating, in every concrete situation and by means of a specific inquiry, the real possibilities offered to man. For all the Existentialists, however, the choice among possibilities—i.e., the projection of existence—implies risks, renunciation, and limitation. Among the risks, the most serious is man's descent into inauthenticity or into alienation, his degradation from a person into a thing. Against this risk, for the theological forms of Existentialism (as in Gabriel Marcel, a Socratic dramatist; Karl Barth, a Swiss Neo-orthodoxist; Rudolf Bultmann, a biblical interpreter), there is the guarantee of the transcendent help from God, which in its turn is guaranteed by faith.

Existentialism, consequently, by insisting on the individuality and nonrepeatability of existence (following Kierkegaard and Nietzsche), is sometimes led to regard one's coexistence with other people (held to be, however, an ineluctable fact of the human situation) as a condemnation or alienation of man. Marcel has said that all that exists in society beyond the individual is "expressible by a minus sign," and Sartre has affirmed in his major work *L'Être et le néant* (1943; Eng. trans., *Being and Nothingness*, 1956) that "the Other is the hidden death of my possibilities." For the other forms of Existentialism, however, a coexistence that is not anonymous (as that of a mob) but is grounded on personal communication conditions man's authentic existence.

Existentialism has had ramifications in various areas of contemporary culture. In literature, Franz Kafka, author of haunting novels, walking in Kierkegaard's footsteps, described human existence as the quest for a stable, secure, and radiant reality that continually eludes it (*Das Schloss* [1926; Eng. trans., *The Castle*, 1930]); or he described it as threatened by a guilty verdict about which it knows neither the reason nor the circumstances but against which it can do nothing—a verdict that ends with death (*Der Prozess* [1925; Eng. trans., *The Trial*, 1937]).

The theses of contemporary Existentialism were then diffused and popularized by the novels and plays of Sartre, by the writings of the French novelists and dramatists Simone de Beauvoir and Albert Camus. In *L'Homme révolté* (1951; Eng. trans., *The Rebel*, 1953), Camus described the "metaphysical rebellion" as "the movement by which a man protests against his condition and against the whole of creation." In art, the analogues of Existentialism may be considered to be Surrealism, Expressionism, and in general those schools that view the work of art not as the reflection of a reality external to man but as the free immediate expression of human reality.

Existentialism made its entrance into psychopathology through Karl Jaspers' *Allgemeine Psychopathologie* (1913; Eng. trans., *General Psychopathology*, 1965), which was inspired by the need to understand (in Dilthey's sense) the world in which the mental patient lives, by means of a sympathetic participation in his experience. Later, Ludwig Binswanger, a Swiss psychiatrist of the *Daseinsanalyse* school, in one of his celebrated works,

Broader cultural ramifications

Kierkegaard,  
Marx, and  
Nietzsche

*Über Ideenflucht* (1933; "On the Flight of Ideas"), inspired by Heidegger's thought, viewed the origin of mental illness as a failure in the existential possibilities that constitute human existence (*Dasein*). From Jaspers and Binswanger, the Existentialist current became diffused and variously stated in contemporary psychiatry.

In theology, Barth's *Römerbrief* (1919; Eng. trans., *The Epistle to the Romans*, 1933) started the "Kierkegaard revival," the emblem of which was expressed by Barth himself; it is "the relation of this God with this man; the relation of this man with this God—this is the only theme of the Bible and of philosophy." Within the bounds of this current, on the one hand, there was an insistence upon the absolute transcendence of God with respect to man, who could place himself in relationship with God only by denying himself and by abandoning himself to a gratuitously granted faith. On the other hand, there was the requirement to demythologize the religious content of faith, particularly of the Christian faith, in order to allow the message of the eschatological event (of salvation) to emerge from among the existential possibilities of man.

#### METHODOLOGICAL ISSUES IN EXISTENTIALISM

The methods that the Existentialists employ in their interpretations have a presupposition in common: the immediacy of the relationship between the interpreter and the interpreted, between the interrogator and the interrogated, between the problem of being and Being itself. The two terms coincide in existence; for the man who poses the question "What is Being?" cannot but pose it to himself and cannot respond without starting from his own being.

This common ground notwithstanding, each Existentialist thinker has defended and worked out his own method for the interpretation of existence. Heidegger, an Existentialist with ontological (nature of Being) concerns, availed himself of the philosophy of Edmund Husserl, founder of Phenomenology, which, as *logos* of the *phainomenon*, employs speech that manifests or discloses what it is that one is speaking about and that is true—in the etymological use of the Greek word *alētheia* (i.e., the sense of uncovering or manifesting what was hidden). The phenomenon is, from Heidegger's point of view, not mere appearance, but the manifestation or disclosure of Being in itself. Phenomenology is thus capable of disclosing the structure of Being and hence is an ontology of which the point of departure is the being of the one who poses the question about Being, namely man.

Jaspers, an authority in psychopathology as well as in the philosophy of human existence, on the other hand, employed the method of the rational clarification of existence; he maintained that existence, as the quest for Being, is man's effort of rational self-understanding, or universalizing, of communicating—a method that presupposes that existence and reason are the two poles of man's being. Reason is possible existence; i.e., existence that, as Jaspers writes in his *Vernunft und Existenz* (1935; Eng. trans., *Reason and Existenz*, 1955), becomes "manifest to itself and as such real, if, with, through and by another existence, it arrives at itself." This activity, however, is never consummated; thus, when the impossibility of its achievement is recognized, it is changed into faith, into the recognition of transcendence as providing the only possibility of its final achievement.

According to Sartre, the foremost philosopher of mid-20th-century France, the method of philosophy is existential psychoanalysis; i.e., the analysis of the "fundamental project" in which man's existence consists. In contrast to Freudian psychoanalysis, which stops short at the irreducibility of the libido, or primitive psychic drive, existential psychoanalysis tries to determine the "original choice" through which man constructs his world and decides in a preliminary way upon particular choices (which, however, may place in crisis the primordial choice itself).

According to Marcel, a Christian Existentialist philosopher and dramatist, the method of philosophy depends upon a recognition of the mystery of Being (*Le Mystère*

*de l'être* [1951; Eng. trans., *The Mystery of Being*, 1950–51]); i.e., on the impossibility of discovering Being through objective or rational analyses or demonstrations. Philosophy should lead man up, however, to the point of making possible for him "the productive illumination of Revelation."

Finally, according to humanistic Existentialism, as represented by Abbagnano, the leading Italian Existentialist, and by Merleau-Ponty, a French Phenomenologist, the method of philosophy consists of the analysis and the determination—by employing all available techniques including those of science—of the structures that constitute existence; i.e., of the relations that connect man with other beings and that figure, therefore, not only in the constitution of man but in the constitution of the other beings as well.

#### SUBSTANTIVE ISSUES IN EXISTENTIALISM

**Fundamental concepts and contrasts.** Both the ontology and manner of human existence are of concern to Existentialism.

*Ontic structure of human existence.* The fundamental characteristic of Existentialist ontology is the primacy that that study of the nature of existence gives to the concept of possibility. This priority dominated the philosophy of Kierkegaard and also was amply utilized by Husserl, who had explicitly affirmed the ontological priority of possibility over reality. Possibility, however, is not understood by the Existentialists in the purely logical sense as absence of contradiction nor in the sense of traditional metaphysics as potentiality destined to become actuality but, rather, in the sense of ontic or objective possibility, which is the very structure of human existence; it is thus the specific modality of man's being.

Another way of expressing this thesis is the affirmation of Heidegger and Sartre that "existence precedes essence," which signifies that man does not have a nature that determines his modes of being and acting but that, rather, these modes are simply possibilities from which he may choose and on the basis of which he can project himself. In this sense, Heidegger has said that "*Dasein* is always its own possibility," and Sartre has written: "It is true that the possible is—so to speak—an option on being, and if it is true that the possible can come into the world only through a being which is its own possibility, this implies for human reality the necessity of being its being in the form of an option on its being."

As possibility, human existence is the anticipation, the expectation, the projection of the future. The future is its fundamental temporal dimension, to which the present and the past are subordinate and secondary; existence is always stretched out toward the future. As possibility, existence is also transcendence, being beyond, because all of its constitutive possibilities organize it beyond itself toward the other beings of the world and toward the world in its totality. To transcend thus means to move toward something that is not one's own existence; i.e., toward things and toward other men, with which man is related in every situation in which he finds himself.

Yet for some Existentialists, the being of these other entities has a modality that differs from the being of man's existence: their existence is not possible being but real or factual being. To existence, Heidegger contrasts the presence of the things in the world—a presence that assumes, as man takes notice of these things for his needs, the aspect of utilizability. But utilizability is not a simple quality of things; it is their very being. Analogously, Sartre distinguishes the for-itself—the mode of being of man's existence that he identifies, following Descartes and Husserl, with consciousness—from the in-itself, the being or reality of things that he identifies with their utilizability. According to Jaspers, over against the existence of the possible (man, *Dasein*) stands the world as the infinite horizon that encompasses within itself each possible existence and, therefore, cannot itself be encompassed by any one of them. This is a world that is a reality of fact, at the origin of which there is a Being that is pure transcendence and that, therefore, never reveals itself.

Mystery of Being and the structures of existence

Phenomenology, clarification, psychoanalysis

Existence  
as the  
nothing-  
ness of  
Being

Similarly, the religious forms of Existentialism insist on transcendence, considering it to be the property of the Being that is beyond the existential possibilities and that can enter among them solely under the form of mystery (Marcel) and of the extratemporal revelation of faith (Barth, Jaspers). Marcel, in this regard, has contrasted Being, which is a mystery, with having, which is the condition of man in the world; that is to say, man has objects before him that are foreign to his subjectivity. He tries to organize them and discover the bond that ties them together so as to control and use them.

In all of these doctrines, there is the dominating theme of the contrast between the modality proper to existence, which is possibility, and the modality proper to Being, which is reality or facticity. As a result of this contrast, existence (as possibility) appears as the nothingness of Being, as the negation of every reality of fact. In a brief but famous essay, *Was ist Metaphysik?* (1929), Heidegger affirmed that "Human existence cannot have a relationship with being unless it remains in the midst of nothingness." Rudolf Carnap, a semanticist and leading Logical Positivist, in an equally famous essay, "Überwindung der Metaphysik durch die logische Analyse der Sprache" (1931; "The Elimination of Metaphysics Through Logical Analysis of Language"), criticized this hypostatization (or making real) of Nothingness as one of the grosser fallacies of metaphysics. In truth, Nothingness is, for the Existentialists, possible existence, as the negation of the reality of fact. Sartre has written: "The possible is the *something* which the For-itself lacks *in order* to be itself"; it is what the subject lacks in order to be an object; thus it does not exist except as a lacking.

This is also true of value, which is such insofar as it does not exist. For even when value occurs or is perceived in certain acts, it lies beyond them and constitutes the limit or the goal toward which they aim. Analogously, knowledge, in which the object (the in-itself) presents itself to consciousness (the for-itself), is a relationship of nullification, because the object cannot be offered to consciousness except as that which is not consciousness. Furthermore, another existence is such insofar as it is not mine; thus this negation is "the constitutive structure of the being-of-others."

But this reduction of existence to Nothingness can lead in two directions: it can lead to insisting on the lack of meaning—*i.e.*, on the absurdity of existence and of every possible project—as it does in Sartre, in Camus, and in atheistic Existentialism; or it can lead toward the quest for a more direct relationship of existence with Being, beyond the constitutive possibilities of existence, so that Being reveals itself, at least partly, in existence—through language or through faith or through some mystical form of religiousness, as happens in the later phase of Heidegger's thought, in Jaspers, and in all of the forms of theological Existentialism.

*Manner and style of human existence.* Existentialism is never a solipsism in the proper sense of the term (that I alone exist), because every existential possibility relates man to things and to other men. Sometimes it is presented as humanism in the sense that it places human destiny in the hands of men themselves. But this version is rejected by all of the currents of the movement that, starting with Heidegger, insist on the priority and the initiative of Being with regard to human existence. The opposition between these two points of view depends on how the different Existentialists solve the problem of freedom.

Man always finds himself in a situation in which his constitutive possibilities are rooted. For Heidegger and Jaspers, this situation determines the choice that he makes among these possibilities; for Sartre, conversely, the situation is determined by the choice. Existentialism fluctuates in this way between the concept of a destiny in which, like Nietzsche's *amor fati*, man accepts what has already been chosen and the concept of a radical freedom whereby the choices are offered to man in an absolute indifference. From the first point of view, every project of life falls back on or is reduced to the situation from which it starts; thus the possibility of being, of acting, of

willing, of choosing is really, as Jaspers points out in his *Philosophie* (1932), the impossibility of being, acting, willing, and choosing in a manner different from the way things are; *i.e.*, from the factual conditions of the situation. From the second point of view, the fundamental project, which is the primordial choice, has no conditions; as Sartre says: "Since I am free, I project my total possible, but I thereby posit that I am free and that I can always nihilate this first project and make it past." From the first, or deterministic, point of view, the past determines the future and assimilates it to itself; from the second, or libertarian, point of view, the meaning of the past depends upon the present project. In the latter instance, freedom is a kind of damnation: as Sartre affirms: "We said that freedom is not free not to be free and that it is not free not to exist."

A choice, however, is offered to man even from the destinarian point of view: that between understanding and not understanding one's own nothingness. According to Heidegger, a man achieves what he calls "authentic existence" when he understands the impossibility of all of the possibilities of existence—the impossibility of which the sign or term is death. Jaspers affirms, in his turn, that the only choice offered to man is that between accepting or rejecting the situation with which he is identified. The rejection of it, however, is a betrayal that plunges him back into the situation itself.

Existentialist ontology thus fluctuates between Being and Nothingness and concludes by regarding Nothingness as the only possible revelation of Being. In the atheistic version, it is man, as Sartre affirms, who "strives to be God" and consumes himself vainly in the effort. In the cosmological or theological version, it is Being that intervenes, in a way that is more or less mysterious or hidden, to redeem man from Nothingness.

**Problems of Existentialist philosophy.** The key problems for Existentialism are those of man himself, of his situation in the world, and of his more ultimate significance.

*Man and human relationships.* Existentialist anthropology is strictly connected with its ontology. The traditional distinction between soul and body is completely eliminated; thus the body is a lived-through experience that is an integral part of man's existence in its relationship with the world. According to Sartre, "In each project of the For-itself, in each perception the body is there; it is the immediate Past in so far as it still touches on the Present which flees it." As such, however, the body is not reduced to a datum of consciousness, to subjective representation. Consciousness, according to Sartre, is constant openness toward the world, a transcendent relationship with other beings and thereby with the in-itself. Consciousness is existence itself, or, as Jaspers says, it is "the manifestation of being." In order to avoid any subjectivistic equivocation, Heidegger went so far as to renounce the use of the term consciousness, preferring the term *Dasein*, which is more appropriate for designating human reality in its totality. For the same reasons, the traditional opposition between subject and object, or between the self and the nonself, loses all sense. *Dasein* is always particular and individual. It is always a self; but it is also always a project of the world that includes the self, determining or conditioning its modes of being.

All of these modes of being thus arise, as Heidegger shows in his masterpiece *Sein und Zeit* (1927; *Being and Time*, 1962), from the relationship between the self and the world. Heidegger has regarded concern (in the Latin sense of the term) to be the fundamental aspect of this relationship, insofar as it is man's concern to obtain the things that are necessary for him and even to transform them with his work as well as to exchange them so as to make them more suitable to his needs. Concern demonstrates that man is "thrown into the world," into the midst of other beings, so that in order to project himself he must exist among them and utilize them. Being thrown means, for man, being abandoned to the whirling flow of things in the world and to their determinism.

This happens inevitably, according to Heidegger, in inauthentic existence—day-to-day and anonymous exist-

Self, body,  
and relation-  
ship

world

Destiny  
versus  
freedom  
of choice

Difficulty  
of inter-  
subjective  
communi-  
cation

tence in which all behaviour is reduced to the same level, made "official," conventional, and insignificant. Chatter, idle curiosity, and equivocation are the characteristics of this existence, in which "One says this" and "One does that" reign undisputed. Anonymous existence amounts to a simple "being together" with others, not a true coexistence, which is obtained only through the acceptance of a common destiny (see below).

All of the Existentialists are in agreement on the difficulty of communication; *i.e.*, of well-grounded intersubjective relationships. Jaspers has perhaps been the one to insist most on the relationship between truth and communication. Truths are and can be different from existence. But if fanaticism and dogmatism (which absolutize an historical truth) are avoided on the one hand while relativism and skepticism (which affirm the equivalence of all truths) are avoided on the other, then the only other way is a constant confrontation between the different truths through an always more extended and deepened intersubjective communication.

Sartre, however, denies that there is authentic communication. According to him, consciousness is not only the nullification of things but also the nullification of the other person as other. To look at another person is to make of him a thing. This is the profound meaning of the myth of Medusa. Sexuality itself, which Sartre holds to be an essential aspect of existence, fluctuates between sadism and masochism, in which either the other person or oneself is merely a thing. On this basis, the intersubjective relationship is obviously impossible.

*The human situation in the world.* Heidegger has pointed to the foundation of the intersubjective relationship in dread. When a man decides to escape from the banality of anonymous existence—which hides the nothingness of existence, or the nonreality of its possibilities, behind the mask of daily concerns—his understanding of this nothingness leads him to choose the only unconditional and insurmountable possibility that belongs to him: death. The possibility of death, unlike the possibilities that relate him to other things and to other men, isolates him. It is a certain possibility, not through its apodictic evidence but because it continuously weighs upon existence. To understand this possibility means to decide for it, to acknowledge "the possibility of the impossibility of any existence at all" and to live for death. The emotive tonality that accompanies this understanding is dread, through which man feels himself to be "*face to face* with the 'nothing' of the possible impossibility of [his] existence."

But neither the understanding of death nor its emotive accompaniment opens up a specific task for man, a way to transform his own situation in the world. They enable him only to perceive the common destiny to which all men are subject; and they offer to him, therefore, the possibility of remaining faithful to this destiny and of freely accepting the necessity that all men share in common. In this fidelity consists the historicity of existence, which is the repetition of tradition, the return to the possibilities from which existence had earlier been constituted, the wanting for the future what has been in the past. And in this historicity participate not only man but all of the things of the world, in their utilizability and instrumentality, and even the totality of Nature as the locus of history.

Dread, therefore, is not fear in the face of a specific danger. It is rather the emotive understanding of the nullity of the possible, or, as Jaspers says, of the possibility of Nothingness. It has, therefore, a therapeutic function in that it leads human existence to its authenticity. From the fall into factuality into which every project plunges him, man can save himself only by projecting not to project; *i.e.*, either by abandoning himself decisively to the situation in which he finds himself or by being indifferent to any possible project—with regard to which Sartre says, "Thus it amounts to the same thing whether one gets drunk alone or is a leader of nations."

The pivotal point of that conclusion—the conclusion most widely held among the Existentialists and the one in fact often identified with Existentialism—is the antithesis

between possibility and reality. On the one hand, existence is interpreted in terms of possibilities that are not purely logical possibilities or manifestations of a man's ignorance of what exists but are, rather, effective, or ontic, possibilities that constitute man as such; on the other hand, contrasted to possibilities in this sense is a reality, a for-itself, a world, a transcendence that is a factual presence, insurmountable and oppressive, with respect to which possibility is a pure Nothingness. The contradiction to which this antithesis leads becomes clear when the same reality is interpreted in terms of possibility: when the being of things, for example, is reduced to their possibility of being utilized; when the being of other men is reduced to the possibility of anonymous or personal relationships that the individual can have with them; and when the being of transcendence, or of God, is reduced to the possibility of the relationship, although ineffable and mysterious, between transcendence, or God, and man.

It has been said that a coherent Existentialism should avoid the constant mortal leap between Being and Nothingness; should not confuse the problematic character of existence with the fall into factuality; should not confuse the finitude of possibilities with resignation to the situation, choice with determinism; freedom conditioned by the limits of the situation with the acknowledgment of the omnipresent necessity of the Whole. In this inquiry, it is held, Existentialism could well benefit from a more attentive consideration of science, which it has viewed until now only as a preparatory, imperfect, and objectifying knowledge in comparison with the authentic understanding of Being, which it considers to be a more fundamental mode of the being of man in the world. Science, it is submitted, offers today the example of an extensive and coherent use of the concept of the possible in the key notions that it employs, especially in those branches that are interdisciplinary—among them such notions as indeterminacy, chance, probability, field, model, project, structure, and conditionality.

Some steps in this direction have been taken by Abagnano and by Merleau-Ponty. According to the latter, considerations of probability are rooted in the being of man, inasmuch as he is situated in the world and invested with the ambiguity of his events. Merleau-Ponty has written in his *Phénoménologie de la perception* (1945):

Our freedom does not destroy our situation, but is engaged with it. The situation in which we live is open. This implies both that it appeals to modes of privileged resolution and that it is of itself powerless to obtain one of them.

From this point of view, there is always a certain freedom in situations, although its degree varies from situation to situation.

*Significance of Being and transcendence.* Among the thinkers most frequently mentioned here, the concept of the necessity of Being prevails as the basis of their metaphysical or theological orientations. Heidegger has come more and more to insist on the massive presence of Being in the face of human existence, by attributing to Being all initiative and to man only the possibility of abandoning himself to Being and to the things that are the modes of the language of Being. For Heidegger, Being is interpreted better through the etymology of those words that designate the most common things of daily life than through the analysis of existential possibilities. Jaspers has seen the revelation of transcendence in ciphers—*i.e.*, in persons, doctrines, or poems—all of which can be interpreted as symbols of existential situations and above all of limit situations, the insurmountability of which, in provoking the total "shipwreck" of human possibilities, makes man feel the presence of absolute transcendence. In a less philosophically elaborate form, Being has been understood as mystery by Marcel; as the perfect actuality that guarantees the existential possibilities by Louis Lavelle, a leader of the French *philosophie de l'esprit*; and as the absolute value that man encounters in his own spiritual intimacy by René Le Senne, also of the *philosophie de l'esprit*.

**Problems of Existentialist theology.** Existentialism has a theological dimension. Though Heidegger rejects

the label of atheist, he also denies to the Being of which he speaks the essential qualifications of divinity, inasmuch as it is not the ultimate cause and the Good. But Jaspers, in his last writings, emphasized more and more the religious character of faith in transcendence. Faith is the way to withdraw from the world and to resume contact with the Being that is beyond the world. Faith is life itself, in that it returns to the encompassing Whole and allows itself to be guided and fulfilled by it. Jaspers has even developed a theology of history. He speaks of an axial age, which he places between the 8th and 2nd centuries before Christ, the age in which the great religions and the great philosophers of the Orient arose—Confucius and Lao-tzu, the *Upanishads*, Buddha, Zoroaster, the great prophets of Israel—and in Greece the age of Homer and of classical philosophy as well as Thucydides and Archimedes. In this age, for the first time, man became aware of Being in general, of himself, and of his limits. The age in which man now lives, that of science and technology, is perhaps the beginning of a new axial age that is the authentic destiny of man but a destiny that is far off and unimaginable.

For Bultmann, the theologian of the demythologization of Christianity, inauthentic existence is tied to the past, to fact, to the world, while authentic existence is open to the future, to the nonfact, to the nonworld; *i.e.*, to the end of the world and to God. Thus, authentic existence is not the self-projection of man in the world but, rather, the self-projection of man in the love of and obedience to God. But this self-projection is no longer the work of human freedom; it is the saving event that enters miraculously through faith into the future possibilities of man.

In these theological speculations and in others that are comparable, the common presupposition of the Existentialists is recognized—*i.e.*, the gap between human existence and Being. There is either an acknowledgment of that gap, with existence assuming the role of the demonic (the alternative that Sartre and others have all illustrated above all in their literary works), or an acknowledgment of the hidden participation of human existence in Being through a gratuitous initiative on the part of Being.

Kierkegaard had earlier distinguished three stages of existence between which there is neither development nor continuity but gaps and jumps: the aesthetic stage is the one in which one lives for the pleasure of the moment; the ethical stage is the one based on the stability and continuity of life in work and in matrimony; and the religious stage is the one characterized by faith, which is always a "dreadful certainty"—*i.e.*, a dread that becomes certain of a hidden relationship with God.

The ethical and religious stages correspond roughly to what Heidegger and Jaspers call, respectively, the inauthenticity and the authenticity of existence. Art is not as a rule recognized by contemporary Existentialists as an autonomous stage; it is almost always for them an essential manifestation of existence itself. For Jaspers, it is a mode of reading in nature, in history, and in men the cipher of transcendence; *i.e.*, the negative symbol in which transcendence is revealed. According to Camus, it is an aspect of man's revolt against the world. The artist tries to remake the sketch of the world that is before him and to give it the style—that is to say, the coherence and unity—that it lacks. For this purpose, he selects the elements of the world and freely combines them in order to create a value that escapes man continuously but that the artist perceives and tries to salvage from the flux of history.

From this point of view, art would be a way of reshaping the world beyond its factual forms, in order that it might show their negative and troublesome characteristics. The directions of contemporary art that have deliberately forsaken the imitation of reality find their justification in this point of view.

#### SOCIAL AND HISTORICAL PROJECTIONS OF EXISTENTIALISM

The metaphysical or theological dimension of Existentialism does not leave man with nothing to do. Once the nullity of the existential possibilities is recognized, man cannot but resign himself to Being, which, in one of its

new manifestations in the world or beyond it, conducts him to a new epoch. Even someone like José Ortega y Gasset, the leading Spanish Existentialist and writer, who, in examining the social aspects of existence, has characterized the present epoch by the advent of the masses and the socialization of man, has halted at the recognition of the crisis and the total uncertainty that dominates the future of man (*La Rebelión de las masas* [1929; Eng. trans., *The Revolt of the Masses*, 1932]).

On the other hand, humanistic Existentialism has recognized the positive and the to-some-degree determining function that man may have in history. It has insisted, as in Merleau-Ponty, on man's duty to assume the responsibility of an effective action for the transformation of society and, in general, of the world that he inhabits.

Along this line of assuming responsibility, Existentialism has moved toward Marxism, with which it shares the diagnoses of existence as the primordial and ineradicable relationship of man with nature and with society. In the *Critique de la raison dialectique* (1960; "Critique of Dialectical Reason"), Sartre attempted a synthesis between Existentialism and Marxism by modifying the notion of "project" that he defended in *L'Être et le néant* and by utilizing the notion of dialectic as understood by Marx. The project of which existence consists is not the result of an arbitrary choice (as Sartre had previously maintained); it is, instead, that of a conditioning by the objective possibilities that Sartre identifies (as does Marx) with "the material conditions of existence." The project remains, however, that of the particular individual of a unique consciousness—but of a consciousness that tries to become totalized; *i.e.*, to enter into relationship with others so as to constitute, with others, human groups that are more and more comprehensive. In this manner it tends toward a complete and definitive totalization without appeals. Dialectical reason would be precisely such a process of growing totalization; and it becomes, moreover, the true protagonist of history and becomes that with which the interior freedom of any individuals who participate in history is identified.

From the defense of the freedom of the individual, Sartre has thus moved to the defense of the absolute dialectical necessity of history despite its being interiorized and lived by individuals. An historical project of human life that tries to remove the characteristics of inauthenticity or of alienation from existence—a project that may bring Existentialism and Marxism close together—thus ends by losing, in this form, its risky and problematic character and the awareness of the conditions and the modalities of its realization. These features are also lost in the "transcendental project" of a new society elaborated by one of the leaders of the New Left, the German-born American Herbert Marcuse. While insisting on the requirement that the "transcendental project" be "in accord with the real possibilities open at the attained level of the material and intellectual culture," Marcuse entrusts its realization to an impersonal and contemplative Reason, which cannot but invite the "great refusal" of contemporary society.

Having developed in different and contrasting directions, Existentialism has furnished philosophy and the whole of contemporary culture with conceptual tools, of which the nature and techniques of employment have still not been clarified—as, for example, terms like "problematicity," "chance," "condition," "choice," "freedom," and "project." Although these tools can be employed usefully for the interpretation of existence—*i.e.*, to orient philosophical inquiry in the fields of epistemology, ethics, aesthetics, education, and politics—it is nonetheless indispensable that the pivot on which they turn, "possibility," be granted its own ontological status that does not reduce it either to Nothingness or to Being. It is indispensable, moreover, that a positive datum be perceived in possibility, a datum that is verifiable with appropriate techniques and that, while not offering infallible guarantees, allows man to project and to act in the world with calculated risks and with a prudent trust.

## Exploration, Surface and Underground

Exploration has played a historic role in human affairs, probably since before recorded times; the 20th century has witnessed the last stages of exploration on the surface of the earth and the first explorations of space. For an account of the history of early exploration of the earth's surface, see GEOGRAPHY. For a history of the exploration of space, see SPACE EXPLORATION. The present article focusses on modern earth exploration. Because of the facility of surface exploration by aircraft, the earth's surface has virtually lost its mystery; therefore scientific attention today is primarily directed beneath the surface of the earth.

*The era of scientific exploration.* Scientific interest in the earth increased considerably during the 19th century. Early efforts were characterized by a strong element of national competition and a lack of international coordination. After World War I a new era of international cooperation began. A dozen international scientific unions were coordinated by the International Council of Scientific Unions. Developments in communication and transportation during World War II improved the possibilities of international cooperation in scientific exploration. After World War II the United Nations Educational, Scientific, and Cultural Organization (UNESCO) provided a centre for coordination and a certain amount of financial assistance for the exchange of information.

One of the first major international scientific efforts was a systematic study of the earth and its environment undertaken by more than 70 nations during the International Geophysical Year, which began on July 1, 1957, and was ultimately extended to December 31, 1959. The exploration of Antarctica was greatly advanced by inter-

ested nations, which on December 1, 1959, signed the Antarctic Treaty, suspending all territorial claims in Antarctica for a period of 30 years and promoting international cooperation in scientific research. At the end of the International Geophysical Year the work was continued under special committees for oceanographic, antarctic, and space research. Later, an Upper Mantle Committee was established by the International Council of Scientific Unions to coordinate the Upper Mantle Project, an international program of research on the solid earth that began in 1961.

### PURPOSES OF EXPLORATION

Only about 30 percent of the earth's surface lies above sea level, and of this only about one-third, or 10 percent, is generally suitable for human occupation; the remainder is either too cold, too dry, too high, or too infertile. Modern exploration of the earth is directed largely beneath the surface in search of new mineral, fuel, and water resources or for the planning and construction of human facilities. The most interesting, however, is probably that carried out for scientific purposes.

**Scientific exploration.** Present knowledge of the earth's interior is based on indirect observations and is therefore subject to considerable uncertainty. The International Upper Mantle Committee has done much to encourage participating countries to extend scientific knowledge by a coordinated program of drilling into the crust. One of the most ambitious exploration projects of the last decade was the abortive U.S. Project Mohole, the primary objective of which was to obtain a core record through the layers of the earth's crust and the upper part of the underlying mantle. The ultimate objective was to drill to a total depth of 35,000 feet (10,500 metres), of which 15,000 feet (4,500 metres) was through water, from a ship stationed at a point in the ocean where the thickness of the earth's crust is minimum. Information from such boring would include heat flow measurements, thermal and electrical conductivity values, seismic velocities (that is, the speed at which earthquakes and tremors travel), radioactive and magnetic values, and other physical properties of the crust and upper mantle helpful in determining the origin and character of the earth.

Drilling grows progressively more expensive; a 25,000-foot (7,600-metre) borehole may cost 10 times as much as a 10,000-foot (3,000-metre) borehole in the same material. Consequently, after an expenditure of some \$20 million the National Science Foundation withdrew its support of the project in 1967 before the deep hole had been begun.

Another venture is the Deep Sea Drilling Project begun in 1966 and aimed at the recovery of cored samples from the sedimentary layer of the deep ocean basins. Scientific planning for the program was conducted under the auspices of the Joint Oceanographic Institutions for Deep Earth Sampling, a consortium of oceanographic institutes and universities.

In addition to deep-drilling activities, an extensive cooperative program of shallow and intermediate drilling is proceeding under the guidance of the Upper Mantle Committee. In this program scientists are profiting from a great deal of expertise acquired by the resource industries in subsurface exploration.

**Resource exploration.** Exploration for new resources is usually carried out in remote areas with indirect techniques which measure gravity or magnetic anomalies or the seismic response of the earth to artificially induced shock waves. Seismic methods are most commonly used for oil and gas exploration in areas where the geological structure shows promise. If the seismic survey is encouraging it is followed by drilling because the actual occurrence can be proved only when the drill penetrates the deposit. The cost of drilling depends on the depth, the type of material through which the drill must pass, and the remoteness of the area. The deepest hole ever drilled, just over 25,000 feet (7,600 metres), is located in Texas.

Economic mineral resources usually are found nearer

Project  
Mohole

the surface than are oil and gas reservoirs. The largest mines in the world are open-pit mines, although the deepest mine was dug for gold (11,246 feet or 3,410 metres) in South Africa. Though many large mineral resources have been discovered by individual prospectors, airborne devices for detecting slight changes in the earth's magnetic field are much more important today.

**Water supply.** Water is one of the oldest motives for exploration. Almost all water comes to the earth as precipitation; some evaporates from the surface or is used by vegetation, while some runs off into lakes and streams, or sinks into the ground. Most urban supplies have always been obtained from lakes and rivers or from storage reservoirs designed to provide a continuous supply when rainfall is seasonal. Even when supplies are reasonably abundant, large amounts of water may be taken from the ground. The city of London, for example, obtains about one-sixth of its municipal water supply from wells.

Urban  
water con-  
sumption

Ancient villages required only about 3 to 5 gallons (11–20 litres) of water per person per day; modern cities consume more than 60 gallons (227 litres) per person per day. Once a city is established, its steadily increasing demand for water must be met and often groundwater is the only source. The little Middle Eastern nation of Kuwait, rich in oil but desperate for freshwater, which has to be either imported or distilled from the sea, persisted in exploration until the discovery, by drilling, of a significant source of groundwater in 1960.

**Exploration for construction.** Though the depth of exploration required for surface construction is seldom more than 100 feet (30 metres), for very heavy structures and for tunnels it is considerably deeper. The cost of the investigation is a small fraction of total construction cost, but for major structures, such as large dams, long-span bridge foundations, and deep or underwater tunnels, such exploration may be critically important. Exploration may seek information on earth materials relating to potential excavation difficulties, sand and gravel supplies for construction, groundwater characteristics, the stability of natural slopes, flooding hazards, and earthquake potential.

#### METHODS OF SUBSURFACE EXPLORATION

Exploration methods are of two general types: direct and indirect. Direct methods involve the collection and examination of samples; indirect methods are all those that do not. The methods selected for any particular purpose are necessarily based on economic considerations. Large programs are conducted in stages, with plans for each stage made on the basis of information derived from earlier stages.

**Use of maps.** Ordinary topographic maps show boundaries between water and land, contours of elevation, and the location of important features, but give no indication of subsurface conditions. Soil, or pedologic, maps describe the surface soils and their value for agricultural purposes. Geologic maps show the thicknesses and relative positions of bedrock materials and surface soils lying above them. All new subsurface investigations, whether for oil, minerals, construction materials, water supply, or civil-engineering construction, begin with the study of available maps. Map information is supplemented by studies of geological and engineering reports describing previous experiences in the area.

**Remote sensing.** The earliest form of remote sensing was visual observation from hills and treetops, often for military purposes. Balloons widened the horizon and aerial photography provided a permanent record of the view. Modern photographs from spacecraft and satellites show huge sections of the earth in minute detail. Even more remarkable than the ability to photograph is the development of photo interpretation into a reliable technique.

Photographs from aircraft, because they exaggerate the relief features of the earth when viewed stereoscopically, can be used to prepare extremely accurate contour maps at a fraction of the cost of ground surveys. Trained interpreters can identify landforms, interpret geology, lo-

cate sand and gravel deposits, predict landslide and flooding hazards, and conduct inventories of natural resources. In remote areas aerial photographs guide the selection of campsites and access routes; in built-up areas they assist land-use planning, expose traffic problems, and assist with man's studies and activities in many other ways.

Radar (*q.v.*), perfected during World War II, is an especially valued tool for remote sensing because it does not require clear weather conditions, is effective at night, and can penetrate dense vegetation. Radar operates near the long-wavelength end of the electromagnetic spectrum, well outside the visible light range, and provides an indirect image by scanning its target. Another recently developed method of imagery is the scanning infrared sensor that, operating at wavelengths between radar and visible light, provides relative surface temperature information and is useful in detecting moist areas, underground water, and other terrain features.

Sensors now being developed extend into the microwave region or beyond it into radio-frequency ranges and can penetrate the earth to a considerable depth. Their practical application is based on the premise that all materials have characteristic signatures at different wavelengths. Most of the early development took place in the military sphere and the results were not generally available in the early 1970s.

**Geophysical methods.** Geophysical exploration makes use of variations in the physical properties of earth materials to explore geologic structures. The most notable variations in earth materials are related to their density, magnetism, elasticity, and electrical conductivity; and the four related major geophysical methods are gravitational, magnetic, seismic, and electrical. Geophysical methods find practical application in the search for oil and minerals and, in engineering, in building-foundation investigations. Since geophysical methods are indirect and require careful interpretation, they are most effective when used in conjunction with other more direct observations.

Major geo-  
physical  
methods

The gravity method is based on the fact that the force of gravity varies from point to point on the surface because of variations in density of the underlying strata. A variation between a measured value and the computed normal value for any point will, therefore, reveal irregularities in the distribution of mass in the earth's crust. Gravity measurements are usually made with a pendulum, a torsion balance, or a gravimeter in which gravity is compared with an elastic spring force.

The law of magnetic attraction is similar to the law of gravitation and the method of searching for magnetic anomalies in the earth is similar to the gravitational method. Some remarkable mineral discoveries have been made with specially designed airborne magnetometers. Like gravity measurements, magnetic observations are subject to wide interpretation and require supplementary investigation for most uses.

The seismic method of exploration is based on the fact that shock waves travel through earth materials at speeds ranging from a few hundred to many thousands of feet per second, depending upon the elastic properties of the material, and that precise measurements can be made of the time required for an induced shock wave to travel between two or more points (see illustration). The shock wave is received at a series of detectors placed on the surface in such a way that a distinction can be made between reflected (directly returned) waves and refracted (bent) waves. Depths from the surface to changes in strata can be estimated from the arrival times of reflected and refracted waves if the wave velocity in the natural materials is known. In engineering, the method is particularly useful in estimating the depth of the soil over bedrock and in detecting the differences in the subsurface geology between two boreholes. In oil exploration it is most useful in searching large areas for promising geologic structures.

The variations in the electrical properties of soils, rocks, and minerals are used in a variety of ways to explore beneath the surface. Some ore bodies generate natural electrical currents by which they can be detected. The most

Seismic reflection method for geophysical prospecting. Field equipment is shown above, seismic wave paths below, and a seismogram at the right.

common method is to place electrodes in the ground and measure the resistance between them. The method is useful for detecting the depth of surface soil and rocks, subsurface anomalies, water-bearing strata, and other necessary information at large construction sites.

**Geochemical prospecting.** Geochemistry is concerned with the distribution and movement of chemical elements in the earth over long periods of time. Geochemical prospecting involves the systematic measurement of trace contents of certain elements in natural materials such as rock, surface materials, vegetation, and water that may indicate geochemical anomalies or patterns associated with the presence of ore in the vicinity. Early prospectors learned to associate various ore bodies with stains or the colour of the water or even with types of vegetation, but the large-scale systematic investigation of geochemistry as a method of prospecting was not begun until the early 1930s. The method has been facilitated by the development of rapid and reliable techniques of chemical analysis. It is still in an early stage of use and requires experienced judgment for planning, sampling, and interpretation of results.

**Excavation, boring, and sampling.** The indirect methods of exploration already described, however useful, cannot prove an oil or mineral deposit or ensure the adequacy of a construction site. They must be followed by more direct observation of the earth materials. This is usually achieved by boring, though for shallow observations it is often economical to excavate pits or trenches to the required depth. Construction excavations are watched carefully for confirmation of predicted ground conditions and, if necessary, designs may be changed at this stage.

The first questions to be settled, whether exploring for oil or evaluating a building site, are the number, type, and depth of borings. These decisions are largely dependent on the information gathered by indirect methods. In exploring for oil or minerals the first boring is aimed at the supposed deposit. Subsequent borings, if any, are

dictated by the geological information revealed by the first. In evaluating a specific construction site, the boring program depends on the size, value, and type of proposed construction, the anticipated properties and variability of the subsurface materials, and the amount of previous experience in the area. Variations in the program are usually required as the investigation proceeds.

The principal purpose of borings is to obtain samples of the ground for examination and testing. In resource exploration the soil above the bedrock is usually merely a barrier in the path of exploration. In civil engineering works, however, it is usually the main object of the investigation. Consequently, the tools for drilling and sampling are many and varied.

When the main objective is to penetrate the earth, a percussion or churn drill is often used. This consists of a heavy bit that is alternately raised and dropped to chop through the soil or rock. The various strata are evaluated both by the rate of drilling and by the sample cuttings that are periodically taken. This method is still widely used for finding water, but for oil it has been replaced by rotary drilling in which the hole is advanced by a rapidly rotating bit and the cuttings are removed by a pressure circulated drilling fluid. For shallow drilling in soils, a variety of hand- and power-operated augers are used.

It is important to know how well samples required for engineering evaluation represent the actual subsurface condition. It is impossible to obtain perfect samples of soil; the stresses on an element in the ground are changed by the insertion of the sampler and by the extraction of the sample, although these effects are minimized by keeping the borehole full of water or mud and by use of ingeniously designed samplers. The best samples of soft cohesive soils are obtained in thin-walled piston samplers. The sampler is inserted to the bottom of the borehole with the piston at the lower end; the piston is then held in place while the thin-walled tube is advanced into fresh soil. With the piston locked in position at the top of the tube, the assembly is withdrawn, carrying the sample with it; the tube is detached, sealed at both ends, and transported carefully to the laboratory.

It is extremely difficult to obtain good samples of sands and gravels, because of their poor cohesion. In some cases the ground has been frozen artificially and cored, though this is very expensive. Various materials have been injected into sands and gravels to stabilize them for sampling, but this involves the complication of removing the injection material. Some recent experiments with chemical grouts (mortars) have been successful.

Strangely, rock is often the most difficult material to sample for engineering purposes, partly because of the difficulty of drilling. The first modern diamond core drill was built in 1862 by a Swiss engineer. It is standard equipment for mining and engineering exploration. Difficulties arise, not with the ability to obtain good cores from sound rock, but with the problem of identifying joints, fissures, and other defects in the rock. These are the features that control the engineering design, and not only may they be missed but the soundness of the core recovered may give a misleading impression of the mass.

**On-site testing.** The limitations of sampling and laboratory testing have led to the development of many tools for assessing the structural properties of soils on-site. The simplest test is to observe the effort required to drive or push a rod into the soil, but this reveals very little information. A widely used dynamic method, called the standard penetration test, measures the number of blows applied in a standard manner to a standard sampler to cause a penetration of a certain depth. The results of such tests have been correlated with the properties of many soils. This method has the advantage that a sample of the soil is obtained at the same time. A European method involves using a standard size cone on the end of a string of drill rods. Such dynamic penetration tests are useful only for evaluating coarse granular soils. Static penetration tests are used for fine-grained cohesive soils. Of these the "Dutch cone" is the best known. It is similar to the dynamic cone, but it is pushed slowly into the soil at a constant rate and the resistance to penetration is measured.

Piston  
samplers

Boring

Another method of measuring soil strength employs a "vane borer." Though various designs are available, this device is essentially a four-bladed vane attached to the bottom of a rod. The assembly is pushed into the soil and then rotated slowly, causing the soil to shear along a cylindrical surface. The shearing resistance is computed from the measured torque (twist) required.

A fairly recent device, the pressure meter, is a flexible cylindrical bag that can be inserted into a borehole and expanded under increasing pressure. The degree of deformation of the material surrounding the borehole for a given amount of pressure is used to compute the structural properties of the material. Though used in all soils and rocks, it is especially useful for those that cannot be properly sampled.

Miniature geophysical tools have been developed to provide measurements of electrical and nuclear properties of earth materials. One of the most useful devices for evaluation in place is the borehole camera, a specially designed instrument that is lowered down small-diameter boreholes to take photographs through 360 degrees at any level. These devices can be hooked up to closed-circuit television for continuous viewing. They are especially useful in studying boreholes in defective rock.

**Sampling of permafrost and ice.** Exploration in permafrost regions is complicated by their remoteness and the frozen ground. Aerial photographs and other indirect exploration methods are significant in these regions because they are usually so far from easy transport. For many engineering purposes, however, because it is necessary to know how much ice is in the soil, samples must be obtained.

For shallow sampling, test pits are commonly dug, especially in stony soils or gravel. If these are excavated by hand during summer, natural thawing may aid the operation. The use of jackhammers to depths of 20 or 30 feet (6 to 9 metres) is now more common. Core drilling of stony material is extremely difficult, but it is quite successful for frozen fine-grained soils. Photographs record ice contents of fresh core samples because preservation in frozen condition is often difficult. Methods of diamond core drilling of rock are used for coring frozen soils; water, air, or oil is employed as the drilling fluid. Special precautions must be taken to prevent thawing of the core; drilling is usually continued without interruption to prevent "freezing-in" of the drill or caving of the hole.

Drilling for oil through permafrost introduces the problem of surface thawing and settlement due to melting ice. The warm drilling fluid from depth not only thaws the ground around the hole but, unless it is carefully controlled, can cause the whole area around the huge drill rig to deteriorate. In some cases the footings for the rigs have been underlain by refrigerated pipes to preserve the permafrost.

Special coring tools have been developed for taking ice samples. One of these consists of a perforated tube with saw teeth around the lower end. Samples to relatively shallow depths in glaciers have been easily obtained with this device. Samples to depths greater than 1,000 feet (300 metres) have been obtained in Antarctica, using a rotary well-drilling rig with compressed air as the drilling fluid. If samples are not required, a boring can be advanced by a thermal drill, an electrical resistance element on the end of a rod. Drilling of ice covers on lakes and rivers can be accomplished with a variety of hand- or machine-powered auger drills or core augers. Light-weight equipment is normally not as important as it is for the drilling of glaciers far from access routes.

**Underwater exploration.** Until recently, only very crude data about the depths of seawater and the character of the sea bottom were available (see also UNDERSEA EXPLORATION). Observations of the British "Challenger" expedition from 1872 to 1876 provided the first soundings and samples from the ocean bottom, but these were too infrequent to provide a serious picture. The development of echo-sounding devices in the early 1920s showed, for the first time, the actual irregularities of the seabed, and only since World War II has enough information been gathered to provide reliable ocean-floor maps.

Seismic methods are among the most useful for determining the structure and thickness of the earth's crust beneath the sea. These involve the measurement of the rate of propagation of sonic energy from an artificial source to a series of hydrophones (pressure detectors) suspended from buoys or enclosed in cables. The measurements are made at depths below the influence of wave action and as far as possible from ship noise. The development of underwater sparking and similar devices as controlled sound sources has led to the use of continuous seismic-reflection techniques for rapid mapping of the ocean floor.

Mapping is only the first step; cores must be obtained for further study. Many problems arise in a drilling operation at sea, not the least of which is accurate determination and maintaining of position. In shallow water the drilling platform can be anchored or even mounted on legs, but in very deep water the ship must be manoeuvred to maintain position. A recent development is to use a reference system of acoustic beacons resting on the sea floor. For deep drilling into bottom sediments a casing must be provided so that the sampler can be extracted and returned to the same hole, but for shallow sampling (up to 100 feet or 30 metres) the sampler can be dropped through the water and retrieved by a cable. Technology is now available for drilling and coring successfully in water depths of 20,000 feet (6,000 metres). Conventional rotary drills are used for this purpose.

Scientists believe that the sea is a yet untapped source of food and energy for the world's people. Many of its secrets will be unlocked by the cooperative explorations under way in the 1970s.

(C.B.C.)

## Explosives

An explosive is any substance or device that can be made to produce a volume of rapidly expanding gas in an extremely brief period. There are three fundamental types: mechanical, nuclear, and chemical. A mechanical explosive is one that depends on a physical reaction, such as overloading a container with compressed air. Such a de-

Seismic  
methods

Use of the  
borehole  
camera

vice has some application in mining, where the release of gas from chemical explosives may be undesirable, but otherwise is very little used. A nuclear explosive is one in which a sustained nuclear reaction can be made to take place with almost instant rapidity, releasing large amounts of energy. Experimentation has been carried on with nuclear explosives for possible petroleum extraction purposes; for a discussion of this field see PETROLEUM AND GAS EXTRACTION. Military applications of nuclear explosives are discussed under NUCLEAR WEAPONS. This article is concerned with chemical explosives, which account for virtually all explosive applications in engineering up to the 1970s.

#### TYPES OF CHEMICAL EXPLOSIVES

Basically, chemical explosives are of two types: (1) detonating, or high, explosives and (2) deflagrating, or low, explosives. Detonating explosives, such as TNT and dynamite, are characterized by extremely rapid decomposition and development of high pressure, whereas deflagrating explosives, such as black and smokeless powders, involve merely fast burning and produce relatively low pressures. Under certain conditions, such as the use of large quantities and a high degree of confinement, some normally deflagrating explosives can be caused to detonate.

Detonating explosives are usually subdivided into two categories, primary and secondary. Primary explosives detonate by ignition from some source such as flame, spark, impact, or other means that will produce heat of sufficient magnitude. Secondary explosives require a detonator and, in some cases, a supplementary booster. A few explosives can be both primary and secondary depending on the conditions of use.

#### BLACK POWDER

It may never be known with certainty who invented the first explosive, black powder, which is a mixture of saltpetre (potassium nitrate), sulfur, and charcoal (carbon). The consensus is that it originated in China in the 10th century, but that its use there was almost exclusively in fireworks and signals. It is possible that the Chinese also used black powder in bombs for military purposes and there is written record that, in mid-13th century, they put it in bamboo tubes to propel stone projectiles.

There is, however, some evidence that the Arabs invented black powder. By about 1300, certainly, they had developed the first real gun, a bamboo tube reinforced with iron, which used a charge of black powder to fire an arrow.

A strong case can also be made that black powder was discovered by the English medieval scholar Roger Bacon, who wrote explicit instructions for its preparation in 1242, in the strange form of a Latin anagram, difficult to decipher. But Bacon read Arabic, and it is possible that he got his knowledge from Arabic sources.

Some scholars attribute the invention of firearms to an early 14th-century German monk named Berthold Schwarz. In any case they are frequently mentioned in 14th-century manuscripts from many countries, and there is a record of the shipment of guns and powder from Ghent to England in 1314.

Not until the 17th century was black powder used for peaceful purposes. There is a doubtful claim that it was used in mining operations in Germany in 1613, and fairly authentic evidence that it was employed in the mines of Schemnitz, Hungary, in 1627. For various reasons, such as high cost, lack of suitable boring implements, and fear of roof collapse, the use of black powder in mining did not spread rapidly, though it was widely accepted by 1700. The first application in civil engineering was in the Malpas Tunnel of the Canal du Midi in France in 1679.

For 300 years the unvarying composition of black powder has been approximately 75 percent saltpetre (potassium nitrate), 15 percent charcoal, and 10 percent sulfur. The saltpetre was originally extracted from compost piles and animal wastes. Deposits found in India provided a source for many years. During the 1850s tremendous

quantities of sodium nitrate were discovered in Chile, and saltpetre was formed by reaction with potassium chloride, of which there was a plentiful supply.

Chilean nitrate was not at first considered satisfactory for the manufacture of black powder because it too readily absorbed moisture. Lamot du Pont, an American industrialist, solved this problem and started making sodium nitrate powder in 1858. It became popular in a short time because, although it did not produce as high a quality explosive as potassium nitrate, it was suitable for most mining and construction applications and was much less expensive. To distinguish between them, the potassium nitrate and sodium nitrate versions came to be known as A and B blasting powder respectively. The A powder continued in use for special purposes that required its higher quality, principally for firearms, military devices, and safety fuses.

**Manufacture of black powder.** Manufacture of black powder was accomplished originally by hand methods. Ingredients were ground together with a mortar and pestle. The next step was to use crushing devices of wood (wooden stamps), also operated by hand, in wooden or stone bowls. The stamping process was gradually mechanized and, about 1435, the first powder mill driven by water power was erected near Nuremberg, Germany.

Metallic crushing devices, introduced in the early 1800s, slowly and steadily replaced the wooden stamp mills.

In the modern process, charcoal and sulfur are placed in a hollow drum along with heavy steel balls. As the drum rotates, the steel balls pulverize the contents; this device is called a ball mill. The saltpetre is crushed separately by heavy steel rollers. Next, a mixture of several hundred pounds of saltpetre, charcoal, and sulfur is placed in a heavy iron device shaped like a cooking pan. There it is continuously turned over by devices called plows, then ground and mixed by two rotating iron wheels, which weigh from 10 to 12 tons each. The process takes several hours; water is added periodically to keep the mixture moist.

The product of the mills is next put through wooden rolls to break up the larger lumps and is then formed into cakes under 3,000–4,000 pounds per square inch pressure. Coarse-toothed rolls crack the cakes into manageable pieces and the corning mill, which contains rolls of several different dimensions, reduces them to the sizes desired.

Glazing (the next operation) consists of tumbling the grains for several hours in large wooden cylinders, during which friction rounds off the corners, and, aided by forced air circulation, brings the powder to a specified moisture content. The term glazing derives from the fact that graphite is added during this process, forming a thin film over the individual powder grains. Glazed powder flows more readily than unglazed powder and is more moisture resistant.

After glazing the powder is graded by sieves into different sizes. Packaging is usually in 25-pound (11-kilogram) kegs.

Because the burning of black powder is a surface phenomenon, a fine granulation burns faster than a coarse one. Grain sizes are designated as F, 2F, etc., up to 7F, which is the finest, and from C up as the grains become larger. For the A powder the letter indicating the fineness becomes 3FA, etc., and if the powder is glazed, this is followed by the letter g; e.g., 3FAG. For many years the B blasting material was offered in pellet as well as granular form. Four pellets, each two inches (five centimetres) in length and from 1½ to 2½ inches (2.75 to 6.25 centimetres) in diameter, were packed in waxed paper cartridges. Each pellet had a hole through its centre to accommodate a safety fuse or an electric device used to ignite the powder. Pelleted powder was used almost entirely in underground coal mines, but federal regulations now prohibit both it and the granular type.

**Ignition of black powder.** Black powder is relatively insensitive to shock and friction and must be ignited by flame or heat. In the early days such devices as torches, glowing tinder, and heated iron rods were used to ignite

Chinese  
fireworks

Composi-  
tion of  
black  
powder

the powder and, in most cases, a train of the powder was led to the main charge in order to give the firer time to get to a safe place.

In cannons a small touchhole was drilled into the breech and filled with fine powder. Ignition was usually by means of a slow-burning punk. The same principle was employed in flintlock muskets and rifles except that ignition resulted from sparks produced by contact between flint and steel.

Percussion methods of firing guns have long been in universal use. In the most common procedure, pulling the trigger releases a hammer, which strikes an impact-sensitive explosive mixture. This explosion then ignites the black powder or other powder charge.

Some black powder is still used as the propellant in guns in spite of the superiority of smokeless powder. Besides antique gun experts, who employ it mostly with hand-loaded shells and cartridges, hunters in South and Central America still use guns that require black powder.

In mining, a succession of crude means for ignition (fuses) included straws filled with pulverized black powder, reeds in which the pith was scooped out and replaced with a paste of powder and water (later bound with string and dried), or powder paste spread on wool threads. All of these fuses were ignited either by a piece of wool yarn impregnated with sulfur, called a sulfur mannikin, or some equivalent slow-burning device. A later, and extremely popular, type of fuse was formed of goose quills. The quills were cut so that they could be inserted one into the other and then filled with powder. Quill fuses could be ignited directly, that is, without any delaying element such as the sulfur mannikin. Unfortunately, their reliability was not high, and they often burned erratically.

**Safety fuse.** A major contributor to progress in the use of explosives was William Bickford, a leather merchant who lived in the tin-mining district of Cornwall, England. Familiar with the frequency of accidents in the mines and the fact that many of them were caused by deficiencies inherent in the quill fuse, Bickford sought to devise an improvement. In 1831 he conceived the safety fuse: a core of black powder tightly wrapped in textiles, one of the most important of which was jute yarn. The present-day version is not very different from the original model. The cord is coated with a waterproofing agent, such as asphalt, and is covered with either textile or plastic.

The safety fuse provided a dependable means for conveying flame to the charge. Its timing (the time required for a given length to burn) was amazingly accurate and consistent, compared to that of its predecessors, and it was much better from the standpoints of resistance to water and abuse.

Underground coal mining was formerly by far the largest consumer of black powder. From a performance standpoint, it is probably the best explosive for that purpose. Its relatively gentle, heaving action gives a high yield of lump and leaves the coal in good position for rapid loading. Before the advent of oil, gas, and electric heating and cooking, coal was produced in tremendous quantities for household use and lump demanded a premium price. But black powder has a dangerous tendency to ignite coal gas (mostly methane) and coal dust, and many mine explosions occurred. Around 1880 several European governments, seeking to develop safer substitutes for black powder, set up testing stations. Similar action was taken in the United States a few years later. The result was a series of special dynamites approved for use in gassy and dusty coal mines when used in the specified manner. Their blasting action was not as good as that of black powder, but they were very much safer. These dynamites are discussed below.

The use of black powder in underground coal mines is no longer allowed in most countries. As a result, black powder production has decreased tremendously. Further, black powder is now more expensive than dynamite and is used only for special purposes. There is, for example, no substitute for black powder in certain military applications and nothing equal to it has yet been found for the

manufacture of safety fuse. The fact that black powder is relatively nonshattering is of value in blasting certain types of stone.

#### NITROGLYCERIN

Nitroglycerin, another chemical explosive, was discovered by an Italian chemist, Ascanio Sobrero, in 1846. Though he first called it pyroglycerin, it soon came to be known generally as nitroglycerin, or blasting oil. Because of the risks inherent in its manufacture and the lack of dependable means for its detonation, nitroglycerin was largely a laboratory curiosity until Immanuel Nobel and his son Alfred made extensive studies of its commercial potential in the years 1859–61. In 1862 they built a crude plant at Heleneborg, Sweden; Alfred, a chemist, was basically responsible for the design of this factory that was efficient and relatively safe considering the state of knowledge of the times. Nevertheless, it exploded in 1864 and killed, among others, Alfred's youngest brother Emil Oskar. Though deeply affected by the accident, Alfred continued work, at first on a barge that he moored in the middle of a lake. In 1865 he erected a plant at Krümmel, Germany, and another in Sweden at Vinterviken near Stockholm. A third plant was built a year later in Norway. Nobel was granted a patent for the manufacture and use of nitroglycerin in the United States, in 1866, and since importation on a large scale was impractical, he visited the United States in an effort to interest local capital. The victim of a number of unscrupulous businessmen, he finally sold his American holdings in 1885 for only \$20,000.

Even today most experts regard Nobel's invention of the blasting cap, a device for detonating explosives, in 1865, as the greatest advance in the science of explosives since the discovery of black powder. Combined with Bickford's safety fuse, the blasting cap provided a dependable means for detonating nitroglycerin and the many other high explosives that followed it. After a number of attempts that were only partially successful, Nobel settled on a charge of mercury fulminate, which had been known for many years, in a copper capsule. With one or two minor changes, this blasting cap remained in general use until the 1920s.

#### DYNAMITE

The second most important of Nobel's inventions was dynamite, in 1867. He coined the name from the Greek *dynamis*, "power." The basis for the invention was his discovery that kieselguhr, a porous siliceous earth, would absorb large quantities of nitroglycerin, giving a product that was much safer to handle and easier to use than nitroglycerin alone.

Dynamite No. 1, as Nobel called it, was 75 percent nitroglycerin and 25 percent guhr. Shortly after its invention, Nobel realized that guhr, an inert substance, not only contributed nothing to the power of the explosive but actually detracted from it because it absorbed heat that otherwise would have improved the blasting action. He turned, therefore, to active ingredients such as wood pulp for an absorbent, and sodium nitrate for an oxidizing agent. By varying the ratio of nitroglycerin to these "dopes," as they came to be called, Nobel not only improved the efficiency of dynamite but also was able to prepare it in varying strengths, termed straight dynamites. Thus 40 percent straight dynamite contained 40 percent nitroglycerin and 60 percent dope. Dynamites of this type are still in limited use.

Nobel patented the use of active ingredients in dynamite in 1869. Several others obtained similar patents at about the same time, however, and the result was that no one could establish a clear-cut claim to the invention.

Nobel's next outstanding contribution was his invention of gelatinous dynamites in 1875. There is a legend that he hurt a finger and used collodion, a solution of relatively low nitrogen content nitrocellulose in a mixture of ether and alcohol, to cover the wound. Later, unable to sleep because of the pain, Nobel went to the laboratory to find out what effect collodion would have on ni-

gelatinous  
dynamites

trolycerin. To his great satisfaction, he found that after evaporation of the solvents, there remained a tough, plastic material. He discovered that he could duplicate this by the direct addition of 7 to 8 percent of collodion-type nitrocotton to nitroglycerin and that lesser quantities of nitrocotton decreased the viscosity and enabled him to add other active ingredients. He called the original material *blasting gelatin* and the dope mixtures *gelatin dynamites*. The principal advantages of these products were their high water resistance and greater blasting action power than the comparable dynamites. This added power resulted from a combination of higher density and a degree of plasticity that allowed complete filling of the borehole (the hole that was bored in the coal seam or elsewhere for implantation of the explosive).

The first large-scale manufacture of nitroglycerin in the United States is attributed to George Mowbray, a chemist of considerable ability who had followed the work of Sobrero and others in Europe with great interest. Mowbray published an advertisement offering to supply nitroglycerin. This led to an invitation to manufacture it for completion of the Hoosac Tunnel at North Adams, Massachusetts. Mowbray's plant was built near North Adams in the latter part of 1867. Most of its product went to the tunnel, but a substantial amount was shipped, frozen, throughout the eastern United States and Canada. Pure nitroglycerin, relatively insensitive in frozen form, freezes at about 52° F (11° C) and is, therefore, easy to keep frozen by packing it in ice. Before closing his plant down because of patent difficulties, Mowbray made about 1,000,000 pounds of nitroglycerin without accidents in either manufacture or shipment.

One of the earliest major uses of nitroglycerin in the United States was in blasting oil wells to increase the flow of oil. E.A.L. Roberts in that country obtained a patent covering this procedure and later acquired the right to manufacture and use nitroglycerin under the Nobel patents. Theoretically, this gave him a monopoly on shooting oil wells, and his company dominated the field, but many of his competitors ignored his patent rights.

After 1883 the use of nitroglycerin was, with a few unimportant exceptions, restricted to oil-well shooting. In recent years more efficient means have been developed for increasing oil flow. Nitroglycerin is still used occasionally because it is more economical in small wells.

Three tunnels stand out as benchmarks in the history of the use of explosives: first is Mont Cenis, a seven-mile railway tunnel driven through the Alps between France and Italy in 1857-71, much the largest construction job with black powder up to that time; second was the four-mile Hoosac, also a railway project, during the construction of which (1855-66) nitroglycerin first replaced black powder in large-scale construction; third was the Sutro mine development tunnel in Nevada (1864-74) where the switch from nitroglycerin to dynamite for this type of work started.

**Ammonium nitrate.** After the straight dynamites and gelatins, the next important advance in dynamite was the substitution of ammonium nitrate for part of the nitroglycerin to give a safer and less expensive product. The use of ammonium nitrate in explosives had been patented by others in Sweden in 1867, but it was Nobel who made the new "extra dynamites" successful by devising gelatins that contained from 20 to 60 percent ammonium nitrate.

During the period 1867-84, many people worked to develop nongelatinous ammonium nitrate mixtures, but nothing of value resulted, largely because ammonium nitrate is too hygroscopic; that is, it picks up moisture too readily. In 1885 R.S. Penniman, an American, found a solution to the problem by coating the ammonium nitrate with a small percentage of paraffin, or some similar substance, prior to use. With this development, a series of ammonia dynamites soon became popular. Coating was discontinued when other, safer means were developed to handle the moisture problem.

All major underground-coal-mining countries have similar explosives and regulations. In the United States explosives that have been approved by the U.S. Bureau of

Mines for use in underground coal mines are called permissible. Besides passing the Bureau's safety tests, these explosives must be used in a manner specified by the Bureau. In England the explosives are known as permitted; in France, *explosifs antigrisouteux*; in Belgium, *explosifs S. G. P. (sécurité, grisou, poussière)*, and in Germany, *schlagwetterssichere Sprengstoffe*. Almost without exception, the major ingredient in these explosives is ammonium nitrate, chosen because of its low explosion temperature, and nearly all of them contain a cooling agent such as sodium chloride (common salt) or ammonium chloride to prevent the heat of their explosion in a mine from igniting underground gases such as methane, or a combination of them and coal dust, and causing a fire or disastrous secondary explosion. The sensitizer is usually a small amount of nitroglycerin but in some cases it is TNT, trinitrotoluene (discussed later); for example, it is said that a typical Russian permissible would be 68 percent ammonium nitrate, 10 TNT, 20 sodium chloride, and 2 powdered bark.

As synthetic ammonia became less expensive, because of improvements in manufacture and a raw material change from coal to natural gas, the explosives industry concentrated its efforts on substituting ammonium nitrate for nitroglycerin. Two important products were (1) low-density ammonia dynamites and (2) semigelatins. Prior to their development, the density of most dynamites was about the same and was quite high. Strength was changed in the different grades by varying the amount of explosives used. The new concept was to employ the strongest formula possible, with a minimum of nitroglycerin and a maximum of ammonium nitrate, and to dilute it systematically with suitable low-density ingredients such as bagasse (the pulp remaining after extraction of sugar from the cane) so that one stick of the new product would give the same blasting action as one of the old. This provided a substantial saving to the user because the cost per stick of the new product was much lower.

The only difference between the low-density ammonia dynamites and the semigelatins is that the latter are partially gelatinized through the use of nitrocellulose and a higher nitroglycerin content. This gelatinization provides good water resistance and a degree of plasticity that is desirable in loading holes prior to blasting.

Means are available to obtain a moderate amount of water resistance in the ammonia dynamites without resorting to gelatinization of the nitroglycerin. The most common involve the use of water-repellents such as calcium stearate, and ingredients that form a water gel on the surface of the dynamite that slows down the further penetration of water. Examples of the latter are pregelatinized starch products and rye flour.

**Low-freezing dynamite.** Attempts to reduce the freezing point of nitroglycerin began shortly after the Nobels introduced it commercially. Frozen dynamite is very insensitive, sometimes so much so that it will not give dependable performance, and it is difficult to use, since it cannot be punched for the insertion of a blasting cap or slit and tamped into a borehole. Consequently, almost all of it had to be thawed for use and careless thawing methods caused many accidents. Not until 1907 was a reasonably successful procedure for producing low-freezing dynamite developed. This involved adding 20 to 25 percent of the liquid isomers (molecules with identical formulas but different structure) of TNT to the nitroglycerin. This was replaced for a short time by a nitrated solution of sugar in glycerin. In 1911 a practical way to manufacture diglycerin (a glycerin polymer) was discovered. Its nitration product, tetranitrodiglycerin, when mixed with nitroglycerin, reduced its freezing point materially.

The ultimate solution to the freezing problem was found in 1925, when synthetic ethylene glycol became available. The explosive properties of ethylene glycol dinitrate are practically identical with those of nitroglycerin and its low-freezing qualities are extremely good. Dynamite containing a mixture of it and nitroglycerin was stored in the open at Point Barrow, Alaska, for four years without freezing.

Explosives used in underground mines

Synthetic ammonia and its products

Major tunnels blasted by explosives

## OTHER EXPLOSIVES

**Chlorates and perchlorates.** Interest in the chlorates and perchlorates (salts of chloric or perchloric acid) as a base for explosives dates back to 1788. They were mixed with various solid and liquid fuels. Many plants were built in Europe and the United States for the manufacture of this type of explosive, mostly using potassium chlorate, but so far as can be determined, all of them either blew up or burned up, and no chlorate explosives have been manufactured for many years.

**Sprengel explosives.** In England in 1871, Hermann Sprengel patented combinations of oxidizing agents such as chlorates, nitrates, and nitric acid with combustible substances such as nitronaphthalene, benzene, and nitrobenzene. These differed from previous explosives in that one of the ingredients was liquid and the mixture was made just prior to use. Sprengel explosives were quite popular in Europe but consumption in the United States was relatively small except for the spectacular Hell Gate blast in New York harbour in 1885, in which a combination of 75,000 pounds of No. 1 dynamite and 240,000 pounds of potassium chlorate-nitrobenzene were used to remove "Flood Rock," a menace to navigation. Cloth bags of the chlorate were soaked in the nitrobenzene and loaded directly from the soaking tank into the boreholes. The mixture was called Rack-a-rock.

**Liquid oxygen explosives.** In 1895 the German Carl von Linde (1842-1934) introduced carbon black packed in porous bags and dipped in liquid oxygen. This, which was a Sprengel-type explosive, came to be known as LOX. Because of the shortage of nitrates, LOX was widely used in Germany during World War I. Little if any was used in World War II, however, because ample supplies of nitrates could be obtained from synthetic ammonia.

Because the manufacture of liquid oxygen requires complicated and expensive equipment, the use of LOX was limited to areas that could consume very large quantities. In the United States several of the tremendous strip coal mines in the Midwest met this requirement. Maximum consumption of LOX explosive was 22,465,000 pounds in 1953, but it fell to zero in 1968. Cheap as LOX is, it cannot compete with ammonium nitrate-fuel oil mixtures.

**Nitrostarch explosives.** Nitrostarch, which is closely related to nitrocellulose, attracted early attention, but it was not until about 1905 that it proved possible to produce it in a stable form. In general nitrostarch explosives are similar to the straight and ammonia dynamites except that nitrostarch is used in place of nitroglycerin. Disadvantages are its relatively low strength, mediocre water resistance, and the fact that it cannot be transformed into gelatinous products. Nitrostarch explosives, however, do not produce the headaches from skin contact that are characteristic of mixtures containing nitroglycerin. For that reason they are still marketed.

**Nitramon and Nitramex explosives.** An important advance in explosives technology was the development by du Pont in 1934 of Nitramon, a canned product with a typical formula of 92 percent ammonium nitrate, 4 percent dinitrotoluene, and 4 percent paraffin wax. Some grades contain metallic ingredients such as aluminum and ferrosilicon. Nitramon is insensitive to the action of a line of detonating cord, a commercial blasting cap, shock and friction, or the impact of small-calibre ammunition. A large primer is required for its detonation and the one normally used is known as a Nitramon primer. This is also a canned product with Nitramon at each end but a centre section of amatol that can be detonated by either detonating cord or a blasting cap. The cans are provided in varying sizes. A minimum diameter of four inches for regular Nitramon is necessary to insure proper explosive effect if individual cans in a column become separated by some material such as a rock. Special grades are made for use in seismic exploration for gas and oil in 2- and 2½-inch diameters. In this case, however, the cans are threaded and intimate contact is assured because the column is screwed together.

Nitramex is similar to Nitramon but is much stronger because it contains TNT and a metallic ingredient such as

aluminum. Both it and Nitramon have been largely replaced by the water gels, which are described later.

So far as is known, the largest commercial, non-nuclear blast was made on April 5, 1958, in Seymour Narrows, which lies between Vancouver Island and the mainland of British Columbia. The object of the blast was to remove the top of a submerged twin-peak mountain, known as Ripple Rock, which was only 9 feet below the surface at low tide. More than 120 vessels had been lost because of this obstacle. In preparing for the blast, a shaft was sunk on shore to the proper depth. From it a tunnel was driven to a point directly under the twin peaks, from which a vertical shaft finally was driven to the desired depth below the peaks. A series of small horizontal drifts and pockets was prepared for placement of the explosives, consisting of 2,756,000 pounds (1,253,000 kilograms) of Nitramex 2H and a special primer, fired by means of detonating cord.

After the blast the top of the rock was a minimum of 50 feet below the surface and no longer a menace to navigation.

## MODERN HIGH EXPLOSIVES

The year 1955, marking the beginning of the most revolutionary change in the explosives industry since the invention of dynamite, saw the development of ammonium nitrate-fuel oil mixtures (ANFO) and ammonium nitrate-base water gels, which together now account for at least 70 percent of the high explosives consumption in the United States. The technology of these products is far more advanced in the U.S. than it is in other countries; so, at the present time, they have not replaced nearly as much of the older explosives in the rest of the world. In addition to a variety of packages, both ANFO and water gels are delivered in bulk by special trucks and loaded directly into boreholes.

**Ammonium nitrate-fuel oil mixtures.** In 1955 it was discovered that mixtures of ammonium nitrate and fine coal dust would give very satisfactory blasting results in the large (about 9-inch, 22.5-centimetre) holes used in open-pit coal mines to remove the rock and soil covering the coal. Polyethylene bags for this material both stretched to fill the holes and provided a moderate amount of water resistance.

Shortly thereafter, ANFO was extensively evaluated in the open-pit iron mines of Canada and the United States, with a high degree of success. From there ANFO spread to other open pits, such as copper, and to construction work such as road building and pipeline installation. It was then found that the mixture could be air blown into holes two inches (5 centimetres) in diameter, or even smaller, with excellent results. This led to its adoption in many underground mines.

ANFO applications were based on prilled rather than crystallized ammonium nitrate. Prills, or free-flowing pellets, were developed for the fertilizer market, which requires a coarse product that has little tendency to set and can be spread easily and smoothly. A small amount of kieselguhr is generally added to improve the flowing properties. Prills are made by allowing droplets of ammonium nitrate that is almost molten to fall freely from a high tower. When they reach the bottom, they are dry and solidified, and slightly porous, which allows them to absorb and hold a greater amount of oil and gives a more sensitive product. ANFO is almost universally prepared by mixing 94 percent of prills with 6 percent of No. 2 fuel oil. The latter imparts some water resistance and, if that is not enough, polyethylene bags can often be used to give the necessary protection.

**Water gels.** Water gels, or slurries, were introduced in 1958. These were, at first, mixtures of ammonium nitrate, TNT, water, and gelatinizing agents, usually guar gum and a cross-linking agent such as borax. (Cross-linking is a form of chemical bonding.) Later, aluminum and other metallic fuels were sometimes used and vastly better gelatinizers were discovered. In addition nonexplosive sensitizers were developed that could replace the TNT if desired. When the highest possible concentration of

Removal  
of a moun-  
tain top

Prills

strength is needed, however, large quantities of TNT are still used.

Water gels have many advantages. Among them are a high concentration of strength, a high degree of water resistance, plasticity that permits them to displace air or water and completely fill the borehole, economy, ease of handling and loading, and good safety characteristics. These advantages were quickly recognized. In 1968 the consumption of water gels in the United States alone was 206,000,000 pounds, over 10 percent of all the industrial explosives used there.

#### NITROCELLULOSIC EXPLOSIVES

When Christian Schoenbein invented nitrocotton (gun-cotton) in 1845 by dipping cotton in a mixture of nitric and sulfuric acids and then removing the acids by washing with water, he hoped to obtain a propellant for military weapons. It proved, however, to be too fast and violent. About 1860 Maj. E. Schultze of the Prussian Army produced a useful nitrocellulosic propellant. He nitrated small pieces of wood by placing them in nitric acid and then, after removing the acid, impregnated the pieces with barium and potassium nitrates. The purpose of the latter was to provide oxygen to burn the incompletely nitrated wood. Schultze's powder was highly successful in shotguns but was too fast for cannon or even most rifles.

In 1884 a French chemist, Paul Vieille, made the first smokeless powder as it is now known. He partially dissolved nitrocellulose in a mixture of ether and alcohol until it became a gelatinous mass, which he rolled into sheets and then cut into flakes. When the solvent evaporated, it left a hard, dense material resembling horn. This product gave satisfactory results in all types of guns.

In 1887 Nobel introduced another of his revolutionary inventions, which he called Ballistite. He mixed 40 percent of a lower nitrogen content, more soluble nitrocellulose and 60 percent of nitroglycerin. Cut into flakes, this made an excellent propellant and it continued in use for over 75 years. The British refused to recognize Nobel's patent and developed a number of similar products under the generic name cordite.

The progress of smokeless powder in the United States was much slower than it was in Europe. Long-continued work, principally by E.I. du Pont de Nemours & Company, finally resulted in a material that was excellent for guns of all types and sizes. It was first marketed about 1909 and was the most important type of smokeless powder used by the Allies in World War I. It was made from a nitrocotton of relatively low nitrogen content, called pyrocellulose, because that type is quite soluble in ether-alcohol. A small amount of diphenylamine was used as a stabilizer and, after forming the grains and removing the liquid, a coating of graphite was added. The smokeless powder most widely used in the United States at the present time is much the same. Other popular types are mostly double-base and may contain from about 20 to 35 percent nitroglycerin. Cotton linters for nitration have been almost, if not entirely, replaced by purified wood cellulose.

#### BLASTING CAPS

Nobel's original fuse-type blasting cap remained virtually unchanged for many years, except for the substitution of 90-10 and 80-20 mixtures of mercury fulminate and potassium chlorate for the pure fulminate. This did not affect the performance materially and provided a substantial economy. Mercury fulminate is an example of an explosive that can be both primary and secondary. In its more compressed form it is a high density base charge; less compressed, a low density primer charge. Hexanitro-mannitol (nitromannite) functions in the same manner and is used that way in a very successful blasting cap.

Extensive work was carried out on replacements for the costly mercury fulminate; by 1930 very little of it remained in use, and by the 1970s it had disappeared from commercial use. Experience has shown that the cheaper replacements are actually superior.

The dominant base-charge materials are now pentaerythritol tetranitrate (PETN) and cyclotrimethylenetrinitramine (RDX). These are as strong as nitroglycerin, quite safe to manufacture and handle, and relatively inexpensive. In addition to low density nitromannite, diazodinitrophenol, lead styphnate, and lead azide are widely used as ignition-primer charges. One other departure from Nobel's blasting cap is the fact that aluminum has now almost entirely replaced copper as the material used for the shell.

**Electrical firing.** The principal advantages of electric over fuse firing are exact control of the time when the blast is initiated, the simultaneous firing of a number of shots, if that is desired, and the ability to obtain a very high degree of water resistance. Attempts to make electric blasting caps date back to the 1700s, but nothing of a really practical nature was developed until late in the 19th century. There were two separate problems, the cap and the means to fire it.

**Blasting machines.** The first satisfactory electrical blasting machine was invented by H. Julius Smith, an American, in 1878. It comprised a gear-type arrangement of rack bar and pinion that operated an armature to generate electricity. When the rack bar was pushed down rapidly, it revolved the pinion and armature with sufficient speed to obtain the desired current. This current was released into the external, or cap, circuit when the rack bar struck a brass spring in the bottom of the machine. Smith's blasting machine was improved and made in a range of capacities; also, a small twist-type machine that employed basically the same principles was introduced. These machines are still in widespread use, although they have been replaced to a considerable extent by power firing, and capacitor-discharge blasting machines. The latter have a battery power source for energizing one or more capacitors and a safe, dependable means for discharging the stored energy. They have high capacity for their weight and size and are rapidly displacing the other firing systems.

**Ignition systems.** Except for the means of firing, there is little difference between electric and fuse-type blasting caps. With minor variations, the explosives used are the same.

It was in the 1880s that the forerunner of the modern electric blasting cap was first assembled. In contrast to the spark-type ignitions previously used, it employed a fine, high-resistance wire soldered between two insulated leg wires and embedded in, or coated with, an ignition mixture. The resistance wire was either platinum or one of its alloys, and the ignition mixture was based on mercury fulminate. The leg wires were insulated with two layers of cotton thread, wound in opposite directions. Except for coal-mine caps, the wire was then run through a bath of molten asphalt. Paraffin wax was used for the coal-mine caps because its white colour provided good contrast with the black coal. Sulfur, or a mixture of sulfur and mica or graphite, was used to hold the leg wires in place and seal the cap. Sulfur was well suited for this purpose because its melting point is very low and it is compatible with the explosive ingredients. Later, to obtain better water resistance, part of the sulfur was replaced by asphalt.

In 1939 the du Pont company introduced a revolutionary new type of ignition system. Nylon plastic was substituted for the cotton insulation, a rubber plug to hold the leg wires replaced the sulfur plug, and the bridge wire was welded to the leg wires instead of soldered. By that time alloys such as nichrome had largely replaced the platinum bridge wires. The shell was crimped tightly to the rubber plug, with the result that the cap would stand as much as 1,000 feet of water pressure. All electric blasting caps are now made substantially in this way. Polyvinyl chloride is widely used for the leg wire insulation and plastic is sometimes substituted for rubber in the plug.

Match-head ignition is very popular in Europe and is used by one manufacturer in this country. This consists of a piece of cardboard with a thin sheet of metal glued

Mercury  
fulminate

Introduc-  
tion of  
nylon  
insulation

to each side. A bridge wire is soldered to these sheets, around the end of the cardboard, and this part of the assembly is dipped in a slurry of ignition mixture, usually based on copper acetylide. After drying, the match head is given a protective coating and is then soldered to the leg wires.

Most countries require explosives in underground coal mines to be fired electrically but prohibit the use of aluminum-shell electric blasting caps. This is because aluminum burns with a very hot flame and is much more likely than copper to ignite coal gas. Otherwise, almost all electric blasting-cap shells are made of aluminum.

**Delay systems.** Delay, or rotational, shooting, has many advantages over instantaneous firing in almost all types of blasting. It generally gives better fragmentation, more efficient use of the explosive, reduced vibration and concussion, and better control of the rock. For these, and sometimes other reasons, most blasting operations are now conducted with a delay system.

It is probable that the first use of delay firing was in tunnels. The centre was shot out first and then successive rings around it until the desired tunnel dimensions were reached. The procedure was to cut all of the fuses to the same length and then trim them toward the centre; for example, the outside ring of fuses would be full length, the next ring a few inches shorter, and so on. Each cut was about  $\frac{1}{2}$  inch per foot of fuse (that is, a 3-inch cut for a 6-foot fuse, etc.). In addition, the fuses were lit from the centre out, causing a little more delay in the desired direction. This method of shooting could not be used until Bickford's safety fuse, which had a very uniform burning speed, became available.

Delay electric blasting caps are the most commonly used means for obtaining rotational firing. They are of two types: (1) the so-called regular delay, which has been in use since the early 1900s; and (2) the short-interval, or millisecond, delay, which was introduced about 1943. Except for a delay element placed between the ignition and primer charges, they are the same as instantaneous electric caps.

A typical series of regular delays would comprise 14 periods ranging from a few milliseconds to about 12 seconds. To avoid overlapping and because there is some variation in the burning speed of the delay element, the intervals are made longer in the higher periods; for example, the delay between periods 1 and 2 might be 0.8 seconds, whereas for 13 and 14 it might be 1.5 seconds. Ordinary delays have been largely replaced by short-interval delays but are still used to a considerable extent for such purposes as driving tunnels and sinking shafts.

The periods in short-interval delays are usually separated by 25 milliseconds up to 200 milliseconds, by 50 up to 500, and by 100 up to 1,000 (one second). This close spacing gives improved fragmentation, the ability to fire many holes with hardly any more vibration or concussion than would be obtained with one hole, less chance that the detonation of one hole will cut off an adjacent hole, and a reduction in the quantity and cost of explosives. Short-interval delays are used above ground in such work as excavating and quarrying, and for almost all types of underground mining. Their acceptance has been phenomenal and their development one of the major advances in explosives.

Delay elements for electric blasting caps function in about the same way as black powder in safety fuse, except that the chemical mixtures used are much faster. At times the delay mixture is simply pressed on top of the primer mix. Usually, however, it is put in the centre of a metallic tube in lengths that will give the desired delay interval.

#### DETONATING CORD

Detonating cord (detonating fuse) resembles safety fuse but contains a high explosive instead of black powder. The first successful one, patented in France in 1908, consisted of a lead tube, about the same diameter as safety fuse, filled with a core of TNT. It was made by filling a large tube with molten TNT that was allowed to solidify.

The tube was then passed through successively smaller rolls until it reached the specified diameter. In France the product was called *cordeau détonant*, elsewhere shortened to cordeau. Its velocity was about 16,000 feet per second.

Cordeaux

In 1936 the Ensign-Bickford Company, Simsbury, Connecticut, the American manufacturers of cordeau, developed Primacord, based on French patents and comprising a core of PETN covered with various combinations of textiles, waterproofing materials, and plastics. The velocity is approximately 21,000 feet per second. Many types of Primacord are available, for both military and commercial use, but the industrial varieties generally contain from 25 to 60 grains of PETN per foot. RDX is sometimes used in place of PETN for high temperatures, because the melting points are, respectively, 398.3° and 284° F (203.5° and 140° C).

Detonating cord has many applications in blasting. Any number of holes can be connected with it in just about any desired pattern. Attached to the blasting charge and knotted to a trunk line, it is fired by means of either a fuse-type or electric blasting cap. Sequential shooting may be obtained by cutting the trunk lines and inserting delay connectors, which have delay periods ranging from about 5 to 25 milliseconds.

#### MILITARY EXPLOSIVES

Military requirements for high explosives differ in many respects from those for commercial users. Military explosives must have insensitivity to shock and friction and must be unlikely to detonate from small-arms fire and yet have excellent shattering power. They must have the ability to withstand long periods of adverse storage without deterioration and must be able to be fired in projectiles or dropped in aerial time bombs without premature explosion. Some types are required to possess almost unlimited water resistance. Many types must have complex fuzes for detonation.

**TNT.** Trinitrotoluene (TNT) is the most useful military high explosive. Although it had been known for many years and was used extensively in the dye industry, it was not employed as an explosive until 1904. It is an excellent military explosive in itself, but its most valuable property is that it can be safely melted and cast either alone or as a slurry with other explosives. This is because there is a wide spread between its melting point and its decomposition temperature.

It has two shortcomings: first, it is extremely insensitive in the cast form, and second, it is difficult to cast without air holes. The first problem can be overcome by drilling a hole, about 1 inch (2.5 centimetres) in diameter, the length of the charge in the shell and filling it with trinitrophenylmethyl nitramine (tetryl); the second, by using a mixture of 40 percent trinitroxylen (TNX) and 60 percent TNT. This mixture not only casts perfectly but can be detonated with a smaller tetryl booster. There is no indication that any TNX was used in World War II; it is believed to have been replaced by PETN and RDX.

**Picric acid and ammonium picrate.** Picric acid was used as a shell explosive in Europe during the 1880s and carried through World War I on a very large scale. Quantities of it were made in the United States but the Army and Navy used mainly TNT.

Ammonium picrate (Explosive D) has exceptional value as a charge for armour-piercing projectiles. Loaded in a shell with a suitably insensitive primer, it can be fired through 12 inches of armour plate and made to detonate on the far side. These armour-piercing shells were used in both World Wars.

Early in World War I it was found that mixtures of molten TNT and ammonium nitrate were almost as effective for shell loadings as pure TNT. The mixtures most commonly used were 80-20 and 50-50 AN and TNT, known as amatol. Their principal advantages were that they made the supply of TNT go further and were considerably cheaper. In World War II the amatols were used in aerial bombs as well as artillery shells.

To conserve TNT in World War I, a nitrostarch-base

Amatol

Types of  
delay caps

composition was also developed for loading hand grenades and trench-mortar shells.

Several explosives, although previously known, only came into use during World War II. The most important of these were RDX, PETN, and ethylenediaminedinitrate (EDNA), all of which were cast with varying amounts of TNT, usually 40 to 50 percent, and used where the highest possible shattering power was desired. For example, cast 60–40 RDX-TNT, called cyclotol, develops a detonation pressure of about 4,000,000 pounds per square inch. Corresponding mixtures of PETN and TNT have almost as much shattering effect. The EDNA mixtures, or ednatol, were used only to a limited extent and for special purposes. Probably the most powerful of all nonatomic military explosives are the cast mixtures containing aluminum. The torpedo warhead torpex, for example, is a cast mixture of RDX, TNT, and aluminum.

A series of plastic demolition explosives with great shattering power, designated Composition C-1 to Composition C-4, has had considerable publicity. These contain about 80 percent RDX combined with a mixture of various oils, waxes, and plasticizers. The only significant difference is in the temperature range through which they remain useful. C-3 stays plastic to  $-20^{\circ}\text{F}$  ( $-29^{\circ}\text{C}$ ) and does not exude oil below  $120^{\circ}\text{F}$  ( $49^{\circ}\text{C}$ ). In contrast, C-4 remains plastic to  $-70^{\circ}\text{F}$  ( $-57^{\circ}\text{C}$ ) and does not leak below  $170^{\circ}\text{F}$  ( $77^{\circ}\text{C}$ ).

**Shaped charges.** The shaped charge, principally the hand-fired rocket, is another highly publicized product introduced during World War II. A shaped charge normally consists of a cone made of metal or glass surrounded by a high strength, high density explosive and means to obtain the proper standoff, or distance to the target.

When the explosive is detonated, the cone is collapsed and vaporized, forming a small, high-temperature jet containing particles of liner material moving at 10,000 to 30,000 feet per second. This strikes the target with such heat and force that the target simply flows radially from the point of impact leaving a deep, nearly round hole. Spectacular as the results are, only about 15 percent of the explosive energy is focussed.

Only two commercial applications have been found for shaped charges. One is for drawing off molten iron or slag from open hearth and blast furnaces in the steel industry, and the other for perforating casings in the oil industry. In the first case, the principal advantage is safety as compared with oxygen lancing. In the second, shaped charges are almost always more efficient than the bullets they replace.

#### OTHER INDUSTRIAL APPLICATIONS

**Explosive rivets.** Blind rivets are needed when space limitations make conventional rivets impractical. One type of these is explosive; it has a hollow space in the shank containing a small charge of heat-sensitive chemicals. When a suitable amount of heat is applied to the head, an explosion takes place and expands the rivet shank tightly into the hole. The shank is normally open but can be sealed to eliminate noise and the ejection of metal fragments. Most explosive rivets are aluminum but they can be obtained in stainless steel and certain other metals. Their use is mainly in aircraft.

**Explosive bonding.** Explosives are sometimes used to bond various metals to each other. For example, when silver was removed from United States coinage, much of the so-called sandwich metal that replaced it was obtained by the explosive bonding of large slabs, which were then rolled down to the required thickness. These slabs are placed parallel to each other and approximately  $\frac{1}{4}$  inch apart. An explosive developed especially for the purpose is placed on the top slab and its detonation slams the slabs together with such force that they become welded. Stainless steel is often joined to ordinary steel in this manner. One especially valuable feature of explosion cladding is that it can frequently be applied to metallurgically incompatible metals. Examples of this are aluminum to steel and titanium to steel.

Finally, the very fine industrial-type diamonds used for grinding and polishing are produced by the carefully controlled action of explosives on carbon.

**BIBLIOGRAPHY.** A.P. VAN GELDER and H. SCHLATTER, *History of the Explosives Industry in America* (1927), a highly detailed book covering the origin and development of all explosives of any importance throughout the world up to the date of its publication; M.A. COOK, *The Science of High Explosives* (1958), an advanced mathematical work devoted almost exclusively to theory, with a brief, interesting section on the history of explosives; C.H. JOHANSSON and P.A. PERSSON, *Detonics of High Explosives* (1970), an outstanding book describing the behaviour of high explosives, with emphasis on experimental data; E.I. DU PONT DE NEMOURS AND COMPANY, INC., *Blasters' Handbook*, 15th ed. (1969), a practical discussion of commercial blasting; INSTITUTE OF MAKERS OF EXPLOSIVES, "Safety in the Transportation, Storage, Handling and Use of Explosives" (1970), a pamphlet primarily designed for the guidance of the consumer; T.L. URBANSKI, *Chemistry and Technology of Explosives*, 3 vol. (1967), an excellent treatment of these subjects, highly recommended; N.B. WILKINSON, *Explosives in History: The Story of Black Powder* (1966), a popular account, written primarily as a science supplement for high school students; U.S. BUREAU OF MINES, *Apparent Consumption of Industrial Explosives and Blasting Agents in the United States* (annual).

(N.G.J.)

## Eyck, Jan and Hubert van

Two 15th-century painters surnamed van Eyck, presumably after their birthplace in the Belgian village of Maa-seik, are, respectively, the most renowned and the most perplexing artists of their era. The life of Jan van Eyck is well documented, and more than 18 works securely attributed to him survive. For Hubert van Eyck, on the other hand, there are only a few ambiguous documents and no authenticated painting, and, were it not for his association with Jan, he certainly would have remained an obscure archive note.

Jan van Eyck must have been born before 1395, for in October 1422 he is recorded as the *varlet de chambre et peintre* ("honorary equerry and painter") of John of Bavaria, count of Holland. He continued to work in the palace of The Hague until the Count's death in 1425 and then settled briefly in Bruges before he was summoned, that summer, to Lille to serve Philip the Good, duke of Burgundy, the most powerful ruler and foremost patron of the arts in Flanders. Jan remained in the Duke's employ until his death, performing for him the duties of not only court painter but also diplomatic envoy. On behalf of his sponsor he undertook a number of secret missions during the next decade, of which the most notable were two journeys to the Iberian peninsula, the first in 1427 to try to contract a marriage for Philip with Isabella of Spain and a more successful trip between 1428 and 1429 to seek the hand of Isabella of Portugal. As a confidant of Philip the Good, Jan may have participated directly in these marriage negotiations, but he also was charged to present the Duke with a portrait of the intended. In 1431 Jan purchased a house in Bruges and about the same time he married a lady named Margaret, about whom little more is known than that she was born in 1406 and was to bear him at least two children. Jan's frank portrait of his wife is the most complete document of her life that remains. Residing now in Bruges, Jan continued to paint, and in 1436 he again made a secret voyage for Philip. He died shortly before July 9, 1441, and was buried in the church of Saint-Donatian, in Bruges.

Securely attributed paintings survive only from the last decade of Jan's career; therefore, his artistic origins and early development must be deduced from his mature work. Traditionally, Jan has been acclaimed the founder of Flemish painting, and scholars have sought his artistic roots in the last great phase of medieval manuscript illumination. It is clear that the naturalism and elegant compositions of Jan's later painting owe much to such early 15th-century illuminators as the anonymous Boucicaut Master and Pol, Herman, and Jehanequin de Limburg (the "Limburg Brothers"), who worked for the Bur-

artistic  
formation

gundian dukes, including the grandfather of Philip the Good and his illustrious granduncle, Jean, duc de Berry. A document of 1439 reports that Jan van Eyck paid an illuminator for preparing a book for the Duke; but central to the discussion of his ties to manuscript illustration has been the attribution to Jan of several miniatures, identified as Hand G, in a problematic prayer book known as the Turin-Milan Hours (Museo Civico, Turin). So long as these "Eyckian" miniatures were dated in the 1420s or even earlier, their authorship by Jan seemed indubitable; but recent investigations and manuscript discoveries strongly indicate that these miniatures were painted at least 20 years later and, hence, that they are by an imitator of the great master. With the elimination of the Turin-Milan Hours from Jan van Eyck's early *oeuvre*, his connections with International Gothic style illumination appear to have been less direct.

Certainly as important for Jan's artistic formation were the panel paintings of Robert Campin (c. 1378–1444), a Tournai painter whose important role in the history of Flemish art has only recently been re-established. Jan must have met Campin at least once—when he was feted by the Tournai painter's guild in 1427; and from Campin's art he seems to have learned the bold realism, the method of disguised symbolism, and perhaps the luminous oil technique that became so characteristic of his own style. In contrast to Campin, who was a Tournai burgher, Jan was a learned master at work in a busy court, and he signed his paintings, the first Flemish artist to do so. The majority of Jan's panels present the proud inscription: IOHANNES DE EYCK, and several bear his aristocratic motto, "*Als ich chan*" ("As best I can"). It is small wonder, therefore, that Campin's reputation faded and his influence on Jan was forgotten; nor is it surprising that many of Campin's artistic achievements were credited to the younger master whose fame remained undiminished.

Despite the fact that nine paintings by Jan van Eyck are signed and ten are dated, the establishment of his *oeuvre* and the reconstruction of its chronology present problems. The major difficulty is that Jan's masterpiece, the "Adoration of the Lamb" altarpiece in the Cathedral of Saint-Bavon in Ghent, has a wholly questionable inscription that introduces Hubert van Eyck as its principal master. This has caused art historians to turn to less ambitious but more secure works to plot Jan's development, including, most notably: the "Portrait of a Young Man" ("Leal Souvenir") of 1432, "The Marriage of Giovanni Arnolfini and Giovanna Cenami (?) of 1434, the "Madonna With Canon van der Paele" of 1434–36, the triptych "Madonna and Child with Saints" of 1437, and the panels of "St. Barbara" and the "Madonna at the Fountain," dated, respectively, 1437 and 1439. Although they fall within a brief span of seven years, these paintings present a consistent development in which Jan moved from the heavy, sculptural realism associated with Robert Campin to a more delicate, rather precious pictorial style.

On stylistic grounds there seems little difficulty in placing the "Ghent Altarpiece" at the head of this development as indicated by the date 1432 in the inscription, but the question of Hubert's participation in this great work has yet to be resolved. The inscription itself is definite about this point: "The painter Hubert van Eyck, greater than whom no one was found, began [this work]; and Jan, his brother, second in art [carried] through the task . . ." On the basis of this claim, art historians have attempted to distinguish Hubert's contribution to the "Ghent Altarpiece" and have even assigned to him certain of the more archaic "Eyckian" paintings, including "The Annunciation" (Metropolitan Museum of Art, New York) and "The Three Marys at the Tomb" (Museum Boymans-van Beuningen, Rotterdam). A problem arises, however, because the inscription itself is a 16th-century transcription and earlier references make no mention of Hubert's part in the "Ghent Altarpiece." The great 16th-century German artist Albrecht Dürer, for instance, praised only Jan van Eyck during his visit to Ghent in 1521; and as late as 1562 the Flemish historian Marcus

van Vaernewyck referred to Jan alone as the author of the altarpiece. Furthermore, a recent philological study casts serious doubt on the dependability of the inscription, which scans more smoothly when the phrase naming Hubert is dropped. Thus, Hubert's participation in the Ghent polyptych is highly suspect, and any knowledge of his art must await new discoveries.

On the other hand, there is little doubt that Hubert did exist, the dubious reference to him on the "Ghent Altarpiece" aside. A "meester Hubrecht de scildere" (Master Hubert, the painter) is mentioned three times in the City Archives of Ghent; and a transcription of his epitaph reports that he died on September 18, 1426. Whether this Hubert van Eyck was related to Jan and why in the 16th century he was credited with the major share of the "Ghent Altarpiece" are questions that remain unanswered.

The confusion concerning his relationship to Hubert, the doubt about his activities as an illuminator, and the re-emergence of Robert Campin as a pre-eminent master do not diminish the achievement and significance of Jan van Eyck. He may not have invented painting with oils as early writers asserted; but he perfected the technique to mirror the textures, light, and spatial effects of nature. The realism of his paintings—admired as early as 1449 by the Italian humanist Cyriacus D'Ancona, who observed that the works seemed to have been produced "not by the artifice of human hands but by all-bearing nature herself"—has never been surpassed. For Jan, as for Campin, naturalism was not merely a technical tour de force, however. For him, nature embodied God, and so he filled his paintings with religious symbols disguised as everyday objects. Even the light that so naturally illuminates Jan van Eyck's landscapes and interiors is a metaphor of the Divine.

Because of the refinement of his technique and the abstruseness of his symbolic programs, the successors of Jan van Eyck borrowed only selectively from his art. Campin's foremost student, Rogier van der Weyden, tempered his master's homey realism with Eyckian grace and delicacy; in fact, at the end of his career, Campin himself succumbed somewhat to Jan's courtly style. Even Petrus Christus, who may have been apprenticed in Jan's atelier and who finished the "Virgin and Child, with Saints and Donor" (Frick Collection, New York) after Jan's death, quickly abandoned the intricacies of Jan's style under the influence of Rogier. During the last third of the century, the Netherlandish painters Hugo van der Goes and Justus van Gent revived the Eyckian heritage; but, when such early 16th-century Flemish masters as Quentin Massys and Jan Mabuse turned to Jan's work, they produced pious copies that had little impact on their original creations. In Germany and France the influence of Jan van Eyck was overshadowed by the more accessible styles of Campin and Rogier, and only in the Iberian peninsula—which Jan had visited twice—did his art dominate. In Italy his greatness was recognized by Cyriacus and by the humanist Bartolomeo Facio, who lists Jan, together with Rogier and the Italian artists Pisanello and Gentile da Fabriano, as one of the leading painters of the period. But Renaissance artists, as painters elsewhere, found him easier to admire than to imitate.

Interest in his painting and acknowledgment of his prodigious technical accomplishment have remained high. Jan's works have been copied frequently and have been avidly collected. He is referred to in the Treaty of Versailles, which specifies the return of the "Ghent Altarpiece" to Belgium before peace with Germany could be concluded after the end of World War I.

#### MAJOR WORKS

RELIGIOUS PAINTINGS: "The Adoration of the Lamb" ("Ghent Altarpiece," 1432; Cathedral of Saint-Bavon, Ghent); "The Annunciation" (c. 1434; National Gallery of Art, Washington, D.C.); "Madonna with Canon van der Paele" (1434–36; Groninger Museum, Brugge); "The Lucca Madonna" (c. 1435–36; Städtisches Kunstinstitut, Frankfurt); "Madonna with Chancellor Rolin" (c. 1436; Louvre, Paris); "St. Barbara" (1437; Musée Royal des Beaux-Arts, Antwerp); "Triptych" (1437; Gemäldegalerie, Dresden); "Annunciation" (undated; Thyssen-Bornemisza Collection,

Hubert's participation in the Ghent altarpiece

Influence of Jan's style

Castagnola, Switz.); "Madonna at the Fountain" (1439; Musée Royal des Beaux-Arts, Antwerp).

PORTRAITS: "Portrait of a Young Man" ("Leal Souvenir," 1432; National Gallery, London); "A Man in a Turban" (c. 1433; National Gallery, London); "The Marriage of Giovanni Arnolfini and Giovanna Cenami (?)" (1434; National Gallery, London); "Cardinal Albergati" (c. 1435; Kunsthistorisches Museum, Vienna); "The Goldsmith Jan de Leeuwe" (1436; Kunsthistorisches Museum, Vienna); "Portrait of Baulduyn de Lannoy" (c. 1436-37; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Margaret van Eyck" (1439; Groeninge Museum, Brugge).

**BIBLIOGRAPHY.** Two monographs, the early study by W.H.J. WEALE, *Hubert and John van Eyck: Their Life and Work* (1908), indispensable for its documentary material; and the more recent volume by LUDWIG BALDASS, *Jan van Eyck* (1952), present basic surveys of the careers and art of the van Eyck brothers. A catalogue raisonné, which includes all attributed works and copies, is available in vol. 1 of M.J. FRIEDLANDER, *Early Netherlandish Painting* (1967), a translation from the German, updated in notes. The fundamental study of the entire period, ERWIN PANOFKY, *Early Netherlandish Painting* (1953), considers Jan and Hubert van Eyck in great detail. Although Panofsky's attributions and chronology must be modified, his iconographic interpretations remain essential to an understanding of Eyckian painting. The technical examination of the Ghent Altarpiece inscription by A. AMPE, "De metamorfozen van het authentieke Jan-Van-Eyck-kwatrijn op het Lam Gods," *Jaarboek van het Museum voor Schone Kunsten-Antwerpen* (1969), with English summary, introduces serious questions about the role of Hubert van Eyck.

(H.L.Ke.)

## Eye and Vision, Human

The eye is the organ through which man acquires knowledge of his environment by virtue of the light reflected from, or emitted by, the objects within the environment; it is the photoreceptor organ that, together with other types of receptors, allows the organism to react to, and to understand, the world around it. For man, the information provided by the eyes undoubtedly plays the dominant role in the interpretation of his environment; and one might, at first thought, expect to find man's visual apparatus more highly developed than that of lower animals. Thus, the dog seems to have poor vision compared with man, relying on his sense of smell to recognize objects rather than on his eyes. Examination of the respective eyes, however, fails to reveal differences of such magnitude as to suggest any fundamental inferiority on the part of the dog. Such an expectation of inferiority would, moreover, reveal a rather naïve approach to the study of vision, which does not merely consist in "seeing" but also in understanding; the dog's eye may well focus as accurate an image on its light-sensitive retina as does the human eye, but the power to integrate this image—to recognize its contours, its colours, and its relation to other objects, its probable feeling in response to touch, its motion, and so on—depends on the way the light-sensitive receptive cells are connected to the central nervous system; of this system the eye, as a whole, forms an integral part, being, in fact, an outgrowth of the forebrain. Similarly, the power to use visual information to govern bodily movements, so important to man in the execution of skilled tasks, and of vital importance to, for example, the swallow catching midges in flight, depends in great measure on the linking of the visual information with the motor centres of the brain. Thus the scope of this article, if it is to cover the true extent of the function of the human eye, must be wide; it must cover not only the manner in which the light from an external object is focussed as an image on the body's "photographic plate," the retina, but also the manner in which this light is converted into a message, and how this message is interpreted.

In general, sensory organs develop around a layer of nerve cells (neuroepithelium) that acquires a special sensitivity to one form of physical stimulus; with the eye, the light-sensitive layer must be accessible to light, and this means either having the layer on the surface of the body, as in lower forms of life, or having it deeper in the body and allowing light to reach it through a transparent cornea. The human eye, and that of all vertebrates, is

built on this plan. The light-sensitive layer is in the retina, lining the rear wall of the globe, or eyeball.

This article is divided into the following sections:

- Anatomy of the visual apparatus
  - Structures auxiliary to the eye
    - The orbit
    - The eyelids
    - The glandular apparatus
    - Extraocular muscles
  - The eye
    - General description
    - Outer and middle tunics of the globe
    - The inner tunic of the globe
    - The transparent media
  - The visual process
    - The work of the auxiliary structures
      - The protective mechanisms
      - Movements of the eyes
    - The work of the optical lens system
      - Refraction by cornea and lens
      - Normal sightedness and near- and farsightedness
      - Accommodation
      - The pupil
      - The near response
    - The work of the retina
      - Some basic facts of vision
      - Synaptic organization of the retina
      - Absolute threshold and minimum stimulus for vision
      - Inhibition
      - Flicker
      - Visual acuity
      - Electrophysiology of the retina
      - Colour vision
      - The photochemical process
    - The higher visual centres
      - The visual pathway
      - Integration of the retinal halves
    - Some perceptual aspects of vision
      - Projection of the retina
      - Visual estimates
      - The perception of depth
      - Retinal rivalry
    - Electrophysiology of the visual centres
      - Ganglion cells
      - Geniculate neurons
      - Cortical neurons
      - Stereoscopic vision

## Anatomy of the visual apparatus

### STRUCTURES AUXILIARY TO THE EYE

**The orbit.** The eye is protected from mechanical injury by being enclosed in a socket, or orbit, which is made up of portions of several of the bones of the skull to form a four-sided pyramid the apex of which points back into the head. Thus, the floor of the orbit is made up of parts of the maxilla, zygomatic, and palatine bones, while the roof is made up of the orbital plate of the frontal bone and, behind this, by the lesser wing of the sphenoid. The optic foramen, the opening through which the optic nerve runs back into the brain and the large ophthalmic artery enters the orbit, is at the nasal side of the apex; the superior orbital fissure is a larger hole through which pass large veins and nerves. These nerves may carry nonvisual sensory messages—e.g., pain—or they may be motor nerves controlling the muscles of the eye. There are other fissures and canals transmitting nerves and blood vessels. The eyeball and its functional muscles are surrounded by a layer of orbital fat that acts much like a cushion, permitting a smooth rotation of the eyeball about a virtually fixed point, the centre of rotation. The protrusion of the eyeballs—proptosis—in exophthalmic goitre is caused by the collection of fluid in the orbital fatty tissue.

**The eyelids.** It is vitally important that the front surface of the eyeball, the cornea, remain moist. This is achieved by the eyelids, which during waking hours sweep the secretions of the lacrimal apparatus and other glands over the surface at regular intervals and which during sleep cover the eyes and prevent evaporation. The lids have the additional function of preventing injuries from foreign bodies, through the operation of the blink reflex. The lids are essentially folds of flesh covering the front of the orbit and, when the eye is open, leaving an almond-shaped aperture. The points of the almond are

The layers in the lids

called canthi; that nearest the nose is the inner canthus, and the other is the outer canthus (Figure 1). The lid may be divided into four layers: (1) the skin, containing glands that open onto the surface of the lid margin, and the eyelashes; (2) a muscular layer containing principally the orbicularis oculi muscle, responsible for lid closure; (3) a fibrous layer that gives the lid its mechanical stability, its principal portions being the tarsal plates, one in each lid, which border directly upon the opening between the lids, called the palpebral aperture; and (4) the innermost layer of the lid, a portion of the conjunctiva. The conjunctiva is a mucous membrane that serves to attach the eyeball to the orbit and lids but permits a considerable degree of rotation of the eyeball in the orbit.

*The conjunctiva.* The conjunctiva lines the lids and then bends back over the surface of the eyeball, constituting an outer covering to the forward part of this and terminating at the transparent region of the eye, the cornea. The portion that lines the lids is called the palpebral portion of the conjunctiva; the portion covering the white of the eyeball is called the bulbar conjunctiva. Between the bulbar and the palpebral conjunctiva there are two loose, redundant portions forming recesses that project back toward the equator of the globe. These recesses are called the upper and lower fornices, or conjunctival sacs; it is the looseness of the conjunctiva at these points that makes movements of lids and eyeball possible. (The ophthalmologist finds the lower conjunctival sac a useful cavity in which to place drops containing drugs by merely pulling the outer lid away from the globe. The drops are retained in the cavity long enough to act directly on the cornea and to diffuse through this into the internal structures of the eye.)

*The fibrous layer.* The fibrous layer, which gives the lid its mechanical stability, is made up of the thick, and relatively rigid, tarsal plates, bordering directly on the palpebral aperture, and the much thinner palpebral fascia, or sheet of connective tissue; the two together are called the septum orbitale. When the lids are closed, the whole opening of the orbit is covered by this septum. Two ligaments, the medial and lateral palpebral ligaments, attached to the orbit and to the septum orbitale, stabilize the position of the lids in relation to the globe. The medial ligament, by far the stronger, is well illustrated in Figure 1.

*The muscles.* Closure of the lids is achieved by contraction of the orbicularis muscle, a single oval sheet of muscle extending from the regions of the forehead and face and surrounding the orbit into the lids. It is divided into orbital and palpebral portions, and it is essentially the palpebral portion, within the lid, that causes lid closure. The palpebral portion passes across the lids from a ligament called the medial palpebral ligament and from the neighbouring bone of the orbit in a series of half ellipses that meet outside the outer corner of the eye, the

lateral canthus, to form a band of fibres called the lateral palpebral raphe. Additional parts of the orbicularis have been given separate names—namely, Horner's muscle and the muscle of Riolan; they come into close relation with the lacrimal apparatus and assist in drainage of the tears. The muscle of Riolan, lying close to the lid margins, doubtless contributes to keeping the lids in close apposition, an important feature for maintaining the junction watertight. The orbital portion of the orbicularis is not normally concerned with blinking, which may be carried out entirely by the palpebral portion; however, it is concerned with closing the eyes tightly. The skin of the forehead, temple, and cheek is then drawn toward the medial (nose) side of the orbit, and the radiating furrows, formed by this action of the orbital portion, eventually lead to the so-called crow's feet of elderly persons. It must be appreciated that the two portions can be activated independently; thus, the orbital portion may contract, causing a furrowing of the brows that reduces the amount of light entering from above, while the palpebral portion remains relaxed and allows the eyes to remain open.

Opening of the eye is not just the result of passive relaxation of the orbicularis muscle but also is the effect of the contraction of the levator palpebrae superioris muscle of the upper lid. This muscle takes origin with the extraocular muscles at the apex of the orbit (the back of the eye socket) as a narrow tendon and runs forward into the upper lid as a broad tendon, the levator aponeurosis, which is attached to the forward surface of the tarsus and the skin covering the upper lid. Contraction of the muscle causes elevation of the upper eyelid. The nervous connections of this muscle are closely related to those of the extraocular muscle required to elevate the eye, so that when the eye looks upward the upper eyelid tends to move up in unison.

The orbicularis and levator are striped muscles under voluntary control. The lids contain, in addition, unstriped (involuntary) muscle fibres that are activated by the sympathetic division of the autonomic system and tend to widen the palpebral fissure (the eye opening) by elevation of the upper, and depression of the lower, lid.

In addition to the muscles already described, other facial muscles often cooperate in the act of lid closure or opening. Thus, the corrugator supercilii muscles pull the eyebrows toward the bridge of the nose, making a projecting "roof" over the medial angle of the eye and producing characteristic furrows in the forehead; the roof is used primarily to protect the eye from the glare of the sun. The pyramidalis, or procerus, muscles occupy the bridge of the nose; they arise from the lower portion of the nasal bones and are attached to the skin of the lower part of the forehead on either side of the midline; they pull the skin into transverse furrows. In lid opening, the frontalis muscle, arising high on the forehead, midway between the coronal suture, a seam across the top of the skull, and the orbital margin, is attached to the skin of the eyebrows. Contraction therefore causes the eyebrows to rise and opposes the action of the orbital portion of the orbicularis; the muscle is especially used when one gazes upward. It is also brought into action when vision is rendered difficult either by distance or the absence of sufficient light.

*The skin.* The outermost layer of the lid is the skin, with features not greatly different from skin on the rest of the body, with the possible exception of large pigment cells, which, although found elsewhere, are much more numerous in the skin of the lids. The cells may wander, and it is these movements of the pigment cells that determine the changes in coloration seen in some people with alterations in health. The skin has sweat glands and hairs. As the junction between skin and conjunctiva is approached, the hairs change their character to become eyelashes (Figure 2).

*The glandular apparatus.* The eye is kept moist by secretions of the lacrimal glands (tear glands). These almond-shaped glands under the upper lids extend inward from the outer corner of each eye. Each gland has two portions. One portion is in a shallow depression in the

Horner's muscle and the muscle of Riolan

Tear glands

part of the eye socket formed by the frontal bone. The other portion projects into the back part of the upper lid. The ducts from each gland, three to 12 in number, open into the superior conjunctival fornix, or sac. From the fornix, the tears flow down across the eye and into the puncta lacrimalia, small openings at the margin of each eyelid near its inner corner. The puncta are openings into the lacrimal ducts; these carry the tears into the lacrimal sacs, the dilated upper ends of the nasolacrimal ducts, which carry the tears into the nose.

The evaporation of the tears as they flow across the eye is largely prevented by the secretion of oily and mucous material by other glands. Thus, the meibomian, or tarsal glands, consist of a row of elongated glands extending through the tarsal plates; they secrete an oil that emerges onto the surface of the lid margin and acts as a barrier for the tear fluid, which accumulates in the grooves between the eyeball and the lid barriers.

**Extraocular muscles.** Six muscles outside the eye govern its movements. These muscles are the four rectus muscles—the inferior, medial, lateral, and superior recti—and the superior and inferior oblique muscles. The rectus muscles arise from a fibrous ring that encircles the optic nerve at the optic foramen, the opening through which the nerve passes, and are attached to the sclera, the opaque portion of the eyeball, in front of the equator, or widest part, of the eye. The superior oblique muscle arises near the rim of the optic foramen and somewhat nearer the nose than the origin of the rectus medialis. It ends in a rounded tendon that passes through a fibrous ring, the trochlea, that is attached to the frontal bone. The trochlea acts as a pulley. The tendon is attached to the sclera back of the equator of the eye (Figure 3).

The inferior oblique muscle originates from the floor of the orbit, passes under the eyeball like a sling, and is attached to the sclera between the attachments of the su-

perior and lateral rectus muscles. The rectus muscles direct the gaze upward and downward and from side to side. The inferior oblique muscle tends to direct the eye upward, and the superior oblique to depress the eye; because of the obliqueness of the pull, each causes the eye to roll, and in an opposite direction.

The oblique muscles are strictly antagonistic to each other, but they work with the vertical rectus muscles in so far as the superior rectus and inferior oblique both tend to elevate the gaze and the inferior rectus and superior oblique both tend to depress the gaze. The superior and inferior recti do not produce a pure action of elevation or depression because their plane of action is not exactly vertical; in consequence, as with the obliques, they cause some degree of rolling, but by no means so great as that caused by the obliques; the direction of rolling caused by the rectus muscle is opposite to that of its synergistic oblique; the superior rectus causes the eye to roll inward, and the inferior oblique outward.

## THE EYE

**General description.** The eyeball is not a simple sphere but can be viewed as the result of fusing a small portion of a small, strongly curved sphere with a large portion of a large, not so strongly curved sphere (Figure 4). The small piece, occupying about one-sixth of the whole, has a radius of eight millimetres (0.3 inch); it is transparent and is called the cornea; the remainder, the scleral segment, is opaque and has a radius of 12 millimetres (0.5 inch). The ring where the two areas join is called the limbus. Thus, on looking directly into the eye from in front one sees the white sclera surrounding the cornea; because the latter is transparent one sees, instead of the cornea, a ring of tissue lying within the eye, the iris. The iris is the structure that determines the colour of the eye. The centre of this ring is called the pupil. It appears dark because the light passing into the eye is not reflected back to any great extent. By use of an ophthalmoscope, an instrument that permits the observer to illuminate the interior of the eyeball while observing through the pupil, the appearance of the interior lining of the globe can be made out; this is called the fundus; it is characterized by the large blood vessels that supply blood to the retina; these are especially distinct as they cross over the pallid optic disk, or papilla, the region where the optic nerve fibres leave the globe.

The dimensions of the eye are reasonably constant, varying among individuals by only a millimetre or two; the sagittal (vertical) diameter is about 24 millimetres (about one inch) and is usually less than the transverse diameter. At birth the sagittal diameter is about 16 to 17 millimetres (about 0.65 inch); it increases rapidly to about 22.5 to 23 millimetres (about 0.89 inch) by the age of three years; between three and 13 the globe attains its full size. The weight is about 7.5 grams (.25 ounce), and its volume 6.5 millilitres (0.4 cubic inch).

The eye is made up of three coats, which enclose the

Visible parts of the eye

Figure 3: The extraocular muscles.

Figure 4: Horizontal section of the eye.

optically clear aqueous humour, lens, and vitreous body (Figure 4). The outermost coat consists of the cornea and the sclera; the middle coat contains the main blood supply to the eye and consists, from the back forward, of the choroid, the ciliary body, and the iris. The innermost layer is the retina, lying on the choroid and receiving most of its nourishment from the vessels within the choroid, the remainder of its nourishment being derived from the retinal vessels that lie on its surface and are visible in the ophthalmoscope. The ciliary body and iris have a very thin covering, the ciliary epithelium and posterior epithelium of the iris, which is continuous with the retina.

Within the cavities formed by this triple-layered coat there are the crystalline lens, suspended by fine transparent fibres—the suspensory ligament or zonule of Zinn—from the ciliary body; the aqueous humour, a clear fluid filling the spaces between the cornea and the lens and iris; and the vitreous body, a clear jelly filling the much larger cavity enclosed by the sclera, the ciliary body, and the lens. The anterior chamber of the eye is defined as the space between the cornea and the forward surfaces of the iris and lens, while the posterior chamber is the much smaller space between the rear surface of the iris and the ciliary body, zonule, and lens; the two chambers both contain aqueous humour and are in connection through the pupil.

**Outer and middle tunics of the globe.** *The outermost coat.* The outermost coat is made up of the cornea and the sclera. The cornea is the transparent window of the eye. It contains five distinguishable layers; the epithelium, or outer covering; Bowman's membrane; the stroma, or supporting structure; Descemet's membrane; and the endothelium, or inner lining. Up to 90 percent of the thickness of the cornea is made up of the stroma. The epithelium, which is a continuation of the epithelium of the conjunctiva, is itself made up of about six layers of cells. The superficial layer is continuously being shed, and the layers are renewed by multiplication of the cells in the innermost, or basal, layer.

The stroma appears as a set of lamellae, or plates, running parallel with the surface and superimposed on each other like the leaves of a book; between the lamellae lie the corneal corpuscles, cells that synthesize new collagen (connective tissue protein) essential for the repair and maintenance of this layer. The lamellae are made up of microscopically visible fibres that run parallel to form sheets; in successive lamellae the fibres make a large angle with each other. The lamellae in man are about 1.5 to 2.5 microns (one micron = 0.001 millimetre) thick, so that there are about 200 lamellae in the human cornea. The fibrous basis of the stroma is collagen.

Immediately above the stroma, adjacent to the epithelium, is Bowman's membrane, about eight to 14 microns thick; in the electron microscope it is evident that it is really stroma, but with the collagen fibrils not arranged in the orderly fashion seen in the rest of the stroma.

Beneath the stroma are Descemet's membrane and the endothelium. The former is about five to ten microns thick and is made up of a different type of collagen from that in the stroma; it is secreted by the cells of the endothelium, which is a single layer of flattened cells. There is apparently no continuous renewal of these cells as with the epithelium, so that damage to this layer is a more serious matter.

The sclera is essentially the continuation backward of the cornea, the collagen fibres of the cornea being, in effect, continuous with those of the sclera. The sclera is pierced by numerous nerves and blood vessels; the largest of these holes is that formed by the optic nerve, the posterior scleral foramen. The outer two-thirds of the sclera in this region continue backward along the nerve to blend with its covering, or dural sheath—in fact, the sclera may be regarded as a continuation of the dura mater, the outer covering of the brain. The inner third of the sclera, combined with some choroidal tissue, stretches across the opening, and the sheet thus formed is perforated to permit the passage of fasciculi (bundles of fibres) of the optic nerve. This region is called the lamina

cribrosa (Figure 4). The blood vessels of the sclera are largely confined to a superficial layer of tissue, and these, along with the conjunctival vessels, are responsible for the bright redness of the inflamed eye. As with the cornea, the innermost layer is a single layer of endothelial cells; above this is the lamina fusca, characterized by large numbers of pigment cells.

The most obvious difference between the opaque sclera and the transparent cornea is the irregularity in the sizes and arrangement of the collagen fibrils in the sclera by contrast with the almost uniform thickness and strictly parallel array in the cornea; in addition, the cornea has a much higher percentage of mucopolysaccharide (a carbohydrate that has among its repeating units a nitrogenous sugar, hexosamine) as embedding material for the collagen fibrils. It has been shown that the regular arrangement of the fibrils is, in fact, the essential factor leading to the transparency of the cornea.

When the cornea is damaged—*e.g.*, by a virus infection—the collagen laid down in the repair processes is not regularly arranged, with the result that an opaque patch called a leukoma, may occur.

When an eye is removed, or a man dies, the cornea soon loses its transparency, becoming hazy; this is due to the taking in of fluid from the aqueous humour, the cornea becoming thicker as it becomes hazier. The cornea can be made to reassume its transparency by maintaining it in a warm, well-aerated chamber, at about 31° C or 88° F (its normal temperature); associated with this return of transparency is a loss of fluid.

Modern studies have shown that, under normal conditions, the cornea tends to take in fluid, mainly from the aqueous humour and from the small blood vessels at the limbus, but this is counteracted by a pump that expels the fluid as fast as it enters. This pumping action depends on an adequate supply of energy, and any situation that prejudices this supply causes the cornea to swell—the pump fails, or works so slowly that it cannot keep pace with the leak. Death is one cause of the failure of the pump, but this is primarily because of the loss of temperature; place the dead eye in a warm chamber and the reserves of metabolic energy it contains in the form of sugar and glycogen are adequate to keep the cornea transparent for 24 hours or more. When it is required to store corneas for grafting, as in an eye bank, it is best to remove the cornea from the globe to prevent it from absorbing fluid from the aqueous humour. The structure responsible for the pumping action is almost certainly the endothelium, so that damage to this lining can lead to a loss of transparency with swelling.

The cornea is exquisitely sensitive to pain. This is mediated by sensory nerve fibres, called ciliary nerves, that run just underneath the endothelium; they belong to the ophthalmic branch of the fifth cranial nerve, the large sensory nerve of the head. The ciliary nerves leave the globe through holes in the sclera, not in company with the optic nerve, which is concerned exclusively with responses of the retina to light.

*The uvea.* The middle coat of the eye is called the uvea (from the Latin for “grape”) because the eye looks like a reddish-blue grape when the outer coat has been dissected away. The posterior part of the uvea, the choroid, is essentially a layer of blood vessels and connective tissue sandwiched between the sclera and the retina. The forward portion of the uvea, the ciliary body and iris, is more complex, containing as it does the ciliary muscle and the sphincter and dilator of the pupil.

The blood supply to the human eye is twofold, consisting of the retinal and uveal circulations, both of which derive from branches of the ophthalmic artery. The two systems of blood vessels differ in that the retinal vessels, which supply nutrition to the innermost layers of the retina, derive from a branch of the ophthalmic artery, called the central artery of the retina, that enters the eye with the optic nerve, while the uveal circulation, which supplies the middle and outer layers of the retina as well as the uvea, is derived from branches of the ophthalmic artery that penetrate the globe independently of the optic nerve.

Differences between sclera and cornea

The layers of the cornea

Ciliary body and iris

The ciliary body is the forward continuation of the choroid. It is a muscular ring, triangular in horizontal section, beginning at the region called the ora serrata and ending, in front, as the root of the iris (Figure 5). The

Figure 5: The anteronasal portion of a horizontal (meridional) section through a right eye. Shaded area of inset locates magnified portion. (See text).

surface is thrown into folds, called ciliary processes, the whole being covered by the ciliary epithelium, which is a double layer of cells; the layer next to the vitreous body (see below), called the inner layer, is transparent, while the outer layer, which is continuous with the pigment epithelium of the retina, is heavily pigmented. These two layers are to be regarded embryologically as the forward continuation of the retina, which terminates at the ora serrata. Their function is to secrete the aqueous humour.

The ciliary muscle is an unstriated, involuntary, muscle concerned with alterations in the adjustments of focus—accommodation—of the optical system; the fibres run both across the muscle ring and circularly, and the effect of their contraction is to cause the whole body to move forward and to become fatter, so that the suspensory ligament that holds the lens in place is loosened.

The most forward portion of the uvea is the iris. This is the only portion that is visible to superficial inspection, appearing as a perforated disc, the central perforation, or pupil, varying in size according to the surrounding illumination and other factors. A prominent feature is the collarette at the inner edge, representing the place of attachment of the embryonic pupillary membrane that, in embryonic life, covers the pupil. As with the ciliary body, with which it is anatomically continuous, the iris consists of several layers: namely, an anterior layer of endothelium, the stroma; and the posterior iris epithelium. The stroma contains the blood vessels and the sphincter and dilator muscles; in addition, the stroma contains pigment cells that determine the colour of the eye. Posteriorly, the stroma is covered by a double layer of epithelium, the continuation forward of the ciliary epithelium; here, however, both layers are heavily pigmented and serve to prevent light from passing through the iris tissue, confining the optical pathway to the pupil. The pink iris of the albino is the result of the absence of pigment in these layers. The cells of the anterior layer of the iris epithelium have projections that become the fibres of the dilator muscle; these projections run radially, so that when they contract they pull the iris into folds and widen the pupil; by contrast, the fibres of the sphincter pupillae muscle run in a circle around the pupil, so that when they contract the pupil becomes smaller.

Usually, a baby belonging to the white races is born with blue eyes because of the absence of pigment cells in the stroma; the light reflected back from the posterior epithelium, which is blue because of scattering and selective absorption, passes through the stroma to the eye of the observer. As time goes on, pigment is deposited, and the colour changes; if much pigment is laid down the eye becomes brown or black, if little, it remains blue or gray.

**The inner tunic of the globe.** The inner tunic of the rear portion of the globe, as far forward as the ciliary body, is the retina, including its epithelia or coverings. These epithelia continue forward to line the remainder of the globe.

**The epithelia.** Separating the choroid (the middle tunic of the globe) from the retina proper is a layer of pigmented cells, the pigment epithelium of the retina; this acts as a restraining barrier to the indiscriminate diffusion of material from the blood in the choroid to the retina. The retina ends at the ora serrata, where the ciliary body begins (Figure 4). The pigment epithelium continues forward as a pigmented layer of cells covering the ciliary body; farther forward still, the epithelium covers the posterior surface of the iris and provides the cells that constitute the dilator muscle of this diaphragm. Next to the pigment epithelium of the retina is the neuroepithelium, or rods and cones (see below). Their continuation forward is represented by a second layer of epithelial cells covering the ciliary body, so that by the ciliary epithelium is meant the two layers of cells that are the embryological equivalent of the retinal pigment epithelium and the receptor layer (rods and cones) of the retina. This unpigmented layer of the ciliary epithelium is continued forward over the back of the iris, where it acquires pigment and is called the posterior iris epithelium.

**The retina.** The retina is the part of the eye that receives the light and converts it into chemical energy. The chemical energy activates nerves that conduct the messages out of the eye into the higher regions of the brain. The retina is a complex nervous structure, being, in essence, an outgrowth of the forebrain.

Ten layers of cells in the retina can be seen microscopically. In general, there are four main layers: (1) Next to the choroid is the pigment epithelium, already mentioned. (2) Beneath the epithelium is the layer of rods and cones, the light-sensitive cells. The changes induced in the rods and cones by light are transmitted to (3) a layer of neurons (nerve cells) called the bipolar cells, which are analogous to the sensory neurons that carry messages from the touch and heat receptors of the skin and transmit them to the cells of the spinal cord or the medulla (the part of the brain that is a continuation of the spinal cord). These bipolar cells connect with (4) the innermost layer of neurons, the ganglion cells; and the transmitted messages are carried out of the eye along their projections, or axons, which constitute the optic nerve fibres. Thus, the optic nerve is really a central tract, rather than a nerve, connecting two regions of the nervous system, namely, the layer of bipolar cells, and the cells of the lateral geniculate body, the latter being a visual relay station in the diencephalon (the rear portion of the forebrain).

The arrangement of the retinal cells in an orderly manner gives rise to the outer nuclear layer (layer 4 in Figure 6), containing the nuclei of the rods and cones; the inner nuclear layer (layer 6), containing the nuclei and perikarya (main cell bodies outside the nucleus) of the bipolar cells, and the ganglion cell layer (layer 8), containing the corresponding structures of the ganglion cells. The plexiform layers are regions in which the neurons make their interconnections. Thus, the outer plexiform layer (layer 5) contains the rod and cone projections terminating as the rod spherule and cone pedicle; these make connections with the dendritic processes of the bipolar cells, so that changes produced by light in the rods and cones are transmitted by way of these connections to the bipolar cells. (The dendritic process of a nerve cell is the projection that receives nerve impulses to the cell; the axon is the projection that carries impulses from the cell.) In the inner plexiform layer (layer 7) are the axons of the bipolar cells and the dendritic processes of the ganglion and amacrine cells (see below). The association is such as to allow messages in the bipolar cells to be transmitted to the ganglion cells, the messages then passing out along the axons of the ganglion cells as optic nerve messages.

The photosensitive cells are, in the human and in most vertebrate retinas, of two kinds, called rods and cones,

The pigment epithelium

The rods and cones

Figure 6: The retinal cells directly involved in the visual process.

the rods being usually much thinner than the cones but both being built up on the same plan. The light-sensitive pigment is contained in the outer segment (layer 2), which rests on the pigment epithelium (layer 1). Through the other end, called the synaptic body, effects of light are transmitted to the bipolar and horizontal cells. When examined at high magnification in the electron microscope, the outer segments of the rods and cones are seen to be composed of stacks of disks, apparently made by the infolding of the limiting membrane surrounding the outer segment; the visual pigment, which is located on the surfaces of these disks, is thus spread over a very wide area, and this contributes to the efficiency with which light is absorbed by the visual cell.

The arrangement of the retina makes it necessary for light to pass through the layers not sensitive to light first before it reaches the light-sensitive rods and cones. The optical disadvantages of this arrangement are largely overcome by the development of the fovea centralis, a localized region of the retina, close to the optic axis of the eye, where the inner layers of the retina are absent. The result is a depression, the foveal pit, where light has an almost unrestricted passage to the light-sensitive cells. It is essentially this region of the retina that is employed for accurate vision, the eyes being directed toward the objects of regard so that their images fall in this restricted region. If the object of interest is large, so as to subtend a large angle, then the eye must move rapidly from region to region so as to bring their images successively onto the fovea; this is typically seen during reading. In the central region of the fovea there are cones exclusively; toward its edges, rods also occur, and as successive

zones are reached the proportion of rods increases while the absolute density of packing of the receptors tends to decrease. Thus, the central fovea is characterized by an exclusive population of very densely packed cones; here, also, the cones are very thin and in form very similar to rods. The region surrounding the fovea is called the parafovea; it stretches about 1,250 microns from the centre of the fovea, and it is here that the highest density of rods occurs. Surrounding the parafovea, in turn, is the perifovea, its outermost edge being 2,750 microns from the centre of the fovea; here the density of cones is still further diminished, the number being only 12 per hundred microns compared with 50 per hundred microns in the most central region of the fovea. In the whole human retina there are said to be about 7,000,000 cones and from 75,000,000 to 150,000,000 rods.

The fovea is sometimes loosely referred to as the macula lutea; actually this term, which means the yellow spot, defines a rather vague area, characterized by the presence of a yellow pigment in the nervous layers, stretching over the whole central retina; *i.e.*, the fovea, parafovea, and perifovea.

The blind spot in the retina corresponds to the optic papilla, the region on the nasal side of the retina through which the optic nerve fibres pass out of the eye.

Although the rods and cones may be said to form a mosaic, the retina is not organized in a simple mosaic fashion in the sense that each rod or cone is connected to a single bipolar cell that itself is connected to a single ganglion cell. There are only about 1,000,000 optic nerve fibres, while there are at least 150,000,000 receptors, so that there must be considerable convergence of receptors on the optic pathway. This means that there will be considerable mixing of messages. Furthermore, the retina contains additional nerve cells besides the bipolar and ganglion cells; these, the horizontal and amacrine cells, operate in the horizontal direction, allowing one area of the retina to influence the activity of another. In this way, for example, the messages from one part of the retina may be suppressed by a visual stimulus falling on another, an important element in the total of messages sent to the higher regions of the brain. Finally, it has been argued that some messages may be running the opposite way; they are called centrifugal and would allow one layer of the retina to affect another, or higher regions of the brain to control the responses of the retinal neurons. In primates the existence of these centrifugal fibres has been finally disproved, but in such lower vertebrates as the pigeon, their existence is quite certain.

The pathway of the retinal messages through the brain is described later in this article; it is sufficient to state here that most of the optic nerve fibres in primates carry their messages to the lateral geniculate body, a relay station specifically concerned with vision. Some of the fibres separate from the main stream and run to a mid-brain centre called the pretectal nucleus, which is a relay centre for pupillary responses to light.

**The transparent media.** Within the cavities enclosed by the three layers of the globe described above there are the aqueous humour in the anterior and posterior chambers; the crystalline lens behind the iris; and the vitreous body, which fills the large cavity behind the lens and iris (Figure 4).

**The aqueous humour.** The aqueous humour is a clear colourless fluid with a chemical composition rather similar to that of blood plasma (the blood exclusive of its cells) but lacking the high protein content of the latter. Its main function is to keep the globe reasonably firm. It is secreted continuously by the ciliary body into the posterior chamber, and flows as a gentle stream through the pupil into the anterior chamber, from which it is drained by way of a channel at the limbus; that is, the juncture of the cornea and the sclera. This channel, the canal of Schlemm, encircles the cornea and connects by small connector channels to the blood vessels buried in the sclera and forming the intrascleral plexus or network. From this plexus the blood, containing the aqueous humour, passes into more superficial vessels; it finally leaves the eye in the anterior ciliary veins. The relation of the

Retinal organization

Secretion and course of aqueous humour

canal of Schlemm to the aqueous humour is clear from Figure 5. The wall of the canal that faces the aqueous humour is very delicate and allows the fluid to percolate through by virtue of the relatively high pressure of the fluid within the eye. Obstruction of this exit, for example, if the iris is pushed forward to cover the wall of the canal, causes a sharp rise in the pressure within the eye, a condition that is known as glaucoma. Often the obstruction is not obvious, but is caused perhaps by a hardening of the tissue just adjacent to the wall of the canal—the trabecular meshwork (Figure 5), in which case the rise of pressure is more gradual and insidious. Ultimately the abnormal pressure damages the retina and causes a variable degree of blindness. The normal intraocular pressure is about 15 millimetres of mercury above atmospheric pressure, so that if the anterior chamber is punctured by a hypodermic needle the aqueous humour flows out readily. Its function in maintaining the eye reasonably hard is seen by the collapse and wrinkling of the cornea when the fluid is allowed to escape. An additional function of the fluid is to provide nutrition for the crystalline lens and also for the cornea, both of which are devoid of blood vessels; the steady renewal and drainage serve to bring into the eye various nutrient substances, including glucose and amino acids, and to remove waste products of metabolism, such as lactic acid.

**The vitreous body.** The vitreous body is a jelly. It is remarkable for the small amount of solid matter required to give it this semisolid structure; the solid material is made up of a form of collagen, vitrosin, and a mucopolysaccharide, hyaluronic acid. Thus, its composition is rather similar to that of the cornea, but the proportion of water is much greater, about 98 percent or more, compared with about 75 percent for the cornea. The jelly is probably secreted by certain cells of the retina. In general, the vitreous body is devoid of cells, in contrast with the lens, which is packed tight with cells. Embedded in the surface of the vitreous body, however, there is a population of specialized cells, the hyalocytes of Balazs, which may contribute to the breakdown and renewal of the hyaluronic acid. The vitreous body serves to keep the underlying retina pressed against the choroid.

**The crystalline lens.** The lens is a transparent body, flatter on its anterior than on its posterior surface, and suspended within the eye by the zonular fibres of Zinn attached to its equator; its anterior surface is bathed by aqueous humour, and its posterior surface by the vitreous body. The lens is a mass of tightly packed transparent fibrous cells, the lens fibres, enclosed in an elastic collagenous capsule. The lens fibres are arranged in sheets that form successive layers; the fibres run from pole to pole of the lens, the middle of a given fibre being in the equatorial region. On meridional (horizontal) section, the fibres are cut longitudinally to give an onion-scale appearance, whereas a section at right-angles to this—an equatorial section—would cut all the fibres across, and the result would be to give a honeycomb appearance. The epithelium, covering the anterior surface of the lens under the capsule, serves as the origin of the lens fibres, both during embryonic and fetal development and during infant and adult life, the lens continuing to grow by the laying down of new fibres throughout life.

## The visual process

### THE WORK OF THE AUXILIARY STRUCTURES

**The protective mechanisms.** The first line of protection of the eyes is provided by the lids, which prevent access of foreign bodies and assist in the lubrication of the corneal surface. Lid closure and opening are accomplished by the orbicularis oculi and levator palpebri muscles; the orbicularis oculi operates on both lids, bringing their margins into close apposition in the act of lid closure. Opening results from relaxation of the orbicularis muscle and contraction of the levator palpebri of the upper lid; the smooth muscle of the upper lid, Müller's muscle, or the superior palpebral muscle, also assists in widening the lid aperture. The lower lid does not possess a muscle corresponding to the levator of the upper lid, and the only muscle available for causing an

active lowering of the lid, required during the depression of the gaze, is the inferior palpebral muscle, which is analogous to the muscle of Müller of the upper lid (called the superior palpebral muscle). This inferior palpebral muscle is so directly fused with the sheaths of the ocular muscles that it provides cooperative action, opening of the lid on downward gaze being mediated, in effect, mainly by the inferior rectus.

**Innervation.** The seventh cranial nerve—the facial nerve—supplies the motor fibres for the orbicularis muscle. The levator is innervated by the third cranial nerve—the oculomotor nerve—that also innervates some of the extraocular muscles concerned with rotation of the eyeball, including the superior rectus. The smooth muscle of the eyelids and orbit is activated by the sympathetic division of the autonomic system. The secretion of adrenaline during such states of excitement as fear would also presumably cause contraction of the smooth muscle, but it seems unlikely that this would lead to the protrusion of the eyes traditionally associated with extreme fear. It is possible that the widening of the lid aperture occurring in this excited state, and dilation of the pupil, create the illusion of eye protrusion.

Blinking is normally an involuntary act, but may be carried out voluntarily. The more vigorous "full closure" of the lids involves the orbital portion of the orbicularis muscle and may be accompanied by contraction of the facial muscles that have been described as accessory muscles of blinking: namely, the corrugator supercilii, which on contraction pulls the eyebrows toward the bridge of the nose; and the procerus or pyramidalis, which pulls the skin of the forehead into horizontal folds, acting as a protection when the eyes are exposed to bright light. The more vigorous full closure may be evoked as a reflex response.

**Blink reflexes.** Reflex blinking may be caused by practically any peripheral stimulus, but the two functionally significant reflexes are (1) that resulting from stimulation of the endings of the fifth cranial nerve in the cornea, lid, or conjunctiva—the sensory blink reflex, or corneal reflex—and (2) that caused by bright light—the optical blink reflex. The corneal reflex is rapid (0.1 second reflex time) and is the last to disappear in deepening anaesthesia, impulses being relayed from the nucleus of the fifth nerve to the seventh cranial nerve, which transmits the motor impulses. The reflex is said to be under the control of a medullary centre. The optical reflex is slower; in man, the nervous pathway includes the visual cortex (the outer substance of the brain; the visual centre is located in the occipital—rear—lobe). The reflex is absent in children of less than nine months.

**Normal rhythm.** In the waking hours the eyes blink fairly regularly at intervals of two to ten seconds, the actual rate being a characteristic of the individual. The function of this is to spread the lacrimal secretions over the cornea. It might be thought that each blink would be reflexly determined by a corneal stimulus—drying and irritation—but the results of extensive studies indicate that this view is wrong; the normal blinking rate is apparently determined by the activity of a "blinking centre" in the globus pallidus of the caudate nucleus, a mass of gray matter—nerve cells—between the base and the outer substance—of the brain. This is not to deny, however, that the blink rate is modified by external stimuli.

There is a strong association between blinking and the action of the extraocular muscles. Eye movement is generally accompanied by a blink, and it is thought that this aids the eyes in changing their fixation point.

**Secretion of tears.** The exposed surface of the globe (eyeball) is kept moist by the tears secreted by the lacrimal apparatus, together with the mucous and oily secretions of the other secretory organs and cells of the lids and conjunctiva; these have been described earlier. The secretion produces what has been called the pre-corneal film, which consists of an inner layer of mucus, a middle layer of lacrimal secretion, and an outer oily film that reduces the rate of evaporation of the underlying watery layer. The normal daily (24-hour) rate of secretion has been estimated at about 0.75 to 1.1

Voluntary full closure of lids

Blinking

Tear  
reflexes

grams; secretion tends to decrease with age. Chemical analysis of the tears reveals a typical body fluid with a salt concentration similar to that of blood plasma. An interesting component is lysozyme, an enzyme that has bactericidal action by virtue of its power of dissolving away the outer coats of many bacteria.

Tears are secreted reflexly in response to a variety of stimuli—e.g., irritative stimuli to the cornea, conjunctiva, nasal mucosa; hot or peppery stimuli applied to the mouth and tongue; or bright lights. In addition, tear flow occurs in association with vomiting, coughing, and yawning. The secretion associated with emotional upset is called psychical weeping. Severing of the sensory root of the trigeminal (fifth cranial) nerve prevents all reflex weeping, leaving psychical weeping unaffected; similarly, the application of cocaine to the surface of the eye, which paralyzes the sensory nerve endings, inhibits reflex weeping, even when the eye is exposed to potent tear gases. The afferent (sensory) pathway in the reflex is thus by way of the fifth cranial, or the trigeminal nerve. The motor innervation is by way of the autonomic (involuntary) division; the parasympathetic supply derived from the facial nerve (the seventh cranial nerve) seems to have the dominant motor influence. Thus, drugs the effect of which mimics the parasympathetic, such as acetylcholine, provoke secretion, and secretion may be blocked by such typical anticholinergic drugs (drugs the action of which counters that of acetylcholine) as atropine. Innervation of the lacrimal gland is not always complete at the time of birth, so that the newborn infant is generally said to cry without weeping. Because absence of reflex tearing fails to produce any serious drying of the cornea, and surgical destruction of the main lacrimal gland is often without serious consequences, it seems likely that the subsidiary secretion from the accessory lacrimal glands is adequate to keep the cornea moist. The reflex secretion that produces abundant tears may be regarded as an emergency response.

A drainage mechanism for tears is necessary only during copious secretion. The mechanism, described as the lacrimal pump, consists of alternately negative and positive pressure in the lacrimal sac caused by the contraction of the orbicularis muscle during blinking.

**Movements of the eyes.** Because only a small portion of the retina, the fovea, is actually employed for distinct vision, it is vitally important that the motor apparatus governing the direction of gaze be extremely precise in its operation, and rapid. Thus, the gaze must shift swiftly and accurately during the process of reading. Again, if the gaze must remain fixed on a single small object—e.g., a golf ball—the eyes must keep adjusting their gaze to compensate for the continuous small movements of the head and to maintain the image exactly on the fovea. The extraocular muscles that carry out these movements are under voluntary control; thus, the direction of regard can be changed deliberately. Most of the actual movements of the eyes are carried out without awareness, however, in response to movements of the objects in the environment, or in response to movements of the head or the rest of the body, and so on. In examining the mechanisms of the eye movements, then, one must resolve them into a number of reflex responses to changes in the environment or the individual, remembering, of course, that there is an overriding voluntary control.

**The axes of the eye.** It is worthwhile at this point to define certain axes of the eyes employed during different types of study. The optic axis of the eye is a line drawn through the centre of the cornea and the nodal (central) point of the eye; it actually does not intersect with the retina at the centre of the fovea as might be expected, but toward the nose from this, so that there is an angle of about five degrees between (1) the visual axis—the line joining the point fixated (the point toward which the gaze is directed) and the nodal point—and (2) the optic axis.

**Actions of muscles.** The general modes of action of the six extraocular muscles have been described in connection with their anatomy: rotation of the eye toward the nose is carried out by the medial rectus; outward

movement is by the lateral rectus. Upward movements are carried out by the combined actions of the superior rectus and the inferior oblique muscles, and downward movements by the inferior rectus and the superior oblique. Intermediate directions of gaze are achieved by combined actions of several muscles. When the two eyes act together, as they normally do, and change their direction of gaze to the left, for example, the left eye rotates away from the nose by means of its lateral rectus, while the right eye turns toward the nose by means of its medial rectus. These muscles may be considered as a linked pair; that is, when they are activated by the central nervous system this occurs conjointly and virtually automatically. This linking of the muscles of the two eyes is an important physiological feature and has still more important pathological interest in the analysis of squint, when the two eyes fail to be directed at the same point.

**Binocular movements.** The binocular movements (the movements of the two eyes) fall into two classes, the conjugate movements, when both eyes move in the same direction, as in a change in the direction of gaze, and disjunctive movements, when the eyes move in opposite directions. Thus, during convergence onto a near object both eyes move toward the nose; the movement is horizontal, but disjunctive, by contrast with the conjugate movement when both eyes move, say, to the right. The disjunctive movement of convergence can be carried out voluntarily, but the act is usually brought about reflexly in response to the changed optical situation—i.e., the nearness of the object of gaze. A seesaw movement of the eyes, whereby one eye looks upward and the other downward, is possible, but not voluntarily; to achieve this a prism is placed in front on one eye so that the object seen through it appears displaced upward or downward; the other eye sees the object where it is. The result of such an arrangement is that, unless the eye with the prism in front makes an upward or downward movement, independent of the other, the images will not fall on corresponding parts of the retinas in the two eyes. Such a noncorrespondence of the retinal images causes double vision; to avoid this, there is an adjustment in the alignment of the eyes so that a seesaw movement is actually executed. In a similar way, the eyes may be made to undergo torsion, or rolling. A conjugate torsion, in which both eyes rotate about their anteroposterior (fore-and-aft) axes in the same sense, occurs naturally; for example, when the head tips toward one shoulder the eyes tend to roll in the opposite direction, with the result that the image of the visual field on the retina tends to remain vertical in spite of the rotation of the head.

**Nervous control.** The nerves controlling the actions of the muscles are the third, fourth, and sixth cranial nerves, with their bodies (nuclei) in the brainstem; the third, or oculomotor nerve, controls the superior and inferior recti, the medial rectus, and inferior oblique; the fourth cranial nerve, the trochlear nerve, controls the superior oblique; and the sixth, the abducens nerve, controls the lateral rectus. The nuclei of these nerves are closely associated; especially, there are connections between the nuclei of the sixth cranial nerve, controlling the lateral rectus, and the nucleus of the third, controlling the medial rectus; it is through this close relationship that the linking of the lateral rectus of one eye and the medial rectus of the other, indicated above, is achieved. Another type of linking is concerned with reciprocal inhibition; that is, when there are two antagonistic muscles, such as the medial and the lateral rectus, contraction of one is accompanied by a simultaneous inhibition of the other. Muscles show a continuous slight activity even when at rest; this keeps them taut; this action, called tonic activity, is brought about by discharges in the motor nerve to the muscle. Hence, when the agonist muscle contracts its antagonist must be inhibited.

**Reflex pathways.** In examining any reflex movement one must look for the sensory input—i.e., the way in which messages in sensory nerves bring about discharges in the motor nerves to the muscles; this study involves

# Fixation reflex

the connections of the motor nerves or nuclei with other centres of the brain.

When a subject is looking straight ahead and a bright light appears in the periphery of his field of vision, his eyes automatically turn to fix on the light; this is called the fixation reflex. The sensory pathway in the reflex arc leads as far as the cerebral cortex because removal of the occipital cortex (the outer brain substance at the back of the head) abolishes reflex eye movements in response to light stimuli. If the occipital cortex is stimulated electrically, movements of the eyes may be induced, and in fact one may draw a pattern of the visual field on the occipital cortex corresponding with the directions in which the gaze is turned when given points on the cortex are stimulated. This pattern corresponds with the pattern obtained by recording the visual responses to light stimuli from different parts of the visual field.

The remainder of the pathway—i.e., from the occipital cortex to the motor neurons in the brainstem—has long been considered to involve the superior colliculi as relay stations, and they certainly have such a role in lower animals; but in human beings a pathway from the cortex to the eye-muscle nuclei independent of the superior colliculi is now generally assumed (the superior colliculi are areas in the midbrain).

Continual movements of the eyes occur even when an effort is made to maintain steady fixation of an object. Some of these movements may be regarded as manifestations of the fixation reflex; thus, the eyes tend to drift off their target, and, because of this, the fixation reflex comes into play, bringing the eyes back on target.

# Nystagmus

Experimentally, the fixation reflex can be studied by observation of the regular to-and-fro movements of the eyes as they follow a rotating drum striped in black and white. (Such movements of the eyes directed at a moving object are called optokinetic nystagmus; nystagmus itself is the involuntary movement of the eye back and forth, up and down, or in a rotatory or a mixed fashion.) While the eyes watch the moving drum, they involuntarily make a slow movement as a result of fixing their gaze on a particular stripe. At a certain point, fixation is broken off, and the eyes spring back to fix on a new stripe. Thus, the nystagmus consists of a slow movement with angular velocity equal to that of the rotation of the drum, then a fast saccade, or jump from one point of fixation to another, in the opposite direction; the process is repeated indefinitely.

Another type of nystagmus reveals the play of another set of reflexes. These are mediated by the semicircular canals—i.e., the organs of balance or the vestibular apparatus. Such a reflex may be evoked by rotating the subject in a chair at a steady speed; the eyes move slowly in the opposite direction to that of rotation and, at the end of their excursion, jump back with a fast saccade in the direction of rotation. If rotation suddenly ceases, the eyes go into a nystagmus in the opposite direction, the postrotatory nystagmus.

During rotation, certain semicircular canals are being stimulated, and the important point is that any acceleration of the head that stimulates these canals will cause reflex movements of the eyes; thus, acceleration of the head to the right causes a movement of the eyes to the left, the function of the reflex being to enable the eyes to maintain steady fixation of an object despite movements of the head. The reflex occurs even when the eyes are shut, and, when the eyes are open, it obviously co-operates with the fixation reflex in maintaining steady fixation. In many lower animals this connection between organs of balance and eyes is very rigid; thus, one may move the tail of a fish, and its eyes will move reflexly. In man, not only do the semicircular canals function in close relation to the eye muscles but so also do the gravity organ—the utricle—and the stretch receptors in the muscles of the neck. Thus, when the head is turned upward, there is a reflex tendency for the eyes to move downward, even if the eyes are shut. The actual movement is probably initiated by the reflex from the semicircular canals, which respond to acceleration, but the maintenance of the position is brought about by a reflex

through the stretch of the neck muscles and also through the pull of gravity on the utricle, or otolith organ, in the inner ear.

*Voluntary centre.* The eyes are under voluntary control, and it is thought that the cortical area subserving voluntary eye movements is in the frontal cortex. Stimulation of this in primates causes movements of the eyes that are well coordinated, and a movement induced by this region prevails over one induced by stimulation of the occipital cortex. The existence of a separate centre in man is revealed by certain neurological disorders in which the subject is unable to fixate voluntarily but can do so reflexly; i.e., he can follow a moving light.

*The nature of eye movements.* So far, the relation of the movements of the eyes to the requirements of the visual apparatus and their control have been touched upon. To examine the character of the movements in some detail requires rapid, accurate measurement of the movements that the eyes undergo. Modern studies of this subject employ a contact lens fitting on to the globe; on the lens is a small plane mirror, and a parallel bundle of rays is reflected off this mirror onto a moving film.

By the use of refined methods of measuring the position of the eyes at any moment, it becomes immediately evident that the eyes are never stationary for more than a fraction of a second; the movements are of three types: (1) irregular movements of high frequency (30–70 per second) and small excursions of about 20 seconds of arc; (2) flicks, or saccades, of several minutes of arc occurring at regular intervals of about one second; and between these saccades there occur (3) slow irregular drifts extending up to six minutes of arc. The saccades are corrective, serving to bring the fixation axis on the point of regard after this has drifted away from it too far, and thus are a manifestation of the fixation reflex.

The significance of these small movements during fixation was revealed by studies on the stabilized retinal image: by a suitable optical device the image of an object could be held stationary on the retina in spite of the movements of the eye. It was found that under these conditions the image would disappear within a few seconds. Thus, the movements of the eye are apparently necessary to allow the contours of the image to fall on a new set of rods and cones at repeated intervals; if this does not occur, the retina adapts to their stimulus and ceases to send messages to the central nervous system. The small flicks mentioned above are essentially the same as the larger movement made when the two eyes fixate (fix on) a light when it suddenly appears in the peripheral field; this is given the general name of the saccade, to distinguish it from the slower movements occurring during convergence and smooth following. The dynamics of the saccade have been studied in some detail by several workers. There is a reaction time of about 120 to 180 milliseconds, after which both eyes move simultaneously; there is a definite overshoot and, with an excursion of 20°, the operation is completed in about 90 milliseconds. The maximum velocity increases with the extent of the movement, being 300° per second for 10° and 500° per second for 30°. A remarkable feature is the apparent absence of significant inertia in the eyeball, so that movement is halted, not by any checking action of antagonistic muscles but simply by cessation of contraction of the agonists; thus, the movement is not ballistic. Once under way, the saccade is determined in amount, so that the subject cannot voluntarily alter its direction and extent. The control mechanism for the saccadic type of movement can be described as a sampled data system, in the sense that the brain makes discontinuous samples of the position of the eyes in relation to the target and corrects the error. This is in contrast to a continuous feedback system that takes account of the error all the time.

The movements of the eyes when they converge onto a near object are in remarkable contrast to the saccade; the angular velocity is only about 25° per second, compared with values as high as 500° per second in the saccade. The great difference in speed suggested to two investigators that the two movements are executed by different muscle fibres. In fact, the extraocular muscles do

The saccade, disjunctive movements, and tracking

contain two types of muscle fibre with characteristically different nerve supplies, and some recent studies tend to support this view of a dual mechanism.

If a moving light suddenly appears in the field of view, and if its rate of movement is less than about  $30^\circ$  per second, the response of the eyes is remarkably efficient; a saccade brings the eyes on target, and they follow the motion at almost exactly the same angular velocity as that of the target; inaccuracies in following lead to corrective saccades. When the rate of movement of the target is greater than about  $30^\circ$  per second, these corrective saccades become more obvious because now smooth following is not possible; the eyes make constant-velocity movements, but the velocity rarely matches that of the moving target, so that there must be frequent corrective saccades. Studies have shown that the following movements are highly integrated and must involve a continuous feedback system whereby errors are used to modify the performance. Thus, the systems for control of saccades and tracking movements are fundamentally different.

*Vision suppression during a saccade.* If one looks into a mirror and fixates one of one's eyes and then fixates the other, one does not see the eyes moving; and it has been argued that, during an eye movement, vision is suppressed; if vision were not suppressed, moreover, it seems likely that the images of the external world would appear smeared during a movement. Experimental studies have shown that there is, indeed, a suppression of vision during a saccade.

#### THE WORK OF THE OPTICAL LENS SYSTEM

**Refraction by cornea and lens.** The optical system of the eye is such as to produce a reduced inverted image of the visual field on the retina; the system behaves as a convex lens but is, in fact, much more complex, refraction taking place not at two surfaces, as in a lens, but at four separate surfaces—at the anterior and the posterior surfaces of the cornea and of the crystalline lens. Each of these surfaces is approximately spherical, and at each optical interface—e.g., between air and the anterior surface of the cornea—the bending of a ray of light is toward the axis, so that, in effect, there are four surfaces tending to make rays of light converge on each other. If the rays of light falling on the cornea are parallel—i.e., if they come from a distant point—the net effect of this series of refractions at the four surfaces is to bring these rays to a point focus of the optical system, which in the normal, or emmetropic, eye corresponds with the retina. The greatest change of direction, or bending of the rays, occurs where the difference of refractive index is greatest, and this is when light passes from air into the cornea, the refractive index of the corneal substance being 1.3376; the refractive indices of the cornea and aqueous humour are not greatly different, that of the aqueous humour being 1.336 (as is that of the vitreous); thus, the bending, as the rays meet the concave posterior surface of the cornea and emerge into a medium of slightly less refractive index, is small. The lens has a greater refractive index than that of its surrounding aqueous humour and vitreous body, 1.386 to 1.406, so that its two surfaces contribute to convergence, the posterior surface normally more than the anterior surface because of its greater curvature (smaller radius).

**Normal sightedness and near- and farsightedness.** In contrast to the focussing of the normal (emmetropic) eye, in which the image of the visual field is focussed on the retina, the image may be focussed in front of the retina (nearsightedness, or myopia), or behind the retina (farsightedness or hyperopia). In myopia the vision of distant objects is not distinct because the image of a distant point falls within the vitreous and the rays spread out to form a blur circle on the retina instead of a point. In this condition the eye is said to have too great dioptric (refractive) power for its length. When the focus falls behind the retina, the image of the distant point is again a circle on the retina; and the farsighted eye is said to have too little dioptric power. The important point to appreciate is that emmetropia, or normal sight, requires

that the focal power of the dioptric system be matched to the axial length of the eye; it certainly is remarkable that emmetropia is indeed the most common condition when it is appreciated that just one millimetre of error in the matching of axial length with focal length would cause a person to require a spectacle correction. In general, however, the effects of variations in dimensions tend to compensate each other. Thus, for example, an unusually large eye might, at first thought, be expected to be myopic, but a large eye tends to be associated with a large radius of curvature of the cornea, and this would reduce the power—i.e., increase the focal length—and so an unusually large eye is not necessarily a myopic one.

**Accommodation.** *Effects of accommodation.* The image of an object brought close to the eye would be formed behind the retina if there were no change in the focal length of the eye. This change to bring the image of an object upon the retina is called accommodation. The point nearer than which accommodation is no longer effective is called the near point of accommodation. In very young people, the near point of accommodation is quite close to the eye, namely about seven centimetres (about three inches) in front at ten years old; at forty years the distance has increased to about 16 centimetres (about 6 inches), and at 60 years it is 100 centimetres or one metre (39 inches). Thus, a 60-year-old would not be able to read a book held at the convenient distance of about 40 centimetres (16 inches), and the extra power required would have to be provided by convex lenses in front of the eye, an arrangement called the presbyopic correction.

*Mechanism of accommodation.* It is essentially an increase in curvature of the anterior surface of the lens that is responsible for the increase in power involved in the process of accommodation. A clue to the way in which this change in shape takes place is given by the observation that a lens that has been taken out of the eye is much rounder and fatter than one within the eye; thus, its attachments by the zonular fibres to the ciliary muscle within the eye preserve the unaccommodated or flattened state of the lens; and modern investigations leave little doubt that it is the pull of the zonular fibres on the elastic capsule of the lens that holds the anterior surface relatively flat. When these zonular fibres are loosened, the elastic tension in the capsule comes into play and remolds the lens, making it smaller and thicker. Thus, the physiological problem is to find what loosens the zonular fibres during accommodation. The ciliary muscle has been described earlier, and it has been shown that the effect of contracting its fibres is, in general, to pull the whole ciliary body forward and to move the anterior region toward the axis of the eye by virtue of the sphincter action of the circular fibres. Both of these actions will slacken the zonular fibres and therefore allow the change in shape. As to why it is the anterior surface that changes most is not absolutely clear, but it is probably a characteristic of the capsule rather than of the underlying lens tissue. Defective accommodation in presbyopia is not due to a failure of the ciliary muscle but rather to a hardening of the substance of the lens with age to the point that readjustments of its shape become ever more difficult.

*Nerve action.* Accommodation is an involuntary reflex act, and the ciliary muscle belongs to the smooth involuntary class. Appropriate to this, the innervation is through the autonomic system, the parasympathetic nerve cells belonging to the oculomotor nerve (the third cranial nerve) occupying a special region of the nucleus in the midbrain called the Edinger-Westphal nucleus; the fibres have a relay point in the ciliary ganglion in the eye socket, and the postganglionic fibres enter the eye as the short ciliary nerves. The stimulus for accommodation is the nearness of the object, but the manner in which this nearness is translated into a stimulus is not clear. Thus, the fact that the image is blurred is not sufficient to induce accommodation; the eye has some power of discriminating whether the blurredness is due to an object being too far away or too close, so that something more than mere blurredness is required.

The near point of accommodation

Four refractive surfaces

The light  
and near  
reflexes

**The pupil.** The amount of light entering the eye is restricted by the aperture in the iris, the pupil.

When a person is in a dark room his pupil is large, perhaps eight millimetres (0.3 inch) in diameter, or more. When the room is lighted there is an immediate constriction of the pupil, the light reflex; this is bilateral, so that even if only one eye is exposed to the light both pupils contract to nearly the same extent. After a time the pupils expand even though the bright light is maintained, but the expansion is not large. The final state is determined by the actual degree of illumination; if this is high, then the final state may be a diameter of only about three to four millimetres; if it is not so high, then the initial constriction may be nearly the same, but the final state may be with a pupil of four to five millimetres. During this steady condition, the pupils do not remain at exactly constant size; there is a characteristic oscillation in size that, if exaggerated, is called *hippus*.

A pupillary constriction will also occur when a person looks at a near object—the near reflex. Thus, accommodation and pupillary constriction occur together reflexly and are excited by the same stimulus. The function of the pupil is clearly that of controlling the amount of light entering the eye, and hence the light reflex. The constriction occurring during near vision suggests other functions, too; thus, the aberrations of the eye (failure of some refracted rays to focus on the retina) are decreased by reducing the aperture of its optical system. In the dark, aberrations are of negligible significance, so that a person is concerned only with allowing as much light into the eye as possible; in bright light high visual acuity is usually required, and this means reducing the aberrations. The depth of focus of the optical system is increased when the aperture is reduced, and the near reflex is probably concerned with increasing depth of focus under these conditions.

Dilation of the pupil occurs as a result of strong psychical stimuli and also when any sensory nerve is stimulated; dilation thus occurs in extreme fear and in pain.

**Neuromuscular mechanisms.** The muscles of the iris have been described earlier. It is clear from their general features that constriction of the pupil is brought about by shortening of the circular ring of fibres—the sphincter; dilation is brought about by shortening of the radially oriented fibres. The sphincter is innervated by parasympathetic fibres of the oculomotor nerve, with their cell bodies in the Edinger-Westphal nucleus, as are the nerve cells controlling accommodation; thus, the close association between the accommodation and pupillary reflexes is reflected in a close anatomical contiguity of their motor nerve cells.

The sensory pathway in the light reflex involves the rods and cones, bipolar cells, and ganglion cells. As indicated earlier, a relay centre for pupillary responses to light is the pretectal nucleus in the midbrain. There is a partial crossing-over of the fibres of the pretectal nerve cells so that some may run to the motor nerve cells in the Edinger-Westphal nucleus of both sides of the brain, and it is by this means that illumination of one eye affects the other. The Edinger-Westphal motor neurons have a relay point in the ciliary ganglion, a group of nerve cells in the eye socket, so that its electrical stimulation causes both accommodation and pupillary constriction; similarly, application of a drug, such as pilocarpine, to the cornea will cause a constriction of the pupil and also a spasm of accommodation; atropine, by paralyzing the nerve supply, causes dilation of the pupil and paralysis of accommodation (*cycloplegia*).

The dilator muscle of the iris is activated by sympathetic nerve fibres. Stimulation of the sympathetic nerve in the neck causes a powerful dilation of the iris; again, the influx of adrenalin into the blood from the adrenal glands during extreme excitement results in pupillary dilation.

Many involuntary muscles receive a double innervation, being activated by one type of nerve supply and inhibited by the other; modern experimentation indicates that the iris muscles are no exception, so that the sphinc-

ter has an inhibitory sympathetic nerve supply, while the dilator has a parasympathetic (cholinergic) inhibitor. Thus, a drug like pilocarpine not only activates the constrictor muscle but actively inhibits the dilator. A similar double innervation has been described for the ciliary muscle. In general, any change in pupillary size results from a reciprocal innervation of dilator and constrictor; thus, activation of the constrictor is associated with inhibition of the dilator and vice versa.

**The near response.** In general, as has been indicated, pupillary constriction and accommodation occur together, in response to the same stimulus; a third element in this near response is, of course, the convergence (turning in) of the eyes, mediated by voluntary muscles, the medial recti. Experimentally, it is often possible to separate these activities, in the sense that one may cause convergence without accommodation by placing appropriate prisms in front of the eyes; or one may cause accommodation without convergence by placing diverging lenses in front of the eyes. There are many experiments that show that accommodation and convergence are neurologically linked to some extent, however.

#### THE WORK OF THE RETINA

**Some basic facts of vision.** So far, attention has been directed to what are essentially the preliminaries to vision; it is now time to examine some of the elementary facts of vision and to relate them to the structure of the retina and, later, to chemically identifiable events.

**Measurement of the threshold.** An important means of measuring a sensation is to determine the threshold stimulus—i.e., the minimum energy required to evoke the sensation. In the case of vision, this would be the minimum number of quanta of light entering the eye in unit time. If it is found that the threshold has altered because of a change of some sort, then this change can be said to have altered the subject's sensitivity to light, and a numerical value can be assigned to the sensitivity by use of the reciprocal of the threshold energy. Practically, a subject may be placed in the dark in front of a white screen, and the screen may be illuminated by flashes of light; for any given intensity of illumination of the screen, it is not difficult to calculate the flow of light energy entering the eye. One may begin with a low intensity of flash and increase this successively until the subject reports that he can see the flash. In fact, at this threshold level, he will not see every flash presented, even though the intensity of the light is kept constant; for this reason, a certain frequency of seeing—e.g., four times out of six—must be selected as the arbitrary point at which to fix the threshold.

When measurements of this sort are carried out, it is found that the threshold falls progressively as the subject is maintained in the dark room. This is not due to dilation of the pupil because the same phenomenon occurs if the subject is made to look through an artificial pupil of fixed diameter. The eye, after about 30 minutes in the dark, may become about 10,000 times more sensitive to light. Vision under these conditions is, moreover, characteristically different from what it is under ordinary daylight conditions. Thus, in order to obtain best vision, the eye must look away from the screen so that the image of the screen does not fall on the fovea; if the screen is continuously illuminated at around this threshold level it will be found to disappear if its image is brought onto the fovea, and it will become immediately visible on looking away. The same phenomenon may be demonstrated on a moonless night if the gaze is fixed on a dim star; it disappears on fixation and reappears on looking away. This feature of vision under these near-threshold or scotopic conditions suggests that the cones are effectively blind to weak light stimuli, since they are the only receptors in the fovea. This is the basis of the duplicity theory of vision, which postulates that when the light stimulus is weak and the eye has been dark-adapted, it is the rods that are utilized because, under these conditions, their threshold is much lower than that of the cones. When the subject first enters the dark, the rods are the less sensitive type of receptor, and the thresh-

Decline in  
visual  
threshold

Duplicity  
theory of  
vision

Dilator  
response

old stimulus is the light energy required to stimulate the cones; during the first five or more minutes the threshold of the cones decreases; *i.e.*, they become more sensitive. The rods then increase their sensitivity to the point that they are the more sensitive, and it is they that now determine the sensitivity of the whole eye, the threshold stimuli obtained after ten minutes in the dark, for example, being too weak to activate the cones.

**Scotopic sensitivity curve.** When different wavelengths of light are employed for measuring the threshold, it is found, for example, that the eye is much more sensitive to blue-green light than to orange. The interesting feature of this kind of study is that the subject reports only that the light is light; he distinguishes no colour. If the intensity of a given wavelength of light is increased step by step above the threshold, a point comes when the subject states that it is coloured, and the difference between the threshold for light appreciation and this, the chromatic threshold, is called the photochromatic interval. This suggests that the rods give only achromatic, or colourless, vision, and that it is the cones that permit wavelength discrimination. The photochromatic interval for long wavelengths (red light) is about zero, which means that the intensity required to reach the sensation of light is the same as that to reach the sensation of colour. This is because the rods are so insensitive to red light; if the dark-adaptation curve is plotted for a red stimulus it is found that it follows the cone path, like that for foveal vision at all wavelengths.

**Loss of dark adaptation.** If, when the subject has become completely dark-adapted, one eye is held shut and the other exposed to a bright light for a little while, it is found that, whereas the dark-adapted eye retains its high sensitivity, that of the light-exposed eye has decreased greatly; it requires another period of dark adaptation for the two eyes to become equally sensitive.

These simple experiments pose several problems, the answers to which throw a great deal of light on the whole mechanism of vision. Why, for example, does it require time for both rods and cones to reach their maximum sensitivity in the dark? Again, why is visual acuity so low under scotopic conditions compared with that in daylight, although sensitivity to light is so high? Finally, why do the rods not serve to discriminate different wavelengths?

**Bleaching of rhodopsin.** It may be assumed that a receptor is sensitive to light because it contains a substance that absorbs light and converts this vibrational type of energy into some other form that is eventually transmuted into electrical changes, and that these may be transmitted from the receptor to the bipolar cell with which it is immediately connected. When the retina of a dark-adapted animal is removed and submitted to extraction procedures, a pigment, originally called visual purple but now called rhodopsin, may be obtained. If the eye is exposed to a bright light for some time before extraction, little or no rhodopsin is obtained. When retinas from animals that had been progressively dark-adapted were studied, a gradual increase in the amount of rhodopsin that could be extracted was observed. Thus, rhodopsin, on absorption of light energy, is changed to some other compound, but new rhodopsin is formed, or rhodopsin is regenerated, during dark adaptation. The obvious inference is that rhodopsin is the visual pigment of the rods, and that when it is exposed to relatively intense lights it becomes useless for vision. When the eye is allowed to remain in the dark the rhodopsin regenerates and thus becomes available for vision. There is now conclusive proof that rhodopsin is, indeed, the visual pigment for the rods; it is obtained from retinas that have only rods and no cones—*e.g.*, the retinas of the rat or guinea pig, and it is not obtained from the pure cone retina of the chicken.

When the absorption spectrum is measured, it is found that its maximum absorption occurs at the point of maximum sensitivity of the dark-adapted eye. Similar measurements may be carried out on animals, but the threshold sensitivity must be determined by some objective means—*e.g.*, the response of the pupil, or, better

still, the electrical changes occurring in the retina in response to light stimuli. Thus, the electroretinogram (ERG) is the record of changes in potential between an electrode placed on the surface of the cornea and an electrode placed on another part of the body, caused by illumination of the eye.

The high sensitivity of the rods by comparison with the cones may be a reflection of the greater concentration in them of pigment that would permit them to catch light more efficiently, or it may depend on other factors—*e.g.*, the efficiency of transformation of the light energy into electrical energy. The pigments responsible for cone vision are not easily extracted or identified, and the problem will be considered in the material on colour vision. An important factor, so far as sensitivity is concerned, is the actual organization of the receptors and neurons in the retina.

**Synaptic organization of the retina.** The basic structure of the retina has been indicated earlier. As in other parts of the nervous system, the messages initiated in one element are transmitted, or relayed, to others. The regions of transmission from one cell to another are areas of intimate contact known as synapses. An impulse conveyed from one cell to another travels from the first cell body along a projection called an axon, to a synapse, where the impulse is received by a projection, called a dendrite, of the second cell. The impulse is then conveyed to the second cell body, to be transmitted further, along the second cell's axon.

It will be recalled that the functioning cells of the retina are the receptor cells—the rods and cones; the ganglion cells, the axons of which form the optic nerve; and cells that act in a variety of ways as intermediaries between the receptors and the ganglion cells. These intermediaries are named bipolar cells, horizontal cells, and amacrine cells.

**Plexiform layers.** As was indicated earlier, the synapses occur in definite layers, the outer and inner plexiform layers. In the outer plexiform layer the bipolar cells make their contacts, by way of their dendrites, with the rods and cones, specifically the spherules of the rods and the pedicles of the cones. In this layer, too, the projections from horizontal cells make contacts with rods, cones, and bipolar cells, giving rise to a horizontal transmission and thereby allowing activity in one part of the retina to influence the behaviour of a neighbouring part. In the inner plexiform layer, the axons of the bipolar cells make connection with the dendrites of ganglion cells, once again at special synaptic regions. (The dendrites of a nerve cell carry impulses to the nerve cell; its axon, away from the cell.) Here, too, a horizontal interconnection between bipolar cells is brought about, in this case by way of the axons and dendrites of amacrine cells.

The bipolar cells are of two main types: namely, those that apparently make connection with only one receptor—a cone—and those that connect to several receptors. The type of bipolar cell that connects to a single cone is called the midget bipolar. The other type of bipolar cell is called diffuse; varieties of these include the rod bipolar, the dendritic projections of which spread over an area wide enough to allow contacts with as many as 50 rods; and the flat cone bipolar, which collects messages from up to seven cones.

Ganglion cells are of two main types: namely, the midget ganglion cell, which apparently makes a unique connection with a midget bipolar cell, which in turn is directly connected to a single cone; and a diffuse type, which collects messages from groups of bipolar cells.

**Convergence of the messages.** The presence of diffuse bipolar and ganglion cells collecting messages from groups of receptors and bipolar cells, and, what may be even more important, the presence of lateral connections of groups of receptors and bipolar cells through the horizontal and amacrine cells, means that messages from receptors over a rather large area of the retina may converge on a single ganglion cell. This convergence means that the effects of light falling on the receptive field may be cumulative, so that a weak light stimulus

Inner  
plexiform  
layer

Rhodopsin  
as the  
photo-  
pigment

spread over about 1,000 rods is just as effective as a stronger stimulus spread over 100 or less; in other words, a large receptive field will have a lower threshold than a small one; and this is, in fact, the basis for the high sensitivity of the area immediately outside the fovea, where there is a high density of rods that converge on single bipolar cells. Thus, if it is postulated that the cones do not converge to anything like the same extent as the rods, the greater sensitivity of the latter may be explained; and the anatomical evidence favours this postulate.

It has been indicated above that the regeneration of visual pigment is a cause of the increased sensitivity of the rods that occurs during dark adaptation. This, apparently, is only part of the story. An important additional factor is the change in functional organization of the retina during adaptation. When the eye is light-adapted, functional convergence is small, and sensitivity of rods and cones is low; as dark adaptation proceeds, convergence of rods increases. The anatomical connections do not change, but the power of the bipolar cells and ganglion cells to collect impulses is increased, perhaps by the removal of an inhibition that prevents this during high illumination of the retina.

**Absolute threshold and minimum stimulus for vision.** As was indicated earlier, the threshold is best indicated in terms of frequency of seeing since, because of fluctuations in the threshold, there is no definite luminance of a test screen at which it is always seen by the observer, and there is no luminance just below this at which it is never seen. Experiments, in which 60 percent was arbitrarily taken as the frequency of seeing and in which the image of a patch of light covered an area of retina containing about 20,000,000 rods, led to the calculation that the mean threshold stimulus represents 2,500 quanta of light that is actually absorbed per square centimetre of retina. This calculation leads to two important conclusions: namely, that at the threshold only one rod out of thousands comes into operation, and that during the application of a short stimulus the chances are that no rod receives more than a single quantum.

A quantum, defined as the product of Planck's constant ( $6.55 \times 10^{-27}$  erg seconds) times the frequency of light, is the minimum amount of light energy that can be employed. A rod excited by a single quantum cannot excite a bipolar cell without the simultaneous assistance of one or more other rods. Experiments carried out in the 1940s indicated that a stimulus of about 11 quanta is required; thus it may require 11 excited rods, each receiving one quantum of light, to produce the sensation of light.

**Quantum fluctuations.** With such small amounts of energy as those involved in the threshold stimulus, the uncertainty principle becomes important; according to this, there is no certainty that a given flash will have the expected number of quanta in it, but only a probability. Thus, one may speak of a certain average number of quanta and the actual number in any given flash, and one may compute on statistical grounds the shape of curve that is obtained by plotting frequency with which a flash contains, say, four quanta or more against the average number in the flash. One may also plot the frequency with which a flash is seen against the average number of quanta in the flash, and this frequency-of-seeing curve turns out to be similar to the frequency-of-containing-quanta curve when the number of quanta chosen is five to seven, depending on the observer. This congruence strongly suggests that the fluctuations in response to a flash of the same average intensity are caused by fluctuations in the energy content of the stimulus, and not by fluctuations in the sensitivity of the retina.

**Spatial summation.** In spatial summation two stimuli falling on nearby areas of the retina add their effects so that either alone may be inadequate to evoke the sensation of light, but, when presented simultaneously, they may do so. Thus, the threshold luminance of a test patch required to be just visible depends, within limits, on its size, a larger patch requiring a lower luminance, and vice versa. Within a small range of limiting area, namely that

subtending about 10 to 15 minutes of arc, the relationship called Ricco's law holds; *i.e.*, threshold intensity multiplied by the area equals a constant. This means that over this area, which embraces several hundreds of rods, light falling on the individual rods summates, or accumulates, its effects completely so that 100 quanta falling on a single rod are as effective as one quantum falling simultaneously on 100 rods. The basis for this summation is clearly the convergence of receptors on ganglion cells, the chemical effects of the quanta of light falling on individual rods being converted into electrical changes that converge on a single bipolar cell through its branching dendritic processes. Again, the electrical effects induced in the bipolar cells may summate at the dendritic processes of a ganglion cell so that the receptive field of a ganglion cell may embrace many thousands of rods.

**Temporal summation.** In temporal summation, two stimuli, each being too weak to excite, cause a sensation of light if presented in rapid succession on the same spot of the retina; thus, over a certain range of times, up to 0.1 second, the Bunsen-Roscoe law holds: namely, that the intensity of light multiplied by the time of exposure equals a constant. Thus it was found that within this time interval (up to 0.1 second), the total number of quanta required to excite vision was 130, irrespective of the manner in which these were supplied. Beyond this time, summation was still evident, but it was not perfect, so that if the duration was increased to one second the total number of quanta required was 220. Temporal summation is consistent with quantum theory; it has been shown that fluctuations in the number of quanta actually in a light flash are responsible for the variable responsiveness of the eye; increasing the duration of a light stimulus increases the probability that it will contain a given number of quanta, and that it will excite.

**Inhibition.** In the central nervous system generally, the relay of impulses from one nerve cell or neuron to excite another is only one aspect of neuronal interaction. Just as important, if not more so, is the inhibition of one neuron by the discharge in another. So it is in the retina. Subjectively, the inhibitory activity is reflected in many of the phenomena associated with adaptation to light or its reverse. Thus, the decrease in sensitivity of the retina to light during exposure to light is only partially accounted for by bleaching of visual pigment, be it the pigment in rod or cone; an important factor is the onset of inhibitory processes that reduce the convergence of receptors on ganglion cells. Some of the rapidly occurring changes in sensitivity described as alpha adaptation are doubtless purely neural in origin.

Many so-called inductive phenomena indicate inhibitory processes; thus, the phenomenon of simultaneous contrast, whereby a patch of light appears much darker if surrounded by a bright background than by a black, is due to the inhibitory effect of the surrounding retina on the central region, induced by the bright surrounding. Many colour-contrast phenomena are similarly caused; thus, if a blue light is projected onto a large white screen, the white screen rapidly appears yellow; the blue stimulus falling on the central retina causes inhibition of blue sensitivity in the periphery; hence, the white background will appear to be missing its blue light—white minus blue is a mixture of red and green—*i.e.*, yellow. Particularly interesting from this viewpoint are the phenomena of metacontrast; by this is meant the inductive effect of a primary light stimulus on the sensitivity of the eye to a previously presented light stimulus on an adjoining area of retina. It is a combination of temporal and spatial induction. The effect is produced by illuminating the two halves of a circular patch consecutively for a brief duration. If the left half only, for example, is illuminated for 10 milliseconds it produces a definite sensation of brightness. If, now, both halves are illuminated for the same period, but the right half from 20 to 50 milliseconds later, the left half of the field appears much darker than before and, near the centre, may be completely extinguished. The left field has thus been inhibited by the succeeding, nearby, stimulus. The right field,

Uncertainty principle

Meta- and para-contrast

moreover, appears darker than when illuminated alone—it has been inhibited by the earlier stimulus (paracontrast).

**Flicker.** Another visual phenomenon that brings out the importance of inhibition is the sensation evoked when a visual stimulus is repeated rapidly; for example, one may view a screen that is illuminated by a source of light the rays from which may be intercepted at regular intervals by rotating a sector of a circular screen in front of it. If the sector rotates slowly, a sensation of black followed by white is aroused; as the speed increases the sensation becomes one of flicker—i.e., rapid fluctuations in brightness; finally, at a certain speed, called the critical fusion frequency, the sensation becomes continuous and the subject is unaware of the alterations in the illumination of the screen.

At high levels of luminance, when cone vision is employed, the fusion frequency is high, increasing with increasing luminance in a logarithmic fashion—the Ferry-Porter law—so that at high levels it may require 60 flashes per second to reach a continuous sensation. Under conditions of night, or scotopic, vision, the frequencies may be as low as four per second. The difference between rod and cone vision in this respect probably resides in the power of the eye to inhibit activity in cones rapidly, so that the sensation evoked by a single flash is cut off immediately, and this leaves the eye ready to respond to the next stimulus. By contrast, the response in the rod lasts so much longer that, when a new stimulus falls even a quarter of a second later, the difference in the state of the rods is insufficient to evoke a change in intensity of sensation; it merely prolongs it. One interesting feature of an intermittent stimulus is that the intensity of the sensation of brightness, when fusion is achieved, is dependent on the relative periods of light and darkness in the cycle, and this gives one a method of grading the effective luminance of a screen; one may keep the intensity of the illuminating source constant and merely vary the period of blackness in a cycle of black and white. The effective luminance will be the average luminance during a cycle; this is known as the Talbot-Plateau law.

**Visual acuity.** As has been stated, the ability to perceive detail is restricted in the dark-adapted retina when the illumination is such as to excite only the scotopic type of vision; this is in spite of the high sensitivity of the retina to light under the same conditions. The power of distinguishing detail is essentially the power to resolve two stimuli separated in space, so that, if a grating of black lines on a white background is moved farther and farther away from an observer, a point is reached when he will be unable to distinguish this stimulus pattern from a uniformly gray sheet of paper. The angle subtended at the eye by the spacing between the lines at the point where they are just resolvable is called the resolving power of the eye; the reciprocal of this angle, in minutes of arc, is called the visual acuity. Thus, a visual acuity of unity indicates a power of resolving detail subtending one minute of arc at the eye; a visual acuity of two indicates a resolution of one-half minute, or 30 seconds of arc. The visual acuity depends strongly on the illumination of the test target, and this is true of both daylight (photopic) and night (scotopic) vision; thus, with a brightly illuminated target, with the surroundings equally brightly illuminated (the ideal condition), the visual acuity may be as high as two. When the illumination is reduced, the acuity falls so that, under ordinary conditions of daylight viewing, visual acuity is not much better than unity. Under scotopic conditions, the visual acuity may be only 0.04 so that lines would have to subtend about 25 minutes at the eye to be resolvable; this corresponds to a thickness of 4.4 centimetres (1.7 inches) at a distance of six metres (20 feet).

**Measurement.** In the laboratory, visual acuity is measured by the Landolt C, which is a circle with a break in it. The subject is asked to state where the break is when the figure is rotated to successive random positions. The size of the C, and thus of its break, is reduced until the subject makes more than an arbitrarily chosen percentage of mistakes. The angle subtended at the eye by the

break in the C at this limit is taken as the resolving power of the eye. The testing of the eyes by the optician is essentially a determination of visual acuity; here the subject is presented with the Snellen chart, rows of letters whose details subtend progressively smaller angles at the eye. The row in which, say, five out of six letters are seen correctly is chosen as that which measures the visual acuity. If the details subtended one minute of arc, the visual acuity would be unity. The notation employed is somewhat obscure; a visual acuity of unity would be expressed as 6/6; an acuity of a half as 6/12, and so on; here the numerator is the viewing distance in metres from the chart and the denominator the distance at which details on the letters of the limiting row subtend one minute of arc at the eye.

**Anatomical basis; the retinal mosaic.** From an anatomical point of view one may expect the limit to resolving power to be imposed by the "grain" of the retinal mosaic in the same way that the size of the grains in a photographic emulsion imposes a limit to the accuracy with which detail may be photographed. Two white lines on a black ground, for example, could not be appreciated as distinct if their images fell on the same or adjacent sets of receptors. If a set of receptors intervened between the stimulated ones, there would be a basis for discrimination because the message sent to the central nervous system could be that two rows of receptors, separated by an unstimulated row, were sending messages to their bipolar cells. Thus, the limit to resolution, on this basis, should be the diameter of a foveal cone, or rather the angle subtended by this at the nodal point of the eye; this is about 30 seconds of arc and, in fact, corresponds with the best visual acuity attainable. If this grain of the retinal mosaic is to be the basis of resolution, however, one must postulate, in addition, a nervous mechanism that will transmit accurately the events taking place in the individual receptors, in this case the foveal cones; i.e., there must be a one-to-one relationship between cones, bipolar cells, ganglion cells, and lateral geniculate cells so that what is called the local sign of the impulses from a given foveal cone may be obtained. It must be appreciated that restriction on convergence (or its reverse, spread) of messages may be achieved by inhibition; the anatomical connections may be there, but they may be made functionally inoperative by inhibition exerted by other neurons; thus, the horizontal and amacrine cells might well exert a restraining influence on certain junctions, thereby reducing the spread, or convergence, of messages, and it seems likely that the improvement in foveal visual acuity from one to two, brought about by increased luminance of the target and its surroundings, is achieved by an increase in inhibition that tends to make transmission one-to-one in the fovea.

It must be appreciated that true one-to-one connections in the retina do not exist; a cone, although making an exclusive type of synapse with a midget bipolar, may also make a less exclusive contact with a flat bipolar cell; furthermore, midget bipolars and cones are connected laterally by amacrine and horizontal cells so that it is most unlikely that a given optic nerve fibre carries messages from only a single cone. The one-to-one relationship may in fact exist under certain conditions, but that is because pathways from other receptors have been blocked or occluded by inhibitory processes that keep the line clear for a given cone.

The low visual acuity obtained in night, or rod, vision is now understandable. It has been pointed out that a high sensitivity to light is achieved by the convergence of rods on the higher neurons to allow spatial summation, and it is this convergence that interferes with the resolution of detail. If hundreds of rods converge on a single bipolar cell and if many bipolar cells converge on a single ganglion cell, it is understandable that the unit responsible for resolution may be very large and thus that the visual acuity is very small.

**The retinal image.** It has been implied, in the comments on visual acuity, that the limiting factor is one of an anatomical arrangement of receptors and of their neural organization. A very important feature, however,

The  
Snellen  
chart

Resolving  
power and  
visual  
acuity

Scotopic  
acuity

must be the accuracy of the formation of an image of external objects by the optical system of the eye. It may be calculated, for example, that the image of a grating produces lines 0.5 micron wide on the retina, but this is on the basis of ideal geometrical optics; in fact, the optics of the eye are not perfect, while diffraction of light by its passage through the pupil further spoils the image. As a result of these defects, the image of a black and white grating on the retina is not sharp, the black lines being not completely black but gray because of spread of light from the white lines. (When the optical system of the eye is defective, moreover, as in nearsightedness, the imagery is worse, but this can be corrected by the use of appropriate lenses.) Physiologically, the eye effectively improves the retinal image by enhancing contrasts; thus, the image of a fine black line on a white background formed on the retina is not a sharply defined black line but a relatively wide band of varying degrees of grayness; yet to the observer the line appears sharply defined, and this is because of lateral inhibition, the receptors that receive most light tending to inhibit those that receive less; the result is a physiological "sharpening of the image," so that the eye often behaves as though the image were perfect. This applies to chromatic aberration, too, which should cause black and white objects to appear fringed with colour, yet, because of suppression of the chromatic responses, one is not aware of the coloured fringes that do in effect surround the images of objects in the external world.

The pupil

The iris behaves as a diaphragm, modifying the amount of light entering the eye; probably of greater significance than control of the light entering the eye is the influence on aberrations of the optical system; the smaller the pupil the less serious, in general, are the aberrations. The smaller the pupil, however, the more serious become the effects of diffraction, so that a balance must be struck. Experimentally, it is found that at high luminances with pupils below three millimetres (0.12 inch) in diameter the visual acuity is not improved by further reduction of the diameter; increasing the pupil size beyond this reduces acuity, presumably because of the greater optical aberrations. It is interesting that when a subject is placed in a room that is darkened steadily, the size of the pupil increases, and the size attained for any given level of luminance is, in fact, optimal for visual acuity at this particular luminance. The reason that visual acuity increases with the larger pupils is that the extra light admitted into the eye compensates for the increased aberrations. When the gaze is fixed intently on an object for a long time, peripheral images that tend to disappear reappear immediately when the eyes are moved. This effect is called the Troxler phenomenon. To study it reproducibly it is necessary to use an optical device that ensures that the image of any object upon which the gaze is fixed will remain on the same part of the retina however the eyes move. Two investigators found, when they did this, that the stabilized retinal image tended to fade within a few seconds. It may be assumed that in normal vision the normal involuntary movements—the microsaccades and drifts mentioned earlier—keep the retinal image in sufficient movement to prevent the fading, which is essentially an example of sensory adaptation, the tendency for any receptive system to cease responding to a maintained stimulus.

**Electrophysiology of the retina.** *Neurological basis.* Subjective studies on human beings can traverse only a certain distance in the interpretation of visual phenomena; beyond this the standard electrophysiological techniques, which have been successful in unravelling the mechanisms of the central nervous system, must be applied to the eye; this, as repeatedly emphasized, is an outgrowth of the brain.

Receptive fields

Records from single optic nerve fibres of the frog and from the ganglion cell of the mammalian retina indicated three types of response. In the frog there were fibres that gave a discharge when a light was switched on the "on-fibres." Another group, the "off-fibres," remained inactive during illumination of the retina but gave a powerful discharge when the light was switched off. A third

group, the "on-off fibres," gave discharges at "on" and "off" but were inactive during the period of illumination. The responses in the mammal were similar, but more complex than in the frog. The mammalian retina shows a background of activity in the dark, so that on- and off-effects are manifest as accentuations or diminutions of this normal discharge. In general, on-elements gave an increased discharge when the light was switched on, and an inhibition of the background discharge when the light was switched off. An off-element showed inhibition of the background discharge during illumination and a powerful discharge at off; this off-discharge is thus a release of inhibition and reveals unmistakably the inhibitory character of the response to illumination that takes place in some ganglion cells. Each ganglion cell or optic nerve fibre tested had a receptive field; and the area of frog's retina from which a single fibre could be activated varied with the intensity of the light stimulus. The largest field was obtained with the strongest stimulus, so that, in order that a light stimulus, falling at some distance away from the centre of the field, might affect this particular fibre it had to be much more intense than a light stimulus falling on the centre of the field. This means that some synaptic pathways are more favoured than others.

The mammalian receptive field is more complex, the more peripheral part of the field giving the opposite type of response to that given by the centre. Thus, if, at the centre of the field, the response was "on" (an on-centre field) the response to a stimulus farther away in the same fibre was at "off," and in an intermediate zone it was often mixed to give an on-off element. In order to characterize an element, therefore, it must be called on-centre or off-centre, with the meaning thereby that at the centre of its receptive field its response was at "on" or at "off," respectively, while in the periphery it was opposite. By studying the effects of small spot stimuli on centre and periphery separately and together, one investigator demonstrated a mutual inhibition between the two. A striking feature was the effect of adaptation; after dark adaptation the surrounding area of opposite activity became ineffective. In this sense, therefore, the receptive field shrinks, but, as it is a reduction in inhibitory activity between centre and periphery, it means, in fact, that the effective field can actually increase during dark adaptation—i.e., the regions over which summation can occur—and this is exactly what is found in psychophysical experiments on dark adaptation.

*Anatomical basis.* The receptive field is essentially a measure of the number of receptors—rods or cones or a mixture of these—that make nervous connections with a single ganglion cell. The organization of centre and periphery implies that the receptors in the periphery of an on-centre cell tend to inhibit it, while those in the centre of the field tend to excite it, so that the effects of a uniform illumination covering the whole field tend to cancel out. This has an important physiological value, as it means, in effect, that the brain is not bombarded with an enormous number of unnecessary messages, as would be the case were every ganglion cell to send discharges along its optic nerve fibre as long as it was illuminated. Instead, the cell tends to respond to change—i.e., the movement of a light or dark spot over the receptive field—and to give an especially prominent response, often when the spot passes from the periphery to the centre, or vice versa. Thus, the centre-periphery organization favours the detection of movement; in a similar way it favours the detection of contours because these give rise to differences in the illumination of the parts of the receptive fields. The anatomical basis of the arrangement presumably is given by the organization of the bipolar and amacrine cells in relation to the dendrites of the ganglion cell; it is interesting that the actual diameter of the centre of the receptive field of a ganglion cell is frequently equal to the area over which its dendrites spread; the periphery exerts its effects presumably by means of amacrine cells that are capable of connecting with bipolars over a wide area. These amacrine cells could exert an inhibitory action on the bipolar cells connected to the receptors of the central zone of the field, preventing them

Inhibitory effect of periphery receptors

from responding to these receptors; in this case, the ganglion cell related to these bipolars would be of an on-centre and off-periphery type.

**Direction-sensitive ganglion cells.** When examining the receptive fields of rabbit ganglion cells, investigators found some that gave a maximal response when a moving spot of light passed in a certain "preferred" direction, while they gave no response at all when the spot passed in the opposite direction; in fact, the spontaneous activity of the cell was usually inhibited by this movement in the "null" direction. It may be assumed that the receptors connected with this type of ganglion cell are organized in a linear fashion, so that the stimulation of one receptor causes inhibition of a receptor adjacent to it. This inhibition would prevent the excitatory effect of light on the adjacent receptor from having a response when the movement was in the null direction, but would arrive too late at the adjacent receptor if the light was moving in the preferred direction.

**The electroretinogram.** If an electrode is placed on the cornea and another, indifferent electrode, placed, for example, in the mouth, illumination of the retina is followed by a succession of electrical changes; the record of these is the electroretinogram or ERG. Modern analysis has shown that the electrode on the cornea picks up changes in potential occurring successively at different levels of the retina, so that it is now possible to recognize, for example, the electrical changes occurring in the rods and cones—the receptor potentials—those occurring in the horizontal cells, and so on. In general, the electrical changes caused by the different types of cell tend to overlap in time, so that the record in the electroretinogram is only a faint and attenuated index to the actual changes; nevertheless, it has, in the past, been a most valuable tool for the analysis of retinal mechanisms. Thus, the most prominent wave—called the *b*-wave—is closely associated with discharge in the optic nerve, so that in animals, or man, the height of the *b*-wave can be used as an objective measure of the response to light. Hence, the sensitivity of the dark-adapted frog's retina to different wavelengths, as indicated by the heights of the *b*-waves, can be plotted against wavelength to give a typical scotopic sensitivity curve with a maximum at 5000 angstroms corresponding to the maximum for absorption of rhodopsin.

**Flicker.** Electrophysiology has been used as a tool for the examination of the basic mechanism of flicker and fusion. The classical studies based on the electroretinogram indicated that the important feature that determines fusion in the cone-dominated retina is the inhibition of the retina caused by each successive light flash, inhibition being indicated by the *a*-wave of the electroretinogram. In the rod-dominated retina—e.g., in man under scotopic conditions—the *a*-wave is not prominent, and fusion depends simply on the tendency for the excitatory response to a flash to persist, the inhibitory effects of a succeeding stimulus being small. More modern methods of analysis, in which the discharges in single ganglion cells in response to repeated flashes are measured, have defined fairly precisely the nature of fusion, which, so far as the retinal message is concerned, is a condition in which the record from the ganglion cell becomes identical with the record observed in the ganglion cell during spontaneous discharge during constant illumination.

**Visual acuity.** Although the resolving power of the retina depends, in the last analysis, on the size and density of packing of the receptors in the retina, it is the neural organization of the receptors that determines whether the brain will be able to make use of this theoretical resolving power. It is therefore of interest to examine the responses of retinal ganglion cells to gratings, either projected as stationary images on to the receptive field or moved slowly across it. One group of investigators showed that ganglion cells of the cat differed in sensitivity to a given grating when the sensitivity was measured by the degree of contrast between the black and white lines of the grating necessary to evoke a measurable response in the ganglion cell. When the lines

were made very fine (i.e., the "grating-frequency" was high), a point was reached at which the ganglion cell failed to respond, however great the contrast; this measured the resolving power of the particular cell being investigated. The interesting feature of this work is that individual ganglion cells had a special sensitivity to particular grating-frequencies, as if the ganglion cells were "tuned" to particular frequencies, the frequencies being measured by the number of black and white lines in a given area of retina. When the same technique was applied to human subjects, the electrical changes recorded from the scalp being taken as a measure of the response, the same results were obtained.

**Colour vision.** The spectrum, obtained by refracting light through a prism, shows a number of characteristic regions of colour—red, orange, yellow, green, blue, indigo, and violet. These regions represent large numbers of individual wavelengths; thus, the red extends roughly from 7600 angstrom units to 6500; the yellow from 6300 to 5600; green from 5400 to 5000; blue from 5000 to 4200; and violet from 4200 to 4000. Thus, the limits of the visual spectrum are commonly given as 7600 to 4000 angstroms. In fact, however, the retina is sensitive to ultraviolet light to 3500 angstroms, the failure of the short wavelengths to stimulate vision being due to absorption by the ocular media. Again, if the infrared radiation is strong enough, wavelengths as long as 10,000–10,500 angstroms evoke a sensation of light.

Within the bands of the spectrum, subtle distinctions in hue may be appreciated. The power of the eye to discriminate light on the basis of its wavelength can be measured by projecting onto the two halves of a screen lights of different wavelengths. When the difference is very small—e.g., five angstroms—no difference can be appreciated. As the difference is increased, a point is reached when the two halves of the screen appear differently coloured. The hue discrimination (hue is the quality of colour that is determined by wavelength) measured in this way varies with the region of the spectrum examined; thus, in the blue-green and yellow it is as low as ten angstroms, but in the deep red and violet it may be 100 angstroms or more. Thus, the eye can discriminate several hundreds of different spectral bands, but the capacity is limited. If it is appreciated that there are a large number of nonspectral colours that may be made up by mixing the spectral wavelengths, and by diluting these with white light, the number of different colours that may be distinguished is high indeed.

**Spectral sensitivity curve.** At extremely low intensities of stimuli, when only rods are stimulated, the retina shows a variable sensitivity to light according to its wavelength, being most sensitive at about 5000 angstroms, the absorption maximum of the rod visual pigment, rhodopsin. In the light-adapted retina one may plot a similar type of curve, obtained by measuring the relative amounts of light energy of different wavelengths required to produce the same sensation of brightness; now the different stimuli appear coloured, but the subject is asked to ignore the colours and match them on the basis of their luminosity (brightness). This is carried out with a special instrument called the flicker-photometer. There is a characteristic shift in the maximum sensitivity from 5000 angstroms for scotopic (night) vision to 5550 angstroms for photopic (day) vision, the so-called Purkinje shift. It has been suggested that the cones have a pigment that shows a maximum of absorption at 5550 angstroms, but the phenomena of colour vision demand that there be three types of cone, with three separate pigments having maximum absorption in the red, green, and blue, so that it is more probable that the photopic luminosity curve is a reflection of the summated behaviour of the three types of cone rather than of one.

The Purkinje shift has an interesting psychophysical correlate; it may be observed, as evening draws on, that the luminosities of different colours of flowers in a garden change; the reds become much darker or black, while the blues become much brighter. What is happening is that, in this range of luminosities, called mesopic, both rods and cones are responding, and, as the rod responses be-

Hue discrimination

The nature of fusion

come more pronounced—i.e., as darkness increases—the rod luminosity scale prevails over that of the cones.

It may be assumed that the sensation of luminosity under any given condition is determined by certain ganglion cells that make connections to all three types of cone and also to rods; at extremely low levels of illumination their responses are determined by the activity aroused in the rods. As the luminance is increased, the ganglion cell is activated by both rods and cones, and so its luminosity curve is governed by both rod and cone activity. Finally, at extremely high luminances, when the rods are “saturated” and ceasing to respond, the luminosity curve is, in effect, compounded of the responses of all three types of cone.

**Colour mixing.** The fundamental principle of colour mixing was discovered by Isaac Newton when he found that white light separates spatially into its different component colours on passing through a prism. When the same light is passed through another prism, so that the individual bands of the spectrum are superimposed on each other, the sensation becomes one of white light. Thus, the retina, when white light falls on it, is really being exposed to all the wavelengths that make up the spectrum. Because these wavelengths fall simultaneously on the same receptors, the evoked sensation is one of white. If the wavelengths are spread out spatially, they evoke separate sensations, such as red or yellow, according to which receptors receive which bands of wavelengths. In fact, the sensation of white may be evoked by employing much fewer wavelengths than those in the spectrum: namely, by mixing three primary hues—red, green, and blue.

Three  
primary  
hues

Furthermore, any colour, be it a spectral hue or not, may be matched by a mixture of these three primaries, red, green, and blue, if their relative intensities are varied. Many of the colours of the spectrum can be matched by mixtures of only two of the primary colours, red and green; thus the sensations of red, orange, yellow, and green may be obtained by adding more and more green light to a red one.

To one accustomed to mixing pigments, and to mixing a blue pigment, for example, with yellow to obtain green, the statement that red plus green can give yellow or orange, or that blue plus yellow can give white, may sound strange. The mixing of pigments is essentially a subtractive process, however, as opposed to the additive process of throwing differently coloured lights on a white screen. Thus, a blue pigment is blue because it reflects mainly blue (and some green) light and absorbs red and yellow; and a yellow pigment reflects mainly yellow and some green and absorbs blue and red. When blue and yellow pigments are mixed, and white light falls on the mixture, all bands of colour are absorbed except for the green colour band.

**Colour defectiveness.** The colour-defective subject is one whose wavelength discrimination apparatus is not as good as that of the majority of people, so that he sees many colours as identical that normal people would see as different. About one percent of males are dichromats; they can mix all the colours of the spectrum, as they see them, with only two primaries instead of three. Thus, the protanope (red blind) requires only blue and green to make his matches; since, for the normal (trichromatic) subject the various reds, oranges, yellows, and many greens are the result of mixing red and green, the protanope matches all these with a green. In other words, he is unable to distinguish all these hues from each other on the basis of their colour; if he distinguishes them, it is because of their different luminosity (brightness). The protanope matches white with a mixture of blue and green and is, in fact, unable to distinguish between white and bluish-green. The deuteranope (green blind) matches all colours with a mixture of red and blue; thus, his white is a mixture of red and blue that appears purple to a person with normal vision. The deuteranope also is unable to discriminate reds, oranges, yellows, and many greens, so that both types of dichromat are classed as red-green-blind. For the protanope, however, the spectrum is more limited because he is unable to appreciate red. The trit-

anope (blue blind) is rare, constituting only one in 13,000 to 65,000 of the population; because he is blue blind, his colour discrimination is best in the region of red to green, where that of the protanope and deuteranope is worse.

**Responses of uniform population of receptors.** The scotopic (night) visual system, mediated by rods, is unable to discriminate between different wavelengths; thus, a threshold stimulus of light with a wavelength of 4800 angstroms gives a sensation of light that is indistinguishable from that evoked by a wavelength of 5300 angstroms. If the intensities are increased, however, the lights evoke sensations of blue and green, respectively. Rods are unable to mediate wavelength, or colour, discrimination while the cones can because the rods form a homogeneous population, all containing the same photopigment, rhodopsin. Thus, the response of a nerve cell connected with a rod or group of rods will vary with the wavelength of light, and probably in the manner indicated by Figure 7, in which the response, measured in

Figure 7: Theoretical wavelength response curve for a single receptor of *Limulus* retina. The maximum response will occur at 5200 Å, the absorptional maximum of the retinal pigment. With wavelengths of light corresponding to the points A and B, the responses will be identical, so that no discrimination between these two wavelengths is possible. When the intensity of the light is changed and a new curve is obtained (the dotted line), the responses at A' and B' are also identical.

frequency of discharge in the bipolar or ganglion cell, is plotted against the wavelength of the stimulating light. The curve is essentially similar to the absorption spectrum of rhodopsin when the same amount of energy is in each stimulus; thus, blue-green of 5000 angstroms has the most powerful effect because it is absorbed most efficiently, while violet and red have the smallest effects. In this sense, the rods behave as wavelength discriminators, but it is to be noted that there are pairs of wavelengths on each side of the peak to which the same response is obtained; thus, a blue of 4800 angstroms and a yellow of 6000 angstroms give the same discharge. Moreover, if the intensity of the stimulus is varied, a new curve is obtained (as in the dotted line of Figure 7), and now the same response is obtained with a high intensity of violet at 4000 angstroms as with blue at the lower intensity. In general, it is easy to show that, by varying the intensity of the stimulus of a single wavelength, all types of response may be obtained, so that the brain would never receive a message indicating, in a unique fashion, that the retina was stimulated with, say, green light of 5300 angstroms; the same message could be given by blue light of 4800 angstroms, red light of 6500 angstroms, and so on.

Ideally, colour discrimination would require a large number of receptors specifically sensitive to small bands of the spectrum, but the number would have to be extremely large because the capacity for hue discrimination is extremely great, as has been indicated. In fact, however, the phenomena of colour mixing suggest that the number of receptors may be limited.

**Young-Helmholtz theory.** It was the phenomena of colour mixing that led Thomas Young in 1802 to postulate that there are three receptors, each one especially sensitive to one part of the spectrum; these receptors were thought to convey messages to the brain, and, de-

Why rods  
fail to  
discriminate  
between  
colours

pending on how strongly they were stimulated by the coloured light, the combined message would be interpreted as that due to the actual colour. The theory was developed by Hermann Ludwig Ferdinand von Helmholtz, and is called the Young-Helmholtz trichromatic theory. As expressed in modern terms, it is postulated that there are three types of cone in the retina, characterized by the presence of one of three different pigments, one absorbing preferentially in the red part of the spectrum, another in the green, and another in the blue. A coloured stimulus—e.g., a yellow light—would stimulate the red and green receptors, but would have little effect on the blue; the combined sensation would be that of yellow, which would be matched by stimulating the eye with red and green lights in correct proportions of relative intensity. A given coloured stimulus would, in general, evoke responses in all three receptors, and it would be the pattern of these responses—e.g., blue strongly, green less strongly, and red weakest—that would determine the quality of the sensation. The intensity of the sensation would be determined by the average frequencies of discharge in the receptors. Thus, increasing the intensity of the stimulus would clearly change the responses in all the receptors, but if they maintained the same pattern, the sensation of hue might remain unaltered and only that of intensity would change; the observer would say that the light was brighter but still bluish green. Thus, with several receptors, the possibility is reduced of confusion between stimuli of different intensity but the same wavelength composition; the system is not perfect because the laws of colour mixing show that the eye is incapable of certain types of discrimination, as, for example, between yellow and a mixture of red and green, but as a means of discriminating subtle changes in the environment the eye is a very satisfactory instrument.

The direct proof that the eye does contain three types of cone has been secured, but only relatively recently. This was done by examining the light emerging from the eye after reflection off the retina; in the dark-adapted eye the light emerging was deficient in blue light because this had been preferentially absorbed by the rhodopsin. In the light-adapted eye, when only cone pigments are absorbing light, the emerging light can be shown to be deficient in red and green light because of the absorption by pigments called erythrolabe and chlorolabe. Again, the light passing through individual cones of the excised human retina can be examined by a microscope device, and it was shown by such examination that cones were of three different kinds according to their preference for red, green, and blue lights.

*The nervous messages.* If the three types of cones respond differently to light stimuli, one may expect to find evidence for this difference in type of response by examining the electrophysiological changes taking place in the retina; ideally, one should like to place a microelectrode in or on a cone, then in or on its associated bipolar cell, and so on up the visual pathway. In the earliest studies, the optic nerve fibres of the frog were examined—i.e., the axons of ganglion cells. The light-adapted retina was stimulated with wavelengths of light stretching across the spectrum, and the responses in arbitrarily selected single fibres were examined. The responses to stimuli of the same energy but different wavelengths were plotted as frequency of discharge against wavelength, and the fibres fell into several categories, some giving what the investigator called a dominator response, the fibre responding to all wavelengths and giving a maximum response in the yellow-green at 5600 angstroms. Other fibres gave responses only over limited ranges of wavelengths, and their wavelengths of maximum response tended to be clustered in the red, green, and blue regions. The investigator called these modulators, and considered that the message in the dominator indicated to the brain the intensity of the stimulus—i.e., it determined the sensation of brightness—while the modulators indicated the spectral composition of the stimulus, the combined messages in all the modulators resulting in a specific colour sensation. In the dark-adapted retina, when only rods were being stimulated, the response was of the dominator

type, but this time the maximum response occurred with a wavelength of 5000 angstroms, the absorption maximum of rhodopsin.

A more careful examination of the responses in single fibres, especially in the fish, which has good colour vision, showed that things were not quite as simple as the original investigator had thought because, as has been seen, the response of a ganglion cell, when light falls on its receptive field in the retina, is not just a discharge of action potentials that ceases when the light is switched off. This type of response is rare; the most usual ganglion cell or optic nerve fibre has a receptive field organized in a concentric manner, so that a spot of light falling in the central part of the field produces a discharge, while a ring of light falling on the surrounding area has the opposite effect, giving an off-response—i.e., giving a discharge only when the light is switched off. Such a ganglion cell would be called an on-centre-off-periphery unit; others behaved in the opposite way, being off-centre-on-periphery.

When these units are examined with coloured lights, and when care is taken to stimulate the centres and surrounding areas separately, an interesting feature emerges; the centre and surrounding areas usually have opposite or opponent responses. Thus, some may be found giving an on-response to red in the centre of the field and an off-response to green in the surrounding area, so that simultaneous stimulation of centre with red and surrounding area with green gives no response, the inhibitory effect of the off-type of response cancelling the excitatory effect of the on-type. With many other units the effects were more complex, the centre giving an on-response to red and an off-response to green, while the surrounding area gave an off-response to red and an on-response to green, and vice versa. This opponent organization probably subserves several functions. First, it enables the retina to emphasize differences of colour in adjacent parts of the field, especially when the boundary between them moves, as indeed it is continually doing in normal vision because of the small involuntary movements of the eyes. Second, it is useful in "keeping the retina quiet"; there are about one million optic nerve fibres, and if all these were discharging at once the problem of sorting out their messages, and making meaning of them, would be enormous; by this "opponence," diffuse white light falling on many of these chromatic units would have no effect because the inhibitory surrounding area cancelled the excitatory centre, or vice versa. When the light became coloured, however, the previously inactive units could come into activity.

These responses show that by the time the effect of light has passed out of the eye in the optic nerve the message is well colour-coded. Thus all the evidence points to the correctness of the Young-Helmholtz hypothesis with respect to the three-colour basis. The three types of receptor, responding to different regions of the spectrum in specific manners, transmit their effects to bipolar and horizontal cells. The latter neurons have been studied from the point of view of their colour-coding. The potentials recorded from them were called *S*-potentials; these were of two types, which classified them as responding to colour (*C*-units) and luminosity (*L*-units).

The *C*-type of cell gave an opponent type of response, in the sense that the electrical sign varied with the wavelength band, red and green having opponent effects on some cells, and blue and yellow on others. These responses reflect the connections of the horizontal cells to groups of different cones, the blue-yellow type, for example, having connections with blue and red and green cones, while the red-green would have connections only with red and green cones.

*Lateral geniculate cells.* As indicated above, the cells at the next stage, the ganglion cells, give a fairly precisely coded set of messages indicating the chromatic (colour) quality and the luminosity (brightness) of the stimulus, organized in such a way, however, as to facilitate the discrimination of contrast. At higher stages—e.g., in the cells of the lateral geniculate body—this emphasis on opponence, or contrast, is maintained and extended; thus,

*S*-  
potentials

Dominator  
impulse

several types of cell have been described that differ in accordance with the organization of their receptive fields from the colour aspect; some were very similar to ganglion cells, while others differed in certain respects. Some showed no opponence between colours when centre and periphery were compared, so that if a red light on the periphery caused inhibition, green and blue light would also do so. Others had no centre-periphery organization, the receptive field consisting of only a central spot; different colours had different effects on this spot; and so on.

In the cerebral cortex there is the same type of opponence with many units, but because cortical cells require stimuli of definite shape and often are not activated by simple spot stimuli, early studies carried out before these requirements were known probably failed to elucidate the true chromatic requirements of these high-order neurons. In general, the responses are what might be predicted on the basis of connections made to lateral geniculate neurons having the chromatic responses already known. Thus the final awareness of colour probably depends on the bombardment of certain higher-order cortical neurons by groups of primary cortical neurons, each group sending a different message by virtue of the connections it makes to groups of cones, connections mediated, of course, through the neurons of the retina and lateral geniculate body.

**The photochemical process.** For the energy of light to exert its effect it must be absorbed; it has been stated above that the action-spectrum for vision (the sensitivity of the eye to light) in the completely dark-adapted eye has a maximum in the region of 5000 angstroms, and that this corresponds with the maximum of absorption of light by the pigment, rhodopsin, extracted from the dark-adapted retina of the same species. The chemical nature of rhodopsin must now be examined, as well as its localization in the rod and the changes it undergoes in response to the absorption of light. It must be appreciated at the outset that the amount of light energy absorbed by a single rod at the threshold for vision is extremely small—namely, one quantum—and this is quite insufficient to provide the energy required to cause an electrical change in the membrane of the rod that will be propagated from the point of absorption of the light to the rod spherule (which takes part in the synapse between rod and bipolar cell). There must, therefore, be a chemical amplification process taking place within the rod, and the absorption of a quantum must be viewed as the trigger that sets off other changes, which in turn provide the required amount of energy.

**Rhodopsin.** Visual purple, or rhodopsin, is a chromoprotein, a protein, opsin, with an attached chromatophore ("pigment-bearing") molecule that gives it its colour—i.e., that allows it to absorb light in the visible part of the spectrum. In the absence of such a chromatophore, the protein would only absorb in the ultraviolet and so would appear colourless to the eye. The chromatophore group was identified as retinal, which is the substance formed by oxidation of vitamin A; on prolonged exposure of the eye to light, retinal can be found, free from the protein opsin, in the retina. When the eye is allowed to remain in the dark, the rhodopsin is regenerated by the joining up of retinal with opsin. Thus one may write:

The incidence of light on the retina causes the reaction to go to the right (that is, causes rhodopsin to form retinal plus opsin), and this photochemical change causes the sensation of light. The process is reversed by a thermal—i.e., non-photochemical—reaction, so that for any given light intensity a steady state is reached with the regenerative process just keeping pace with the photochemical bleaching. Dark adaptation, or one element in it, is the regenerative process. The change in the rhodopsin molecule that leads to its bleaching—i.e., the splitting off of the retinal molecule—takes place in a succession of steps; and there is reason to believe that the electrical change in the rod that eventually evokes the sensation of light occurs at a stage well before the splitting off of the

retinal. One may describe as a transduction process the chemical events that take place between the absorption of light and the electrical event, whatever that may be; the rod behaves as a transducer in that it converts light into electrical or neural energy.

**The transduction process.** Immediately after absorption of a quantum, the rhodopsin molecule is changed into a substance called prelumirhodopsin, recognized by its different colour from that of rhodopsin; this product is so highly unstable that at body temperature it is converted, without further absorption of light, into a series of products. These changes may be arrested by cooling the solution to  $-195^{\circ}\text{C}$  ( $-319^{\circ}\text{F}$ ), at which temperature prelumirhodopsin remains stable; on warming to  $-140^{\circ}\text{C}$  ( $-220^{\circ}\text{F}$ ) prelumirhodopsin becomes lumirhodopsin, with a slightly different colour; on warming further, successive changes are permitted until finally retinal is split off from the opsin to give a yellow solution. The important point to appreciate is that only at this stage is the chromatophore group split off; the earlier products have involved some change in the structure of the chromoprotein, but not so extreme as to break off the retinal. The precise nature of these changes is not yet completely elucidated, but the most fundamental one—namely, that occurring immediately after absorption of the quantum—has been shown to consist in a change in shape of the retinal molecule while it is still attached to opsin.

Thus retinal, like vitamin A, can exist in several forms because of the double bonds in its carbon chain—the so-called *cis-trans* isomerism. In other words, the same group of atoms constituting the retinal molecule can be twisted into a number of different shapes, although the sequence of the atoms is unaltered. While attached to the opsin molecule in the form of rhodopsin, the retinal has a shape called *11-cis*, being somewhat folded, while on conversion to prelumirhodopsin the retinal has a straighter shape called *all-trans*; the process is called one of photoisomerization, the absorption of light energy causing the molecule to twist into a new shape. Having suffered this alteration in shape, the retinal presumably causes some instability in the opsin, making it, too, change its shape, and thereby exposing to the medium in which it is bathed chemical groupings that were previously shielded by being enveloped in the centre of the molecule. It may be assumed that these changes in shape induce alterations in the light-absorbing character of the molecule that permit the recognition of the new forms of molecule represented by lumirhodopsin, metarhodopsins I and II, and so on.

The final change is more drastic because it involves the complete splitting off of the retinal; an earlier stage—namely, the conversion of metarhodopsin I to metarhodopsin II—has been shown recently to involve a bodily change in position of the retinal, which in rhodopsin is linked to the lipid (fatty) portion of the molecule, whereas in metarhodopsin II it is found to have become attached to an amino acid in the backbone-chain of the protein (amino acids are subunits of proteins). Thus, in its native unilluminated state, retinal is attached to a lipid, which is presumably linked to the protein, so that rhodopsin is more properly called a chromolipoprotein rather than a chromoprotein. The outer segments of the rods are, as has been stated, constituted by membranous disks, and it is well established that the material from which these membranes are constructed is predominantly lipid, so that one may envisage the rhodopsin molecules as being, in fact, part of the membrane structure. The techniques used for extraction presumably tear the molecules from the main body of the lipid, but some of the lipid remains with the protein and retinal to constitute the link holding these two parts together.

Within the retina these chemical changes are all reversible, so that when a steady light is maintained on the retina the latter will contain a mixture of several or all of the intermediate compounds. In the dark, all will be gradually reconverted to rhodopsin. Because lack of vitamin A, from which retinal is derived, causes night blindness, some of the retinal must get lost from the eye to the

Prelumirhodopsin

Photoisomerization

Opsin and retinal

general circulation; and it is actually replaced by the cells of the pigment epithelium, which are closely associated with the rods.

As to which of these chemical changes acts as the trigger for vision, there is some doubt. The discovery that the transition from metarhodopsin I to metarhodopsin II involves an actual shift of the retinal part of the molecule from linkage to lipid to linkage to protein reinforces the belief that this particular shift is sufficient to lead ultimately to electrical discharges in the optic nerve.

**Cone pigments.** So far as colour vision is concerned, the changes that take place in the three cone pigments have not been analyzed, simply because, so far, they have defied isolation, presumably because their concentrations are so much less than that of the rod pigment.

#### THE HIGHER VISUAL CENTRES

**The visual pathway.** The axons of the ganglion cells converge on the region of the retina called the papilla or optic disk. They leave the globe as the optic nerve, in which they maintain an orderly arrangement in the sense that fibres from the macular zone of the retina occupy the central portion, the fibres from the temporal half of the retina take up a concentric position, and so on; when outside the orbit, there is a partial decussation (cross-over). The fibres from the nasal halves of each retina cross to the opposite side of the brain, while those from the temporal halves remain uncrossed. This partial decussation is called the chiasma. The optic nerves after this point are called the optic tracts, containing nerve fibres from both retinas. The result of the partial decussation is that an object in, say, the right-hand visual field produces effects in the two eyes that are transmitted to the left-hand side of the brain only. With cutaneous (skin) sensation there is a complete crossing-over of the sensory pathway; thus, information from the right half of the body, and the right visual field, is all conveyed to the left-hand part of the brain by the time that it has reached the diencephalon (the posterior part of the forebrain, Figure 8).

Partial decussation

From H. Davson and M.G. Eggleton (eds.), *Principles of Human Physiology*

**Fusion of retinal images.** Partial decussation is an arrangement that serves the needs of frontally directed eyes and permits binocular vision, which consists in the fusion of the responses of both eyes to a single object—more loosely, one speaks of the fusion of the retinal images. In many lower mammals, with laterally directed eyes and therefore limited binocular vision, the degree of decussation is much greater, so that in the rat, for example, practically all of the optic nerve fibres pass to the opposite side of the brain.

The fibres of the optic tracts relay their messages to nerve cells in those parts of the diencephalon called the lateral geniculate bodies, and from the lateral geniculate bodies the messages are relayed to nerve cells in the occipital cortex of the same side. (The occipital cortex is the outer substance in the posterior portion of the brain.)

**The visual field.** If one eye is fixed on a point in space, the visual field for this eye may be thought of as the part of a surface of a sphere on to which all visible objects are projected. The limits to this field will be determined by the sensitivity and extent of the retina and the accessibility of light rays from the environment. Experimentally or clinically, the field is measured on a perimeter, a device for ascertaining the point on a given meridian where a white spot just appears or disappears from vision when moved along this meridian. (A meridian is a curve on the surface of a sphere that is formed by the intersection of the sphere surface and a plane passing through the centre of the sphere.) The field is recorded on a chart, illustrated by Figure 9. On the nasal side, the field is restricted to about 60° from the midline. This is due to the obstruction caused by the nose, since the retina extends nearly as far forward on the temporal side of the globe as on the nasal side. It is customary to refer to the binocular visual field as that common to the two eyes, the unocular field being the extreme temporal (outside) region peculiar to each eye. It will be clear from the field of the single eye shown in Figure 9 that the binocular field is determined in the horizontal meridian by the nasal field of each eye, and so will amount to about 60° to either side of the vertical meridian.

**Lateral geniculate body.** The dorsal (posterior) nucleus of the lateral geniculate body, where the optic tract fibres relay, has six layers, and the crossed fibres relay in layers 1, 4, and 6, while the uncrossed relay in layers 2,

3, and 5; thus, at this level, the impulses from the two eyes are kept separate, and when the discharges in geniculate neurons are recorded electrically it is rare to find any responding to stimuli in both eyes.

**Striate area.** The optic tract fibres make synapses with nerve cells in the respective layers of the lateral geniculate body, and the axons of these third-order nerve cells pass upward to the calcarine fissure (a furrow) in each occipital lobe of the cerebral cortex. This area is called the striate area because of bands of white fibres—axons from nerve cells in the retina—that run through it. It is also identified as Brodmann's area 17. It is at this level that the impulses from the separate eyes meet at common cortical neurons, or nerve cells, so that when the discharges in single cortical neurons are recorded it is usual to find that they respond to light falling in one or the other eye. It is probable that it is when the retinal messages have reached this level of the central nervous system, and not before, that the human subject becomes aware of the visual stimulus, since destruction of the area causes absolute blindness in man. Because of the partial decussation, however, the removal of only one striate cortex will not cause complete blindness in either eye, since only messages from two halves of the retinas will have been blocked; the same will be true if one optic tract is severed or one lateral geniculate body is destroyed. The result of such lesions will be half-blindness, or hemianopia, the messages from one half of the visual field being obliterated.

**Pupillary pathways.** Some of the fibres in the optic tracts do not relay in the lateral geniculate bodies but pass instead to a midbrain region—the pretectal centre—where they mediate (transmit) reflex alterations in the size of the pupil. Thus, in bright light, the pupils are constricted; this happens by virtue of the pupillary light reflex mediated by these special nerve fibres. Removal of the occipital cortex, although it causes blindness in the opposite visual field, does not destroy the reaction of the pupils to light; if the optic nerve is cut, however, the eye will be both completely blind and also unresponsive to light falling on this eye. The pupil of the blind eye will react to light falling on the other eye by virtue of a decussation in the pupillary reflex pathway.

**Point-to-point representation.** Because of the ordered manner in which the optic tract fibres relay in the lateral geniculate bodies and from there pass in an orderly fashion to the striate area, when a given point on the retina is stimulated, the response recorded electrically in either the lateral geniculate body or the striate area is localized to a small region characteristic for that particular retinal spot. When the whole retinal field is stimulated in this point-to-point way, and the positions on the geniculate or striate gray matter on which the responses occur are plotted, it is possible to plot on these regions of the brain maps of the retinal fields or, more usually, maps of the visual fields.

**Visuopsychic or circumstriate areas.** Area 17, the striate area, is the primary visual centre in the sense that, in primates at any rate, all of the geniculate fibres project onto it and none projects onto another region of the cortex. There are two other areas containing neurons that have close connections with the eye; these are the parastriate and peristriate areas, or Brodmann's areas 18 and 19, respectively, in close anatomical relationship to one another and to area 17. They are secondary visual areas in the sense that messages are relayed from area 17 to area 18 and from area 18 to area 19, and, because area 17 does not relay to regions beyond area 18, these circumstriate areas are the means whereby visual information is brought into relation with more remote parts of the cortex. Thus in writing, the eyes direct the activities of the fingers, which are controlled by a region of the frontal cortex, so that one may presume that visual information is relayed to this frontal region. In the monkey, bilateral destruction of the areas causes irrecoverable loss of a learned visual discrimination, but this can be relearned after the operation. In man, lesions in this region are said to cause disturbances in spatial orientation and stereoscopic vision, but much more knowledge is required

before specific functions can be attributed to these circumstriate areas, if, indeed, this is possible.

**Integration of the retinal halves.** The two halves of the retina, and thus of the visual field, are represented on opposite cerebral hemispheres, but the visual field is perceived as a unity and hence one would expect an intimate connection between the two visual cortical areas.

**Corpus callosum.** The great bulk of the connections between the two sides of the cerebral mantle are made by the interhemispheric commissure (the point of union between the two hemispheres of the cerebrum) called the corpus callosum, which is made up of neurons and their axons and dendrites that make synapses with cortical neurons on symmetrically related points of the hemispheres. Thus, electrical stimulation of a point on one hemisphere usually gives rise to a response on a symmetrically related point on the other, by virtue of these callosal connections. The striate area is an exception, however, and it is by virtue of the connections of the striate neurons with the area 18 neurons that this integration occurs, the two areas 18 on opposite hemispheres being linked by the corpus callosum.

**Stereopsis in the midline.** Usually stereopsis, or perception of depth, is possible by the use of a single hemisphere because the images of the same object formed by right and left eyes are projected to the same hemisphere; however, if the gaze is fixed on a distant point and a pin is placed in line with this but closer to the observer, a stereoscopic perception of the distant point and the pin can be achieved by the fusion of disparate images of the pin, but the images of the pin actually fall on opposite retinal halves, so that this fusion must be brought about by way of the corpus callosum.

**Callosal transfer.** In experimental animals it is possible, by section of the chiasma, to ensure that visual impulses from one eye pass only to one hemisphere. If this is done, an animal trained to respond to a given pattern and permitted to use only one eye during the training is just as efficient, when fully trained, in making the discrimination with the other eye. There has thus been a callosal transfer of the learning so that the hemisphere that was not directly involved in the learning process can react as well as that directly involved. If the corpus callosum is also sectioned, this transfer is impossible, so that the animal, trained with one eye, must be trained again if it is to carry out the task with the other eye only.

**Superior colliculi.** The visual pathway so far described is called the geniculostriate pathway, and in man it may well be the exclusive one from a functional aspect because lesions in this pathway lead to blindness. Nevertheless, many of the optic tract fibres, even in man, relay in the superior colliculi, a paired formation on the roof of the midbrain. From the colliculi there is no relay to the cortex, so that any responses brought about by this pathway do not involve the cortex. In man, as has been said, lesions in the striate area, which would of course leave the collicular centres intact, cause blindness, so that the visual fibres in these centres serve no obvious function. In lower animals, including primates, removal of the striate areas does not cause complete blindness; in fact, it is often difficult to determine any visual impairment from a study of the behaviour of the animals. Thus, in reptiles and birds, vision is barely affected, so that a pigeon that has been subjected to the operation can fly and avoid obstacles as well as a normal one. In rodents, such as the rabbit, removal of the occipital lobes causes some impairment of vision, but the animal can perform such feats as avoiding obstacles when running and recognizing food by sight. In the monkey, the effects are more serious, but the animal can be trained to discriminate lights of different intensity and even the shapes of objects, provided that these are kept in continual motion. It seems likely, then, that it is the visual pathway through the colliculi that permits the use of the eyes in the absence of visual cortex, although the connections of the optic tract fibres with the pulvinar of the thalamus (an area in the diencephalon), established in some animals, may well permit the use of regions of the cortex other than those denoted as visual.

Point of awareness of visual stimulus

Effect of cutting the corpus callosum

## SOME PERCEPTUAL ASPECTS OF VISION

So far, the visual process has been considered from rather elementary aspects; the ability to detect light and changes in its intensity, and to discriminate colour and form. It is now time to deal with more complex features, particularly some phenomena of binocular vision. It will then be in order to return to the electrophysiology of the visual pathway to see how some of the phenomena can be interpreted.

**Projection of the retina.** Objects are perceived in definite positions in space—positions definite in relation to each other and to the percipient. The first problem is to analyze the physiological basis for this spatial perception or, as it is expressed, the projection of the retina into space.

**Relative positions of objects.** The perception of the positions of objects in relation to each other is essentially a geometrical problem. Take, for the present, the perception of these relationships by one eye, monocular perception: a group of objects, as in Figure 10, produces images

Figure 10: Projection of retinal images into space. (A) A group of objects, C, D, E, produces images on the retina, c, d, e; the retinal images are projected outward in space toward the points evoking them. (B) The eye has moved to the left so that the image of c falls on d, previously projected to D but now projected to C; E no longer produces an image on the retina.

on the retina in a certain fixed geometrical relationship; for the perception of the fact that C is to the left of D, that D is to the left of E, and so on, it is necessary that the incidence of images at c, d, and e on the retina be interpreted in a similar, but, of course, inverted geometrical relationship. The neural requirements for this interpretation are (1) that the retina be built up of elements that behave as units throughout their conducting system to the visual cortex, and (2) that the retinal elements have "local signs." The local sign could represent an innate disposition or could result from experience—the association of the direction of objects in space, as determined by such evidence as that provided by touch, with the retinal pattern of stimulation. In neurophysiological terms, the retinal elements are said to be connected to cortical cells, each being specific for a given element, so that when a given cortical cell is excited the awareness is of a specific local sign. Studies of the projection of the retina on the cerebral cortex have confirmed this.

The retinal stimuli at c, d, and e in Figure 10 are appreciated as objects outside the eye, the retina is said to be projected into space, and the field of vision is thus the projection of the retina through the nodal point. (In Figure 10 the nodal point is the point of intersection of Cc, Dd, and Ee.) It will be seen that the geometrical relationship between objects and retinal stimuli is reversed; in the retina c is to the right of d, and so on.

**Position in relation to observer.** The recognition of the directions of objects in relation to the observer is more complex. If the eye (Figure 10B) is turned to the left,

the image of C falls on the retinal point d, so that if d were always projected into the same direction in space, C would appear to be in D's place. In practice, one knows that C is perceived as fixed in space in spite of the movements of the eye; hence, the direction of projection of a retinal point is constantly modified to take into account movements of the eye; this may be called psychological compensation. It will be seen that correct projection is achieved by projecting the stimulated retinal point through the nodal point of the eye. Movements of the eye caused by movements of the head must be similarly compensated. As a result, any point in space remains fixed in spite of movements of the eye and head. Given this system of compensated projection, the recognition of direction in relation to the individual is now feasible. D may be said to be due north or, more vaguely, "over there"; when the head is turned, since D is perceived to be in the same place, it is still due north or "over there." In some circumstances, the human subject makes an error in projecting his retinal image, so that the object giving rise to the image appears to be in a different place from its true one; the image is said to be falsely projected. If the eye is moved passively, for example, by pulling on the conjunctiva with forceps, the subject has the impression that objects in the outside world are moving in a direction opposite to that of the eye.

False projection

The apparent movement of an afterimage, when the eye moves, is an excellent illustration of psychological compensation. A retinal stimulus, being normally projected through the nodal point, is projected into different points in space as the eye moves; an afterimage can be considered to be the manifestation of a continued retinal impulse, and its projection changes as the eye moves. The afterimage thus appears to move in the same direction as that of the movement of the eye. Whether the drift of an afterimage across the field of view is entirely due to eye movements is difficult to say. One certainly has the impression that the eye is chasing the afterimage.

**Visual estimates.** *The directions of lines.* So far, consideration has been given to the problem of estimating the positions of points in relation to each other and to the percipient. The estimate of the directions of lines involves no really new principles, since, if two points, A and B, are exactly localized, the direction of the line AB can be appreciated. As will be seen, the organization of the neural connections of the retina and higher visual pathway is such as to favour the accurate recognition of direction; for the moment, the question of the maintenance of a frame of reference must be considered, in the sense that a map has vertical and horizontal lines with which to compare other directions. In fact, the vertical and horizontal meridians of the retina seem to be specialized as frames of reference; the accuracy with which a human subject can estimate whether a line is vertical or horizontal is very great.

An important point in this connection is that of the effects of eye movements on interpretation of the directions of lines because, when the eye moves to positions different from the primary straight-ahead position, the images of vertical lines will not necessarily fall on its vertical meridian. This can be due to an actual torsion of the eye about its anteroposterior (fore and aft) axis or to distortion of the retinal image. This means, then, that the line on the retina that corresponds to verticality in one position of the eye does not correspond to verticality in another, so that, once again, the space representation centre must take account not only of the retinal elements that have been stimulated but also of the corollary motor discharge.

Effects of eye movements

*Comparison of lengths.* The influence of the movements of the eyes in the estimation of length was emphasized by Helmholtz. An accurate comparison of the lengths of two parallel lines AB and CD can be made, whereas if an attempt is made to compare the nonparallel lines A'B' and C'D', quite large errors occur. According to Helmholtz, the eye fixates first the point A, and the line AB falls along a definite row of receptors, thereby indicating its length. The eye is now moved to fixate C, and if the image of CD falls along the same set of recep-

tors the length of  $CD$  is said to be the same as that of  $AB$ . Such a movement of the eye is not feasible with lines that are not parallel. Similarly, the parallelism, or otherwise, of pairs of lines can be perceived accurately because on moving the eye over the lines the distance between them must remain the same.

Fairly accurate estimates of relative size may be made, nevertheless, without movements of the eyes. If two equal lines are observed simultaneously, the one with direct fixation and the other with peripheral vision, their images fall, of course, on different parts of the retina; if the images were equally long it could be stated that a certain length of stimulated retina was interpreted as a certain length of line in space. It is probable that this is roughly the basis on which rapid estimates of length depend, although there are such complications as the fact that the retina is curved so that lines of equal length in different parts of the retina do not produce images of equal length on the retina.

**Optical illusions.** Many instances have been cited of well-defined and consistent errors in visual estimates under special conditions. There is probably no single factor by which the errors can be explained, but the tendency for distinctly perceptible differences to appear larger than those more vaguely perceived is important.

**The perception of depth.** *Monocular cues.* The image of the external world on the retina is essentially flat or two-dimensional, and yet it is possible to appreciate its three-dimensional character with remarkable precision; to a great extent this is by virtue of the simultaneous presentation of different aspects of the world to the two eyes, but even when the subject views the world with a single eye it does not appear flat to him and he can, in fact, make reasonable estimates of the relative positions of objects in all three dimensions. Examples of monocular cues are the apparent movements of objects in relation to each other when the head is moved. Objects nearer the observer move in relation to more distant points in the opposite direction to the movement of the head. Perspective, by which is meant the changed appearance of an object when it is viewed from different angles, is another important clue to depth. Thus the projected retinal image of an object in space may be represented as a series of lines on a plane—e.g., a box—these lines, however, are not a unique representation of the box because the same lines could be used to convey the impression of a perfectly flat object with the lines drawn on it, or of a rectangular, but not cubical, box viewed at a different angle. In order that a three-dimensional object be correctly represented to the subject on a two-dimensional surface, he must know what the object is; i.e., it must be familiar to him. Thus a bicycle is a familiar object. If it is viewed at an angle from the observer the wheels seem elliptical and apparently differ in size. Because the observer knows that the wheels are circular and of the same size, he perceives depth in a two-dimensional pattern of lines. The perception of depth in a two-dimensional pattern thus depends greatly on experience—the knowledge of the true shape of things when viewed in a certain way. Other cues are light and shade, overlapping of contours, and relative sizes of familiar objects.

**Binocular vision.** The cues to depth mentioned above are essentially unocular; they would permit the appreciation of three-dimensional space with a single eye. When two eyes are employed, two additional factors play a role, the one not very important—namely, the act of convergence or divergence of the eyes—and the other very important—namely, the stereoscopic perception of depth by virtue of the dissimilarity of the images presented by a three-dimensional object, or array of objects, to the separate eyes.

When a three-dimensional object or array is examined binocularly, the nearer points or objects require greater convergence for fixation than the more distant points or objects, so that this provides a cue to the three-dimensional character of the presentation. It is by no means a necessary cue, since presentation of the array for such a short time that movements of the eyes cannot occur still permits the three-dimensional perception, which is

achieved under these conditions by virtue of the dissimilar images received by the two retinas.

A stereogram contains two drawings of a three-dimensional object taken from different angles, chosen such that the pictures are right- and left-eyed views of the object. When the stereogram is placed in a stereoscope, an optical device for enabling the two separate pictures to be fused and seen single, the impression created is one of a three-dimensional object. The perception is immediate, and is not a matter of interpretation. Clearly, with the stereoscope the situation is simulated as it normally occurs. To appreciate the full implications of the stereoscopic perceptual process, one must examine some simpler aspects of binocular vision.

Figure 11 illustrates the situation in which a subject is fixating (fixing his gaze on) the point  $F$  so that the images of  $F$  fall on the foveal (retinal) points  $f_L$  and  $f_R$ , respectively.  $F$  is seen as a single point because the retinal points  $f_L$  and  $f_R$  are projected to the same point in space, and the projection is such that the subject says that the point  $F$  is straight in front of him, although it is to the right of his left eye and to the left of his right eye. The two eyes in this case are behaving as a single eye, "the cyclopean eye," situated in the centre of the forehead, and one may represent the projection of the two separate retinal points,  $f_L$  and  $f_R$ , as the single projection of the point  $f_C$  of the cyclopean eye. As will be seen, the cyclopean eye is a useful concept in consideration of certain aspects of stereoscopic vision.

The points  $f_L$  and  $f_R$  may be defined as corresponding points because they have the same retinal direction values. The images formed by the points  $A$  and  $B$ , in the same frontal plane as  $F$ , fall on  $a_L$  and  $a_R$  and  $b_L$  and  $b_R$ ; once again the pairs of retinal points are projected to the same points, namely, to  $A$  and  $B$ , and they are treated as being on the left and right of  $F$ , respectively. On the cyclopean projection, they may be said to be localized by the outward projections of  $a_C$  and  $b_C$ , respectively.

In Figure 12, the subject is once again fixing the point  $F$ , but the point  $A$  is now no longer in the same frontal plane as the point  $F$ , but closer to the observer. The images of  $F$  fall on corresponding points and are projected to a single point in front. The images of  $A$ , on  $a_L$  and  $a_R$ , do not fall on corresponding points and are, in fact, projected into space in different directions, as in-

Corresponding points

Figure 11: The Cyclopean system of projection. The images of the points  $F$ ,  $A$ , and  $B$  on the two retinas are transposed to the retina of a hypothetical eye midway between the two. The pairs of images,  $a_L$  and  $a_R$ ,  $b_L$  and  $b_R$ , and so on, coincide on the cyclopean retina indicating that the stimulated retinal points are projected to a common direction (see text).

Figure 12: Physiological diplopia caused by an object,  $A$ , closer to the observer than the fixation point,  $F$ . The images of  $A$  fall on disparate or noncorresponding points on the two retinas, and these are projected to different points  $A'$  and  $A''$  (see text).

indicated by the cyclopean projection. This means that  $A$  is seen simultaneously at two different places, a phenomenon called physiological diplopia, and this in fact does happen, as can be seen by fixing one's gaze on a distant point and holding a pencil fairly close to the face; with a little practice the two images of the pencil can be distinguished. Thus, when the eyes are directed into the distance the objects closer to the observer are seen double, although one of the double images of any pair is usually suppressed. To return to Figures 11 and 12,  $F$  and  $A$  in Figure 11 are seen single and in the same plane because their images each fall on corresponding points.  $F$  is seen single and  $A$  double in Figure 12 because the images of  $A$  fall on noncorresponding, or disparate, points.  $A$  is appreciated as being closer to the observer than  $F$  in Figure 12 by virtue of these double images but, in general, although it is retinal disparity that creates the percept of three-dimensional space, it is not necessarily the formation of double images, since if the disparity is not large the point will be seen single, and this single point will appear to be in a different frontal plane from that containing the fixation point.

To appreciate the nature of this stereoscopic perception one must examine what is meant by corresponding points in a little more detail. In general, it seems that the two retinas are, indeed, organized in such a way that pairs of points are projected innately to the same point in space, and the horopter is defined as the outward projection of these pairs. One may represent this approximately by a sphere passing through the fixation point, or, if one confines attention to the fixation plane, it may be represented by the so-called Vieth-Müller horopter circle, as illustrated in Figure 13. On this basis, the corresponding points are arranged with strict symmetry, and each pair projects to a single point in space on the horopter circle. Theoretically, then, all points on the circle passing through the fixation point,  $F$ , will be seen single, and the point  $X$  will be seen double because it will be projected by the left eye to  $F$  and by the right eye to  $A$ . The actual situation is somewhat more complex than this, since experimentally the horopter turns out to have different shapes according to how close the fixation point is to the observer. The point to appreciate, however, is that the experimentally determined line, be it circular or straight or elliptical, is such that when points are placed on it they all appear to be in the same frontal plane—i.e., there is no stereoscopic perception of depth when one views

Figure 13: The Vieth-Müller horopter circle.  $F$  is the fixation point. If corresponding points are symmetrically distributed about the foveas, the points in space in the fixation plane, whose images fall on the corresponding points, lie on the circle. The images of the point  $X$  lie on disparate points (see text).

From H. Davson, M.D., *Physiology of the Eye*

these points—and one may say that this is because the images of points on the horopter fall on corresponding points of the two retinas.

In Figure 14, to the left, are two eyes viewing an arrow lying in the frontal plane—i.e., with no stereopsis—and to the right the arrow is inclined into the third dimension—i.e., it tends to point toward the observer. All points on the arrow are, in fact, seen single under both conditions, and yet it is clear from the right-hand figure that, if the gaze is fixed on  $A$ , the images of  $B'$  will fall on noncorresponding points.  $B'$  is not seen double but, instead, the noncorresponding points,  $b'_L$  and  $b'_R$ , are projected to a common point  $B'$  and a stereoscopic percept is achieved. Thus the noncorresponding, or disparate, points on the retinas can be projected to a single point, and it is essentially this fusion of disparate images by the brain that creates the impression of depth. If the point  $B'$  were brought much closer to the eyes, its images would fall on such disparate points that fusion would no longer be possible, and  $B'$  would be seen double, or one double image would be suppressed. There is thus a certain zone of disparity that, if not exceeded, allows fusion of disparate points. This is called Panum's fusional area; it is the area on one retina such that any point in it will fuse with a single point on the other retina.

To return to the stereoscopic perception of three-dimensional space, one may recapitulate that it is because the two eyes receive different images of the same object that the stereoscopic percept happens; when the two images of the object are identical, then, except under very spe-

Fusion of disparate images

From H. Davson, M.D., *Physiology of the Eye*

Figure 14: The distinction between corresponding points ( $a_L$  and  $a_R$ ,  $b_L$  and  $b_R$ ) and points that do not correspond ( $b'_L$  and  $b'_R$ ; see text).

cial conditions, the object has no three-dimensionality. A special condition is given by a uniformly illuminated sphere; this is three-dimensional, but the observer would have to use special cues to discriminate this from a flat disk lying in the frontal plane. Such a cue might be the different degree of convergence of the eyes required to fixate the centre from that required to fixate the periphery, or the different degree of accommodation.

The difference in the two aspects of the same object (or group of objects), measured as the instantaneous parallax, is illustrated in Figure 15. *B* is closer to the observer

From Hugh Davson, M.D. *Physiology of the Eye*

Figure 15: Binocular and instantaneous parallax.  $N_L$  and  $N_R$  are the nodal points of the left and right eyes, respectively (see text).

than *A*; the fact is perceived stereoscopically because the line *AB* subtends different angles at the two eyes, and the instantaneous parallax is measured by the difference between the angles *a* and *b*. The binocular parallax of any point in space is given by the angle subtended at it by the line joining the nodal points of the two eyes; hence, the binocular parallax of *A* is *a*; that of *B* is *b*; the instantaneous parallax is thus the difference of binocular parallax of the two points considered.

If one places three vertical wires in front of an observer in the frontal plane, one may move the middle one in front of, or behind, the plane containing the other two and ask the subject to say when he perceives that it is out of the plane; under correct experimental conditions the only cue will be the difference of binocular parallax, and it is found that the minimum difference is remarkably small, of the order of five seconds of arc, corresponding to a disparity of retinal images far smaller than the diameter of a single cone. With two editions of the same book, it is not possible, by mere inspection, to detect that a given line of print was not printed from the same type as the same line in the other book. If the two lines in question are placed in the stereoscope, it is found that some letters appear to float in space, a stereoscopic impression created by the minute differences in size, shape, and relative position of the letters in the two lines. The stereoscope may thus be used to detect whether a bank note has been forged, whether two coins have been stamped by the same die, and so on.

The stereoscopic appearance obtained by regarding two differently coloured, but otherwise identical, plane pictures with the two eyes separately, is probably due to chromatic differences of magnification. If the left eye, for example, views a plane picture through a red glass

and the right eye views the same picture through a blue glass, an illusion of solidity results. Chromatic difference in magnification causes the images on the two retinas to be slightly different in size, so that the images of any point on the picture do not fall on corresponding points; the conditions for a stereoscopic illusion are thus present.

**Retinal rivalry.** Stereoscopic perception results from the presentation to the two eyes of different images of the same object; if two pictures that cannot possibly be related as two aspects of the same three-dimensional object are presented to the two eyes, single vision may, under some conditions, be obtained, but the phenomenon of retinal rivalry enters. Thus, if the letter *F* occupies one side of a stereogram, and *L* the other, the two letters can be fused by the eyes to give the letter *E*; the letters *F* and *L* cannot, however, by any stretch of the imagination be regarded as left and right aspects of a real object in space, so that the final percept is not three-dimensional, and, moreover, it is not a unitary percept in the sense used in this discussion; great difficulty is experienced in retaining the appearance of the letter *E*, the two separate images, *F* and *L*, tending to float apart. This is a mode of binocular vision that may be more appropriately called simultaneous perception; the two images are seen simultaneously, and it is by superimposition, rather than fusion, that the illusion of the letter *E* is created. More frequent than superimposition is the situation in which one or the other image is completely suppressed; thus, if the right eye views a vertical black bar and the left eye a horizontal one, the binocular percept is not that of a cross; usually the subject is aware of the vertical bar alone or the horizontal bar alone. Moreover, there is a fairly characteristic rhythm of suppression, or alternation of dominance, as it is called.

**Ocular dominance.** Retinal rivalry may be viewed as the competition of the retinal fields for attention; such a notion leads to the concept of ocular dominance—the condition when one retinal image habitually compels attention at the expense of the other. While there seems little doubt that a person may use one eye in preference to the other in acts requiring monocular vision—e.g., in aiming a rifle—it seems doubtful whether, in the normal individual, ocular dominance is really an important factor in the final awareness of the two retinal images. Where the retinal images overlap, stereoscopic perception is possible and the two fields, in this region, are combined into a single three-dimensional percept. In the extreme temporal fields (i.e., at the outside of the fields of vision), entirely different objects are seen by the two eyes, and the selection of what is to dominate the awareness at any moment depends largely on the interest it arouses; as a result, the complete field of view is filled in and one is not aware of what objects are seen by only one eye. Where the fields overlap, and different objects are seen by the two eyes—e.g., on looking through a window the bars may obscure some objects as seen by one eye but not as seen by the other—the final percept is determined by the need to make something intelligible out of the combined fields. Thus, the left eye may see a chimney pot on a house, while the other eye sees the bar of a window in its place; the final perceptual pattern involves the simultaneous awareness of both the bar and the chimney pot because the retinal images have meaning only if both are present in consciousness. So long as the individual retinal images can be regarded as the visual tokens of an actual arrangement of objects, it is possible to obtain a single percept, and there seems no reason to suppose that the final percept will be greatly influenced by the dominance of one or other eye. When a single percept is impossible, retinal rivalry enters; this is essentially an alternation of awareness of the two fields—the subject apparently makes attempts to find something intelligible in the combined presentation by suppressing first one field and then the other—and certainly it would be incorrect to speak of ocular dominance as an absolute and invariable imposition of a single field on awareness, since this does not occur. Dominance, however, has a well-defined physiological meaning in so far as certain cells of the cerebral cortex may be activated exclusively

The choice of what is perceived

Ocular dominance

Accuracy of stereoscopic perception

by one eye, either because the other eye makes no neural connections with it or because the influence of the other eye is dominant.

**Binocular brightness sensation.** When the two eyes are presented with differently illuminated objects or surfaces some interesting phenomena emerge. Thus fusion may give rise to a sensation of lustre. In other instances, rivalry takes place, the one or other picture being suppressed, while in still others the brightness sensation is intermediate between those of the two pictures. This gives rise to the paradox whereby a monocularly viewed white surface appears brighter than when it is viewed binocularly in such a way that one eye views it directly and the other through a dark glass. In this second case the eyes are receiving more light, but because the sensation is determined by both eyes, the result is one that would be obtained were one eye to look at a less luminous surface.

#### ELECTROPHYSIOLOGY OF THE VISUAL CENTRES

To elucidate the functions of the various stages in the visual pathway, one must examine the responses to a retinal light-stimulus of the individual neurons at the different stages.

**Ganglion cells.** The main features of the responses of ganglion cells have already been touched upon. These have receptive fields that indicate a dual type of connection with the rods and cones, as indicated by the centre-periphery organization. A spot of light falling on receptors in the centre of this field may provoke a discharge in the ganglion cell or its optic nerve fibre; it is called an on-response and consists usually in an increase in the background discharge occurring in darkness. If a spot of light falls on a ring of retina surrounding this central region, the effect is one of inhibition of the background while the light is on, and as soon as it is switched off there is a pronounced discharge, the off-response. Other ganglion cells have been shown to have a directional sensitivity, responding to a moving spot of light only if this moves in a preferred direction and showing inhibition of background discharge if movement is in the null direction.

**Geniculate neurons.** In general, the lateral geniculate neuron is characterized by an accentuation of the centre-periphery arrangement, so that the two parts of the receptive field tend to cancel each other out completely when stimulated together, by contrast with the ganglion cell in which one or another would predominate. Thus, when the retina is illuminated uniformly there is little response in the geniculate cells because of this cancellation. This represents a useful elaboration of the messages from the retina because, to the animal, uniformity is uninteresting; it is the nonuniformity created by a contour or a moving object that is of interest, and the brain is therefore spared from being bombarded by unnecessary information that would result if every receptor response were transmitted to the brain.

**Cortical neurons.** When investigators made records of responses from neurons in area 17 there was an interesting change in the nature of the receptive fields; there was still the organization into excitatory (on) and inhibitory (off) zones, but these were linearly arranged, so that the best stimulus for evoking a response was a line, either white on black or black on white. When this line fell on the retina in a definite direction, and on a definite part of the retina, there was, say, an on-response, while if it fell on adjacent areas there was an off-response. Changing the orientation of the line by as little as 15° could completely abolish the responses. The simplest interpretation of this type of receptive field is based on the connection of the cortical cell with a set of geniculate cells with their receptive fields arranged linearly.

**Eye dominance.** Most of these units (*i.e.*, cortical cells plus connections) could be excited by a light stimulus falling on either eye, although there was usually dominance of one eye, in the sense that its response was greater; when both eyes were stimulated together, the effects summated. In general, then, when a large number of units are studied, a certain proportion are fired by one

eye alone, others by the opposite eye alone, others by both eyes with dominance of one or other eye, while still others respond only when both eyes are stimulated. It is interesting that when kittens are deprived of the use of one eye from birth for several months, this deprived eye is virtually blind and the distribution of dominance in the cortical neurons is changed dramatically; if the left eye is deprived, the right hemispherical cortical neurons show a marked fall in dominance by the left eye, and an increase by the right eye. Thus, the ability of the eye to make use of cortical neurons is not fully developed at birth.

**Cortical architecture.** When an electrode is directed downward into the cortex it picks up responses in individual units at successive depths; units having the same directional sensitivity are arranged in columns so that the receptive fields of successive neurons are similarly oriented. When units were classified on the basis of eye dominance, a similar vertical distribution of units was found, overlapping with those based on directional preference. The columns for eye preference were about one millimetre wide, but those for directional preference were considerably finer. This columnar organization of cortical cells is not peculiar to the visual area.

**Complex neurons.** The cortical units (cells) described above, with receptive fields organized on a linear basis, have been called simple units in contrast to complex and hypercomplex units. Four types of complex units have been described; as with the simple units, the orientation of a slit stimulus (that is, a line) is of the utmost importance for obtaining maximal response, but unlike the situation with the simple unit, the position on the retina is unimportant. This type of unit makes abstractions of a higher order, responding to direction of orientation but not to position. It is this type of neuron that would be concerned, for example, with determining the verticality or horizontality of lines in space. Space does not permit of a description of the receptive field of a hypercomplex cell, but in general its features could be explained on the basis of connections with complex cells.

**Stereoscopic vision.** Of special interest is the behaviour of binocularly driven (stimulated) cortical cells, since their responses provide a clue to the fusion of retinal images. The cortical nerve cell receiving impulses emanating from both retinas must select those parts of the two retinal images that are the images of the same point on an object; second, for stereopsis, the nerve cell must assess the small displacements from exact symmetry that give the binocular parallax. In experiments, maximal response was often obtained only when the stimuli fell on disparate parts of the two retinas; these cortical cells were obviously disparity detectors, in contrast to others that gave maximal response when the stimuli fell on strictly symmetrically related parts of the two retinas—*i.e.*, on corresponding points. When successive units, during penetration of the electrode, were recorded, it was found that those requiring the same degree of disparity for maximal response were arranged in columns, as with direction sensitivity, so that, in effect, all these nerve cells were responding to stimuli in a strip of space at a definite distance from the fixation point.

**BIBLIOGRAPHY.** H. DAVSON (ed.), *The Eye*, 4 vol. (1962; 2nd ed., vol. 1, 1969), covers the whole field of eye physiology, written by a group of experts in their particular fields; W.S. DUKE-ELDER *et al.* (eds.), *System of Ophthalmology*, 15 vol. (1958– ), authoritative accounts of the anatomy and physiology of the eye; E. WOLFF, *Anatomy of the Eye and Orbit*, 5th ed. (1961), the classic work on this aspect; H. DAVSON, *Physiology of the Eye*, 3rd ed. (1971), an up-to-date account of eye physiology covering all aspects; M.H. PIRENNE, *Vision and the Eye*, 2nd ed. (1967), a simple account of certain features of eye physiology; R.A. WEALE, *The Eye and Its Function* (1960), a short and elementary account; H. VON HELMHOLTZ, *Handbuch der physiologischen Optik*, 3rd ed. (1886–96; Eng. trans., *Physiological Optics*, 3 vol., 1924–25; reprinted in 2 vol., 1962), a classic account of the psychological aspects of vision—not at all out of date, although written nearly 100 years ago; H.H. EMSLEY, *Visual Optics*, 5th ed., 2 vol. (1952–53), a technical account of the detailed optics of the eye.

## Eye Diseases and Visual Disorders

The human visual apparatus includes the eyeball or globe, and its socket, or orbit, and auxiliary structures such as the lids and the muscles that control eye movement. These organs and their normal functioning are covered in the article EYE AND VISION, HUMAN. The visual apparatus of other organisms is discussed in PHOTORECEPTION. The present article briefly describes the more common diseases of the eye and its associated structures, and the methods used in examination and diagnosis; it also indicates the treatment and prognosis. The first section deals with conditions affecting the orbit, lids, and external eye, and the second with diseases of structures within the globe. Later sections deal with injuries, ocular conditions associated with general disease, disorders of vision, methods of examining the eye, and devices for correcting visual defects.

### THE OUTER EYE AND AUXILIARY STRUCTURES

**The orbit and lacrimal apparatus.** The orbit is the bony cavity in the skull that contains the globe of the eye, the muscles that move the eye, the lacrimal gland, and the blood vessels and nerves required to supply these structures. The remaining space within the orbit is filled with a fatty pad that acts as a cushion for the eye and allows free movement of the globe. In old age this pad of fat tends to atrophy so that the globe recedes, causing the sunken appearance often seen in old people.

**Inflammatory conditions of the orbit.** As the bone that separates the orbit from the nose and the nasal sinuses is rather thin, infection sometimes spreads from the nasal sinuses into the orbit, causing the orbital tissue to swell and the eye to protrude. The condition is serious because of the possibility that the infection may spread into the cranial cavity along the pathways of the cranial nerves that enter the orbit to reach the eye. Infections can also spread to the cranial cavity by way of the blood vessels that lie in the upper part of the orbit, from lesions such as a boil on the skin of the lids or face in the neighbourhood of the eye. Large doses of an antibiotic such as penicillin, given immediately, in most cases eliminate such infections. The lacrimal glands, the small glands that secrete tears and are behind the outer part of each upper lid, are rarely inflamed but may become so as a complication of mumps. Inflammations of the lacrimal sac are much more common. The lacrimal or tear sac lies in a hollow at the corner of the eye in the front part of the nasal wall of the orbit; under normal conditions tears run along the edges of the lids toward the nose and are drained through two tiny holes connected by small tubes to the upper part of the lacrimal sac. The lower part of the sac is connected to the nose by a duct, the nasolacrimal duct, and infection may ascend this passage from the nose and cause an acute painful swelling at the inner corner of the eye. Blockage of the nasolacrimal duct prevents the passage of tears into the nose and results in a watering eye. Such a blockage, which is nearly always accompanied by chronic inflammation in the lacrimal sac, is usually best treated by an operation in which a new opening from the lacrimal sac to the nasal cavity is made.

**Tumours of the orbit.** Tumours in this area are comparatively rare, the most common being a tumour of the lacrimal gland. If the tumour is behind the globe in the optic nerve, it will cause a slow and gradual protrusion of the eye; such an abnormal position of the eye may prevent ocular movements from being coordinated with those of the normal eye, and the images of the two eyes, which are normally fused, may separate and give rise to double vision (or diplopia).

**The lids. Inflammatory conditions.** The chronic inflammation of the lid margins known as blepharitis is a common and distressing condition. The inflammation may be mild and consist simply of redness of the lid margin with scaling of the skin, or more severe, affecting the follicles of the eyelashes and leading to their destruction and distortion. Both types tend to be associated with

greasiness of the skin and dandruff. The skin of the lids is particularly sensitive to allergic processes, and itching and scaling of the lids is a common reaction to drugs or cosmetics applied to the eye of a sensitized person.

Another common inflammatory condition of the lid is a sty; i.e., an infection of a lash follicle—the sheath of the eyelash root—corresponding to a boil on the skin elsewhere. It starts as a painful swelling of the whole lid, so that at first it may be difficult to find a localized lesion; but soon one area becomes more swollen and, as pus forms, a yellow point associated with an eyelash can be seen near the lid margin. A rather similar appearance can be produced by an inflammation of the meibomian glands; i.e., tiny glands in the thickness of the lid, opening on the lid margin. As the glands are embedded in tough fibrous tissue, the pain and reaction may be more severe than in an ordinary sty. Examination of the internal surface of the lid will show a red velvety area with a central yellow spot through which pus will later discharge. Sometimes the meibomian glands suffer from a chronic infection, and a painless firm lump appears in the lid and slowly increases in size. The skin can be moved freely over the surface of the lump, showing that the latter is in the deeper tissue of the lid. The inner surface of the lid will show a grayish area surrounded by a little inflammation. The lesion is treated by making an incision on the inner surface of the lid, and scraping out the contents.

Herpes zoster (shingles) may affect the skin of the eyelids and is of particular importance because the cornea (the transparent covering of the front of the eyeball) and the inner eye may also be affected. The condition starts with pain and redness of one part of the forehead and the eyelids of the same side. Vesicles, or small blisters, form later in the affected area. The pain may be severe, and some constitutional disturbance is usual.

**Displacements of the lid.** Malpositioning of the lid is common in elderly people, and although not serious in itself gives rise to considerable discomfort and irritation. The commonest condition is called ectropion, in which the lower lid falls away from the globe so that the tears overflow the lid. This constant wetting of the skin of the lower lid excoriates the skin and causes it to retract, which in turn increases the tendency of the lid to turn out. In the early stages, massage of the lid and the use of a bland ointment on the skin may help, but usually some plastic procedure is necessary to bring the lid back into its normal position.

The opposite condition is entropion, in which the lid turns inward and the lashes cause much irritation by rubbing on the eye. Unlike ectropion, it may affect either the upper or the lower lid. It may be caused by scarring of the deeper tissues of the lid following infection, or may be due to senile changes in muscle tone in which a band of fibres of the circular muscle surrounding the lids contracts more strongly than the peripheral fibres, thus tending to turn the lid inward. Surgical treatment is required to restore the lid to its normal position.

**Tumours.** Benign overgrowths of the blood vessels, called hemangiomas, may occur in the lids and give rise to soft bluish swellings that can be reduced by pressure over them. They are present at birth and tend to grow rapidly in the first few years of life. Often they disappear spontaneously, but they can be treated by surgical removal or the insertion of radioactive material. Simple overgrowths of skin, called papillomas, are common along the lid margin but require no special treatment except excision for cosmetic reasons.

The lids and the skin of the nose near the inner margins of the lids are common sites for the development of skin cancer in older people; the most usual type, called a rodent ulcer, starts as a small nodule in the skin that gradually enlarges and breaks down to form an ulcer with a hard base and rolled edges. Bleeding may occur from the base of the ulcer. Although rodent ulcers are malignant in the sense that they destroy tissue locally, they do not spread to distant areas of the body by means of the lymph system or the blood vessels. A more serious malignant tumour of the lids is a carcinoma, which develops as a more irregular ulcer of the lid and may spread to involve

Ectropion  
and  
entropion

Development of binocular vision; definition of squint

the underlying bone. If left untreated the growth may spread to the lymph nodes in front of the ear or under the jaw.

**Squint.** In the lower vertebrates such as the fish the eyes are situated on either side of the head, to give the maximum view of the surroundings and an early warning of the presence of predators. The field of vision of each eye is separate except for a narrow sector immediately in front of the animal, where the two visual fields overlap. From the evolutionary point of view the improved judgment of distance obtained by viewing an object with both eyes conferred considerable biological advantage in the struggle for survival. In the higher animals, particularly the predatory species of birds and mammals, binocular vision became more and more important and structural changes in the placement of the eyes in the head permitted a larger overlap of the two visual fields, until the situation was reached in the higher mammals in which the visual axes—that is, the line of direct sight—became parallel. This desirable visual function has been fully attained in man. The structural changes necessary to bring this about have, however, lagged behind the function, and the geometrical axes of most eyes are still slightly divergent (*i.e.*, the two eyes at rest are directed slightly away from the nose). The bony structure of the orbit has lagged even further behind, so that the axes of the two orbits make an angle of about  $45^\circ$ .

It is in fact the function of using two eyes together that keeps the optic axes straight in a normal person. If, for example, one eye becomes blind, it tends to revert to an anatomical position of rest in line with the axis of the orbit. A blind eye will therefore appear to be diverging. The visual axes can remain straight only if each eye has reasonably good vision, the ocular muscles can move the eyes in the required direction of gaze, and the complex neuromuscular reflexes required to coordinate the movements of the two eyes are intact. Failure to maintain the visual axes parallel may therefore result from a visual defect in one or both eyes, a muscular defect resulting in loss of normal movement of the eye, or a defect in the central nervous system involving the coordinating nervous pathways. A true squint is a condition in which the visual axes are no longer parallel. An apparent squint may be seen in children as the result of prominent skin folds in the inner sides of the eyes, which make the eyes appear to be converging (*i.e.*, appear to cross). These skin folds usually disappear when the bony structure of the nose develops more fully.

Clinically, squints are divided into concomitant, in which the abnormal angle between the visual axes remains constant in all positions of gaze, and paralytic, in which the angle of squint varies with the direction of gaze. The commonest type of squint is the convergent concomitant type seen in small children (*i.e.*, the children are consistently or intermittently cross-eyed). It is usually first noticed between the ages of one and two and may be precipitated by a systemic disease such as measles. There is often a family history of squint. Children of this age are particularly interested in objects close to them, and in order to view an object clearly at close range two things are necessary: first, the visual axes must converge, so that both eyes can view the same object; and second, the focus of the eye must be adjusted for near vision. The link between convergence of the eyes and focussing, or accommodation, is very strong, and normally the two actions work in harmony. Most small children, however, are long-sighted, which means that, in order to see clearly close to, they have to exert an extra amount of accommodative effort. As accommodation and convergence are closely linked, the extra effort of accommodation tends to produce an overconvergence; but, provided that the visual acuity of each eye is normal and the motor control of the eyes is normal, this tendency is controlled. If the vision of one eye is reduced, for example by disease or an error of refraction, binocular vision breaks down and overconvergence occurs.

Once parallelism of the visual axes is lost, the image of objects no longer lies on a familiar area of retina, and instead of the images from the two eyes being fused into

one, two images are perceived. This condition of double vision, or diplopia, is intolerable to the child, who reacts by "suppressing" the image from the squinting eye. If the suppression is allowed to continue, the central vision of the affected eye drops rapidly to a low level, so that even if the original disturbance that started the squint is corrected, this loss of vision, or amblyopia, of the squinting eye will prevent the restoration of normal binocular vision and thus perpetuate the squint. The longer the suppression is allowed to continue, the less likely is the child to regain normal vision in the squinting eye. Covering the good eye will usually encourage the recovery of the suppressed vision but must be started as soon as the squint is noticed. Any refractive error present—any defect that prevents light rays from focussing properly on the retina—must be corrected by glasses, and retraining of the binocular reflexes can be aided by special exercises. Early treatment on these lines may be all that is necessary, but if the visual axes are still abnormal surgery of the extraocular muscles will be required to correct the deviation.

Paralysis of one of the muscles that control the movement of the eyes results in limitation of movement of the globe in the direction of action of the muscle, with the result that double vision with separation of the images occurs on attempts to move the eye in this direction.

As earlier stated, accommodation and convergence are normally perfectly linked together so that the movements of the two eyes bring the visual axes to the point of focus. In many people this balance is not quite perfect and the eyes tend to converge or diverge too much for a given distance—a condition known as heterophoria.

**The conjunctiva.** The marine origin of the human species is betrayed by the need for the anterior surface of the eye to be bathed in salt water. A thin membrane lines the lids and covers the anterior surface of the globe, forming a sac, the conjunctival sac, the contents of which are lubricated by the tear glands. This warm, moist habitat provides a suitable environment for the growth of bacteria and other organisms, leading to conjunctivitis, inflammation of the conjunctiva. Bacterial conjunctivitis starts with a feeling of grittiness and discomfort, the eye is red and there is a discharge from it. The discharge is particularly noticeable after sleep, when the lids may be stuck together by the exudate on the lashes. Vision is not affected except by the strands of mucus, which can be blinked away from the cornea. Antibiotic drops usually clear the condition in a few days. Vernal conjunctivitis or spring catarrh is, as its name suggests, an allergic condition occurring in the early summer; it is more common in young people and probably results from sensitivity to external irritants such as dust and pollen. It usually responds well to treatment with drops of corticosteroid hormone.

Chronic conjunctivitis, causing a gritty feeling, with redness of the eyes and a slight mucoid discharge, is a common condition, the cause of which may be difficult to find. Often there is an infective element such as a chronic inflammation of the lid margin, and sometimes the condition is allergic and may result from sensitivity to cosmetics or to drugs applied to the eye. An unsuspected foreign body or a deficiency of tear secretion may cause similar symptoms.

**Viral conjunctivitis.** With the enormous increase in the use of antibiotics since the 1940s, bacterial infections in general are becoming less common. This is also true of infections of the eye, and in most western countries bacterial conjunctivitis is now less common than viral infection. Viruses tend to attack the cornea as well as the conjunctiva; the infection is contagious and may be responsible for outbreaks of epidemic keratoconjunctivitis (inflammation of the cornea and the conjunctiva). The onset is acute, with redness and swelling of the eye and lids and a tender swelling of the lymph node in front of the ear.

Trachoma can truly be described as one of the scourges of mankind. Although rare in England and North America, it is the largest single cause of blindness in the world as a whole. Almost universal in some Middle East countries such as Egypt, it has spread to Asia, India, Central and South America, and Africa. It occurs sporadically in

Double vision; suppression of one image

Trachoma

southern and eastern Europe. The agent responsible has now been isolated and shown to belong to the group of organisms known as chlamydiae. They occupy a taxonomic position between bacteria and true viruses and unlike the latter are susceptible to treatment with sulphonamides and some antibiotics. The disease is contagious and thrives where populations are crowded together in poor hygienic surroundings. Shortage of water for washing, and the myriads of flies attracted to human waste, aid the dissemination of the disease. In some ways trachoma is more of a social than a medical problem; if living standards can be improved, overcrowding reduced, flies discouraged, and adequate water supplies ensured, the incidence of trachoma decreases rapidly.

The early symptoms of infection are pain, watering of the eye, and sensitivity to light. At this stage the conjunctival lining of the lids is red and velvety in appearance, and the cornea shows gray areas. Later, the conjunctiva appears to have grains of sand embedded in its tissue. Blood vessels grow into the cornea, which becomes thickened and hazy. Secondary bacterial infections are common, but the real dangers of trachoma lie in the scarring and contracture of tissue that occur when healing takes place. These changes affect the upper lid in particular, causing it to buckle inward so that the lashes rub across the already diseased cornea, and it is the corneal scarring thus produced that can cause blindness.

**Degenerative conditions.** Exposure to wind and dust frequently causes degenerative changes in the exposed part of the conjunctiva, particularly in older people. A yellow nodule forms, first on the nasal side of the cornea and later on the other side. It is without blood vessels and is frequently unnoticed until an incidental conjunctivitis causes it to stand out clearly against the red background of dilated conjunctival vessels. It causes no symptoms and requires no treatment.

A more serious degeneration is that known as a pterygium, found particularly in people who live in hot, dusty climates. It appears as a fleshy growth at the edge of the cornea, with a tendency to progress across its front surface, where it may interfere with vision. Treatment consists of surgical removal, but recurrences are common.

**The cornea and sclera.** The cornea is the clear window of the eye and its most important refractive surface. Any surface irregularity, any scar in the substance of the cornea, is likely to have a profound effect on vision. Almost the whole nerve supply of the cornea consists of nerve fibres sensitive to pain, so that corneal diseases are always painful and elicit a flow of tears by a reflex action that is part of the protective system of the eye.

**Inflammation of the cornea.** As with inflammations of the conjunctiva, bacterial infection of the cornea has become much less common and viral infections are increasingly important. Of these, the virus of herpes simplex, the virus that causes the common "cold sore" of the lips and skin, is the most frequent cause of corneal ulceration. Infection is spread by personal contact: a kiss from someone with an active cold sore on the lips may carry with it infection as well as affection. The herpes virus causes a typical ulcer of the cornea called, from the pattern of the lesion, dendritic ("branching"). The disease starts with an acutely painful eye, with tearing, and sensitivity to light. The ulcer may heal spontaneously or after medical treatment, but the virus often lies dormant in the tissues; recurrences are common, and with each recurrence there is more danger that the virus will extend deeper into the cornea and cause an intractable inflammation.

Application of the drug deoxyuridine (5-iodo-2-deoxyuridine) to the cornea causes the ulcer to heal more rapidly and reduces the recurrence rate. The action of the drug depends upon its limiting the multiplication of the virus by interfering with the formation of virus deoxyribonucleic acid (DNA) in the host cell.

Bacterial infections of the cornea still occur, usually after injury to the corneal surface, as few bacteria have the power to penetrate the intact surface layers of the cornea. Such ulcers may be extremely severe, and there is always a danger of perforation of the eye, particularly in debilitated patients.

The spores of fungi are commonly present in the atmosphere. The normal cornea is resistant to infection by these organisms, but a fungal infection of the cornea can develop after a corneal injury or other lesion, particularly if corticosteroid drugs have been used in treatment. Intensive treatment with antifungal drugs is usually effective in killing the organisms, but a dense scar is usually left.

A corneal inflammation may start in the deeper layers, usually by spread of infection from the bloodstream. It is seen most commonly in adolescents who have congenital syphilis. Both eyes are usually attacked, although there may be an interval before the second eye is affected. The cornea rapidly becomes hazy, and blood vessels grow in from the surrounding tissues to form a red patch. With the decline in congenital syphilis in developed countries, the condition is now becoming a rarity.

**Inflammation of the sclera.** The sclera is the fibrous covering of the eye that shows up as a dense white layer beneath the transparent conjunctiva. A relatively mild nodular inflammation sometimes occurs in the superficial layers of the sclera; it is thought to be allergic in nature and usually responds well to anti-inflammatory treatment. Inflammation of the deeper sclera is more severe and often is painful. It occurs more frequently in older people and may be associated with tuberculosis or rheumatism; however, the cause of the condition is often not discovered.

**Degenerative conditions.** Keratoconus is the name of a curious condition in which the central part of the cornea, normally spherical in shape, begins to bulge and protrude forward as a cone. The only symptom is deterioration of vision due to the irregular astigmatism caused by the changing corneal curvature. Ordinary spectacles cannot correct the irregular refraction, but contact lenses are often of great value, and in more advanced cases corneal grafting is required.

There are numerous other rare types of corneal degeneration, some of which are familial; all produce a deterioration in vision that cannot be corrected with spectacles. Many of these conditions respond well to corneal grafting.

#### THE INNER EYE

**The uveal tract.** The uveal tract is a vascular layer of tissue—that is, a layer rich in blood vessels—lying next to the inner surface of the sclera. It is divided into three structures: the choroid, a highly vascular layer that supplies blood to the outer layers of the retina; the ciliary body, largely muscle tissue, which by its contraction and relaxation alters the focusing of the lens; and the iris, the coloured part of the eye, which forms the variable aperture of the eye, the pupil. The ciliary body, which lies at the base of the iris, also functions by forming the aqueous humour, the production and drainage of which regulate intraocular pressure; the aqueous humour also is the source of nutriment to the lens and cornea, which are avascular (without blood vessels).

**Inflammation.** Inflammations of the uveal tract are always potentially serious because of the secondary effects they may have on the retina and the lens. In most cases the disease affects either the anterior part of the uvea—that is, the iris and ciliary body—or the posterior part, the choroid. An attack of acute anterior uveitis starts with pain, redness, and mistiness of vision. The eye is sensitive to light, and, although there is no discharge as in conjunctivitis, the eye may water. The pupil tends to contract and the normally clear iris markings become less distinct. In chronic anterior uveitis the main symptom is blurring of vision. Acute choroiditis starts with sudden onset of blurring of vision with many black spots floating about in front of the sight.

Except for cases in which the uveitis follows a perforating injury or a corneal ulcer, it is believed that the inflammation is caused by an infective process within the body or by some other mechanism associated with systemic disease. Many infective conditions and parasitic diseases are known to cause uveitis. In a large proportion of cases, however, particularly when the inflammation is confined to the anterior segment, it proves impossible to be sure of

Infection of cornea with herpes virus; bacteria; fungi

the cause in any individual instance, and the investigation of a case of uveitis often poses one of the biggest problems in ophthalmology today. In men, a proportion of cases of anterior uveitis are associated with ankylosing spondylitis, a chronic disease of the joints of the spine, the cause of which is still obscure. Another association, again in men, is with Reiter's disease, a condition that starts as an infection of the urogenital tract with the later development of joint changes, particularly in the sacroiliac joints of the lower back, and recurrent attacks of anterior uveitis. The organism that is responsible for this venereally contracted infection is still unknown, but may be a virus. Infections in the teeth and tonsils have long been held to be a cause of uveitis, and eradication of dental decay does occasionally have a favourable effect on the course of the disease.

Toxoplasmosis and its effect on fetus

Inflammations of the choroid—the posterior portion of the uveal tract—and the retina are more likely to be infective in origin. One of the organisms most commonly involved is *Toxoplasma gondii*, a protozoon of worldwide distribution among domestic animals, small mammals, and man. Although antibodies to the organism can be found in a high proportion of most populations, showing that infection is widespread, overt signs of disease are rarely seen; most people can acquire the infection without being aware of any systemic disturbance at all, and only in special circumstances does the organism cause disease. One of these special circumstances is pregnancy. If a woman becomes infected during pregnancy there is a short period in which invasion of the tissues takes place before circulating antibodies are formed by the mother. During this period it is possible for the organism to pass through the placenta and infect the unborn child. Fetuses appear to be particularly susceptible to the organism, nearly half of those exposed showing some evidence of infection with toxoplasmosis. In severe cases the child may be stillborn or may be born with congenital toxoplasmosis, a serious disease affecting many organs of the body and particularly the brain and eye. In less serious cases small foci of infection are left in the nervous system and the retina of the eye; these may not be apparent at birth and may remain quiescent, only to become active 15 or 20 years later in the form of an inflammation of the choroid and the retina. Children of subsequent pregnancies are unaffected.

The treatment of uveitis has been transformed by the advent of corticosteroid drugs. Even when a specific infection cannot be discovered and treated with the appropriate specific drug, therapy with corticosteroids is usually successful in controlling the worst ravages of the inflammation.

**Tumours of the uveal tract.** Pigmented tumours are the commonest tumours involving the uveal tract. They may be benign (the nevus or mole) or malignant. The choroid is the commonest site of these lesions, which push the retina forward and cause a retinal detachment. Disturbances of vision are the commonest symptom, but the tumour if neglected may enlarge and cause inflammation and raised pressure within the eye. Small portions of the tumour often enter the bloodstream and settle in distant organs, particularly the liver. The growth of these secondary deposits is often slow; they may not be apparent until many years after the diagnosis of the tumour in the eye.

**The lens.** The lens is a transparent, avascular organ surrounded by an elastic capsule. It lies behind the pupil and is suspended from the ciliary body by a series of fine ligaments. Its transparency is the result of the regular arrangement of the lens fibres; since these are being formed continuously, the lens continues to grow throughout life. Interference with this growth pattern will result in the formation of abnormal lens fibres that cannot transmit light as well as the normal lens fibres. A small opacity is thus seen in the lens. Minor irregularities are common in otherwise perfectly normal eyes. If the opacity is severe enough to affect vision it is called a cataract.

Congenital lens opacities of many varieties have been recognized and described since the early days of ophthalmology, but they remained curiosities until the work of

an Australian ophthalmologist, Norman M. Gregg, threw new light on their cause, and, indeed, on that of many other congenital defects. In 1941 Gregg noticed that after an epidemic of German measles (rubella) many of the children whose mothers had contracted the disease in the first two months of pregnancy were born with cataract, sometimes associated with deafness and congenital heart disease. It is now known that the virus can be recovered from the lens for several months after birth.

Cataract in the adult may be the result of injury to the lens by a perforating wound, by exposure to radiation such as X-rays, or as the result of the ingestion of toxic substances or even of some drugs. The lens relies for its nutrition on the aqueous humour secreted by the ciliary body and, if the latter is severely damaged as the result of long-continued uveitis or a tumour, the metabolism of the lens suffers and a cataract develops. The commonest form of cataract is senile cataract, so called because it becomes progressively more common with advancing age. In spite of a large amount of work on the biological and biochemical changes that take place in the lens, the underlying cause of senile cataract is still unknown. Whatever the underlying biochemical changes may be, they result in an increasing clouding of the lens until the whole lens loses its normal transparency and becomes white and opaque. The only symptom is progressive diminution of vision. In the early stages of the condition some visual improvement can usually be obtained with spectacles, but, as the cataract progresses, the visual deterioration becomes sufficiently severe to warrant surgical treatment.

With modern techniques cataract extraction can be done as soon as the visual deterioration interferes with normal activities, and it is no longer necessary for patients to wait for many years in semiblindness to allow the cataract to become mature. Cataract extraction is one of the most successful and satisfying operations in ophthalmic surgery; if the eye is otherwise normal the visual results are excellent, although the refractive power of the lens has to be replaced by a rather thick spectacle lens or special contact lens.

**The retina.** Developmentally, the retina is part of the brain and as such has only a limited capacity for repair of its damaged tissue. In particular, the highly specialized rods and cones (the photoreceptors), which are the structures sensitive to light, and the nerve cells of the retina, like those of the brain, cannot be replaced if they are damaged. Death of these cells inevitably has a permanent effect on vision.

The retina is a thin transparent membrane that lines the inner eye. Its outermost layer, the pigment epithelium, is formed of pigmented cells that are closely adherent to the underlying blood vessels of the choroid. The layer of rods and cones is more loosely attached to the pigment epithelium and has complicated nervous networks that culminate in the innermost layer of nerve fibres. These fibres run back through the optic nerve to the brain. The inner two-thirds of the retina derives its blood supply from a special complex of vessels that enters the eye through the optic nerve.

**Retinal detachment.** A retinal detachment is a condition in which the main part of the retina becomes separated from the pigment epithelium. This may follow an injury to the eye or a tumour; or inflammation of the underlying choroid. The commonest type of detachment, however, has no such predisposing factors: the distinctive feature is the formation of a small hole or tear in the retina, usually at the periphery where the retina is thinner. In most cases the hole is caused by an adhesion forming between the retina and the jelly-like substance called the vitreous humour that fills the interior of the eye. Sudden movement of the eye, or an injury, causes the vitreous to pull on the retina, thus creating a tear or hole. When this has happened, fluid can pass through the hole and strip the retina off the pigment epithelium. Myopic (nearsighted) eyes are particularly prone to retinal detachment because they are larger than normal, and the coats of the eye are thinned and stretched. The periphery of the retina, in particular, often shows weak areas, and the vitreous is usually unduly thin and fluid.

Cataract in newborn child; in adult

Detachment of retina

The history is often quite typical. The pull of the vitreous on part of the retina creates a sensation of light noticed by the person affected as flashes that occur on movement of the eye. When an actual tear has developed, the retina starts to become detached and the person has the sensation of a shadow coming down over the vision.

The essential factor in treatment is to seal off the hole in the retina. The part of the retina containing the hole must be brought into close contact with the choroid and then by means of a gentle inflammatory reaction caused by using heat, cold, or intense light, the retina is made to stick to the underlying choroid and seal off the leak. The remaining fluid can then be drained away, allowing the retina to fall back into place. Provided that the detachment has not been of long standing, the retinal function recovers quite well once the retina is reattached. The small central area of retina, however, that subserves the most acute vision has only one source of blood supply, the underlying choroid; once it is separated from this some permanent damage ensues, even if the retina is subsequently replaced in its correct position. Thus, it is most important therefore that retinal detachments be treated early, before the central area of the retina becomes detached.

**Retinal degeneration.** Cases of retinal degeneration can be grouped in two broad classes: hereditary and genetic, and senile. A large number of genetically determined degenerations of the retina have been described. Although they are quite rare, the bizarre appearances of the retina and the inexorable advance of the disease have excited considerable interest among ophthalmologists. These conditions are typified by the disease known as retinitis pigmentosa, a hereditary condition. The earliest symptom is night blindness, which may first be noticed in childhood and is due to alteration in the function of the rods, which are the visual receptors used in dim light. The more peripheral parts of the retina are affected first, and while central vision may be good the field of vision progressively decreases until only a small "tubular field" remains. Cause of the disease is unknown. It is easily recognizable by the narrowing of retinal vessels and the scattering of clumps of pigment throughout the retina.

In senile degeneration, unlike the hereditary type, it is the central part of the vision that is first affected. The central part of the retina, known as the macula, derives its blood supply only from the choroid, and it is probably for this reason that it is likely to suffer first from the slowing of the metabolic changes and from the deficiency of circulation that occur in old age. While degeneration of the macula does not cause blindness, in the sense that the person affected is unable to see anything, it is extremely disturbing because it affects central visual acuity and makes reading or fine work difficult or impossible. There is as yet no satisfactory medical or surgical treatment, but considerable improvement can be obtained by the use of special magnifying spectacles.

The retinal changes that may occur in diabetes, arteriosclerosis, and vascular hypertension are described in a later section.

**The optic nerve.** The optic nerve, which carries about one million nerve fibres, leaves the globe from the back of the eye and passes through the apex of the orbit into the cranial cavity. It is surrounded by an extension of the membranes that surround the brain and this connection with the intracranial cavity is of some importance, because in some intracranial diseases the pressure within the skull rises and is transmitted along the sheaths of the optic nerve to cause swelling of the optic nerve head, which is visible inside the eye. This swelling of the nerve head, or papilledema, is one of the most important signs of increased intracranial pressure. If the swelling persists, damage to the fibres of the optic nerve takes place, with subsequent loss of vision.

Swelling of the optic nerve may also be caused by inflammatory changes in the nerve itself or in the surrounding sheath; this condition is known as optic neuritis. The symptoms are loss of vision in the central part of the visual field and pain on moving the eye. The condition is most common in young adults and may be due to the

spread of infection from the adjacent nasal sinuses. The majority of cases, however, are manifestations of multiple sclerosis, a condition in which the sheath of the nerves becomes altered and interferes with the transference of nervous impulses. This may occur in any part of the nervous system, but the optic nerve is a common site, and the lesion is often the first to be noticed by the patient because of the visual symptoms that result from it. The disease is characterized by long periods of remission from symptoms, and after optic neuritis it may be ten years or more before other signs are apparent. Usually the function of the optic nerve recovers after an attack of optic neuritis, leaving little, if any, visual disturbance, but there is some atrophy of the fibres.

Optic atrophy may follow any serious disease of the retina involving a large amount of destruction of neural tissue. It may also follow damage to the optic nerve within the skull, or the optic chiasma—that is, the place where the optic nerves crisscross, close to the pituitary gland. Tumours of the pituitary gland nearly always compress the optic nerve fibres and cause some degree of atrophy with loss of vision in that part of the visual field subserved by the fibres concerned. Usually it is the fibres on the inner side of the optic nerve and those that cross at the chiasma that are most involved: these fibres supply the retina on the nasal half. This part of the retina receives visual images from the outer part of the visual field, and in pituitary lesions it is common to find that the outer parts of both visual fields are affected.

Certain chemicals and some drugs can also cause optic atrophy: among them are quinine and methyl alcohol. Optic atrophy is most unlikely to follow normal medical doses of quinine, and when it occurs it is usually from the large doses taken to cause abortion. Methyl alcohol (wood spirit or methylated spirits) is broken down in the body to acetyl aldehyde, which is toxic to neural tissue, and the risks of blindness from drinking methylated spirits are high.

**Glaucoma.** The thin coats of the eye are not sufficiently rigid in themselves to withstand distortion following the pull of the extraocular muscles when the eye is moved. The eyeball is kept rigid by the action of the ciliary body, which secretes sufficient amounts of the fluid called the aqueous humour to pump up the pressure of the eye to a level above the atmospheric pressure. This fluid is constantly being formed and drains away at the base of the iris through specialized drainage channels. Should these channels become blocked the pressure within the eye rises to abnormally high levels and impedes the entry of blood into the eye. The fibres of the optic nerve where it enters the eye are particularly susceptible to a reduction in blood supply, and if the intraocular pressure remains raised for long some of these nerve fibres will atrophy, causing loss of function of the retina from which they are derived. Glaucoma is the name given to a condition in which the intraocular pressure is raised to abnormal levels. In some persons this is due to other disease within the eye—such as inflammation or a tumour—but most have one of two distinct diseases, chronic simple glaucoma or closed-angle glaucoma.

Chronic simple glaucoma is a common disease that may affect one percent of people in the older age groups. Although the actual cause is not known it is almost certainly due to degenerative changes in the outflow channels for aqueous fluid. It is rare below the age of 40 but after this its incidence increases; in one recent survey it was found to affect 10 percent of those examined over the age of 80. Genetic influences are important and relatives of patients with glaucoma are five times more likely than others to develop the disease.

The symptoms are slight or absent in the early stages. The slow rise in pressure does not cause pain, and the early visual loss is in the peripheral parts of the visual field, affecting central vision only late in the disease. Both eyes are usually involved, although one may be more severely affected than the other. Since vision lost from glaucoma cannot be restored, successful treatment can only prevent further loss of vision. It is of great importance, therefore, that the disease be diagnosed as early as

Causes and effects of swelling of optic nerve head

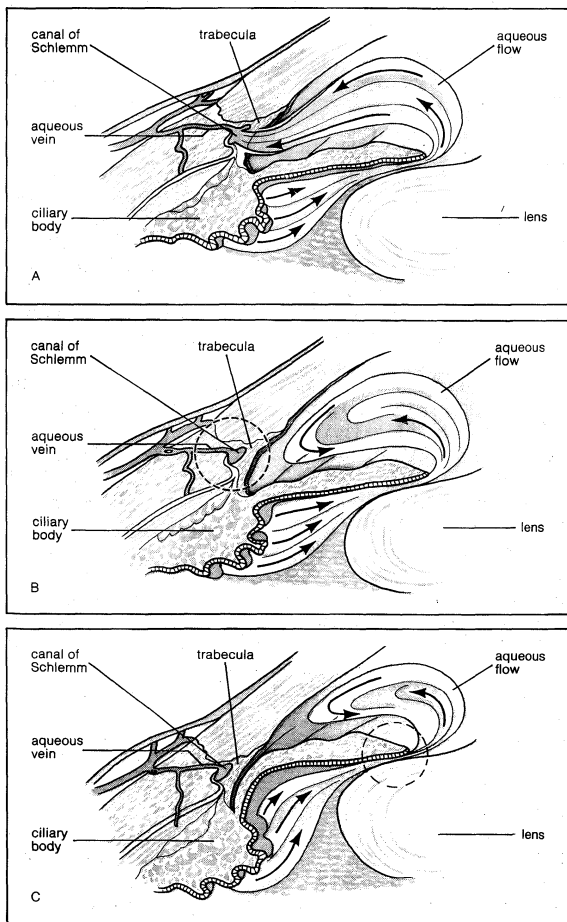

Chronic simple glaucoma

possible. Measurement of the intraocular pressure is of great value in the diagnosis of glaucoma: this is a simple test that can be applied as a screening method for surveys of the normal population.

The medical treatment of chronic simple glaucoma consists of the use of drops that lower the intraocular pressure. Inhibitors of the enzyme carbonic anhydrase, when taken by mouth, reduce the formation of aqueous humour and are used as an additional measure when necessary. If the pressure remains raised in spite of all medical treatment, then surgical methods must be used to increase the drainage of fluid from the eye.

The other common type of glaucoma is called closed-angle glaucoma. This again has a familial incidence and occurs in people who have a rather small, long-sighted eye. Continued growth of the lens in these patients pushes the iris forward and narrows the gap at the root (the outer edge) of the iris where aqueous humour flows out of the eye. This fluid is formed in the ciliary body behind the

From H.G. Scheie, *Medical Ophthalmology: Ophthalmologic Manifestations of Systemic Diseases*

Normal flow of aqueous humour contrasted with two types of obstruction.

(A) Normal flow of aqueous humour. (B) Obstruction to flow of aqueous humour in chronic glaucoma. (C) Obstruction to flow of aqueous humour in closed-angle, or acute, glaucoma. Dotted circles indicate site of obstruction.

iris and flows forward through the pupil to the angle of the anterior chamber. The lens pushing against the iris acts as a valve and impedes the flow of aqueous through the pupil. The root of the iris, which is rather thin, is then pushed forward and may eventually completely close the exit for aqueous, so that the intraocular pressure rises rapidly. The eye becomes painful and the vision is lost; the pain may be so severe as to cause vomiting and prostration. The eye becomes red and stony hard to the touch. Urgent treatment is required to lower the pressure and prevent strangulation of the blood vessels entering the eye.

In some cases an acute attack such as this heralds the onset of the disease, but more frequently minor, sub-acute, attacks, which are relieved by rest and sleep, occur for months or years. Modern methods of medical treatment are usually effective in lowering the pressure in the acute attack; an operation is usually necessary to prevent further recurrences.

#### OCULAR INJURIES

The bony orbit provides excellent protection for the eye from blunt injuries. A blow from in front with a rounded instrument such as a fist or tennis ball, however, can cause a shock wave to travel through the eye and damage the retina at the back of the eye. Central vision may be reduced after such injuries without any very obvious changes in the appearance of the eye. In severe cases the bones of the orbit may be fractured. Perforating wounds from glass, sharp metal fragments, and so on, are always serious. Injuries to the lens will result in the formation of a cataract, and often after penetrating injuries the eye remains inflamed for a considerable time.

One type of inflammation following injury, sympathetic ophthalmitis, is of particular importance; fortunately it is now rarely seen. The sequence of events is that an injured eye remains irritable and after some weeks, months, or even years, the fellow—previously normal—eye may take part in the inflammation. This is the “sympathizing eye.” The cause of sympathetic ophthalmitis is not known, but it is known that if an injured eye is removed within ten days sympathetic ophthalmitis never occurs in the other eye. In the past there was little effective treatment for the condition, but therapy with corticosteroid hormones has proved effective in controlling the inflammation in most cases, so that even if the disease becomes established the consequences are not as serious as they were previously.

**Foreign bodies.** Most foreign bodies that enter the eye remain near the surface. When they touch the cornea they cause intense pain and a flow of tears. The tears may be sufficient to wash the foreign body out of the eye, but if it becomes embedded in the cornea it may have to be removed surgically. Many small foreign bodies lodge in the under surface of the upper lid so that every time the eye blinks the foreign body rubs on the cornea, causing pain and irritation.

Small foreign bodies travelling at high speeds may penetrate the interior of the eye with remarkably few symptoms, and their presence may not be recognized until weeks or months later when inflammatory changes occur. The commonest foreign bodies to enter the eye in this way are fragments of metal from hammer-and-chisel accidents, or from moving parts of machinery. Whenever such injuries are suspected, it is important to locate the position of the fragment as carefully as possible, and to remove it by surgery. If the foreign body is magnetic, a large electro-magnet is invaluable in attracting the foreign body to the site of the incision in the eye, making extraction comparatively simple.

**Chemical and radiation injuries.** Strong acids and alkalis always cause severe injury if they enter the eye. Speed is the vital factor in first-aid treatment, and copious irrigation with water the first essential. Delay of first-aid treatment in the hope of finding a neutralizing substance is a serious error, as strong acids and alkalis quickly become bound to the ocular tissues and cause severe necrosis (death of tissue).

Except for extremely intense light such as that from a laser, the visible wavelengths of the electromagnetic spectrum—i.e., visible light rays—rarely cause ocular injury. Ultraviolet light, however, is strongly absorbed by the cornea and is the cause of the not uncommon condition known as snow blindness. Symptoms, consisting of intense pain and copious flow of tears, may not occur until some time after exposure. Exposure to light is painful. The treatment consists of cold compresses to the eye and soothing lotions; usually the eyes recover without any permanent damage.

Long-continued exposure to infrared radiation, without adequate protection for the eyes, can cause cataract for-

Sympathetic ophthalmitis

Effects of ultraviolet and infrared rays

mation. The lens is also susceptible to X-rays, and the eyes must be shielded when therapeutic irradiation is used for growths around or near the eye. High-intensity microwaves such as those used in some military applications can also cause ocular damage. The widespread use of lasers in research departments and in industry has created a new ocular hazard, and a few cases of accidental exposure have already been reported.

#### MANIFESTATIONS OF SYSTEMIC DISEASE

**The central nervous system.** Since the optic nerve and retina are, embryonically, an extension of the brain, it is not surprising that central nervous system diseases frequently affect the eye, and visual defects may be the earliest evidence of the general disease. The nerve supply to the ocular muscles, particularly the extraocular muscles, may also be involved early in some diseases of the central nervous system: this will result in defective movement of the eyes, causing lack of coordination between the two eyes and diplopia, or double vision.

The nerve fibres that connect the retina with the site of visual sensation in the occipital cortex—*i.e.*, the outer brain substance at the back of the head—are arranged throughout the brain in a regular pattern, and many lesions of the brain, such as tumours, impinge on part of this pathway. From a detailed examination of the sensitivity of the different parts of the retina, using tests of the visual field, it is often possible to localize the exact site of an intracranial lesion. An optic neuritis causing sudden onset of loss of central vision in one eye is a frequent first symptom of multiple sclerosis. Detailed ophthalmic examination is therefore essential in the case of any patient suspected of having disease of the central nervous system.

**Arteriosclerosis and vascular hypertension.** The eye is the one structure in the body in which the blood vessels are easily visible to the examiner, and the changes that can be observed in the retinal vessels mirror those that are taking place in other parts of the body, particularly those in the brain. In arteriosclerosis degenerative changes occur in the walls of the arteries: this leads to thickening of the walls and narrowing of the bloodstream and may give rise to complete occlusion, or blockage of the vessel. If the central retinal artery is affected, loss of vision is complete and sudden and, unless the obstruction can be relieved within an hour or so, permanent. Occlusion of the retinal veins is more common than arterial occlusion and also has dramatic effects: the damming up of blood in the eye results in the bursting of small vessels, and multiple hemorrhages are scattered all over the fundus (that part of the inner eye which can be inspected through the pupil). Some degree of recovery of vision is usual but depends on whether a branch of the central vein or the vein itself is occluded.

Vascular hypertension, or raised blood pressure, usually occurs in association with arteriosclerosis. Typical changes can be recognized in the small vessels of the fundus, and in severe cases multiple hemorrhages and exudates, with swelling of the optic disk (the head of the optic nerve), may be present.

**Diabetes.** The satisfactory control of diabetes with insulin has increased the incidence of eye complications, for it has become apparent that it is the duration of the disease rather than its severity that determines the onset of ocular changes. A special type of cataract may occur in young diabetics with severe untreated disease, but the most serious complication involves the blood vessels of the retina. The actual cause of the changes in the retinal vessels is still unknown, but the natural history of the disease is well recognized. The retinal capillaries dilate at weak points in the vessel wall—*i.e.*, form small aneurysms; these weak portions of the vessel wall may give way and cause hemorrhages into the retina. In the later stages the hemorrhages become more extensive and spread into the vitreous. New vessels grow into hemorrhagic areas and are followed by fibrous changes that may pull on the retina and cause detachment. Extensive changes of this nature lead invariably to blindness.

Destruction of the pituitary gland, either by direct sur-

gery or by the implantation of a radioactive material, has given some hope of alleviating these severe retinal changes. The procedure is, however, a drastic one. Destruction of affected areas of the retina by the use of an intense beam of light, a process called photocoagulation, promises to be a useful form of treatment in selected cases. Degenerative changes in the retina remain the most serious complication of diabetes.

**Thyroid disease.** The staring appearance of persons suffering from thyrotoxicosis, also called exophthalmic goitre or Graves' disease, is believed to be due to the stimulation of smooth muscle in the lids and orbit, causing the lid to retract a little from the globe and the globe itself to advance forward slightly. These changes normally regress if the thyrotoxicosis is treated. There is a more serious ocular complication of thyroid disease, which may follow excision of the thyroid for thyrotoxicosis or may, in some cases, arise in persons with normal or subnormal thyroid activity. It is characterized by swelling of the orbital tissues, including the extraocular muscles, so that the eyes cannot be moved properly and project forward between the lids to such an extent that the cornea becomes permanently exposed; the cornea may then ulcerate and even perforate and cause loss of the eye. Sewing the lids together may be sufficient to protect the cornea, but in many cases surgery to relieve the pressure in the orbit is necessary.

**Rheumatism.** The ocular complications of rheumatoid arthritis mainly involve the sclera, patches of inflammation occurring under the conjunctiva in the scleral and episcleral tissues (the latter are connective tissues between the conjunctiva and the sclera). Although the condition may respond to treatment with corticosteroids, recurrences are common.

#### VISUAL DISORDERS

**Subjective symptoms.** One of the commonest visual symptoms is the sensation of small, black objects floating in front of the eye. These move with the eye but lag slightly at the beginning of an eye movement and overshoot when the movement stops. They are due to cells and fragments of debris in the vitreous cavity of the eye. In certain conditions, as when looking at an empty sky, almost everybody can perceive them, and they are normal phenomena. A sudden increase in their number may indicate degenerative changes in the vitreous, which are particularly likely to occur in shortsighted eyes and in older people. These changes, although annoying, are of no serious import. The appearance of many "floaters," however, may be associated with inflammation or bleeding in the eye.

Blind areas in the field of vision occasionally force people to seek medical advice. Any condition that causes failure of function of part of the retina, the optic nerve, or the optic pathway to the brain, can cause such a blind spot, and the symptom requires careful investigation. There is a naturally occurring "blind spot" in each visual field that corresponds with the lack of retinal elements where the optic nerve enters the eye. The brain is so skillful in filling in the visual pattern that the normal blind spot can be detected only by special methods.

Flashing lights in the field of vision are caused by stimulation of the retina by mechanical means. Most commonly this occurs when the vitreous becomes degenerate and fluid and pulls slightly on its peripheral attachment to the retina. Similar symptoms also arise when the retina becomes detached, causing flashing lights to be seen.

**Night blindness and defects of colour perception.** Defective vision under reduced illumination may be a rare congenital condition or may be acquired as a result of severe deficiency of vitamin A.

Defective colour vision affects about four percent of men and 0.4 percent of women. Total colour blindness is extremely rare and is nearly always associated with poor vision in ordinary light. The colour-defective person is rarely aware of his disability until special matching tests are used, when it is discovered that he is unable to distinguish between hues in one or other part of the visual

"Floaters";  
blind  
areas;

lights

spectrum. Other visual functions are perfectly normal, and the only disadvantage is the restriction of certain types of occupation.

**Eye strain.** Eyestrain, or asthenopia, is the term used to describe symptoms of fatigue and discomfort following the use of the eyes. Although such symptoms may result from intensive close work, particularly if this is unaccustomed, in people with perfectly normal eyes, they may indicate abnormalities of muscle balance or refractive errors. Eyestrain is more likely to be manifest during periods of fatigue or stress and is common among students working for examinations. Refractive errors require correction and muscle imbalance treatment. Psychological factors are often more important than physical factors.

**Refractive errors.** In a normal eye rays of light from distant objects come to a focus on the retina. In near vision, the refractive power of the eye is increased by altering the shape of the lens to focus the image on the retina. A twelve-year-old can focus on an object four inches away from the eye but, with age, the ability of the lens to alter its shape decreases so that at the age of 40 the shortest distance at which an object can be kept in focus is about ten inches. The near point continues to recede with age until fine print, for example, cannot be read at a normal reading distance. This condition is known as presbyopia; it is corrected by the use of convex lenses for reading.

In some eyes rays of light from distant objects are not brought to a focus on the retina but are focused on a plane in front of the retina, as in myopia (short sight), or behind the retina, as in hypermetropia (long sight). In myopia, near objects are brought into focus on the retina but distant objects can only be seen clearly with the aid of concave lenses. In hypermetropia, distant objects can usually be brought into focus by using the accommodative power of the lens, and in young people there is usually sufficient accommodation to enable them to see reasonably near to them. The constant accommodative effort required, however, may produce symptoms, and the necessity for accommodating for distance can be overcome by wearing convex glasses.

Another type of refractive error is astigmatism. In this condition the refractive power of the eye varies in different axes because of variation in curvature so that vision at all distances is distorted and can only be corrected by the use of cylindrical lenses or contact lenses.

Minor degrees of refractive error are extremely common. The refractive state is genetically determined and there are marked racial differences. Myopia, for example, is common in the Far East and rare in the African Negro. Although most refractive errors are easily correctable by spectacles and such errors are rarely accompanied by any serious disease of the eyes, hypermetropia is a factor in the development of some kinds of squint and high degrees of myopia are often associated with serious degenerative changes within the eye.

#### OPHTHALMOLOGICAL EXAMINATION AND CORRECTIVE DEVICES

**Ophthalmological examination.** An ophthalmological examination comprises a history of a patient's symptoms and signs, subjective tests to determine the visual function, and physical examination of the eyes by means of special devices. The most important subjective test is for visual acuity, and this is usually performed by presenting to the patient a series of letters of graded sizes at a set distance. He is required to read the lowest line legible to him; visual acuity can then be expressed in terms of the size of the letter and the distance at which it is read.

The visual field is assessed by moving an illuminated target inward from the periphery toward a central point viewed by the eye: the area in which the target is seen can then be drawn as a map of the visual field for that eye.

Other subjective examinations include colour-vision testing and tests of visual perception under reduced illumination. Examination of the external eye and part of the anterior segment is facilitated by the use of a binocu-

lar microscope mounted horizontally, to which is attached a slit-lamp, a variable source of light that projects the image of a slit onto the eye. The ophthalmoscope has an illuminating system that lights up the interior of the eye and a viewing system through which the fundus can be observed. Photography of the anterior part of the eye and of the fundus is both possible and widely used.

Other specialized methods of examination include examination of the angle of the anterior chamber by means of a specially designed contact lens with the slit-lamp microscope. The electrical responses of the retina and brain to light entering the eye can also be recorded and are of great value in certain conditions.

Estimation of the intraocular pressure is an important part of an ophthalmological examination and is accomplished by an instrument called a tonometer. This instrument is rested lightly on the anesthetized eye and measures the amount by which the eye is deformed by a small known weight or force.

The refractive state of the eye can be measured objectively, or subjectively, or by a combination of both methods. The simplest method is subjective, using lenses of different powers to give a trial-and-error estimate of the best correcting lenses. More accurate results can be obtained by using an instrument known as a retinoscope, which gives an objective assessment of the refraction that can subsequently be modified by subjective methods to suit the individual requirements of the patient.

**Optical aids.** The most widely used optical aids are spectacles, and the technical design of spectacle lenses has advanced considerably in the last 50 years. A simple biconcave or biconvex lens causes considerable distortion of appearances if objects are viewed through the periphery of the lens, but if the back surface of the lens is made concave and the required power attained by altering the curvature of the front surface, improvement in peripheral definition results. All modern spectacle lenses are of this form.

Most older people require an additional lens for reading, and this can be incorporated with the distance correction in the form of a bifocal lens. In some occupations an intermediate distance is also required, and a third segment can be added, forming a trifocal lens. The complete range of correction from distance to near can only be achieved by means of a multifocal lens, and these are now available: the upper segment provides the correction for distance; as the eye moves lower down the lens its power increases, the lowest segment of the lens representing the reading correction. By slightly tilting the head it is possible to find the optimum correction for any intermediate distance.

The distortion of peripheral view when using conventional spectacles occurs because the correcting lens does not move when the eye moves. This problem can be completely overcome by the use of contact lenses, which are thin shells of plastic made to fit the anterior surface of the cornea and thus move with the eye. The earliest types of contact lens were larger than the cornea and were uncomfortable to wear, but the modern small "corneal" lenses have greatly increased the scope and usefulness of contact lenses and offer a practical alternative to the wearing of spectacles. Even so, there is a limit to the length of time for which they can be worn, and they should not be kept in at night. Their small size makes them easy to lose and difficult to manipulate, particularly for elderly persons. Further advances in design and in the use of new materials—for example, the flexible soft lenses—will doubtless extend the use of contact lenses even further.

For those persons who cannot obtain useful vision with ordinary spectacles or contact lenses, much can still be done by the use of compound lens systems known as low vision aids. These devices provide a magnified image but inevitably reduce the visual field. Their main value is to enable a person to read normal print who would otherwise be unable to read. They can be of use for distance, particularly when viewing conditions are relatively static, as with the cinema, theatre, or television.

Finally, for those who are completely blind from ocular

Presbyopia;  
short sight;  
long sight

Types of  
spectacles

causes there is new hope in the development of implants into the visual cortex that can be connected to a small television camera in such a way that electrical signals can be applied to the visual cortex, completely bypassing the normal optic pathways. The miniaturization of electrical circuitry resulting from space research has made the design of such devices a practical possibility. Their application to human subjects is, however, still in the experimental stage.

#### BLINDNESS

It is difficult to obtain reliable statistical information on the incidence of blindness on a worldwide basis. Even in countries in which the registration of blind people is attempted, the definitions of "blindness" vary from one country to another; in large parts of the world there is no registration, and the only estimate that can be made depends on random surveys of small parts of the population. Figures collected by the World Health Organization vary from 39 per 100,000 of the population in Mauritius to 4,000 per 100,000 of the population in Yemen. An incidence of about 200 per 100,000 is fairly representative of countries in which the standard of medical care is high; it is probable that the incidence is ten times higher in countries in which medical care is rudimentary.

There is wide variation in the causes of blindness in different parts of the world. This is partly due to geographic and climatic conditions but, more important, it is also due to differences in standards of hygiene and the availability of medical care. Infections, particularly trachoma, spread most easily in warm countries where the population is often crowded into small villages with lack of adequate hygienic facilities. Cataract is still high on the list of causes of blindness in many countries in the world, and this is all the more tragic in that it is so easily curable by surgical means. As the standards of general medical care increase and the expectation of life increases, so the pattern of blindness changes and degenerative conditions, diabetic disorders of the retina, and genetically determined diseases become predominant. Advances in the prevention and the medical and surgical treatment of blindness can only be of benefit to a population that has access to medical care. Until the nutritional and hygienic standards of a large part of the world population can be improved, preventable blindness will remain at its present high level.

(1959), a description for the layman of the function of the eye and management of the more common eye diseases; F.B. WALSH and W.F. HOYT, *Clinical Neuro-Ophthalmology*, 3rd ed., 3 vol. (1969), a very detailed account of ophthalmic conditions associated with neurological diseases.

(E.S.P.)

## Eyre, Lake

The great, normally dry Australian salt lake (salina) of Lake Eyre lies asymmetrically in the southwestern corner of a 500,000-square-mile (1,300,000-square-kilometre) closed basin of inland drainage in the heart of the continent. The annual rainfall in the lake is less than 5 inches (125 millimetres), making it the driest part of Australia, a factor worsened by a potential evaporation rate of 120 inches (3,050 millimetres) a year. The brutally harsh environment of the lake makes its value, in terms of settlement or exploitation of resources, limited in the extreme. The complex secrets of its origin, and the often bizarre plant and animal life associated with it, have, nevertheless, made Lake Eyre unique for its attraction for scientists, and its wildness offers a strange beauty.

The lake, whose lowest part lies 46 feet (14 metres) be-

low sea level, consists of two sections. Lake Eyre North, 90 miles (144 kilometres) long and 40 miles (64 kilometres) wide, is joined by the narrow Goyder Channel to Lake Eyre South, which is 40 miles (64 kilometres) long and about 12 miles (20 kilometres) in width. The combined area of Lake Eyre North and Lake Eyre South is 3,600 square miles (9,300 square kilometres) so that it ranks about 16th in the list of the world's great lakes.

The lake is normally dry; filling is thought to occur twice in a century, but partial, minor fillings happen much more frequently. During 1949-50, following phenomenal rains in northern and eastern Australia, 25,000,000 acre-feet (31,000,000,000 cubic metres) of water flowed in, principally from such streams as the Cooper Creek and the Diamantina, forming a sheet of water filling Lake Eyre North and covering no less than 3,100 square miles (8,000 square kilometres). This volume of water was insufficient to rise above the highest point in Goyder Channel and thus did not flow into Lake Eyre South. The large deposits of salt on the bed of Lake Eyre North were completely dissolved, and the lake water became as saline as that of the sea. Fish lived and multiplied in it for a short time but soon died as the salinity rose with intense evaporation during the 1950-51 summer. By the end of 1951 the water was reduced to 8 percent of its former volume and had become a saturated salt solution from which crystalline sodium chloride began to separate. Within a year the lake was dry and its 400,000,000 tons of salt were again deposited as a crust in its large southern bays. The complete cycle of filling and drying up occupied 3½ years. The actual evaporation rate was of the order of 80-90 inches (2.0-2.3 metres) per annum.

*Exploration and scientific study.* The lake was first sighted in 1840 by Edward John Eyre, one of the great 19th-century explorers, after whom it was named. Four years later Capt. Charles Sturt, whose expeditions were as important as those of Eyre, suffered terrible privations in the deserts to the east of the lake. Other explorers followed: in 1866, a party recorded the occurrence of salt three inches thick near the middle of the western shore, and established a fall of two and one-half feet in seven miles in the floor of the lake, reckoning from the northern shores; in 1872-73 a map was prepared showing the lake and the courses of the rivers to the east, thus opening the way to the establishment of cattle stations in the latter area.

**Geological and physiographic background.** The present landscapes of the Lake Eyre region can be understood only by tracing their geological evolution, a story of earth movements, erosion, laying down of sediments, and dramatic changes in climate going back hundreds of millions of years. Lake Eyre lies near the southwestern limit of the Great Artesian Basin, filled with sedimentary rock layers of the Mesozoic Era, less than 200,000,000 years ago, overlying a geologically ancient Precambrian basement or, in places, sediments of the Permian Period, about 260,000,000 years old. The earliest known deposits in the Lake Eyre region, however, are Jurassic terrestrial sandstones, laid down about 180,000,000 years ago. These indicate a depositional environment made up of rivers prone to episodic sheet floods, and a climate at first seasonally arid, but later moist and subtropical. The Great Artesian Basin was flooded by the sea some 50,000,000 years later, and its boundaries in South Australia widened as the transgression continued. The sea withdrew in Middle Cretaceous times, just over 100,000,000 years ago, and Lake Dieri, the ancestral Lake Eyre, came into being. From then until the end of the Mesozoic Era, around 70,000,000 years ago, up to 2,000 feet (600 metres) of lagoonal sediments were deposited in Lake Dieri as the region sagged; it is probable that Lake Dieri had an outflow to the sea.

The details of Lake Eyre's evolution during the last 70,000,000 years (that is, during the Cenozoic Era) are still somewhat controversial, and the following account combines the results of geological and geomorphological studies. During the early part of this period, carbonaceous lake sediments some 120 feet (36 metres) thick

The flood  
of 1949-50

Ancestral  
origins

were deposited in the region at present occupied by Lake Eyre, but outside this, thin spreads of gravel and sand were also deposited in places. Prolonged deep weathering and bleaching of rock layers near to the surface took place, forming a hard surface crust.

About 25,000,000 years ago the Lake Eyre Basin was affected by warping; positive movements along the marginal areas were compensated by negative movements near Lake Eyre, which thus accommodated further sediment down to 2,000,000 years ago, the time of early man.

A renewal of uplift then introduced a marked erosional phase ending in the development of broad, river-drained plains, separated by extremely low watersheds. Gypsite sediments, virtually the only resource of the region, were laid down at this time, and a higher rainfall and lower evaporation than at present permitted the existence of large, freshwater, brackish swamps, near which plant-eating marsupials flourished. An uplift of the eastern rim of the Great Artesian Basin resulted in the expulsion of artesian water in springs to the west and southwest of Lake Eyre, and in shallow pools surrounding these springs, the freshwater gastropod dolomitic limestones were formed and have been dated to 40,000 years ago.

Evidence from the western side of Lake Eyre strongly suggests that the present salina depression is a structural depression formed by a downfaulting in the earth's surface about 30,000 years ago, which blocked off the outlet to the sea. The western margin of the lake bed is a steep escarpment still seismically active, and springs occur along north-south lines in the lake bed of this region, presumably making fault zones. About 16 feet (five metres) of sediment have been deposited in the lake bed since this downfaulting, and as the climate became more arid, the finer sediments were blown off the lake surface to form the dunes of the Simpson Desert, to the north. Water reaching the lake now evaporates very rapidly, and the surface of the lake bed has a thin crust evaporated from the salt.

**Water supply and chemical characteristics.** Apart from the very low and intermittent local rainfall and small inflow of ground waters, the lake is fed in times of abnormal rainfall from a great, internal, continental drainage system. From the north, the Sandover, Georgina, and Mulligan rivers join the Diamantina, which enters Lake Eyre North via the Warburton and Kallakoopah Creek channels. The Thomson and Barcoo river systems converge to form the Cooper, and empty into the eastern side of Lake Eyre North as the Cooper, and into the southeastern sector as the Strzelecki Creek. Southern drainage from the Flinders Range enters by way of the Frome Channel. Other southern streams occasionally flood into Lake Eyre South; the biggest of these is the Margaret River. The main streams entering from the western side of Lake Eyre North include the Macumba and the Neales.

Beneath the surface, groundwater flow is centripetal to Lake Eyre, the main contributions coming from the Simpson Desert region to the north. The shallow groundwaters immediately north of Lake Eyre are composed of saturated brines.

The salt of Lake Eyre was once thought to be carried in atmospherically from the sea; but this is discounted by observations from Victoria that suggest that the influence of salts blown from the sea is limited to the immediate coastal zone. The current view is that the salt has been derived by solution from the rocks of the catchment area and carried, predominantly by shallow groundwater, to the hot, arid area of Lake Eyre, where it has been concentrated at various times during the last 2,000,000 years.

The thin salt crust of Lake Eyre North thickens southward, where it is up to nine inches (about 20 centimetres) thick; it is a coarsely crystalline aggregate, almost entirely of sodium chloride, hard and rigid, and capable of supporting heavy vehicles. It is invariably damp and saturated with ground brine. The brines comprise essentially sodium chloride (90-95 percent), with lesser amounts of magnesium sulfate (5-7 percent), magnesium chloride (up to 4 percent), and calcium sulfate (up to 2½ percent).

The proportions of the various salts differ little with depth. The potassium content appears to be fairly constant throughout, being appreciably lower (0.11-0.34 percent) than that derived from solar evaporation of seawater and from the artesian waters of the area (0.6-7.7 percent). Fluorine, bromine, iodine, and boron contents are almost negligible.

**Plant and animal life.** The plant life of the area around Lake Eyre forms part of what is known as the desert complex; the dunes carry cane grass on the crest and spinifex in the sandy interdune corridors; small shrubs, such as needlebush, occur in sandy hollows. Shrub steppe occurs on clayey corridors between the dunes. A restricted, ephemeral plant life of crucifers (four-petalled flowers in the shape of a cross) and grasses is prominent seasonally. The insects of this region, of a type found widely across Central Australia, exhibit mechanisms and behaviour patterns that enable them to survive periods of high temperature and severe desiccation; periodic large-scale fluctuations in their numbers occur. The reptile life is dominated by desert-adapted lizards and numerous snakes. The remarkable and highly specialized white earless dragon, a variety of lizard, was found living on the salt-encrusted surface of Lake Eyre North; it lives in association with a species of harvest ant that feeds on seeds blown out over the surface of the lake; together they form a closed community remote from plant life. The thorny devil, a grotesquely armoured lizard, also feeds on small ants. True desert birds are the gibber bird and the cinnamon quail thrush. Mammals are rare, though subject to periodic local increase. The fossil record of the lake has given clues as to the evolution of marsupials: it includes the giant plant-eating marsupials, which abounded there until extinguished by the increasing aridity that has reached its peak today. The brines contain a number of micro-organisms, algal, protozoal, and bacterial.

**Resources.** The accumulation of chemical evaporites in the bed of Lake Eyre is thin. Being in such a climatically harsh area, and so far removed from centres of usage, the deposits of sodium chloride, calcium sulfate, and dolomite cannot compete with materials more easily obtained from the coastal regions of South Australia. The native sulfur, occurring as cores in shells of gypsum, in Madigan Gulf, is too limited in supply to be of present economic interest, and the main interest in Lake Eyre at present continues to be that of scientific inquiry.

## Ezekiel

Ezekiel was a prophet-priest of ancient Israel, the subject and, certainly in part, the author of a book of the Old Testament that bears his name. His ministry was conducted in Jerusalem and Babylon in the first three decades of the 6th century BC. In the history of Judaism (and Christianity) the faith of Ezekiel (shared especially by the prophet Jeremiah) in the ultimate establishment of a new covenant has been a sustaining factor of inestimable importance; and his insistence that God purposes to do this for his own sake and that of his holy name (an emphasis shared later by the Second Isaiah) has had profound influence on the theology of Judaism and Christianity.

For Ezekiel and his people, the years were bitter ones during which the remnant of the old Israelite domain, the little state of Judah, was subjugated and eliminated by the rising new Babylonian Empire under Nebuchadnezzar (reigned 605-562 BC). The capital city of Jerusalem surrendered to the Babylonians in 597 BC. Resistance was renewed, and in 587-586 the city was de-

the salt

stroyed after a lengthy siege by Nebuchadrezzar's forces. In both debacles, and indeed again in 582, large numbers from the best elements of the surviving population were forcibly deported to Babylonia.

Before the first surrender of Jerusalem, Ezekiel was a functioning priest probably attached to the Jerusalem Temple staff. He was among those deported to Babylonia in 597 where he was located at Tel-abib on the Kebar canal (near Nippur). He lived with his wife in his own house until, apparently very suddenly, she died. Quite apart from his professional status as prophet-priest, it is evident that he was, among his fellow exiles, a person of uncommon stature.

The Book of Ezekiel opens with what remains a standing puzzle:

On the fifth day of the fourth month in the thirtieth year, while I was among the exiles by the river Kebar, the heavens were opened and I saw a vision of God. (Alternative translation, The New English Bible.)

To what or to whom the reference to the thirtieth year applies is not known. But in the next verse, the vision that inaugurated Ezekiel's career as a prophet is unambiguously dated in "the fifth year of the exile of King Jehoiachin"; that is, about 592 BC. His latest datable utterance ("in the twenty-seventh year") would be, then, about 570 BC, 22 years later.

On several matters, interpreters of the Book of Ezekiel have been unable to come to agreement. Repeatedly the prophet addresses himself to those who remain in Judah and Jerusalem, a fact that has led some historians to conclude that the Babylonian setting must be a later fiction, and that Ezekiel in fact fulfilled his career in Jerusalem. This, however, remains a minority judgment. More striking is the conflict in assessment of the person of the prophet. By some he has been read in a strongly negative light—hard and insensitive to the point of being almost inhuman; a fanatic, and in the way of fanatics, arrogant and aggressively intolerant; and even (because in fact the prophet is more given to strange visions and extraordinary acts than any other biblical prophet) as a psychopath. On the other hand, he has been described as having a well-endowed, versatile mind, aware of the problems and doubts of the people he addresses and sensitive to the life about him. It is said that he devoted all his mental powers, his heart, and his imagination to his ministry, and there is wide agreement that he profoundly shaped the Judaism that was reformed in the centuries that followed, especially in the influence of chapters 40–48 upon the postexilic reconstruction and reorganization of Judaism.

With the possible exception of the closing section of the Book of Ezekiel, scholars are reasonably confident that it is the prophet himself who is revealed in the writing that bears his name. The first 24 chapters were written in the years immediately before Jerusalem's destruction and carry the message of violence and destruction. Chapters 33 to 35 bridge the chasm to the articulation of hope and the assurance of restoration in chapters 36 to 39, with a phenomenal vision in chapter 37 of the valley of dry bones—representing the moribund people of Israel—coming alive again.

More than any of the classical biblical prophets—such as Isaiah and Amos and Jeremiah—Ezekiel is given to symbolic actions, strange visions, and even trances (although it is quite gratuitous to deduce from these, and from his words "I fell upon my face" (1:28) that Ezekiel was a cataleptic). He eats a scroll on which words of prophecy are written, to symbolize his appropriation of the message (3:1–3). He lies down for an extended time to symbolize the length of Israel's punishment (4:4ff). He is apparently struck dumb on one occasion for an unspecified length of time (3:26). As other prophets had done before him, he sees the God–People relationship as analogous to the relationship of husband to unfaithful wife, and therefore understands the collapse of the life of Judah as a judgment for essential infidelity. Ezekiel depicts the relationship in chapters 16 and 23 with consummate skill and passion.

There are other distinguished accounts of a prophet's

calling (e.g., in the books of Isaiah and Jeremiah). But Ezekiel's vision, which constitutes his call in chapter 1, is the most sensitive and sophisticated. Ezekiel does not suppose that he has seen Yahweh (God) or even Yahweh's throne. He punctuates his account with repeated qualifying phrases and concludes the vision: such was the appearance of the likeness of the glory of Yahweh. These images of the divine glory were the basis of Mer-kava ("chariot") mysticism in later Judaism.

Finally, it is the majesty of Ezekiel's faith that is his most distinctive quality. Ezekiel is unshakably persuaded of Yahweh's purposeful impingement upon history, of the ultimate redemption of the life of his (the prophet's) people, and implicitly, of their fulfillment of destiny in the eventual blessing of all the peoples of the earth.

## Ezra

Ezra was a religious leader from among the Jewish exiles in Babylon, who, at some time in the 5th century BC or at the beginning of the 4th, went to Jerusalem, where he was instrumental in bringing about a great religious reform that resulted in the reconstitution of the Jewish community on the basis of Pentateuchal law—which was regarded as divinely revealed Torah, or Law; i.e., religious and social regulations laid down in the first five books of the Old Testament (Pentateuch). Since his efforts did much to give Jewish religion the form that was to characterize it for centuries after, Ezra has with some justice been called the father of Judaism; i.e., the specific form the Jewish religion took after the Babylonian Exile. So important was he in the eyes of his people that later tradition regarded him as no less than a second Moses.

Ezra showing the Law to the people, detail of an engraving by Gustave Doré (1832–83).

Knowledge of Ezra is derived from the biblical books of Ezra and Nehemiah, supplemented by the Apocryphal (not included in the Jewish and Protestant canons of the

Problem of dating of Ezra

Visions and symbolic acts

Old Testament) book of I Esdras (Latin Vulgate form of the name Ezra), which preserves the Greek text of Ezra and a part of Nehemiah. It is said that Ezra came to Jerusalem in the seventh year of King Artaxerxes (which Artaxerxes is not stated) of the Persian dynasty then ruling the area. Since he is introduced before Nehemiah, who was governor of the province of Judah from 445 to 433 BC and again, after an interval, for a second term of unknown length, it is sometimes supposed that this was the seventh year of Artaxerxes I (458 BC), though serious difficulties are attached to such a view. Many scholars now believe that the biblical account is not in chronological order and that Ezra arrived in the seventh year of Artaxerxes II (397 BC), after Nehemiah had passed from the scene. Still others, agreeing that Nehemiah preceded Ezra but accepting that the two men were contemporaries, regard the seventh year as a scribal error and believe that perhaps Ezra arrived during Nehemiah's second term as governor. But the matter must be left open.

When Ezra arrived the situation in Judah was discouraging. Religious laxity was prevalent, the law was widely disregarded, and public and private morality was at a low level. Moreover, intermarriage with foreigners posed the threat that the community would mingle with the pagan environment and lose its identity. Although Nehemiah brought the community physical security and corrected various abuses, a sweeping religious reform was needed of the sort that he, a layman, could not manage—especially since laxity involved the high priestly family itself. It was this that Ezra came from Babylon to accomplish.

Ezra was a priest and “a scribe skilled in the law.” He represented the position of stricter Babylonian Jews who had been upset by reports of laxity in Judah and desired to see matters corrected. Perhaps through the influence of highly placed Jews at the Persian court, the King (Artaxerxes) was persuaded to authorize Ezra to go to Jerusalem, together with such Jews as wished to accompany him, and to regulate religious affairs there in accordance with the law; he was also authorized to receive contributions for the Temple and to transmit them to the authorities in Jerusalem. Ezra set out in the spring at the head of a sizable caravan and, four months later, arrived at his destination. Ezra apparently had official status as a commissioner of the Persian government, and his title, “scribe of the law of the God of heaven,” is best understood as “royal secretary for Jewish religious affairs,” or the like. The Persians were tolerant of native cults but, in order to avert internal strife and to prevent religion from becoming a mask for rebellion, insisted that these be regulated under responsible authority. The delegated authority over the Jews of the satrapy (administrative area) “beyond the river” (Avar-nahara), or west of the Euphrates River, was entrusted to Ezra; for a Jew to disobey the law he brought was to disobey “the law of the king.”

The order in which Ezra took the various measures attributed to him is uncertain. He probably presented the law to the people during the Feast of Tabernacles in the autumn, most likely in the year of his arrival. He also took action against mixed marriages and succeeded in persuading the people to divorce their foreign wives voluntarily. His efforts reached their climax when the people engaged in solemn covenant before God to enter into no more mixed marriages, to refrain from work on the sabbath, to levy on themselves an annual tax for the support of the Temple, regularly to present their tithes and offerings, and otherwise to comply with the demands of the law. Ezra's work helped to give Judaism its essential character as a religion in which law was central. Through adherence to the law the Jews were enabled to survive as a definable religious community, even though without national identity and scattered all over the world.

Nothing further is known of Ezra after his reforms. The 1st-century Hellenistic Jewish historian Josephus states in his *Antiquities* that he died and was buried in Jerusalem. According to another tradition, he returned to Babylonia, where his supposed grave is a holy site.

knowledge; JOHN BRIGHT, *A History of Israel*, ch. 10 (1959); MARTIN NOTH, *The History of Israel*, 2nd ed., pp. 315–333 (1960), two recent treatments of Israel's history, both of which advocate the view that Ezra came to Jerusalem during Nehemiah's term as governor (c. 428 BC); H.H. ROWLEY, “The Chronological Order of Ezra and Nehemiah” pp. 135–168 in *The Servant of the Lord*, rev. ed. (1965), a comprehensive review of the history of the discussion, with a defense of the view that Ezra arrived in the seventh year of Artaxerxes II (397 BC); J.S. WRIGHT, *The Date of Ezra's Coming to Jerusalem*, 2nd ed. (1958), perhaps the best defense of the traditional view that Ezra arrived in the seventh year of Artaxerxes I (458 BC).

(Jo.Br.)

## Fabales

Fabales is one of the three largest orders of flowering plants and is second only to the grass order (Poales) in economic importance. It includes a number of such familiar food products as beans, peanuts, and peas, as well as important sources of grazing food for animals, of which alfalfa and clover are the better known. In addition, most of the species are important elements of the natural ecosystem, in that they have the capacity, in conjunction with appropriate micro-organisms, to convert biologically inert atmospheric nitrogen into nitrates, in which form it is readily metabolized by plants. While a few other plant orders possess species with this capacity, the Fabales order is responsible for the great mass of such biological recycling. Because of this factor, together with the high nutritive value of its grazing plants, the species are commonly employed in crop rotation practices.

Latest estimates suggest that the order is composed of approximately 20,000 species distributed among 800 or so genera. Except for the family Krameriaceae, which has been removed from the order by most recent workers, the group is exceedingly natural—i.e., all of its families are closely related. Thus, while nearly all treatments have recognized the order Fabales as being divisible into three families (or sometimes subfamilies), Caesalpiniaceae, Mimosaceae, and Fabaceae, none has suggested that these families might be related to other groups more closely than they are to each other.

### GENERAL FEATURES

The order, while worldwide in distribution, shows the greatest diversity of morphological types in the tropical and subtropical regions of the world. This is particularly true for the predominantly woody families, Caesalpiniaceae and Mimosaceae. The former comprise the dominant tree members of the savanna lands of tropical Africa, South America, and Asia; the latter family is especially abundant as small trees and shrubs in the drier subtropical regions of Africa, America, and Australia.

**Economic uses.** In the more temperate regions of the world, the order is predominantly herbaceous, and most of the species belong to the large family Fabaceae. This family also contains the more important crop plants such as peanuts or groundnuts (*Arachis hypogaea*), chick pea (*Cicer arietinum*), soybean (*Glycine max*), common lentil (*Lens esculenta*), alfalfa or lucerne (*Medicago sativa*), sweet clover (*Melilotus* species), mung bean (*Phaseolus aureus*), kidney beans (*Phaseolus vulgaris*), peas (*Pisum sativum*), clovers (*Trifolium* species), vetches (*Vicia* species), and cowpeas (*Vigna* species).

The families Caesalpiniaceae and Mimosaceae do not contain many food crops and are perhaps best known for their shade and ornamental species, such as the Judas tree or redbud (*Cercis* species), orchid tree (*Bauhinia divaricata*), and huisache (*Acacia farnesiana*), although some of the more rapid growing weedy species, for example, the white popinac (*Leucaena glauca*) and *Albizia* species, are widely used as green manure and fodder crops. *Acacia* species are widely used in the production of gum exudates and wood, especially in South Africa and Australia, where the species are known as wattle trees.

**Diversity of structure.** The order Fabales is a predominantly woody group and most workers believe that

Ezra's  
reforms

Crop  
plants

the more advanced herbaceous plant groups, characteristic of the temperate regions, evolved from such tropical, woody ancestors. Species of the order are abundant on all continents (except Antarctica), occurring as trees, shrubs, vines, delicate annuals, and sometimes, though rarely, as floating aquatics. An example of such an aquatic is *Neptunia oleracea*, a member of the family Mimosaceae, which is often tied to shallow lake bottoms in India so that it might be readily obtained for use as an edible vegetable. Bizarre species are especially abundant in the semidesert and savanna regions of western Australia; most of them belong to the tribe Podalyrieae of the family Fabaceae, and such oddities are presumably a reflection of the long isolation of that continent's flora from Asia.

#### Distinctive character of the fruit

The order Fabales is probably best known by its fruit. In fact, it is often referred to as the Leguminales order, because its fruit, a legume (often highly modified), is the most obvious single character by which the group is recognized. Technically speaking, a legume is typically a one-celled (chambered), two-valved, seed pod with marginal placentation (ovule attachment), such as occurs in the common pea (*Pisum sativum*). The legume assumes a variety of forms, however, such as samaras, which are single-seeded, winged, indehiscent (not splitting open along definite seams) pods and lomentis (many seeded, indehiscent pods, constricted between the seeds, which at maturity break off as separate reproductive units), and others. One of the more unusual legumes is that of the peanut (*Arachis hypogaea*), a fruit that matures underground. The peanut flower itself is produced above ground but as it ages it assumes a position close to the soil surface so the ovary can elongate and develop as a subterranean pod.

Seeds borne within the various legume types are also extremely variable, ranging from the size of a pinhead (in *Lotus* species) to that of a baseball (in *Mora excelsa*). Legume seeds are sometimes quite colourful; the *Abrus precatorius* and *Ormosia* species, for example, produce striking black and red seeds. These seeds have been used as currency by primitive people and because of their usually hard seed coats they are commonly used in the production of beads and handbags, which are sold as tourist merchandise, especially in the more tropical regions. They may be quite poisonous if eaten, however, and for this reason such merchandise is often refused entry by government inspectors.

#### NATURAL HISTORY

The worldwide distribution and large size of the order is undoubtedly a reflection of its early dispersion throughout the tropics and later adaptation to the numerous adjacent, more temperate, habitats. Effective dispersal of the seeds is assured by the large variety of seed pods found in the order and by the largely self-pollinated flowers found in the more advanced tribes of the family Fabaceae. Seed coats are generally quite hard and impermeable to water, which permits the seed to endure long storage periods in nature. In fact, seeds of this order from the genus *Cassia* have been known to germinate after having been in dry storage at ordinary room temperatures for 200 years. Upon fracture of the seed coats, however, germination is readily effected, for dormancy periods, often necessary for seed germination in other plants, are generally not found in legumes. Other reproductive specializations include cross-pollination, cleistogamy (self-pollination resulting from floral modifications that prevent the entry of other pollen—such as non-opening flowers), and vegetative (asexual) reproduction.

An interesting adaptation in a few tropical and subtropical species belonging to the families Mimosaceae and Caesalpinaceae is that of myrmecophilism, in which vegetative specializations have been developed to accommodate ants. Special secretory glands on the leaves that ants use for feeding purposes and unusually large thorns on the stem in which they live are two such features.

The adaptive significance of such mutualism is debatable, but many workers believe that in living off the

Figure 1: Representative fruits of the order Fabales. The characteristic fruit type, known as a legume, is the single character by which the order is best known and is the basis of the classical name of the order (Leguminales), still used by many authorities.

Drawing by M. Pahl based on (all except *Entada spicata*, *Millettia dielsiana*, *Erythrina rubrinervia*) J. Hutchinson, *Evolution and Phylogeny of Flowering Plants*

excretory products of the plant, the ants readily provide protective measures to the plant by warding off potential leaf eaters such as grasshoppers, aphids, and perhaps even some of the larger browsing animals.

Pollen dispersal in outbreeders is largely provided by insects, especially bees, which have relatively heavy abdomens and easily cause pollination through landings made on the keel of the flower, a special structure found in the Fabaceae that encloses most of the reproductive organs. Other pollinators exist, however, and in at least one genus of the family Mimosaceae (*Parkia*), tropical fruit bats are the principal means assuring pollination.

#### FORM AND FUNCTION

**Vegetative characters.** The three families that make up the order Fabales are readily distinguished by their vegetative features. The family Mimosaceae possesses mostly twice-compound leaves, which have several leaflets arranged along either side of a central axis, the leaflets themselves being subdivided into a number of smaller units in a similar arrangement. The family Caesalpinaceae has mostly once-, or less often, twice-compound leaves, and the family Fabaceae has once-compound leaves, these often reduced to a trifoliolate (three leaflets) condition, as in the common clover, or modified with twining tendrils as in the sweet pea.

Certain members of the order are especially interesting

#### Seed dispersal

Figure 2: Floral and vegetative structures representing plants from the three families of the order Fabales.  
Drawing by M. Pahl

Leaves  
sensitive  
to touch

in that their leaves are sensitive to touch, temperature, and light changes. The tropical "sensitive plant" (*Mimosa pudica*) is widely grown in greenhouses for this effect. Touching the plant results in very rapid movements of the entire leaf or its component parts. Similar movements, but not so pronounced, occur in many other species of the order, particularly in the family Mimosaceae. For example, the so-called "mimosa" tree (*Albizia julibrissin*) folds its leaflets together at dusk, decreasing at least by half the amount of leaf surface exposed to the atmosphere. The adaptive significance of such movements is unknown, but the movement itself is caused by water pressure changes in specialized structures at the base of both the leafstalks (petioles) and leaflets.

**Flower and fruit characters.** The single floral feature most characteristic of the entire order is the presence of an hypanthium, a structure formed by the fusion of the base of sepals, petals, and stamens (male reproductive structures) to form a cup (often very small) about the base of the ovary. With the exception of this characteristic, the floral types are quite variable, with flowers ranging from regular (*i.e.*, actinomorphic, radially symmetrical) in the family Mimosaceae to highly irregular (*i.e.*, zygomorphic, bilaterally symmetrical) in the family Fabaceae. Flowers of the family Caesalpiniaceae are somewhat intermediate between these extremes, as regards symmetry.

Especially noteworthy are the floral modifications found in the family Fabaceae. The petals, which are uniformly five in nearly all of the 15,000 or more species, are characteristically modified into a so-called papilionaceous (butterfly-like) flower in which the uppermost petal (the banner) is usually quite enlarged and colourful, the two lateral petals are wing-like structures (and are termed wings) and the two basal petals characteristically are united near their middle to form a boat-shaped structure called the keel.

The stamens, usually 10 in number, are also highly modified in this family. They are joined into a single, tubular structure (the stamens then being termed "monadelphous"), or more often into a set of nine united

stamens that reside in the keel, plus a separate stamen that stands above the nine and just below the banner itself. The latter state is termed "diadelphous." At least two of the more primitive tribes (Sophoreae and Podalyriaceae) of the family Fabaceae, however, possess free stamens and separate keel petals, as do many species belonging to the family Caesalpiniaceae.

Pollen grains in the order are quite distinctive and have proven of value in defining many of the tribal groupings in the several families. The fruiting structures within the order, while uniformly derived from a single carpel (or simple ovary), are variable in size, shape, and texture, ranging from the herbaceous coiled, hispid (rough or bristly) fruits, characteristic of bur clover (*Medicago hispida*) to the elongate (two to three feet long), woody pods of the genera *Cassia* and *Caesalpinia*.

**Physiological features.** Species belonging to the order Fabales are perhaps best known agronomically for their capacity to "fix" atmospheric nitrogen; *i.e.*, to convert it into a form that plants can utilize, usually the nitrate form. This is accomplished by symbiotic fixation, in which root nodules (swellings) are formed on the plant in reaction to infections by soil bacteria belonging to the genus *Rhizobium*. Root nodulation, while occurring in all three families, presumably does not occur in all species, the phenomenon being more common in the family Fabaceae and relatively less so in the families Mimosaceae and Caesalpiniaceae.

**Biochemical features.** The Fabales order is noteworthy for the large range and variety of secondary compounds found in its member's leaves and fruiting parts, such as flavonoids, alkaloids, terpenoids, non-protein amino acids, and others. Some of these, for example the amino acid canavanine, may comprise up to 5 percent of the dry weight of seeds. The interesting chemical compound, rotenone, which is toxic to a number of organisms, is sufficiently abundant in the roots and stems of certain species belonging to the family Fabaceae that primitive peoples commonly used these plants to poison fish. More recently it has been shown that serious bone and neural diseases, afflicting both man (*e.g.*, lathyrism) and livestock may be caused by the ingestion of unusually large amounts of certain free amino acids. In sheep, ingestion of large quantities of the amino acid mimosine, found in *Leucaena glauca* and some other species of the Mimosaceae family, apparently causes the cessation of the growth of hair or wool, and in certain cases the fleece itself has been observed to shed. A wide variety of alkaloids are found in the order, most of them restricted to the family Fabaceae, however. Some alkaloids are found in sufficient concentration in range plants to be quite poisonous to livestock, especially in species belonging to the large genus *Astragalus*. Species of *Astragalus* are commonly referred to as "loco weeds" by cattlemen in North America because, following excessive consumption of these plants, cattle seem to become unmanageable and "go crazy" or "loco."

In spite of the toxic nature of many of the species, most of the plants are highly palatable and are especially nutritious because of the high concentration of vitamins and proteins in their young growing parts (*e.g.*, in alfalfa) and in the storage components in seeds (*e.g.*, beans and peas). The American Indians very early appreciated this and, along with corn, adopted the common bean (*Phaseolus* species) as one of their staple foods.

Except for the soybean and peanut, species of the order are not noted for the oil content of their seeds; most seeds contain only about 10 percent oil content by weight. Indeed, the fat content of many of the legumes used for food by humans is only between 1 and 2 percent. In general, legume seeds are usually highest in nutritive content in carbohydrates, followed by protein and fat.

An interesting biochemical component of the legume seed is phytohemagglutinin, a large protein molecule that has proven specific in its capacity to agglutinate certain human blood types. Approximately 60 percent of the several thousand seeds belonging to this order tested to date contain the compound.

Poisonous  
plants

Arrange-  
ment of  
stamens

Phytohemagglutinin is particularly rich in the common bean (*Phaseolus* species) and has been extracted in a relatively pure state on a commercial scale from species belonging to this genus. In addition to its agglutination properties, the compound has been of interest because of its other biological effects. It is toxic to rats, it inactivates some human tumor cells, and has beneficial effects on aplastic anemia, the shortage of blood cells in man because of destruction of blood forming tissues.

Chromosome size  
and  
number

**Chromosomal features.** Chromosomal data have been assembled for a wide range of species in the order, including representatives from all three families and most of the tribes and subtribes. The chromosomes for any given genus are usually quite uniform, in both number and morphology (form); most of the genera possess a single base number. The incidence of polyploidy (multiples of the basic chromosome number), as contrasted with most plant families, is also relatively low. The family Mimosaceae, in general, has small chromosomes (one to three microns, or about 1- to 3/25,000 inch in length), and most of the species possess haploid (*i.e.*, the base number, one-half the normal number of chromosomes in a typical body cell) numbers of 13 or 14. The family Caesalpiniaceae is quite variable as to chromosome size and structure, possessing genera with base numbers of seven through 12—with the exception of nine; species with this haploid number are strangely absent. The Fabaceae is the most variable family, chromosomally. Woody tropical groups usually have relatively small chromosomes with haploid numbers of 10 and 11; the more temperate, herbaceous derivatives (for example, the genera *Vicia*, *Lathyrus*, and *Lotus*), have mostly larger chromosomes at lower haploid levels such as six, seven, or eight. Although this purview is based upon only about 20 percent of the species in the family, surveys among genera are broad enough to suggest that additional sampling will not change the picture much.

#### EVOLUTION

**Fossil record.** There are abundant fossils of the Fabales order dating back to the Early Tertiary Period (Eocene Epoch, beginning about 54,000,000 years ago), most of which are similar to present-day, woody genera such as *Gleditsia* (Caesalpiniaceae), *Prosopis* (Mimosaceae), and *Robinia* (Fabaceae). Thus, the order was presumably well developed on the several continents even earlier, probably in Cretaceous time (beginning 136,000,000 years ago). By then, the order's three families had already developed in essentially the same form as those represented today by living genera. Fossil materials do not exist that serve to link the order to other orders, consequently most phyletic treatments of the group are based almost entirely on comparative morphological and distributional data among living species.

**Phylogeny.** Most workers consider the Fabales order to be related to the order Rosales. The two groups are similar in possessing mostly alternate leaves with stipules, perigynous flowers (*i.e.*, flowers with a partly enclosed ovary) and fruits derived from one or more separate carpels (in the Rosales the latter often fuse at maturity, as in the apple). Nearly all workers also agree that the order has its origin in the tropical regions from woody ancestors, the herbaceous species being structurally reduced, but more highly evolved types, which arose independently in several phyletic lines, presumably in adapting to the more vigorous climatic conditions that developed in the temperate regions during Tertiary time. Within the order most workers reckon the family Caesalpiniaceae to be an ancestral group that gave rise to the more tropical and subtropical family Mimosaceae, on the one hand, and to the more temperate Fabaceae, on the other. The Mimosaceae and Fabaceae, while quite distinct, are inextricably linked through several genera belonging to the Caesalpiniaceae, such as *Swartzia*, *Amphimas*, and *Mora*.

#### CLASSIFICATION

**Distinguishing taxonomic features.** The Fabales order has been treated classically as consisting of but a single

family (traditionally named Leguminosae) of the large order Rosales. As such, the family was subdivided into four subfamilies, Mimosoideae, Caesalpinoideae, Papilionoideae (sometimes called Faboideae), and Kramerioideae. More recently the trend has been to remove the latter subfamily, consisting of but a single genus (*Krameria*), to the order Polygalales; the three remaining subfamilies are then treated at the familial level as members of the order Fabales. So constructed, the order can be distinguished from the closely related order Rosales by its (usually) solitary carpel, compound leaves, often more numerous, united stamens, and above all by its fruit.

**Annotated classification.** There is no single character that serves to distinguish between the orders Fabales and Rosales, or among the families of the Rosales; but in combination, morphological characters can be found that readily distinguish both the order Fabales and its three families. Nearly all present-day workers accept the validity of the natural groupings indicated below, although many would recognize a larger number of subfamilies and tribes within the families themselves.

#### ORDER FABALES

Herbs, shrubs, trees, or vines; leaves mostly alternate, compound, or simple by suppression of leaflets, stipulate, or infrequently without stipules; flowers bisexual, actinomorphic (radially symmetrical) or zygomorphic (bilaterally symmetrical), perianth (sepals and petals) in two series, the calyx gamosepalous (with fused sepals) and 5-lobed, the corolla typically of 5 petals (rarely absent or reduced to a single petal) distinct or the 2 anterior ones basally fused; stamens mostly 10 (sometimes numerous in Mimosaceae), distinct, monadelphous (stamen-filaments fused), or diadelphous (stamens in 2 bundles of 9 plus 1); the anthers 2-celled, dehiscent (splitting open) by longitudinal slits or infrequently by pores; pistil 1; the ovary superior, 1-loculed, 1-carpelled, the placentation parietal (ovule attachment is to the ovary walls) or seemingly marginal along ventral suture; the ovules 2 to many in 2 alternating rows on a single placenta, amphitropous (half inverted and straight), anatropous (inverted and straight), or infrequently campylotropous (curved, bringing the apex and base nearly together), pendulous or ascending; fruit usually a legume, samara, or loment, sometimes a follicle, or indehiscent or tardily so, seed with a usually leathery testa (covering), funiculus (stalk) sometimes produced into a more or less fleshy aril (appendage) or callosity, the endosperm (starchy nutrient tissue in the seed for the developing embryo) none or very scant. Three families, about 800 genera, and perhaps 20,000 species. The order is cosmopolitan in distribution with the family Fabaceae being relatively more abundant in the temperate regions and the Mimosaceae and Caesalpiniaceae being more tropical.

#### Family Mimosaceae

Trees, shrubs, or rarely perennial herbs; leaves twice-pinnate (compound by branching from a central axis comb-fashion, in this case twice-compound) or rarely once-pinnate (reduced to a phyllode [flattened leafstalk] and appearing simple in certain species of *Acacia*), stipulate, the stipules often persisting as well-developed, paired thorns; flowers small, mostly perigynous but often appearing hypogynous (*i.e.*, with sepals and petals arising at the base of the ovary), bisexual (rarely male only or neuter), actinomorphic and valvate (edges of petals not overlapping) in bud (somewhat irregular and overlapped in tribes Mimosyantherae and Parkieae), usually sessile (without a stalk) in short spikes or globose heads, rarely in racemes (flower clusters having a central axis with flowers on short lateral stalks, maturing from the bottom upward) or in umbels (flower clusters with individual flowers on stalks radiating from a common point, umbrella fashion); sepals and petals 4 or 5; stamens few to numerous, monadelphous or attached to the floral tube and appearing free; anthers small, versatile (attached near their middles, turning freely), sometimes with a glandular body at the apex; ovary single (except in *Affonsea* and *Archidendron*, which have 2 to 6 free carpels), with slender style (upper part of the ovary), small terminal stigma (pollen-receiving surface at the top of the style) and numerous ovules; fruits dehiscent to indehiscent, the seeds ovate to orbicular, compressed, usually quite indurate (hard); aril rarely present; endosperm very thin or absent; cotyledons (seed-leaves) flat, the radicles (root end of the embryo) straight. A largely pantropical group consisting of about 3,000 species in 60 genera dispersed among 5 or 6 tribes. Two of the largest genera, *Acacia* (900 species) and *Mimosa* (600 species) are widely distributed in the drier subtropical regions, especially savanna and desert habitats of both the old and new worlds.

Classical  
treatment  
of  
taxonomic  
position

**Family Caesalpiniaceae**

Trees, shrubs, or rarely herbs; leaves once- or twice-pinnate, rarely simple; stipules present, but often small or soon deciduous (falling), only rarely transformed into thorns; flowers zygomorphic or rarely actinomorphic, perigynous, usually 5-merous (with basic parts in fives or multiples thereof), bisexual and showy; inflorescence (flower cluster) racemose or paniculate (much-branched); petals 4 or 5, or by fusion or reduction fewer, imbricate or (very rarely) valvate in bud; stamens 10 or fewer (rarely numerous), free to variously connate (fused); anthers of various shapes, dehiscing by slits or apical pores; ovary superior, 1-carpellate; fruit a pod, drupe, or samara; seeds often large, arillate or with endosperm; cotyledons fleshy or foliaceous (thin and leaflike), the radicle straight or only slightly oblique, never folded. Distribution largely pantropical. Forms highly variable, the group composed of approximately 3,000 species in 160 genera. The family has been classically treated as consisting of 7 tribes but some recent workers would perhaps double this number and treat these as belonging to two subfamilies, Caesalpinioideae and Brachystegioideae. *Cassia*, with 600 or more species, is the largest genus in the family, being especially abundant in the New World.

**Family Fabaceae**

Trees, shrubs, vines, or annual herbs; leaves once-pinnate and very often reduced to a trifoliolate (with 3 leaflets) or palmate (compound, the leaflets radiating from a common point) condition, rarely simple (single leaves) or reduced to scales, especially in the Australian tribe Podalyrieae; stipules mostly herbaceous, often adnate (joined) to the petiole (leafstalk); flowers zygomorphic (rarely actinomorphic or nearly so), perigynous; sepals and petals 5 or, by reduction, fewer; petals highly modified into banner, wings, and keel, the latter usually housing the reproductive structures; stamens 10 (rarely fewer), monadelphous, diadelphous, or rarely free; anthers uniform or dimorphic (of 2 forms), basifixed (attached near the base) or dorsifixed (attached along one side), often variable in the same androecium (male complex), opening by slits; ovary superior, of 1 carpel, 1-loculate (chambered), sometimes by intrusion of the marginal sutures appearing 2-loculate; fruit various, but typically a dehiscent pod or legume in the more temperate genera; tropical and subtropical groups often possessing indehiscent pods, samaras, drupes, loment, and burrs; seeds without endosperm or seemingly so; cotyledons small, the radicle inflexed (very rarely straight). Distribution worldwide, the group composed of approximately 500 genera and 15,000 species. Most of the woody species belong to tropical or subtropical genera while the herbaceous species are found primarily in temperate regions. The family has been treated classically, largely on grounds of convenience, as composed of 11 or 12 tribes but some recent workers have increased this to 50 or more. The largest genus is *Astragalus* with 1,500 or more species, ranking as one of the largest genera of flowering plants.

**Critical appraisal.** Nearly all workers recognize the order as an exceedingly natural one and most would relate it to the order Rosales. Other orders recognized as being phylogenetically close to the Fabales are the Saxifragales and Cunoniales. Some authorities, however, prefer to treat the three families of Fabales as subfamilies belonging to but a single family within the much larger order Rosales. In such a treatment the Saxifragales and Cunoniales orders are usually accorded familial status. There would be little opposition to the recognition of the Mimosaceae and Fabaceae as distinct families if it were not for the transitional nature of many genera belonging to the Caesalpiniaceae—i.e., they have characteristics similar to both families. Because of the transitional genera, however, some workers believe the Caesalpiniaceae to be ancestral to these two groups. Most of the transitional genera, however, seem to link the Caesalpiniaceae to the Fabaceae, with the Mimosaceae standing somewhat more remote. It has been suggested that the Fabaceae, in part, has ancestors in more than one evolutionary line (i.e., the family is polyphyletic) and that at least some of the tribes have arisen from different phyletic lines within the Caesalpiniaceae. Clearly there is much need of detailed morphological, cytological, and chemical study of the family Caesalpiniaceae for it is poorly known, and is represented in museums by relatively few collections and is generally neglected by cytologists and plant chemists. With more intensive study, especially in the area of chemosystematics (taxonomy systems based

on chemical factors), it is likely that some of the tribes of the Caesalpiniaceae will be elevated to subfamily or family rank. In addition, considerable resorting of the genera among tribes of the Fabaceae seems likely, since at least some of them are believed to be classified on one or more technical characters of the fruit, which may or may not group together those genera with a common phyletic origin.

**BIBLIOGRAPHY.** E.G. HALLSWORTH (ed.), *Nutrition of the Legumes* (1958), a broad treatment of the soil factors affecting the growth of legumes including the rhizobial (bacteria in root nodules) component; J. HUTCHINSON, *The Genera of Flowering Plants* (1964), the most recent intensive taxonomic account of the families and tribes, with keys and descriptions provided for all genera recognized at the time, an indispensable reference; *Evolution and Phylogeny of Flowering Plants* (1969), a highly readable, authoritative account of the phyletic position of the order Fabales within the flowering plants, including an account of the wide morphological variation (nicely illustrated) found in the order; P. TAUBERT, "Leguminosae," in A. ENGLER and K. PRANTL (eds.), *Die Natürlichen Pflanzenfamilien* (1894), a classical text for the order, with keys and descriptions (in German) to the generic level, copiously documented as to the earlier work on the group and references to these; L. CAPITAIN, *Étude analytique et phytogéographique du groupe des légumineuses* (1912), a treatment of the order in which an attempt is made to show the phytogeographic relationships among the 30 or more tribes; R.O. WHYTE, G. NILSSON-LEISSNER, and H.C. TRUMBLE, *Legumes in Agriculture* (1953), an excellent account of the agronomic value of legumes and their role in agriculture with consideration of the regional value of both local and world-wide species in the order; J.B. HARBORNE, D. BOULTER, and B.L. TURNER (eds.), *Chemotaxonomy of the Leguminosae* (1971), a broad treatment of the chemical components (alkaloids, flavonoids, terpenoids, amino acids, proteins, enzymes, etc.) found in the three families, especially as they relate to the systematic treatment of taxa comprising the order.

(B.L.T.)

**Fable, Parable, and Allegory**

Fables, parables, and allegories are forms of imaginative literature or spoken utterance constructed in such a way that their readers or listeners are encouraged to look for meanings hidden beneath the literal surface of the fiction. A story is told or perhaps enacted whose details—when interpreted—are found to correspond to the details of some other system of relations (its hidden, allegorical sense). The poet, for example, may describe the ascent of a hill in such a way that each physical step corresponds to a new stage in the soul's progress toward a higher level of existence.

Many forms of literature elicit this kind of searching interpretation, and the generic term for the cluster is allegory; under it may be grouped fables, parables, and other symbolic shapings. Allegory may involve either a creative or an interpretive process: either the act of building up the allegorical structure and giving "body" to the surface narrative or the act of breaking down this structure to see what themes or ideas run parallel to it.

This article discusses the nature and objectives of fable, parable, and allegory, goes on to cover allegory and cosmology, and the historical development of this imaginative literature in western culture, and, finally, discusses allegorical literature in the East.

**NATURE AND OBJECTIVES OF FABLE, PARABLE, AND ALLEGORY**

**Allegory and myth.** The fate of allegory, in all its many variations, is tied to the development of myth and mythology. Every culture embodies its basic assumptions in stories whose mythic structures reflect the society's prevailing attitudes toward life. If the attitudes are disengaged from the structure, then the allegorical meaning implicit in the structure is revealed. The systematic discipline of interpreting the real meaning of a text (called the hermeneutic process) plays a major role in the teaching and defense of sacred wisdom, since religions have traditionally preserved and handed down the old beliefs by telling exemplary stories; these sometimes appear to conflict with a system of morality that has in the

Need for  
further  
study

meantime developed, and so their "correct" meaning can only be something other than the literal narration of events. Every culture puts pressure on its authors to assert its central beliefs, which are often reflected in literature without the author's necessarily being aware that he is an allegorist. Equally, determined critics may sometimes find allegorical meaning in texts with less than total justification—instances might include the Hebraic-Christian mystical interpretation of the Old Testament's Song of Solomon, an erotic marriage poem, or the frequent allegorizing of classical and modern literature in the light of Freud's psychoanalytic discoveries. Some awareness of the author's intention seems necessary in order to curb unduly fanciful commentary.

**The allegorical mode.** The range of allegorical literature is so wide that to consider allegory as a fixed literary genre is less useful than to regard it as a dimension, or mode, of controlled indirectness and double meaning (which, in fact, all literature possesses to some degree). Critics usually reserve the term allegory itself for works of considerable length, complexity, or unique shape. Thus, the following varied works might be called allegories: the biblical parable of the sower; *Everyman*, the medieval morality play; *The Pilgrim's Progress*, by John Bunyan; Jonathan Swift's *Gulliver's Travels*; *The Scarlet Letter*, by Nathaniel Hawthorne; William Wordsworth's "Ode: Intimations of Immortality"; Nikolay Gogol's *Dead Souls*; *The Picture of Dorian Gray*, by Oscar Wilde; and the plays *Six Characters in Search of an Author*, by Luigi Pirandello; *Waiting for Godot*, by Samuel Beckett; and *Who's Afraid of Virginia Woolf?*, by Edward Albee. No one genre can take in such modal range.

**Fable.** Fable and parable are short, simple forms of naïve allegory. The fable is usually a tale about animals who are personified and behave as though they were humans. The device of personification is also extended to trees, winds, streams, stones, and other natural objects. The earliest of these tales also included humans and gods as characters, but fable tends to concentrate on animating the inanimate. A feature that isolates fable from the ordinary folktale, which it resembles, is that a moral—a rule of behaviour—is woven into the story.

**Parable.** Like fable, the parable also tells a simple story. But, whereas fables tend to personify animal characters—often giving the same impression as does an animated cartoon—the typical parable uses human agents. Parables generally show less interest in the storytelling and more in the analogy they draw between a particular instance of human behaviour (the true neighbourly kindness shown by the good Samaritan in the Bible story, for example) and human behaviour at large. Parable and fable have their roots in preliterate oral cultures, and both are means of handing down traditional folk wisdom. Their styles differ, however. Fables tend toward detailed, sharply observed social realism (which eventually leads to satire), while the simpler narrative surface of parables gives them a mysterious tone and makes them especially useful for teaching spiritual values.

**Derivation of the terms.** The original meanings of these critical terms themselves suggest the direction of their development. Fable (from the Latin *fabula*, "a telling") puts the emphasis on narrative (and in the medieval and Renaissance periods was often used when speaking of "the plot" of a narrative). Parable (from Greek *parabolē*, a "setting beside") suggests a juxtaposition that compares and contrasts this story with that idea. Allegory (from Greek *allos* and *agoreuein*, an "other-speaking") suggests a more expanded use of deceptive and oblique language. (In early Greek, though, the term allegory itself was not used. Instead, the idea of a hidden, underlying meaning is indicated by the word *hyponoia*—literally, "underthought"—and this term is used of the allegorical interpretation of the Greek poet Homer.)

**Diverse objectives.** **Fable.** Fables teach a general principle of conduct by presenting a specific example of behaviour. Thus, to define the moral that "People who rush into things without using judgment run into strange and unexpected dangers," Aesop—the traditional "father" of the fable form—told the following story:

There was a dog who was fond of eating eggs. Mistaking a shell-fish for an egg one day, he opened his mouth wide and swallowed it down in one gulp. The weight of it in his stomach caused him intense pain. "Serve me right," he said, "for thinking that anything round must be an egg."

By a slight change of emphasis, the fabulist could have been able to draw a moral about the dangerous effects of gluttony.

Because the moral is embodied in the plot of the fable, an explicit statement of the moral need not be given, though it usually is. Many of these moral tag lines have taken on the status of proverb because they so clearly express commonly held social attitudes.

The Aesopian fables emphasize the social interactions of human beings, and the morals they draw tend to embody advice on the best way to deal with the competitive realities of life. With some irony, fables view the world in terms of its power structures. One of the shortest Aesopian fables says: "A vixen sneered at a lioness because she never bore more than one cub. 'Only one,' she replied, 'but a lion.'" Foxes and wolves, which the poet Samuel Taylor Coleridge called "Everyman's metaphor" for cunning and cruelty, appear often as characters in fables chiefly because, in the human world, such predatory cunning and cruelty are able to get around restraints of justice and authority. The mere fact that fables unmask the "beast in me," as James Thurber, the 20th-century American humorist and fabulist, put it, suggests their satirical force. Subversive topical satire in tsarist and Soviet Russia is often called "Aesopism"; all comic strips that project a message (such as the Charles Schulz creation "Peanuts" and Walt Kelly's "Pogo") have affinities with Aesop's method.

**Parable.** Parables do not analyze social systems so much as they remind the listener of his beliefs. The moral and spiritual stress of the form falls upon memory rather than on the critical faculty. The audience hearing the parable is assumed to share a communal truth but perhaps to have set it aside or forgotten it. The rhetorical appeal of a parable is directed primarily toward an elite, in that a final core of its truth is known only to an inner circle, however simple its narrative may appear on the surface (a number of the parables that Christ used for teaching, for example, conveyed figuratively the meaning of the elusive concept Kingdom of Heaven).

**Allegory.** Allegory, as the basic process of arousing in the reader or listener a response to levels of meaning, provides writers with the structure of fables, parables, and other related forms. By awakening the impulse to question appearances and by bringing order to mythological interpretation, allegory imparts cultural values. A measure of allegory is present in literature whenever it emphasizes thematic content, ideas rather than events. Generally, the allegorical mode flourishes under authoritarian conditions. Thus it found sustenance during the age of medieval Christendom, when Christian dogma sought universal sway over the mind of Western man. As such, allegory was a means of freedom under conditions of strong restraint. In general, realism, mimetic playfulness, and the resistance to authority tend to counteract the allegorical process, by loosening its stratified forms. This unbinding of symbolic hierarchies has forced allegory to seek new structures in the modern period. Nevertheless, through allegorical understanding, the great myths continue to be reread and reinterpreted, as the human significance of the new interpretations is passed down from one generation to the next. The abiding impression left by the allegorical mode is one of indirect, ambiguous, even enigmatic symbolism, which inevitably calls for interpretation.

**Diversity of forms.** Since an allegorical purpose can inform works of literature in a wide range of genres, it is not surprising to find that the largest allegories are epic in scope. A quest forms the narrative thread of both the Greek epic *Odyssey* and the Latin *Aeneid*, and it is an allegory of the quest for heroic perfection; thus, allegory is aligned with the epic form. Romances, both prose and verse, are inevitably allegorical, although their forms vary in detail with the prevailing cultural ideals of the

Personification of animals

The moral objective of fables

age. By comparison, the forms of fable and parable are relatively stable—yet even they may play down the moral idea or the mysterious element and emphasize instead the narrative interest, which then results in an elaboration of the form. (Such an elaboration may be seen in a given tale, as told by successive fabulists, such as a fable of the town mouse and the country mouse; with each retelling, the story is absorbed into a new matrix of interpretation.)

Shifts from naïve to sophisticated intent are accompanied by shifts in form. The early authors of fable, following Aesop, wrote in verse; but in the 10th century there appeared collected fables, entitled *Romulus*, written in prose (and books such as this brought down into the medieval and modern era a rich tradition of prose fables). This collection in turn was converted back into elegiac verse. Later masters of fable wrote in verse, but modern favourites—such as Joel Chandler Harris, author of “Uncle Remus” stories, Beatrix Potter, creator of Peter Rabbit, or James Thurber in *Fables for Our Time*—employ their own distinctive prose. Again, while for parables prose narrative may be the norm, they have also been told in verse (as in the emblematic poetry of the 17th-century English Metaphysical poets such as George Herbert, Francis Quarles, and Henry Vaughan).

Loosening the allegorical forms further, some authors have combined prose with verse. Boethius’ *Consolation of Philosophy* (c. AD 524) and Dante’s *The New Life* (c. 1293) interrupt the prose discourse with short poems. Verse and prose then interact to give a new thematic perspective. A related mixing of elements appears in Menippean satire (those writings deriving from the 3rd-century-BC Cynic philosopher Menippus of Gadara), as exemplified in Swift’s *Tale of a Tub*. There a relatively simple allegory of Reformation history (the *Tale* proper) is interrupted by a series of digressions that comment allegorically on the story into which they break.

Even the lyric poem can be adapted to yield allegorical themes and was made to do so, for example, in the visionary and rhapsodic odes written during the high Romantic period after the late 18th century throughout Europe.

The lesson seems to be that every literary genre is adaptable to the allegorical search for multiplicity of meaning.

**Diversity of media.** In the broadest sense, allegorical procedures are linguistic. Allegory is a manipulation of the language of symbols. Verbally, this mode underwent a major shift in medium along with the shift from oral to written literature: allegories that had initially been delivered in oral form (Christ’s parables, for example) were written down by scribes and then transcribed by subsequent generations. Much more remarkable transformations, however, take place when the verbal medium is replaced by nonverbal or partially verbal media.

The drama is the chief of such replacements. The enactment of myth in the beginning had close ties with religious ritual, and in the drama of classical Greece both comedy and tragedy, by preserving ritual forms, lean toward allegory. Old Comedy, as represented by the majority of plays by Aristophanes, contains a curious blending of elements—allusions to men of the day, stories suggesting ideas other than the obvious literal sense, religious ceremony, parodies of the graver mysteries, personified abstractions, and stock types of character. Aeschylus’ *Prometheus Bound* uses allegory for tragic ends, while Euripides’ tragedies make a continuous interpretive commentary on the hidden meaning of the basic myths. Allegory is simplified in Roman drama, submitting heroic deeds to the control of the fickle, often malignant goddess Fortuna. Christian symbolism is responsible for the structure of the medieval morality plays, in which human dilemmas are presented through the conflicts of personified abstractions such as the “Virtues” and their “Vice” opponents. The allegory in Renaissance drama is often more atmospheric than structural—though even Shakespeare writes allegorical romances, such as *Cymbeline*, *Pericles*, and *The Winter’s Tale* (and allowed his tragedy of *Coriolanus* to grow out of the “fable of the belly,”

which embodies a commonplace of Renaissance political wisdom and is recounted by one of the characters in the play). In 1598 Ben Jonson introduced the comedy of humours, which was dependent on the biological theory that the humours of the body (blood, phlegm, black bile, yellow bile) affect personality: in Jonson’s play *Epicoene, or The Silent Woman* (1609), the character Morose is possessed by the demon of ill humour. Comic allegory of this kind evolved into the Restoration comedy of manners, and through that channel entered modern drama, with Wilde, Shaw, and Pirandello. Ibsen, the master of realistic drama, himself used a free-style allegory in *Peer Gynt*, while the surrealism of modern dramatists such as Ionesco, Genet, and Beckett serves to reinforce the real meaning of their plays.

The degree to which the cinema has been allegorical in its methods has never been surveyed in detail. Any such survey would certainly reveal that a number of basic techniques in film montage builds up multiple layers of meaning. (Animated cartoons, too, continue the tradition of Aesopian fable.)

From time immemorial men have carved religious monuments and have drawn and painted sacred icons. Triumphant arches and chariots have symbolized glory and victory. Religious art makes wide use of allegory, both in its subject matter and in its imagery (such as the cross, the fish, the lamb). Even in poetry there can be an interaction of visual and verbal levels, sometimes achieved by patterning the stanza form. George Herbert’s “Easter Wings,” for instance, has two stanzas set out by the typographer to resemble the shape of a dove’s wings. Such devices belong to the Renaissance tradition of the “emblem,” which combines a motto with a simple symbolic picture (often a woodcut or engraving) and a concise explanation of the picture motto.

While allegory thrives on the visual, it has also been well able to embrace the empty form of pure mathematics. Number symbolism is very old: early Christian systems of cosmology were often based on the number three, referring to the doctrine of the Trinity (and in fact recalling earlier Hebraic and even Hellenic numerology). Musical symbolism has been discovered in the compositions of the 18th-century Baroque composers such as Johann Sebastian Bach. The most evanescent form of allegory, musical imagery and patterns, is also the closest to pure religious vision, since it merges the physical aspects of harmony (based on number) with the sublime and metaphysical effect on its hearers. The final extension of media occurs in the combination of spectacle, drama, dance, and music that is achieved by grand opera, which is at its most allegorical in the total artwork of Richard Wagner in the second half of the 19th century. His *Ring* cycle of operas is a complete mythography and allegory, with words and music making two levels of meaning and the whole unified by a type of musical emblem, which Wagner called the leitmotif.

#### ALLEGORY AND COSMOLOGY

The allegorical mode has been of major importance in representing the cosmos: the earliest Greek philosophers, for example, speculated on the nature of the universe in allegorical terms; in the Old Testament’s oblique interpretation of the universe, too, the world is seen as a symbolic system. The symbolic stories that explain the cosmos are ritualized to ensure that they encode a message. Held together by a system of magical causality, events in allegories are often surrounded by an occult atmosphere of charms, spells, talismans, genies, and magic rites. Science becomes science fiction or a fantastic setting blurs reality so that objects and events become metamorphically unstable. Allegorical fictions are often psychological dramas whose scene is the mind; then their protagonists are personified mental drives. Symbolic climate is most prominent in romance, whose heroic quests project an aura of erotic mysticism, perfect courtesy, and moral fervour that creates a sublime heightening of tone and a picturesque sense of good order.

The cosmic and demonic character of allegorical thinking is most fully reflected in the period of its greatest

interpre-  
tation"

vogue, the High Middle Ages. During this period poets and priests alike were able to read with increasingly elaborate allegorical technique until their methods perhaps overgrew themselves. A belief had been inherited in the "great chain of being," the Platonic principle of cosmic unity and fullness, according to which the lowest forms of being were linked with the highest in an ascending order. On the basis of this ladderlike conception were built systems of rising transcendence, starting from a material basis and rising to a spiritual pinnacle. The early Church Fathers sometimes used a threefold method of interpreting texts, encompassing literal, moral, and spiritual meanings. This was refined and commonly believed to have achieved its final form in the medieval allegorist's "fourfold theory of interpretation." This method also began every reading with a search for the literal sense of the passage. It moved up to a level of ideal interpretation in general, which was the allegorical level proper. (This was an affirmation that the true Christian believer was right to go beyond literal truth.) Still higher above the literal and the allegorical levels, the reader came to the tropological level, which told him where his moral duty lay. Finally, since Christian thought was apocalyptic and visionary, the fourfold method reached its apogee at the anagogic level, at which the reader was led to meditate on the final cosmic destiny of all Christians and of himself as a Christian hoping for eternal salvation.

While modern scholars have shown that such thinking played its part in the poetry of the Middle Ages and while the Italian poet Dante himself discussed the theological relations between his poems and such a method of exegesis, the main arena for the extreme elaboration of this allegory was in the discussion and the teaching of sacred Scriptures. As such, the fourfold method is of highest import, and it should be observed that it did not need to be applied in a rigid four-stage way. It could be reduced, and commonly was reduced, to a two-stage method of interpretation. Then the reader sought simply a literal and a spiritual meaning. But it could also be expanded. The passion for numerology, combined with the inner drive of allegory toward infinite extension, led to a proliferation of levels. If four levels were good, then five or eight or nine might be better.

#### HISTORICAL DEVELOPMENT IN WESTERN CULTURE

**Development of fable.** The origins of fable are lost in the mists of time. Fables appear independently in ancient Indian and Mediterranean cultures. The Western tradition begins effectively with Aesop (6th century BC), of whom little or nothing is known for certain; but before him the Greek poet Hesiod (8th century BC) recounts the fable of the hawk and the nightingale, while fragments of similar tales survive in Archilochus, the 7th-century-BC warrior-poet. Within 100 years of the first Aesopian inventions the name of Aesop was firmly identified with the genre, as if he, not a collective folk, were its originator. Like the Greek philosopher Socrates, Aesop was reputed to have been ugly but wise. Legend connected him with the island of Samos; the historian Herodotus believed him to have been a slave.

Modern editions list approximately 200 "Aesop" fables, but there is no way of knowing who invented which tales or what their original occasions might have been. Aesop had already receded into legend when Demetrius of Phaleron, a rhetorician, compiled an edition of Aesop's fables in the 4th century BC. The poetic resources of the form developed slowly. A versified Latin collection made by Phaedrus, a freed slave in the house of the Roman emperor Augustus, included fables invented by the poet, along with the traditional favourites, which he retold with many elaborations and considerable grace. (Phaedrus may also have been the first to write topically allusive fables, satirizing Roman politics.) A similar extension of range marks the work of the Hellenized Roman Babrius, writing in the 2nd century AD. Among the classical authors who advanced upon Aesopian formulas may be named the Roman poet Horace, the Greek biographer Plutarch, and the great satirist Lucian of Samosata.

**Beast epic.** In the Middle Ages, along with every other type of allegory, fable flourished. Toward the end of the 12th century, Marie de France made a collection of over 100 tales, mingling beast fables with stories of Greek and Roman worthies. In another compilation, Christine de Pisan's *Othéa* manuscript illuminations provide keys to the interpretation of the stories and support the appended moral tag line. Expanded, the form of the fable could grow into what is called the beast epic, a lengthy, episodic animal story, replete with hero, villain, victim, and endless epic endeavour. (One motive for thus enlarging upon fable was the desire to parody epic grandeur: the beast epic mocks its own genre.) Most famous of these works is a 12th-century collection of related satirical tales called *Roman de Renart*, whose hero is a fox, symbolizing cunning man. The *Roman* includes the story of the fox and Chantecler (Chanticleer), a cock, a tale soon afterward told in German, Dutch, and English versions (in *The Canterbury Tales*, Geoffrey Chaucer took it as the basis for his "Nun's Priest's Tale"). Soon the *Roman* had achieved universal favour throughout Europe. The Renaissance poet Edmund Spenser also made use of this kind of material; in his "Mother Hubbard's Tale," published in 1591, a fox and an ape go off to visit the court, only to discover that life is no better there than in the provinces. More sage and serious, John Dryden's poem of *The Hind and Panther* (1687) revived the beast epic as a framework for theological debate. Bernard de Mandeville's *Fable of the Bees* (first published 1705 as *The Grumbling Hive, or Knaves Turn'd Honest*) illustrated the rapacious nature of humans in society through the age-old metaphor of the kingdom of the bees. In modern times, children's literature has made use of animal fable but often trivialized it. But the form has been taken seriously, as, for example, by the political satirist George Orwell, who, in his novel *Animal Farm* (1945), used it to attack Stalinist Communism.

**Influence of Jean de La Fontaine.** The fable has normally been of limited length, however, and the form reached its zenith in 17th-century France, at the court of Louis XIV, especially in the work of Jean de La Fontaine. He published his *Fables* in two segments: the first, his initial volume of 1668, and the second, an accretion of "Books" of fables appearing over the next 25 years. The 1668 *Fables* follow the Aesopian pattern, but the later ones branch out to satirize the court, the bureaucrats attending it, the church, the rising bourgeoisie—indeed the whole human scene. La Fontaine's great theme was the folly of human vanity. He was a skeptic, not unkind but full of the sense of human frailty and ambition. His satiric themes permitted him an enlargement of poetic diction; he could be eloquent in mocking eloquence or in contrast use a severely simple style. (His range of tone and style has been admirably reflected in a version of his works made by a 20th-century American poet, Marianne Moore.) La Fontaine's example gave new impetus to the genre throughout Europe, and during the Romantic period a vogue for Aesopian fable spread to Russia, where its great practitioner was Ivan Andreyevich Krylov. The 19th century saw the rise of literature written specifically for children, in whom fable found a new audience. Among the most celebrated authors who wrote for them are Lewis Carroll, Charles Kingsley, Rudyard Kipling, Kenneth Grahame, Hilaire Belloc, and Beatrix Potter. There is no clear division between such authors and the "adult" fabulist, such as Hans Christian Andersen, Lewis Carroll, Oscar Wilde, Saint-Exupéry, or J.R.R. Tolkien. In the 20th century there are the outstanding *Fables for Our Time*, written by James Thurber and apparently directed toward an adult audience (although a sardonic parent might well read the *Fables* to his children).

**Development of parable.** In the West, the conventions of parable were largely established by the teachings of Christ. The New Testament records a sufficient number of his parables, with their occasions, to show that to some extent his disciples were chosen as his initiates and followers because they "had ears to hear" the true meaning of his parables. (It has already been noted that the

Tales of  
the  
cunning  
fox

parable can be fully understood only by an elite, made up of those who can decipher its inner core of truth.) Despite a bias toward simplicity and away from rhetorical elaboration, the parable loses little in the way of allegorical richness: the speaker can exploit an enigmatic brevity that is akin to the style of presenting a complex riddle. Parable is thus an immensely useful preaching device: while theologians in the period of the early Christian Church were developing glosses on Christ's enigmatic stories, preachers were inventing their own to drive home straightforward lessons in good Christian conduct. For centuries, therefore, the model of parable that had been laid down by Christ flourished on Sundays in churches all over the Western world. Pious tales were collected in handbooks: the *Gesta Romanorum*, the *Alphabet of Thales*, the *Book of the Knight of La Tour Landry*, and many more. Infinitely varied in subject matter, these exemplary tales used a plain but lively style, presenting stories of magicians, necromancers, prophets, chivalrous knights and ladies, great emperors—a combination bound to appeal to congregations, if not to theologians. An important offshoot of the parable and exemplary tale was the saint's life. Here, too, massive compilations were possible; the most celebrated was *The Golden Legend* of the 15th century, which included approximately 200 stories of saintly virtue and martyrdom.

20th-century  
parables

As long as preaching remained a major religious activity, the tradition of parable preserved its strong didactic strain. Its more paradoxical aspect gained renewed lustre in theological and literary spheres when the 19th-century Danish philosopher Søren Kierkegaard began to use parables in his treatises on Christian faith and action. In *Fear and Trembling* he retold the story of Abraham and Isaac; in *Repetition* he treated episodes in his own life in the manner of parable. Such usage led to strange new literary forms of discourse, and his writing influenced, among others, the German-Czech novelist Franz Kafka and the French "absurdist" philosopher, novelist, and playwright Albert Camus. Kafka's parables, full of doubt and anxiety, meditate on the infinite chasm between man and God and on the intermediate role played by the law. His vision, powerfully expressed in parables of novel length (*The Castle*, *The Trial*, *Amerika*), is one of the most enigmatic in modern literature.

**Development of allegory.** The early history of Western allegory is intricate and encompasses an interplay between the two prevailing world views—the Hellenic and the Hebraic-Christian—as theologians and philosophers attempted to extract a higher meaning from these two bodies of traditional myth.

In terms of allegory, the Greco-Roman and Hebraic-Christian cultures both have a common starting point: a creation myth. The Old Testament's book of Genesis roughly parallels the story of the creation as told by the Greek poet Hesiod in his *Theogony* (and the later Roman version of the same event given in Ovid's *Metamorphoses*). The two traditions thus start with an adequate source of cosmic imagery, and both envisage a universe full of mysterious signs and symbolic strata. But thereafter the two cultures diverge. This is most apparent in the way that the style of the body of poetry attributed to Homer—the ancient Greek "Bible"—differs from the Old Testament narrative. The Greek poet presented his heroes against an articulated narrative scene, a context full enough for the listener (and, later, the reader) to ignore secondary levels of significance. By contrast, the Jewish authors of the Old Testament generally emptied the narrative foreground, leaving the reader to fill the scenic vacuum with a deepening, thickening allegorical interpretation.

**Old Testament.** The Old Testament, including its prophetic books, has a core of historical record focussing on the trials of the tribes of Israel. In their own view an elect nation, the Israelites believe their history spells out a providential design. The prophets understand the earliest texts, Genesis and Exodus, in terms of this providential scheme. Hebraic texts are interpreted as typological: that is, they view serious myth as a theoretical history in which all events are types—portents, foreshadowing the

destiny of the chosen people. Christian exegesis (the critical interpretation of Scripture) inherits the same approach.

Typological allegory looks for hidden meaning in the lives of actual men who, as types or figures of later historical persons, serve a prophetic function by prefiguring those later persons. Adam, for example (regarded as a historical person), is thought to prefigure Christ in his human aspect, Joshua to prefigure the victorious militant Christ. This critical approach to Scripture is helped by the fact of monotheism, which makes it easier to detect the workings of a divine plan. The splendours of nature hymned in the Psalms provide a gloss upon the "glory of God." The Law (the Torah) structures the social aspect of sacred history and, as reformulated by Christ, provides the chief link between Old and New Testaments. Christ appeals to the authority of "the Law and the Prophets" but assumes the ultimate prophetic role himself, creating the New Law and the New Covenant—or Testament—with the same one God of old.

**The Greeks.** Hellenic tradition after Homer stands in sharp contrast to this concentration on the fulfilling of a divine plan. The analytic, essentially scientific histories of Herodotus and Thucydides precluded much confident belief in visionary providence. The Greeks rather believed history to be structured in cycles, as distinct from the more purposive linearity of Hebraic historicism.

Nevertheless, allegory did find a place in the Hellenic world. Its main arena was in philosophic speculation, centring on the interpretation of Homer. Some philosophers attacked and others defended the Homeric mythology. A pious defense argued that the stories—about the monstrous love affairs of the supreme god Zeus, quarrels of the other Olympian gods, scurrility of the heroes, and the like—implied something beyond their literal sense. The defense sometimes took a scientific, physical form; in this case, Homeric turmoil was seen as reflecting the conflict between the elements. Or Homer was moralized; the goddess Pallas Athene, for example, who in physical allegory stood for the ether, in moral allegory was taken to represent reflective wisdom because she was born out of the forehead of her father, Zeus. Moral and physical interpretation is often intermingled.

Plato, the Idealist philosopher, occupies a central position with regard to Greek allegory. His own myths imply that our world is a mere shadow of the ideal and eternal world of forms (the Platonic ideas), which has real, independent existence, and that the true philosopher must therefore be an allegorist in reverse. He must regard phenomena—things and events—as a text to be interpreted upward, giving them final value only insofar as they reveal, however obscurely, their ideal reality in the world of forms. Using this inverted allegorical mode, Plato attacked Homeric narrative, whose beauty beguiles men into looking away from the truly philosophic life. Plato went further. He attacked other fashionable philosophic allegorists because they did not lead up to the reality but limited speculation to the sphere of moral and physical necessity. Platonic allegory envisaged the system of the universe as an ascending ladder of forms, a "great chain of being," and was summed up in terms of myth in his *Timaeus*. Plato and Platonic thought became, through the influence of this and other texts on Plotinus (died 269/270) and through him on Porphyry (died c. 304), a pagan mainstay of later Christian allegory. Medieval translations of Dionysius the Areopagite (before 6th century AD) were equally influential descendants of Platonic vision.

A second and equally influential Hellenic tradition of allegory was created by the Stoic philosophers, who held that the local gods of the Mediterranean peoples were signs of a divinely ordered natural destiny. Stoic allegory thus emphasized the role of fate, which, because all men were subject to it, could become a common bond between peoples of different nations. A later aspect of moral exegesis in the Stoic manner was the notion that myths of the gods really represent, in elevated form, the actions of great men. In the 2nd century BC, under Stoic influence,

Typological  
allegory

Stoic  
allegory

the Sicilian writer Euhemerus argued that theology had an earthly source. His allegory of history was the converse of Hebraic typology—which found the origin of the divine in the omnipotence of the One God—for Euhemerus found the origin of mythological gods in human kings and heroes, divinized by their peoples. His theories enjoyed at least an aesthetic revival during the Renaissance.

*Blending of rival systems: the Middle Ages.* At the time of the birth of Christ, ideological conditions within the Mediterranean world accelerated the mingling of Hellenic and Hebraic traditions. Philo Judaeus laid the groundwork; Clement of Alexandria and Origen followed him. The craft of allegorical syncretism—that is, making rival systems accommodate one another through the transformation of their disparate elements—was already a developed art by the time St. Paul and the author of the Gospel According to St. John wove the complex strands of the Hebraic-Christian synthesis. Over centuries of quarrelling, the timeless philosophy of the Greek allegorists was accommodated to the time-laden typology of the Hebrew prophets and their Christian successors and at length achieved a hybrid unity that permitted great allegories of Western Christendom to be written.

As a hybrid method, allegory could draw on two archetypal story lines: the war and the quest of Homer's *Iliad* and *Odyssey*, which was paralleled by the struggles and wanderings of the children of Israel. Throughout the Middle Ages the figure of the wandering Aeneas (who, in the second half of Virgil's Latin epic, *Aeneid*, fought bloody battles) was seen as a type in a system of hidden Christianity. Virgil's fourth *Eclogue*, a prophetic vision of the birth of a child who would usher in the "golden age," was read as a prophecy of the birth of Christ. Seen by many Christian commentators as the ideal allegorist, Virgil himself was hailed as a proto-Christian prophet. The blending of rival systems of allegory from widely assorted cultures became the rule for later allegory. Adapting the Latin writer Apuleius' fable of Cupid and Psyche, Edmund Spenser combined its elements with ancient Near Eastern lore, Egyptian wisdom, and dashes of Old Testament critical interpretation to convert the enclosed garden of the biblical Song of Solomon into the gardens of Adonis in *The Faerie Queene*, Book III. The pagan gods survived unharmed throughout the Middle Ages if wearing Christian costumes, because Christians were taught that pagan worthies could be read as figures of Christian rulers. The labours of Hercules, for instance, stood for the wanderings and trials of all Christian men; the Hellenic theme of heroic warfare took a Christianized form, available to allegory, when in the 4th century the poet and hymn writer Prudentius internalized war as the inner struggle of Christian man, suspended between virtue and vice. For complete triumph in explaining the significance of the world, Christianity needed one further element: a world-historical theory large enough to contain all other theories of meaning. This it found in the belief that God was the author of the world. His creation wrote the world. The world, read as a text, provided a platform for transforming the piecemeal, postclassical syncretism into some semblance of order. Firmly established in the West, Christianity, for all its strains of discord, slowly achieved a measure of coherence. St. Thomas Aquinas could write its *Summa*. Theocentric, authoritarian, spiritualist, and word oriented, the medieval model of allegory lent itself to the creation of the most wonderful of all allegorical poems, Dante's *Divine Comedy*, completed shortly before his death in 1321.

Before this could happen, however, the Christian world view had been subjected to an important pressure during the 12th century. It may be called the pressure to externalize. Alanus de Insulis (Alain de Lille), Bernard of Sylvestris, John of Salisbury, and other forerunners of the movement known as European Humanism "discovered" nature. Delighting in the wonders of God's cosmic text, they brought theological speculation down to earth. Romances of love and chivalry placed heroes and heroines against the freshness of spring. Everywhere nature shone, sparkling with the beauty of earthly life. The

externalization and naturalizing of Christian belief flowers most obviously in *The Romance of the Rose*, begun in the 13th century by Guillaume de Lorris and completed, in vastly complicated form, by Jean de Meung. The *Romance* personifies the experiences of courtly love, recounting the pursuit of an ideal lady by an ideal knight, set in an enclosed garden and castle, which permits Guillaume to dwell on the beauty of nature. With Jean de Meung the interest in nature is made explicit, and the poem ends in a series of lengthy digressive discourses, several of them spoken by Dame Nature herself. In medieval English poetry this same love of spring and seasonal pleasures is apparent everywhere—certainly in the poems of Geoffrey Chaucer, who, besides creating several allegories of his own, translated *The Romance of the Rose* into English.

Dante's *Divine Comedy* has physical immediacy and contains an immense amount of historical detail. He anchors his poem in a real world, accepting Christian typology as historical fact and adopting an ordered system of cosmology (based on the number three, proceeding from the Trinity). Dante's passion for numerology does not, however, block a closeness to nature that had perhaps not been equalled in poetry since Homer. He enfolds classical thought into his epic by making Virgil one of its main protagonists—again to prefigure Christian heroism. Perhaps only William Langland, the author of *The Vision of Piers Plowman*, could be said to rival Dante's cosmic range. *Piers Plowman* is a simpler apocalyptic vision than the *Comedy*, but it has an existential immediacy, arising from its concern for the poor, which gives it great natural power.

*Renaissance.* Romance and romantic forms provide the main vehicle for the entrance of allegory into the literature of the Renaissance period. The old Arthurian legends carry a new sophistication and polish in the epics of the Italians Boiardo, Ariosto, and Tasso and in the work of Edmund Spenser. By interlacing several simultaneous stories in one larger narrative, the literary technique known as *entrelacement* allowed digression—yet kept an ebbing, flowing kind of unity—while presenting opportunities for moral and ironic commentary. But although the forms and themes of romance were medieval in origin, the new age was forced to accommodate altered values. The Middle Ages had externalized the Christian model; the Renaissance now internalized it, largely by emphasizing the centrality of human understanding. This process of internalization had begun slowly. In rough outline it can be discerned in the belief that biological humours affected personality, in the adaptations of Platonic Idealism from which arose a new emphasis on imagination, in the rise of an introspective, soliloquizing drama in England. It can further be discerned in the gradual adoption of more self-conscious theories of being: Shakespeare's Hamlet, finding himself by thinking out his situation, prefigures the first modern philosopher, René Descartes, whose starting point for argument was "I think, therefore I am." Christopher Marlowe's characterization of Dr. Faustus epitomizes the new age. Pursuing power in the form of knowledge, he is led to discover the demons of allegory within himself. He is an essential figure for later European literature, archetypal in Germany for both Johann Wolfgang von Goethe and Thomas Mann and influential everywhere.

*Modern period.* With the Baroque and Neoclassical periods, allegory began to turn away from cosmology and toward rhetorical ambiguity. John Milton allegorized sin and death in his epic poem *Paradise Lost*, but allegory for him seems chiefly to lie in the ambiguous diction and syntax employed in the poem. Instead of flashing allegorical emblems before the reader, Milton generates a questioning attitude that searches out allegory more as a mysterious form than a visible content. His central allegorical theme is perhaps the analogy he draws between poetry, music, and ideas of cosmic order. This theme, which generates allegory at once, recurs in later English poetry right up to modern times with T.S. Eliot's *Four Quartets*.

The social and religious attitudes of the 18th-century

The importance of the Christian world view in allegory

Milton's allegory: *Paradise Lost*

age of Enlightenment could be expressed coolly and without ambiguity—and thus there was little need for spiritual allegory in the period's literature. Oblique symbolism was used mainly for satirical purposes. John Dryden and Alexander Pope were masters of verse satire, Jonathan Swift of prose satire. Voltaire and the French writers of the Enlightenment similarly employed a wit whose aim was to cast doubt on inherited pieties and attitudes. A new vogue for the encyclopaedia allowed a close, critical commentary on the ancient myths, but the criticism was rationalist and opposed to demonology. Under such conditions the allegorical mode might have dried up entirely. Yet the new Romantic age of the late 18th and early 19th centuries revived the old cosmologies once more, and poetic forms quickly reflected the change, with the Romantic poets and their precursors (Blake, William Collins, Edward Young, Thomas Gray, and others) managing to reinstate the high destiny of the allegorical imagination. The Romantics went back to nature. Poets took note of exactly what they saw when they went out walking, and their awareness of nature and its manifestations found its way into their poetry. Appropriate poetic forms for expressing this sensibility tended to be open, rhapsodic, and autobiographical—qualities notably present in William Wordsworth and in Samuel Taylor Coleridge, for example. Percy Bysshe Shelley is the most strikingly allegorical of English Romantics; he not only followed the Platonic tradition of Spenser and the Renaissance—with ode, elegy, and brief romance—but he also invented forms of his own, such as *Epipsychidion*, a rhapsodic meditation, and he was working on a great Dantesque vision, *The Triumph of Life*, when he died. Visionary masterpieces came from Germany, where Novalis and Friedrich Hölderlin hymned the powers of nature in odes of mythic overtone and resonance. French Romanticism, merging gradually with the theory and practice of the Symbolist movement (dealing in impressions and intuitions rather than in descriptions), in turn followed the same path. The pantheist cosmology of Victor Hugo, the central writer of the somewhat delayed French Romantic movement, created an allegory of occult forces and demonic hero worship. It is fair to say that, in its most flexible and visionary forms, allegory flourished throughout the Romantic period.

There also developed a novelistic mode of allegory by which prose authors brought fate, necessity, the demonic, and the cosmological into their narratives. Emile Zola used a theory of genetics, Charles Dickens the idea of ecological doom, Leo Tolstoy the belief in historical destiny, and Fyodor Dostoyevsky the fatalism of madness and neurosis. Nikolay Gogol revived the art of the grotesque, picturing absurdities in the scene of tsarist Russia. Even the arch-naturalist playwright, Anton Chekov, made an emblem of the cherry orchard and the sea gull in his plays of those titles. However its dates are established, the modern period is exceedingly complex in its mythmaking. Psychoanalytic theory has been both a critical and a creative resource; modern allegory has remained internalized in the Renaissance tradition. But Marxist social realism has kept to the externals of dialectical materialism, though without notable aesthetic success. In the free play of American letters, where Nathaniel Hawthorne, Herman Melville, Edgar Allan Poe, and Henry James (particularly in his later novels) had essayed an allegorical mode, the future of its use is uncertain. T.S. Eliot's enigmatic style in a long poem, "Ash Wednesday," may be related to his search for a Dantesque dramatic style, for which he also tried in plays, most obviously *Murder in the Cathedral* (a morality) and *The Cocktail Party* (a philosophic farce). More clearly popular authors such as George Orwell and William Golding have used the most familiar allegorical conventions. D.H. Lawrence shaped novels such as *The Plumed Serpent* to project a thematic, cultural polemic. W.H. Auden's operatic librettos reflect once more the allegorical potential of this mixture of media.

Modern allegory has in fact no set pattern, or model, although Surrealism has provided a dominant style of discontinuous fragmentary expression. The only rule seems

to be that there is no rule. Science fiction, an ancient field dating back at least to the earliest philosophers of Greece, has set no limits on the speculations it will entertain. The allegorical author now even questions the allegorical process itself, criticizing the very notions of cosmos, demon, and magic. It may be that modern allegory has completed a vast circle begun by the first conflict between ways of interpreting myth, as revealed in Homer and the Hebraic prophets. (A.S.F.)

#### ALLEGORICAL LITERATURE IN THE EAST

**India.** Fables appeared early in India, but it is impossible to determine whether they are older or later than the Greek. Undoubtedly there was mutual influence from very early times, for indirect contacts between Greece and India (by trade routes) had existed long before the time of Alexander the Great. In the form in which they are now known the Greek fables are the older, but this may be an accident of transmission.

The fable was apparently first used in India as a vehicle of Buddhist instruction. Some of the *Jātakas*, birth stories of the Buddha, which relate some of his experiences in previous animal incarnations, resemble Greek fables and are used to point a moral. They may date from as far back as the 5th century BC, though the written records are much later. The most important compilation is the *Pañcatantra*, a Sanskrit collection of beast fables. The original has not survived, but it has been transmitted (via a lost Pahlavi version) as the mid-8th-century Arabic *Kalilah wa Dimnah*. Kalilah and Dimnah are two jackals, counselors to the lion king, and the work is a frame story containing numerous fables designed to teach political wisdom or cunning. From the Arabic this was translated into many languages, including Hebrew, which version John of Capua used to make a Latin version in the 13th century. This, the *Directorium humanae vitae* ("Guide for Human Life"), was the chief means by which oriental fables became current in Europe. In the fables of Bidpai, animals act as men in animal form, and little attention is paid to their supposed animal characteristics. It is in this respect that they differ most from the fables of Aesop, in which animals behave as animals. (O.Ta.)

**China.** Chinese philosophers from the Ch'in dynasty (221–206 BC) onward often used extended metaphors (from which fable is the logical development) to make their points. This is believed to reflect the fact that, as "realistic" thinkers, the Chinese generally did not favour more abstract argument. Thus simple allegory helped to stimulate audience interest and to increase the force of an argument. A century earlier, Mencius, a Confucian philosopher, had used the following little allegory in illustrating his theory that an effort has to be made if man's natural goodness is to be recovered: "A man will begin searching when his dog or chicken is missing; but he does not go searching for the good character he was born with after it is lost. Is this not regrettable?" The same writer also used a parable to bring home his point that mental training could not be hurried, but was a gradual process: "A man in Sung sowed seeds in a field. The seedlings grew so slowly, however, that one day he took a walk through the field pulling at each one of the seedlings. On returning home he announced that he was exhausted, but that he had helped the seedlings' growth. His son, hurrying to the field, found the seedlings dead."

Tales such as this were often borrowed from folklore, but others were probably original creations, including a striking story that opens the *Chuang-tzu*, a summa of Taoist thought. It makes the point that ordinary people frequently deplore the actions of a man of genius because they are unable to understand his vision, which is not answerable to the laws of "common sense": "A giant fish, living at the northern end of the world, transformed itself into a bird so that it could make the arduous flight to the southernmost sea. Smaller birds, measuring his ambition against their own capabilities, laughed at the impossibility of it."

But the full development of fable, as it is understood in the West, was hindered by the fact that Chinese ways of

thinking prohibited them from accepting the notion of animals that thought and behaved as humans. Actual events from the past were thought to be more instructive than fictitious stories, and this led to the development of a large body of legendary tales and supernatural stories. Between the 4th and 6th centuries, however, Chinese Buddhists adapted fables from Buddhist India in a work known as *Po-yü ching*, and they also began to make use of traditional Chinese stories that could further understanding of Buddhist doctrines. (Na.Mo.)

**Japan.** In Japan, the *Koji-ki* (712; "Records of Ancient Matters") and the *Nihon-shoki* (8th century, "Chronicles of Japan"), both of them official histories of Japan, were studded with fables, many of them on the theme of a small intelligent animal getting the better of a large stupid one. The same is true of the *judoki* (local gazetteers dating from 713 and later). The form reached its height in the Kamakura period (1192–1333). Toward the end of the Muromachi period (1338–1573) Jesuit missionaries introduced the fables of Aesop to Japan, and the influence of these can be traced in stories written between then and the 19th century. (T.Io.)

## Fagales

The Fagales, or the beech order, consists of the family Fagaceae, 10 genera with about 1,000 species. The family, and hence the order, is made up exclusively of various shrubs and trees, often forest-forming trees that lend character and beauty to the landscape over great areas. By supplying timber and many other economically valuable products, the Fagales are of considerable importance to man.

#### GENERAL FEATURES

While some species are low shrubs, the majority are tree-like, often reaching mighty proportions. *Lithocarpus cyclophorus*, for example, attains a height of 45 metres (147 feet) and is held to be the largest tree of the Malay Peninsula. The stem girth of the English oak, *Quercus robur*, may reach 16 metres (52 feet), that of *Castanea sativa*, 28 metres (91 feet). The tropical-subtropical members of the order (*Lithocarpus*, *Castanopsis*, *Cyclobalanopsis*) are generally evergreen, with leathery-textured, usually smooth-margined leaves of uniform appearance. Outside the tropics the species as a rule are deciduous; that is, their leaves fall during unfavourable seasons. The leaves are usually lobed or toothed in different degrees around the margins. The species of *Nothofagus*, usually known as southern beeches, that grow in the Southern Temperate Zone often are found to have small, serrate or crenate (having rounded teeth) leaves that have some similarity to birch leaves, often causing the popular Australian name "birches" to be applied to these trees.

**Distribution and abundance.** The beech order is mainly distributed over the Northern Hemisphere. Four of the most important distribution centres may be distinguished. One of these is situated in southeastern Asia: the Indo-chinese peninsula and the East Indian archipelago (islands of Indonesia). Here there is a centre for the genera *Lithocarpus*, *Cyclobalanopsis*, and *Castanopsis*, while the small genus *Trigonobalanus* is restricted to this area and a few oak (*Quercus*) species occur in the northern part. A second important distribution area, which is in connection with the former, is the East Asian one. The genera

Size range

*Cyclobalanopsis*, *Castanopsis*, and *Lithocarpus* also occur here, though the species number decreases toward the north, while the oak species are here more numerous than in southeastern Asia and, moreover, some chestnut (*Castanea*) and beech (*Fagus*) species are added. A third distribution centre, though with a smaller species number, exists in the Mediterranean region together with Asia Minor and Caucasia. In this area there is especially a centre for section *Cerris* of the oak genus *Quercus*. A fourth and important centre is found in the eastern United States and Mexico, where the genus *Quercus* is richly represented.

In addition to these more important distribution centres, the order also occurs, though to a smaller extent, over other areas. In the western coast provinces of North America there is a distribution district where a number of oak species, one *Lithocarpus* species, and the endemic (restricted to that area) genus *Chrysolepis* are found. In middle and north Europe, the genera *Fagus*, *Quercus*, and *Castanea* are represented; only a few species occur, but they are important in the vegetation through their widespread occurrence. In the Southern Hemisphere there are isolated distribution areas for the genus *Nothofagus* (southern beeches) in western South America, Australia, and New Zealand; and in the tropical region, the distribution district of the genus *Trisyngyne* is located on New Guinea and New Caledonia.

**Economic importance.** Numerous species of Fagales are of importance to man through supplying timber for different purposes. The lumber of European and American oaks (*Quercus*) is used for construction and carpentry, including shipbuilding; in America especially, the "white oak lumber," obtained from *Quercus alba*, *Q. macrocarpa*, *Q. prinus*, and others, is much appreciated and used for building purposes. The beeches (*Fagus*) and chestnuts (*Castanea*) of both continents are used for carpentry, piles, railroad ties, etc., though the chestnut blight has reduced the importance of the American chestnut (*C. dentata*). In East Asia, the oaks *Quercus crispula* and *Q. glandulifera*, among others, are used for carpentry and construction, as are the beeches (*Fagus sieboldii* and *F. chinensis*), the chestnuts (*Castanea crenata* and *C. henryi*), and *Cyclobalanopsis glauca*. Among the numerous species used in Southeast Asia are *Lithocarpus spicatus*, *L. platycarpus*, *L. pachyphyllus*, *L. costatus*, *L. cyclophorus*, *Castanopsis argentea*, and *C. indica*, the two latter being used for building purposes. In the Southern Hemisphere, the *Nothofagus* species are much used for the same purposes as the beeches of the Northern Hemisphere.

Among other products obtained from members of the beech order is cork, especially supplied by *Quercus suber*, the cork oak, occurring naturally and cultivated in the western Mediterranean countries. Cork, however, is also obtained from other oak species, notably *Q. occidentalis*, *Q. pseudosuber*, *Q. fontanesii*, and in China from *Q. variabilis*. The bark of several *Quercus* species and of *Lithocarpus densiflorus*, the Californian "tanbark oak," is used for tanning, and the "gall nuts" and cupules of some species are also sources of tannin. The "aleppo galls" of *Quercus infectoria* and "valonia," the cupules of *Q. aegilops*, are well known as sources of tannin. In older times especially, other chemical products were obtained; for example, from *Fagus* species methyl alcohol, acetic acid, creosote, guaiacol, and tar were extracted, and from *Quercus robur* were obtained acetic acid, creosote, guaiacol, and tar. Several species in the order have been used for dyeing; e.g., *Quercus velutina* in N. America, *Q. incana* in India, and *Castanea crenata* in East Asia. The Mediterranean *Quercus coccifera* is host plant for a shieldlouse that supplies a pigment reminiscent of the red cochineal dye.

Many species of Fagales have edible fruits that have been used by man. The European chestnut, *Castanea sativa*, has been of special importance and has been cultivated in numerous varieties, as have some of the oak species, such as *Quercus ilex*, in the Mediterranean. In North America, the chestnut *Castanea dentata* and the chinquapin, *C. pumila*, have been used and also have

been offered for sale in the local markets. Acorns of *Quercus alba*, *Q. prinus*, *Q. lobata*, of *Fagus grandifolia* and *Chrysolepis sempervirens* and others have been used for food, especially by the American Indians. In East Asia, the chestnuts *Castanea crenata* and *C. mollissima* are under much cultivation and their nuts are consumed to a considerable extent in Japan and China; and the nuts of several *Lithocarpus* and *Castanopsis* species have found use in their home countries, for instance, *Lithocarpus edulis* and *Castanopsis delavayi* in China, *Lithocarpus garrettianus* and *Castanopsis boissi*, *C. poilanei*, *C. piriformis* in Indochina, *C. hystrix* and *C. ferox* in India, and *C. schlenckerae* in New Guinea.

Beech and oak acorns have also been of importance as food for domestic animals, and in South America even the wood of *Nothofagus* species is used as cattle food, after decomposition by bacteria and fungi. Some oak species of East Asia are of indirect importance for human nourishment, the logs being used for the cultivation of the edible "shiitake" mushroom, *Lentinus edodes*, which is much consumed, especially in Japan, and for other fungi. In Tierra del Fuego another edible fungus, *Cyttaria darwinii*, of great importance to the inhabitants, occurs on *Nothofagus* species.

Some species in the order are used for silkworm culture in Asia, for example, *Quercus aliena* and *Q. fabri* in China; *Cyclobalanopsis glauca*, *Quercus acutissima*, and *Castanea crenata* in Japan; and *Quercus incana* and *Q. semecarpifolia* in India.

#### NATURAL HISTORY

**Life cycle.** The time from seed germination to flowering in the mature trees of the beech order is usually long, about 50 to 60 years for the English oak, and 40 to 50 for the European beech, if the trees are free-growing. As in the gymnosperms, the time between pollination and fertilization is also long and, in some, the fruit requires two year's time to ripen, as in several species of *Lithocarpus* and *Quercus*. The flowers develop in the deciduous species after the leaves appear, male and female flowers as a rule on the same tree (the monoecious condition); occasionally entirely male or female trees occur (the dioecious condition). In the *Fagus* group especially, the flowering is often periodical, with intervals of up to 7 years between the "acorn years." In the evergreen species the leaves are, in some species, of several years' duration; in others they are one year old and fall when the new foliage develops. The age of the trees is sometimes very high. *Castanea sativa*, for example, may live more than 1,000 years, and *Quercus robur* may, under favourable conditions, attain a similar age. A tree of this species in Germany is reported to be about 1,500 years old. The common beech, however, will rarely be more than 300 years in age.

**Ecology.** In the wide distribution area of the Fagales order, the ecological conditions are, of course, quite varied. In the Southeast-Asiatic area, including the adjacent islands, favourable conditions are found especially on the mountain slopes with high humidity and frequent cloud formation, the temperature being tropical to subtropical. In the East-Asiatic centre and the northern part of the Indochinese peninsula, as well as in the Himalayas, the conditions are somewhat different. The temperature is not as high as in the Southeast-Asiatic area and the precipitation and air humidity are varying, very high on the southern slopes of the Himalayas, but low in some interior continental areas, where the conditions are more or less desert-like.

The special conditions in the Mediterranean area, summer dryness and winter rains, which also are found in part of western North America, give a dry-habitat character to members of the Fagales order occurring there, including such features as small leathery leaves that are spiny or hairy.

In the distribution areas of middle and north Europe and eastern North America, where temperate climate and rather great temperature variations are found to occur, the Fagales, as a rule, are deciduous. While in Europe large forests are formed by a sole species, in North Amer-

Structure and diversity of forms within the Fagales order.

Drawing by M. Pahl based on H. Hjelmqvist, "Studies on the floral morphology and phylogeny of the Amentiferae," *Botanical Notiser* supp. 2:1 (1948)

ica several species occur together mixed with other trees, and some species form low shrubberies on poor sand plains, (such as *Quercus ilicifolia* and *Q. prinoides*). In Mexico, the Fagales, especially the oak genus *Quercus*, find favourable conditions for growth on the eastern slopes of the Mexican highland. Humidity and warmth there are high, and some *Quercus* species develop gigantic leaves. In the interior the conditions are dry and warm, and the species acquire adaptations fitting them for existence where water supply is limited.

The distribution areas of the genus *Nothofagus* in the Southern Hemisphere are not only geographically but also ecologically widely separated from the others. The climatic character is oceanic, with small annual temperature change and great humidity. In parts of the South American district the mean annual temperature is very low and scarcely enough for cereal production; nevertheless, several *Nothofagus* species occur there and may reach up to the snow line.

#### FORM AND FUNCTION

**Vegetative characters.** Among the distinguishing characteristics of the Fagales order are the simple leaves, in the tropical species as a rule with entire unbroken margins and leathery texture, and in the temperate species often with lobed or toothed margins. Stipules, small leaf-like appendages at the bases of leaf stalks, occur but fall soon after development. The leaves are, as a rule, alternate, either evenly distributed around the stem in a spiral, or arranged in two rows. In the genera *Lithocarpus*, *Castanopsis*, and *Castanea* both possibilities occur in different species, but in *Quercus* and *Cyclobalanopsis* only the evenly distributed spiral form is apparent. In *Fagus*, on the other hand, the leaves are arranged exclusively in two rows along the branches, the rows being somewhat nearer to each other on the under side of the shoots. The same arrangement is found in most *Nothofagus* species, but the spiral distribution also occurs. An unusual arrangement is found in one species of *Trigonobalanus*, in which the leaves are in whorls in older shoots.

**Flower and fruit characters.** The flowers of the Fagales order are unisexual, though often with rudiments of the other sex present, and are usually arranged in dichasia (inflorescences with top flower and fork-like ramification) with 3 to 7 flowers, which in their turn are col-

lected in spikelike flower clusters, usually called catkins. With respect to the distribution of male and female flowers, three types of inflorescences (flower clusters) may be discerned: (1) all catkins are male in the upper, female in the lower part (some *Lithocarpus* species); (2) the upper catkins bear both male and female flowers, the lower being entirely male (*Castanea* and *Chrysolepis*); and (3) the upper catkins are wholly female, the lower male (*Quercus*, *Cyclobalanopsis*, *Castanopsis*). The genera *Fagus*, *Nothofagus*, and *Trisyngyne* differ from the usual condition in that the dichasia are not arranged in catkins but occur separately in the leaf axils, the points where leaf stalks join the stem.

An important distinguishing feature of the Fagaceae family (and hence the Fagales order) is the occurrence of a so-called cupule, a structure so characteristic that it provided the origin of the old family name Cupuliferae for the present Fagaceae family. This cupule is a structure that surrounds the fruit (acorn, nut, etc.) as a cup and on the outer side bears modified leaf structures developed as scales, spines, or thin plates. In the genus *Lithocarpus* each fruit is included in a cupule; the different cupules of a dichasium may, however, be more or less grown together. Similar cupules are found in the genera *Cyclobalanopsis* and *Quercus*, whose flowers, however, are solitary. In *Castanopsis* and *Castanea* the whole female dichasium is surrounded by a common cupule, which may burst at fruit-ripening. In *Chrysolepis* the cupule is a compound structure with separating walls between the fruits. In the *Fagus* group the cupule is divided into two to nine lobes; in some species of *Trisyngyne* it is much reduced.

The individual flowers of the Fagales order are simple and inconspicuous. In some genera, the perianth (the combined set of petals and sepals, or both, in a flower) is, in both the male and female flowers, made up of six perianth leaves, which are comparatively well-developed. In others, the perianth leaves of the male flowers are joined together, irregular in shape, and found to be of varying number, and the female flowers may also have a somewhat irregular perianth. Fusion of the flowers and reduction of the perianth is discernible in a few genera. In *Nothofagus* three diminutive perianth lobes may exist in the female flower, and in *Trisyngyne* the male perianth is often cup-like without discernible lobes.

The cupule, a characteristic feature of the order

Geographic isolation of the southern beech

The stamens (male flower parts) are in most genera about 12 in number, partly opposite the lobes of the perianth leaves, partly alternating with them. In *Quercus* the number is reduced, often to six, but in some *Nothofagus* species, on the other hand, it is increased and may be 30 to 40. The anthers (pollen bearing parts of the stamens) are in *Lithocarpus*, *Castanopsis*, *Castanea*, and *Chrysopsis* small, about as broad as high, attached at the middle, and are movable. In *Fagus*, *Nothofagus*, and *Trisyngyne* they are oblong, attached at the base, and immobile. They are also much bigger, especially in *Nothofagus*. The different development of the stamens is possibly connected with the pollination method. Those genera that have stamens of *Lithocarpus* type are—at least mainly—insect-pollinated, while the others are wind-pollinated.

As with the stamens, the pistil (female flower part) is also of different development in different genera and the pistil structure is probably connected with the pollination method. The wind-pollinated genera have a more or less enlarged stigma (sticky pollen-receiving area) surface, which, of course, provides a greater chance to catch the pollen suspended in the air.

Ovary (part of the female pistil) and fruit are rounded in shape in the *Quercus* and *Castanea* groups, except for *Chrysopsis*. Sometimes the nuts, however, are somewhat flattened through pressure of adjacent fruits, and in some *Lithocarpus* species, as *L. lindleyanus*, the fruits are weakly triangular. In *Chrysopsis* this triangular shape is more pronounced, especially in younger stages, and still more in *Trigonobalanus*, in which one of the species even has three-winged fruits. The nuts of *Fagus* and the fruits of *Nothofagus* are also decidedly triangular, while the dimerous (structure based on twos) top flower of *Nothofagus* and all female flowers of *Trisyngyne* develop flattened and more or less two-winged nuts, somewhat reminiscent of *Alnus* (alder) or *Betula* (birch) nuts. The ovules (developing seeds) are generally six in number, two in each of the chambers of the ovary; only one of them develops, however, into a seed.

#### EVOLUTION AND PALEONTOLOGY

**Fossil record.** Fossil Fagales show a high age of the order. *Quercus*, *Fagus*, and *Lithocarpus* are present in finds from Eurasia and North America, belonging to about the middle of the Cretaceous Period (about 100,000,000 years ago), as is the fossil genus *Dryophyllum*, which was apparently related to *Castanea*. In the Southern Hemisphere the genus *Nothofagus* also appears in the Cretaceous. In the Tertiary Period (25,000,000 to 65,000,000 years ago) *Castanopsis* and *Castanea* are reported from different countries and the order on the whole shows a rich development. Fossil pollen of *Nothofagus* from the Cretaceous of New Zealand is known, and in Europe pollen from younger Cretaceous deposits is known that shows great similarity to *Trigonobalanus*.

**Phylogeny.** Since several genera thus appear in the same early period, the fossil finds give scarcely any guidance for an estimate of the evolution in the order. The problems of evolution and relationships are thus better determined by morphology (structure), especially the organization of the cupule. The inflorescence (flower cluster) type, the different style, stigma, and anther types (female and male structures), and other considerations are also important features determining relationships.

#### CLASSIFICATION

##### Annotated classification.

##### ORDER FAGALES

Deciduous or evergreen monoecious trees or shrubs. Leaves alternate, rarely verticillate (whorled), simple, entire (smooth margins) or with shallow incisions, with deciduous stipules. Flowers unisexual, though often with rudiments of the other sex, with simple, inconspicuous perianth, arranged in catkin-like spikes, composed of dichasia or simple, or in dichasia in the leaf axils. Stamens 4 to about 40. Pistil 1, ovary inferior, usually with 3 or 6 loculi, and 3–12 styles; placentation axile, ovules 2 in each locule. Fruit a 1-seeded nut, the nuts or the female dichasium surrounded by a cupule of axial nature. Seed with a large embryo and no endosperm.

##### Family Fagaceae

The only family in the order, hence with the characters of the order.

##### Subfamily Castaneoideae

Catkins composed of dichasia, erect. Perianth well-developed, generally of 6 leaves. Anthers small, dorsifix, styles terete with apical pore. Germination hypogeous.

**Tribe Paniaeae.** Each female flower surrounded by cupule walls. Cupule indehiscent. Two genera, *Lithocarpus* with about 300 species, and *Chrysopsis* with 2 species.

**Tribe Castaneae.** The female dichasium surrounded by a common cupule, often bursting at fruit ripeness. Two genera, *Castanopsis* with about 150 evergreen species, and *Castanea* with about 12 deciduous species.

##### Subfamily Quercoidae

Catkins partly or completely simple, female catkins erect, male catkins pendulous. Perianth more or less irregular. Anthers basifix, stigma surface dilated. Each female flower with a cupule. Germination hypogeous. Two genera, *Cyclobalanopsis* with about 140 species, and *Quercus* with about 375 species.

##### Subfamily Fagoideae

Flowers in dichasia, sometimes reduced to one flower. Perianth sometimes 6-leaved, but often much reduced. Anthers basifix. Stigma surface dilated. Cupule enclosing a whole dichasium, divided into valves. Nut triangular or flat. Germination—as far as known—epigeous. Four genera, *Trigonobalanus* with 2 species, *Fagus* with about 10 species, *Nothofagus* with about 18 species, and *Trisyngyne* with about 20 species.

**Critical appraisal.** The family Fagaceae (hence, the order Fagales) has attracted the interest of many systematists (botanists who study classification of plants), and the opinions have been considerably divergent about the subdivision of the group. Sometimes a very great number of genera has been proposed, the sections of *Lithocarpus* and *Quercus* being given the rank of genera in these treatments. In other cases some of the genera have been united with each other, for example, *Cyclobalanopsis* has been joined with *Quercus*, and *Trisyngyne* with *Nothofagus*. The morphological differences between *Quercus* and *Cyclobalanopsis* are not very great, but the two groups are clearly distinct from each other and there are no transitional forms between them (as may be found between *Cyclobalanopsis* and *Lithocarpus*). They thus apparently belong to two different evolutionary lines, and on this account should be kept apart. Similar conditions are met with in the other case: *Nothofagus* and *Trisyngyne* apparently represent different evolutionary lines, which speaks in favour of the view that they are separate genera.

Among the groups related to the Fagales order, the order Betulales (birches) is the nearest. The 2 orders have, as a matter of fact, often been united into 1. New genera have been added to the family from time to time. The American species formerly placed in the genus *Castanopsis* were in 1948 recognized as a distinct genus, *Chrysopsis*, and, in the 1940s, a great number of species were discovered by an expedition to New Guinea. These, like some earlier known species from New Caledonia, are placed in the genus *Nothofagus* by some authorities but by others are regarded as a separate genus, *Trisyngyne*. In 1961 a new species was found in Borneo that, together with an earlier known but incompletely described species from Indochina, forms the new genus *Trigonobalanus*.

**BIBLIOGRAPHY.** AIMEE CAMUS, "Les châtaigniers," *Encyclopédie Économique de Sylviculture*, vol. 3 (1929), a monograph of the genera *Castanea* and *Castanopsis* with illustrations of all species, "Les chênes," *ibid.*, vol. 6–8 (1934–54), monographs of *Quercus*, *Cyclobalanopsis*, and *Lithocarpus*, with illustrations of all species; H. HJELMQVIST, "Studies on the Floral Morphology and Phylogeny of the Amentiferae," *Bot. Notiser*, suppl. vol. 2, no. 1, (1948), on floral morphology, relationships, and subdivision of the Fagales order.

(H.Hj.)

##### Fa-hsien

Fa-hsien (The Splendour of Religious Law; in Pin-yin romanization Fa-xian) was the spiritual name of a Chinese Buddhist monk, Sehi, who was born at Shansi during

the 4th century AD and whose pilgrimage to India (AD 399–414) first began Sino-Indian relations. Living at the time of the emperor Yao Hsing, when Buddhism enjoyed an imperial favour seldom equalled in Chinese history, Fa-hsien was stirred by a profound faith to go to India, the "Holy Land" of Buddhism, in order to visit the sites of the Buddha's life and to bring back Buddhist texts that were still unknown in China.

The historical importance of Fa-hsien is twofold. On the one hand, a famous record of his journeys—*Fo Kuo Chi* ("Record of Buddhist Kingdoms")—contains valuable information not found elsewhere concerning the history of Indian Buddhism during the early centuries AD. Because of the fairly detailed descriptions of Fa-hsien, it is possible to envision Buddhist India before it was reconquered by the counterreforms of Hinduism and eclipsed by the Muslim invasion. On the other hand, he strengthened Chinese Buddhism by helping provide a better knowledge of Buddhist sacred texts. After studying them for ten years in India, he brought back to China a great number of copies of Buddhist texts and translated them from Sanskrit into Chinese. Among them, two of the most important were the *Mahāparinirvāṇa-sūtra*, a text glorifying the eternal, personal, and pure nature of Nirvāṇa (Enlightenment)—on which the Nirvāṇa school in China then based its doctrines—and the Vinaya (rules of discipline for the monks) of the Mahāsaṅghika school (see below), which thus became available for the regulation of the numerous monastic communities in China.

Fa-hsien first crossed the trackless wastes of Central Asia. His trip across the desert he recalled in a terrifying way:

In the desert were numerous evil spirits and scorching winds, causing death to anyone who would meet them. Above there were no birds, while on the ground there were no animals. One looked as far as one could in all directions for a path to cross, but there was none to choose. Only the dried bones of the dead served as indications.

After arriving at Khotan, an oasis centre for caravans, he defied the terrors of snow during his crossing of the Pamirs; the mountain path was terribly narrow and steep:

The path was difficult and rocky and ran along a cliff extremely steep. The mountain itself was just one sheer wall of rock 8,000 feet high, and as one approached it, one became dizzy. If one wished to advance, there was no place for him to place his feet. Below was the Indus River. In former times people had chiselled a path out of the rocks and distributed on the face of the cliff over 700 ladders for the descent (from Kenneth Ch'en, *Buddhism in China*, © Princeton University Press, 1964).

In northwestern India, which he entered in 402, he visited the most important seats of Buddhist learning: Udyāna, Gandhāra, Peshāwar, and Taxila. Above all, however, he was attracted by eastern India, where Buddha had spent his life and had taught his doctrines. His pilgrimage was completed by visits to the most holy spots: Kapilavastu, where Buddha was born; Bodhi Gayā, where Buddha acquired the supreme Enlightenment; Banāres (Vārāṇasi), where the Buddha preached his first sermon; and Kuśinagara, where the Buddha entered into the perfect Nirvāṇa. Everywhere Fa-hsien was amazed at the extraordinary flowering of the Buddhist faith.

Then he stayed a long time at Pāṭaliputra, conversing with Buddhist monks, studying Sanskrit texts with Buddhist scholars, and transcribing the Vinaya of the Mahāsaṅghika school—a dissident group of the Hīnayāna (Lesser Vehicle) born from the Council of Vesālī (c. 383 BC) that later became the Mahāyāna (Greater Vehicle). He also acquired another version of the Vinaya worked out by the Sarvāstivāda school—an early Buddhist group that taught the equal reality of all mental states (past, present, and future)—and the famous *Mahāparinirvāṇa-sūtra*. When he had deepened his knowledge of Buddhism and was in possession of sacred texts that were not yet translated into Chinese, he decided to go back to China. Instead of once more taking the overland route, however,

Fa-hsien took the sea route, first sailing to Ceylon, at that time one of the most flourishing centres of Buddhist studies. There, by securing the Mahāśāsakā Vinaya—a recension of the Hīnayāna Vinaya—and a selection of the Sarvāstivāda canon, he added to the number of Buddhist texts that he had collected.

After a two-year stay in Ceylon, he set sail for China, but the perils of the sea were as great as the hardships and dangers of desert and mountain he had faced in coming to India. A violent storm drove his ship onto an island that was probably Java. He took another boat bound for Canton. Instead of landing at the south China port, Fa-hsien's ship was driven astray by another storm and was finally blown to a port on the Shantung Peninsula. In all, Fa-hsien spent more than 200 days at sea. After returning to his homeland, Fa-hsien resumed his scholarly tasks and translated into Chinese the Buddhist texts he had taken so much trouble to bring back.

**BIBLIOGRAPHY.** The translations of Fa-hsien are part and parcel of the Chinese canon—edited for the first time under the Sung dynasty (960–1275)—which has not yet been translated into any European language. Several English translations of *A Record of Buddhist Kingdoms* of Fa-hsien are available. See also ABEL REMUSAT, *Foe Koue Ki* (1836); H.A. GILES, *The Travels of Fa-hsien* (1877); and J. LEGGE, *Travels of Fa-Hsien* (1886).

## Faidherbe, Louis

Louis-Léon-César Faidherbe, governor of French Senegal (1854–61, 1863–65), and a principal founder of France's colonial empire in Africa, was born in Lille on June 3, 1818. Graduating from the École Polytechnique, he joined the corps of military engineers in 1840. He showed little inclination for soldiering and fell into debt through gambling. He spent three undistinguished years, from 1843 to 1846, in Algeria. In 1847 he was posted to Guadeloupe, where his reserved and prickly temperament, his strong Republican sympathies, and his support for the campaign of the Republican politician Victor Schoelcher to abolish slavery alienated both the colonists and his fellow officers, and his superiors asked that he be recalled. Only when he returned to Algeria in 1849 and assumed his first independent command did he begin to demonstrate the resolution, administrative talent, and capacity for leadership that was to make his name famous and his progress rapid. His work now won commendation, and after further service in Kabylie he was made chevalier of the Légion d'Honneur.

In 1852 he was transferred to Senegal as deputy director of engineers and soon impressed the local merchant community as a capable and energetic administrator. Two years later, at the age of 36, he was promoted to the rank of major and appointed governor.

Overland  
journey  
to India

Return  
voyage

Faidherbe's years of service in Algeria were to exert a decisive influence on his conduct as governor of Senegal. Like most French officers with Algerian experience, he was impatient of metropolitan control and prepared to act on his own initiative whenever he considered it necessary. He was also preoccupied by the problems of military security and determined to impose French supremacy by military means. Having experienced the ferocity of Muslim resistance in Algeria, he was particularly alarmed by the growing power of the militant Islamic leader al-Hājj 'Umar Tal on the frontiers of Senegal. In true Algerian fashion, therefore, he abandoned the cautious policies of his predecessors and took the offensive against all those who threatened French primacy. In a series of well-executed campaigns, some undertaken against the wishes of the Paris government, he subjugated the Moorish tribes in the north, drove the forces of al-Hājj 'Umar off the lower Sénégal River, and extended French control south toward the Gambia. By 1861 he had transformed his colony from a collection of scattered trading posts into the dominant political and military power in this region of West Africa.

But Faidherbe was no mere conquistador; the glory of conquest appealed to him much less than did the challenges of government. Although not free from the racial prejudices characteristic of his age, he possessed a real sympathy for his African subjects and a genuine concern for their welfare. He remained an uncompromising enemy of slavery in all its forms; in 1858 he threatened to resign when the government attempted to recruit indentured Senegalese labour for the West Indian plantations. He sought to improve indigenous society without destroying it, and to this end he maintained the traditional authority of the chiefs while training their sons to become more efficient agents of French rule. Even his attitude toward Islam was far more sympathetic than his hostility to al-Hājj 'Umar might have suggested.

Faidherbe's other ambition was to make Senegal the cornerstone of a vast French African empire that he hoped might one day rival British India. He was convinced from the start of the West African interior's unlimited wealth and of his colony's potential for economic development. During his first period of office he encouraged experimental farming, founded Dakar, the future capital of French West Africa, and built Médina on the upper Sénégal as a base for further expansion inland. When he reassumed the governorship in 1863, after another tour of duty in Algeria, his principal objective was the extension of French power to the Niger and ultimately to Timbuktu and beyond. This time, however, he was less successful. Although the government allowed him to send an embassy to al-Hājj 'Umar's new empire on the upper Niger, it rejected his proposals for territorial expansion as too expensive. Nevertheless, his far-sighted policies laid the foundations for the West African federation that was finally created at the turn of the 20th century.

Faidherbe left Senegal in 1865 and returned again to Algeria, where he eventually was given command of the Constantine division. Recalled to France after the outbreak of the Franco-Prussian war, he was appointed commander in chief of the Army of the North in December 1870. Faidherbe realized the hopelessness of his task, but, as a good Republican, he remained loyal to the government of national defense and fought with skill and tenacity. In 1871 the three northern *départements* of Pas-de-Calais, Somme, and Nord all elected him to the National Assembly with overwhelming majorities, but he resigned almost immediately because of the assembly's anti-Republican proceedings. He was defeated in the senatorial elections of 1876 but was elected Republican senator for the Nord in 1879 and held the seat till 1888. As a final recognition of his services, he was made grand chancellor of the Légion d'Honneur in 1880.

By then, Faidherbe could no longer participate actively in political life, for years of service in Africa and the rigours of the northern campaign had left him paralyzed and half blind. He retained his interest in West African affairs, however, and continued to exert some influence

over them. In 1883, for example, he persuaded the Senate to vote funds for Senegalese railway construction even after the Chamber of Deputies had refused to do so. His best known book, published just before his death, was about his governorship of Senegal; significantly, it was dedicated to his old friend Victor Schoelcher.

Faidherbe died in Paris on September 29, 1889, revered as a war hero and respected as a great colonial governor. His reputation, particularly in the colonial sphere, has proved remarkably enduring. All historians of French expansion have paid tribute to his exceptional abilities. Even those who stress the authoritarian streak in his character and policies recognize the humanitarianism that set him apart from most of his contemporaries.

**BIBLIOGRAPHY.** There is no completely satisfactory biography of Faidherbe. The two standard works are A. DEMAISSON, *Faidherbe* (1932); and G. HARDY, *Faidherbe* (1947), both in French. R. DELAVIGNETTE, "Faidherbe," in C.A. JULIEN (ed.), *Les Techniciens de la colonisation (XIX<sup>e</sup>-XX<sup>e</sup> siècles)*, 2nd ed. (1947), provides a brief but useful introduction. Faidherbe himself wrote several accounts of his governorship of Senegal, the fullest of which is *Le Sénégal, la France dans l'Afrique occidentale* (1889). He also discussed his role in the Franco-Prussian war in *Campagne de l'Armée du Nord en 1870-1871* (1871).

### Fakhr ad-Dīn ar-Rāzī

Fakhr ad-Dīn ar-Rāzī, one of the foremost Muslim theologians and preachers, was a controversial figure whose intellectual brilliance was recognized even by his opponents.

He was born in 1149 at Rayy in Iran, the son of a preacher. After a broad education, in which he specialized in theology and philosophy, he travelled from country to country in an area comprising present-day north-western Iran and Turkistan (U.S.S.R.) and finally settled in Herāt (now in Afghanistan). Wherever he went, he debated with famous scholars and was patronized and consulted by local rulers. He wrote about 100 books and gained fame and wealth. It was said that wherever he rode, 300 of his students accompanied him on foot; when he moved from one city to another, 1,000 mules carried his possessions, and there seemed no limit to his silver and gold.

Ar-Rāzī lived in an age of political and religious turmoil. The empire of the Baghdad caliphs was disintegrating; its numerous local rulers were virtually independent. The Mongols were shortly to invade the region and strike the final blow against the caliphate. Religious unity, too, had long crumbled; in addition to the division of Islam into two major groups—the Sunnī and the Shī'ah—countless small sects had developed, often with the support of local rulers. Sūfism (Islamic mysticism), too, was gaining ground. Like the philosopher al-Ghazālī, a century earlier, ar-Rāzī was a "middle-roader" who attempted, in his own way, to reconcile a rationalistic theology and philosophy incorporating concepts taken from Aristotle and other Greek philosophers with the Qur'ān (Islamic scripture). This attempt inspired *al-Mabāḥith al-mashriqīyah* ("Eastern Discourses"), a summation of his philosophical and theological positions, and several commentaries on Avicenna (Ibn Sīnā), as well as his extremely wide-ranging commentary on the Qur'ān (*Ma-fāṭih al-ghayb* or *Kitāb at-tafsīr, al-kabīr* "The Keys to the Unknown" or "The Great Commentary"), which ranks among the greatest works of its kind in Islam. Equally famous is his *Muḥaṣṣal afkār al-mutaqaddimīn wa-al-muta'akhhirīn* ("Collection of the Opinions of Ancients and Moderns"), which was accepted from the first as a classic of *kalām* (Muslim theology). His other books, in addition to a general encyclopaedia, dealt with subjects as varied as medicine, astrology, geometry, physiognomy, mineralogy, and grammar.

Ar-Rāzī was not only a persuasive preacher, but a master of debate. His ability to refute the arguments of others, together with his aggressiveness, self-confidence, irritability, and bad temper, made many enemies for him. His worldly success made others jealous of him.

Ar-Rāzī's wide variety of works

Faidherbe's colonial policies

Later career

Moreover, on occasion he could show extreme malice. With his connivance, his elder brother, who openly resented his success, was imprisoned by the Khwārezm-Shāh (ruler of Turkistan), and died in prison. A famous preacher with whom he had quarrelled was drowned by royal command. It is reported, however, that one incident persuaded him to cease attacks against the Ismā'īlis—a Shī'ah sect of Islām also known as Seveners because they believe that Ismā'il, the seventh *imām* (spiritual leader), was the last of the *imāms*. After ar-Rāzī had taunted the Ismā'īlis as having no valid proofs for their beliefs, an Ismā'īlī gained access to him by posing as a pupil and pointed a knife at his chest, saying: "This is our proof." It has been suggested further that ar-Rāzī's death was not from natural causes, but that he was poisoned by the Karrāmiyah (a Muslim anthropomorphist sect), in revenge for his attacks on them.

Ar-Rāzī loved disputation so much that he went out of his way to present unorthodox and heretical religious views as fully and as favourably as possible, before refuting them. This habit gave his opponents grounds for accusing him of heresy. It was said: "He states the views of the enemies of orthodoxy most persuasively, and those of the orthodoxy most unconvincingly." His thorough presentations of unorthodox views make his works a useful source of information about little-known Muslim sects. He himself admitted that, when unable to find a statement of arguments in favour of some position, he went to all lengths to present it as well as possible. He was thus a good "devil's advocate," though he maintained firmly that he championed only orthodoxy.

In his prime he was so keen on learning that he resented time spent eating. But toward the end of his life, he regretted his preoccupation with learning and disputation. In his testament, he stated:

I have examined the methods of theology and philosophy, and have not found in them the benefit I found in the Koran. For the Koran ascribes glory and majesty to God, and forbids meddling with obscurities and contradictions.

Before he died in 1209, he asked his pupils to conceal his body, lest his opponents dishonour it. So they buried him at dusk on a hill facing a village near Herāt. Ar-Rāzī was a many-sided genius and a colourful personality, regarded by some Muslims as a major "renewer of the faith." According to tradition, one such was due to appear each century, and al-Ghazālī had been the one immediately before ar-Rāzī. His aim, like al-Ghazālī's, was doubtless to be a revitalizer and reconciler in Islām, but he did not have al-Ghazālī's originality, nor was he often able to make readers aware of his personal religious experience, as al-Ghazālī could. His genius for analysis sometimes led him into long and tortuous arguments, yet he compensates for these shortcomings by his very wide knowledge, which incorporated most disciplines—even the sciences—into his religious writings. In the centuries after his death, Muslim philosophers and theologians were to turn to his works frequently for guidance.

## Falconiformes

More than any other group of birds, the diurnal birds of prey, order Falconiformes, have long interested men, and for several reasons. They are often large, conspicuous birds of swift, graceful flight, attracting attention from the smaller birds. Falconiforms compete with man for food by occasionally preying on his domestic stock (though on a small scale). But more significantly, they feed upon pests of human food supplies. Because of their

predatory, or raptorial, skill, a few falcons and hawks are used for falconry, mainly for sport, much less importantly to obtain food.

### GENERAL FEATURES

Falconiforms are seldom abundant but may be common or widespread, occurring in varied habitats. All are diurnal, none truly nocturnal, though several are active at dawn and dusk. With few exceptions they feed on the flesh of other animals, taken alive or found dead. Although some, especially in high latitudes, migrate, most do not. Some, especially large eagles, are of economic importance, preying upon animals maintained by man (sheep, game birds, etc.), eating otherwise noxious carrion, or feeding upon pests of human crops (hares, rodents, game birds, locusts). The low population density of most species indicates that their economic importance is usually exaggerated. They do not feed upon man himself (except when he is dead, in the case of vultures), do not eat babies (as eagles have been accused of doing), and are not important disease vectors.

Falconiforms vary from tiny falconets (*Microhierax*), weighing 35 grams (1.2 ounces) or less, to huge vultures and eagles, with weights up to 14 kilograms (31 pounds), certainly the most formidable avian predators. Structure varies according to hunting methods, type of prey, and habitat. Carrion-eating vultures have broad, soaring wings and weak feet; speedy falcons have bullet-shaped bodies and long, pointed wings; manoeuvrable forest-living species, such as accipiters, some eagles, and forest falcons, have short, rounded wings and long, rounded or graduated tails. The beak is always hooked and is used to tear flesh from prey held in the feet; it may be further modified for special types of food, such as snails or bone marrow. The feet, which are the primary means of killing prey, are exceptionally strong, equipped with long, curved talons, except in the vultures, which feed on carrion. Sight and hearing are highly developed, but the sense of smell is usually poor or absent.

Falconiforms occur worldwide, on all continents except Antarctica, and on many oceanic islands. They are found from Arctic to equatorial latitudes, in almost stark desert and in tropical forest, but are commonest and most varied in warm, relatively open country; many, especially in South America, have adapted to forest life. They are never abundant, except locally, where gregarious species may roost or feed together, and are usually dispersed at the rate of a pair to 15 square kilometres (five square miles) or more. Their numbers are not always density dependent on those of food animals, but, where food is abundant, raptor numbers may be limited by territorial behaviour.

### NATURAL HISTORY

**Life history.** Large falconiforms are among the longest lived birds, as shown both by records in captivity and by the slow breeding rates observed in the wild. Where not persecuted, populations of large falconiforms are remarkably stable; breeding rates are presumably adjusted to the mean life-span of individuals, taken from hatching. A species that averages two young annually per pair has a mean life-span of one year; and one that rears one young every two years, a life-span of four years.

The falconiform life cycle includes four stages, each of which varies mainly according to size—the larger the bird, the longer the stage. Latitude also affects these periods, with longer fledging periods in equatorial than in temperate latitudes for species of similar size.

**The fledging period.** The fledging period, from hatching to first flight, varies from 23 days in small accipiters to 120–130 days in large eagles and vultures and up to 150 in condors. In this stage the downy nestling develops to adult size (weight increases up to 40 times), grows feathers, and finally flies. It must be fed at first, but before its first flight it learns to tear up prey brought by the parents. Fledging periods are longer, in birds of a given size, in the tropics, probably associated with shorter summer day length.

Habits and appearance

Distribution

Four stages of life cycle

Assessment

Figure 1: Modifications for specialized types of flight among falconiforms.

Drawing by R. Keane

**The post-fledging period.** The post-fledging period, in which the young remain near the nest and food is brought by the parents, ends when the young become independent, apparently often of their own accord, not, as in some other birds, in response to increasing parental aggression. They grow no larger, but their flight quills harden. These immature birds are not strong on the wing for three to eight weeks after the first flight. This phase varies from one to 11 months or even more, again mainly according to size, but also showing specific variation. In the crowned eagle, the post-fledging period is nine to 11 months, but in the related martial eagle it is much shorter.

**The period as a juvenile.** The period as a juvenile, an independent, sexually immature form, is distinguished by various immature and subadult plumages, often very different from the adult. The young raptor flies about, migrates if necessary, kills its own prey, and behaves like an adult except that it cannot breed. This period varies from about nine months in small species, sexually mature in their first year (sparrow hawks, kestrels, and some kites), to four or more years in large eagles and up to seven years in condors. It is usually a period of heavy mortality, particularly in migrant species of temperate climates.

**The breeding adult life.** The breeding adult life is characterized by mating, nesting, and rearing young. Most adults pair. The duration of this phase has been rarely recorded for wild individuals, but a peregrine falcon (*Falco peregrinus*) bred on the Sun-Life Building in Montreal, Quebec, for 16 years. Two female crowned eagles bred for nine and eight years and one male for 13 years.

Life-spans of wild raptors may be calculated from banding (ringing) records, from observed changes of mate, and from the percentage of immatures in the population, especially if different ages are recognizable.

Recoveries of banded birds indicate that 50–75 percent of young raptors die before sexual maturity. The smaller falcons and accipiters apparently average less than three years total life-span, but some individuals may attain ten to 12 years. Larger species live longer. Ospreys and buteos may average eight to 10 years, but have higher mortality rates (75–80 percent in the first year). Life spans of

more than 20 years have been recorded from both groups, but the longest known life-span among wild falconiforms is that of a red kite of 26 years.

In certain large falconiforms, differences in plumage due to age and individual variation allow an observer to recognize individual birds. Since large eagles mate for life, it may be assumed that a change of mates indicates that one of the pair is dead. L.H. Brown has found that in crowned eagles (*Stephanoaetus coronatus*) such changes occur every six to seven years, giving a mean adult life of 12–14 years or 16–18 years when the four years prior to maturity are included.

In many species immature birds are easily distinguished from adults, and the percentage of immatures in the population can be related to assumed mortality before sexual maturity and to the number of years before adulthood, allowing an estimate of the average age of adults. Immatures comprise about 30 percent of the population in the bateleur (*Terathopius ecaudatus*), 18 percent in the lammergeier (*Gypaetus barbatus*), and 16–25 percent in the African fish eagle (*Haliaeetus vocifer*). With about 75 percent loss during the period of immaturity and the acquisition of adult plumage at seven, five, and four years, respectively, the mean adult life-span in these species may be estimated at 23, 27, and 18–24 years.

Such methods provide, at best, an informed estimate and the potential life-span is rarely, if ever, attained in the wild state. In captivity many large raptors live for over 30 years, eagles and vultures for 40–50 years. A bateleur, at 55, is the oldest acceptable record; records of 60 or more years are poorly documented.

**Behaviour.** Falconiforms hunt by sight in daylight and normally roost on a perch, a tree branch, a rock ledge, or occasionally (harriers) on the ground in long grass. A few, including some falcons and sparrow hawks, are active at twilight; in fact, the bat hawk (*Machaeerhamphus alcinus*) catches all its food in about half an hour at dusk. The only species actually recorded feeding at night are certain Indian vultures (in moonlight on tiger kills). Most raptors sleep all night, with head buried in the feathers of the back or hunched upon the shoulders.

Activity may begin soon after dawn with short "warming-up" flights, serious hunting beginning later. Some accipiters commence hunting at daybreak, when their avian prey is most active. Large, heavy species, however, do not usually start hunting or foraging until some time after dawn. Large vultures are unable to fly until updrafts are generated by thermal activity, but smaller species are able to fly soon after dawn. Certain specialized types with flapping flight, such as harriers, can fly equally easily at any time of the day. Bateleurs get on the wing early and fly most of the day, travelling perhaps 200–300 air miles on most days; however, very large species such as eagles and vultures probably fly for no more than four to six hours a day.

Before the day's flight, a raptor usually preens, casts, and defecates. Castings are regurgitated indigestible balls of fur, feathers, insect hard parts, etc. Preening is performed mainly with the bill, but falconiforms also scratch with their formidable talons. They frequently "rouse," fluffing out and shaking all their feathers.

Many falconiforms hunt daily, others every few days, feeding in the interim on the remains of their kills. Killing frequency depends on appetite and the size of the animal killed; a kestrel consumes many grasshoppers per day, a crowned eagle one suni antelope (about four kilograms; eight pounds) every three to four days. Appetite and crop capacity permit ingestion of several days' ration at a meal, and larger species can go without food for long periods without ill effect. With rare recorded exceptions, falconiforms will not hunt unless hungry and do not kill wantonly. Many species hunt from perches, flying from one to another. Others hunt on the wing, soaring or hovering at up to 100 metres above the ground or water. One species, the secretary bird (*Sagittarius serpentarius*), is mainly terrestrial, and several others (chanting goshawks, honey buzzards, and the spotted eagle) walk about on the ground. The honey buzzard digs out wasps' nests. One

General activity

Hunting and feeding

Life-span

species, the Egyptian vulture (*Neophron percnopterus*), hurls stones at ostrich eggs with its beak to break them.

In warm climates, hunting time may be short, one to two hours in 24; in temperate winters, when prey is scarce, it occupies up to five to seven hours. When not hunting, falconiforms loaf on perches or soar, sometimes at great height. Vultures or eagles encountered soaring very high up are not hunting, especially when their crops are full.

#### Roosting

Toward evening a falconiform may return to a regular roosting place or may settle for the night where it is. Vultures often return nightly up to 100 miles to regular roosting cliffs or trees. In many less active species, the roost is in the same general area as the nest. Members of a pair separated all day may rejoin at roosting time, and gregarious species (vultures, kites, and some others, such as the red-footed falcon) are most gregarious at roosts. Prior to settling to sleep, the bird usually preens again, but activity is reduced once the bird has settled on the perch for the night. Finally, when light fails, the raptor falls asleep on its perch and remains thus without moving until the following morning. If disturbed at night, however, it can fly well enough to save itself but will not travel any distance.

**Locomotion.** All falconiforms fly well, some excellently. Few hunt on the ground, but all can walk or hop. With one exception—the secretary bird—flight is the most important method of locomotion. Modes of flight include flapping, gliding, soaring, or diving (stooping) and are used to locate and kill prey, move from perch to perch, or migrate. Adaptations for swift or slow flight, mainly associated with habitat or type of prey, are varied.

All species can use flapping flight, but it is laboured in heavy species (vultures, condors). Most use it only to get under way or to move from perch to perch, thereafter gliding, hovering, or soaring. Harriers sustain flapping flight, interspersed with short glides, for long periods as they hunt small animals in open, grassy country. This also assists them to migrate across open water, usually avoided by soaring species because of the lack of thermal updrafts. Accipiters accelerate in pursuit by rapid flapping flight, and many other species travel short distances by flapping alternated with gliding, especially when air currents are lacking.

All of the large species are adapted for soaring flight and even accipiters, swift falcons, and the secretary bird can soar well. A typical soaring wing is rather long and moderately broad; i.e., of low aspect ratio. High-aspect-ratio wings (long and extremely narrow), found in seabirds, would presumably be inconvenient to falconiforms, which often require manoeuvrability in tight spaces. The wing usually has the outer four to six primaries more or less emarginated on one or both webs, forming at the spread wing tip slots that reduce turbulence, and permitting each feather to bend as an individual airfoil under a differential load, thereby increasing lift. Such a wing is typical of eagles, buzzards, vultures, and kites. In a few species (Indian black eagle, African harrier hawk), the primaries are long, soft, slightly emarginated, and flexible, probably associated with slow flight.

#### Soaring on updrafts

The ability to soar and circle in thermals is controlled by wing loading (the ratio of weight to wing area). The higher the wing loading, the larger the turning circle and the larger the thermal "bubble" required for soaring to gain height. Smaller species (e.g., the black kite), with low wing loadings, can utilize smaller thermals than can heavy vultures. Wing loading increases proportionately with weight (as the cube of body size) while wing area increases as the square (see also FORM AND FUNCTION, BIOLOGICAL). The general rule is varied by specific adaptations. Some species (lammergeier, harriers) have much lower wing loadings than others of similar weight and have more buoyant, easy flight. In soaring flight, forward velocity is attained by gliding, with the aid of gravity; the bird mounts on rising air. Increasing the angle of glide increases speed until, in a vertical dive (falcons), it is believed to attain 160–240 kilometres (100–150 miles) per hour. Some species (bateleur, lammergeier) are special-

ized for gliding, almost without wing flapping. Bateleurs glide at an airspeed of 55–85 kilometres per hour for much of the day; they have long wings and very short tails, steering by sideways tilting, or canting. Lammergeiers glide rather slowly, assisted by long, diamond-shaped tails.

Falcons, especially the large bird-killing species (peregrine, gyrfalcon, lanner, etc.), have heavy, bullet-shaped bodies and long, pointed wings; their high wing loading provides high diving speed. They often attack in the air and in a dive can overtake species that would easily evade them in straight flapping flight. Few eagles are as swift, but many combine distinguished soaring and gliding ability with swiftness and agility in attack upon prey.

On the ground falconiforms progress by walking or hopping; in especially large vultures hopping is elaborated into bounding threat displays. On a branch they move sideways by sidling or by walking "hand over hand" (vulturine fish eagle, harrier hawk). On the ground eagles walk slowly and deliberately. African harrier hawks and South American crane hawks have long, slim legs that can bend somewhat backward at the tarsal joint, permitting the attainment of peculiar situations and enabling the birds to probe cavities.

The secretary bird is the only primarily terrestrial species. It flies only to move from place to place or in display but nevertheless has been seen soaring at 4,000 metres. It walks with a rapid, steady pace, head jerking to and fro, varying this regular progress with bouts of quick stamping steps, to flush possible prey. It has short toes (like the gruiform bustards) and long, crane like legs, suited for rapid walking over long distances. It roosts in trees but descends to the ground to hunt soon after daybreak.

**Reproduction.** Many falconiforms pair for life; others, notably migrant species, may pair anew each year. Occasionally, immatures pair with adults, but usually only sexually mature individuals attempt to breed. Immatures, however, often perform typical display movements and a pair bond may be formed between an adult and an immature, but the latter may be replaced by an adult if one should appear.

The breeding pattern follows the usual sequence of nuptial display, nest building, incubation, fledging period, and post-fledging period. The length of the breeding period varies from about three months in the smallest species to over 15 months in condors, crowned eagles, and probably harpy eagles. No species regularly produces two broods in a season, but second broods have been recorded, even in some large species. Some nomadic species, such as the elanine kites, may breed more often in response to, for instance, high local rodent populations.

Nuptial displays are often spectacular, sometimes inconspicuous. The common forms are: calling from a perch; calling from soaring flight; undulating flight, diving, and swooping up, often with loud calling; mutual displays, in which the male dives with lowered feet at the female, who turns over and raises her claws to his; rarely, cartwheeling, in which the pair lock feet and descend in whirling flight (e.g., some eagles and kites). Most species perform several types of display, but species inhabiting woodland or forest display more often and more vociferously than related species of open country.

Most species build nests on trees, ledges of cliffs, or, rarely, on the ground. All Accipitridae, Pandionidae, Sagittariidae, and the caracaras construct nests, usually of sticks. The Cathartidae and the remaining Falconidae (forest falcons, falconets, and true falcons) do not make nests but use a hollow tree, another bird's nest, or a scrape on a ledge. Constructed nests vary from small structures of twigs and vines (*Aviceda*) to enormous, annually augmented piles of sticks (many eagles). Small species usually build a new nest annually; large species tend to return to, and repair, an old nest. Imminent occupation is usually indicated by fresh green material, which continues to be added until late in the fledging period but does not necessarily mean that eggs will be laid. The same site, but not always the same nest or ledge,

Walking  
and  
hopping

Nesting

may be occupied for several years, generations, or centuries. Some large eagles use the same nest for 50 years or more, others haphazardly use several alternates.

Many species lay only one egg; few lay more than four. The largest clutches are laid by small falcons and accipiters of temperate latitudes and by ground-nesting harriers. Clutches of related species are smaller in the tropics than in high latitudes. The eggs are laid at two- to four-day intervals, incubation beginning with the first egg. Falconiform eggs are rather large for the size of the birds and are usually rounded ovals, white or greenish, more or less heavily spotted, occasionally completely covered with brown or red-brown pigment. In *Carthartae* the colour of the inside of the shell is yellowish white; in *Accipitridae*, *Sagittariidae*, and *Pandionidae* it is green or blue green; and in *Falconidae*, buff or reddish. Incubation, usually by the female alone (the male sometimes takes a share), occupies from 28 days in small falcons to 50 days or more in large vultures. Buzzards (*Buteo*) incubate for 30–35 days, though some are larger than small eagles with incubation periods of 45 days.

The eggs hatch in the order in which they were laid. By the time the last egg has hatched, the first-hatched chick may have tripled its weight and may kill its sibling, either directly or through competition for food. Newly hatched chicks are covered in natal down, later replaced by a thicker, woollier coat; at this stage parental brooding is reduced by day. Feathers erupt during the fledging period and almost cover the nestling at midpoint. At this stage most young learn to tear up their own prey.

Parental attention is steadily reduced, from continuous brooding day and night to leaving the feathered young entirely alone except for brief feeding visits. The young make their first flights unaided by parental coaxing. The adult roles are usually clear-cut. In the early fledging period, the male kills for himself, his mate, and the brood, doubling or trebling his previous killing rate. When partly feathered young can tear up their prey, the female no longer stays near the nest but hunts and thereafter brings more prey than the male.

After their first flight, the young remain near the nest for several weeks or months. They are provided with food by the parents but may also learn to kill. The longest known post-fledging periods are in crowned eagles and condors; in the crowned eagle the young remains dependent for nine to 11 months, and this species normally breeds only every second year.

Especially in large species, breeding does not necessarily occur annually. The number of young reared per pair per year varies from 2.5 to three in small falcons and sparrow hawks of temperate climates to 0.4 or even less in some tropical eagles and vultures. Breeding success, like clutch size, tends to be lower in related species in the tropics than in temperate zones. Low breeding success may fluctuate with adverse winters, poor food supplies, or even territorial behaviour in crowded habitats.

**Ecology.** Falconiforms prey on small animals or eat carrion; the vulturine fish eagle, however, feeds mainly on oil palm fruits.

Food supplies exert a general influence over populations, but it also seems that when food is superabundant the population does not rise proportionately. In the Scottish golden eagle, the home range of a pair is about 4,400 hectares (11,000 acres), irrespective of food abundance. A breeding pair of raptors apparently maintains a territory containing much more food than it can possibly utilize. In some cases such home ranges are maintained by aggressive behaviour; in others the precise method is obscure. In colonial vultures no home range is maintained, and the only defended territory is the few yards round the nest.

From a combination of factors a reasonably accurate estimate of the minimum daily food need for a raptor can be made. The amount of kills wasted (varying from less than 5 to 20 percent by weight, according to type of prey taken) is added to the minimum daily food demand, to determine the amount that must be killed to maintain a pair and their young for one year. For example, if a

falconiform weighs 1,200 grams, has a mean food requirement of 8 percent of bodyweight, eats 96 grams a day and 36 kilograms each year, and feeds on birds, involving waste of about 15 percent of all kills, it must kill 41 kilograms of prey each year to fulfill its needs.

Individuals of one species do not usually tolerate others of the same species in their home breeding range. The same area, however, may support several other species, preferring different types of prey and so not competing with one another. In an area of varied habitat, up to 20 different species may occur (even more with migrants), exerting a much greater and more complicated, but still broadly quantifiable, pressure on populations of available prey. Closely related groups may show ecological separation. For example, some African vultures feed in groups upon the soft flesh and intestines of preys, while others tear at sinews and hide or snatch meat from other species. Smaller vultures pick up scraps or use their slender beaks to reach cavities inaccessible to birds with heavier beaks. All these birds may feed together at the same carcass, but without competing for food, though individuals of each species maintain a dominance hierarchy by aggressive movements to each other.

In the Arctic only the gyrfalcon does not regularly migrate but subsists on wintering ptarmigan. In summer several other species arrive, but so do many species of prey, and lemmings multiply, greatly increasing food supplies. In African savannas and southern Indian rice fields, resident falconiform populations are greatly augmented in winter by migrant populations of buzzards, kites, harriers, and small falcons. This sharply increases the total predator pressure on prey populations, but it does not appear that this influx of migrants has any adverse effect on the resident populations, which may be breeding while the migrants are present.

In most cases it appears that falconiforms have a slight or negligible effect on prey populations. The annual needs of resident species may vary from  $\frac{1}{20}$  to  $\frac{1}{1,000}$  or even less of available prey. In migrant winter populations, the effect, locally, may be much greater than in resident breeding populations. The availability or visibility of the prey also plays a part. Among the food of the European sparrow hawk (*Accipiter nisus*), conspicuous or gregarious birds of open ground are more often killed than inconspicuous skulking species. Prey risk (the likelihood of an individual being killed) is increased by low prey numbers, reduced cover, and behaviour that exposes the animal. The total effect of falconiforms on their prey is compounded of their own behaviour and that of the animals they feed upon.

#### IMPORTANCE TO MAN

Most falconiforms are directly beneficial to man—feeding on pests or carrion—or neutral—feeding on animals and birds that do not directly affect man. A few species, usually large, spectacular, and uncommon (larger eagles, falcons, and accipiters), may prey on man's domestic stock or poultry or on game birds or fish. In East African grasslands about 86 percent of falconiforms are beneficial, 11 percent neutral, and only 3 percent potentially harmful. Such figures vary from one region to another, but potentially harmful species are always in the minority. It is the more regrettable that, because of ignorance and unreasoning prejudice (especially in the more advanced areas such as North America, Europe, and Australia), beneficial, neutral, and potentially harmless species are all indiscriminately destroyed, even rendered extinct locally.

Detailed quantitative studies invariably have shown that the harm done to man's interests by any falconiform has been grossly exaggerated; even the supposedly harmful species often kill other potentially harmful species (e.g., crows, rats, mustelids). The predation effect of any species is relatively small in relation to the total number of potential prey in any home range. Moreover, even in potentially harmful species, few animals of potential or actual interest to man are taken. In the African fish eagle and Scottish golden eagle, the population may take

Beneficial effects

Food requirements

a fraction of 1 percent of the human fish catch or of the lambs available in an average home range. In North America and Australia, where large eagles have been destroyed on a greater scale than elsewhere, persecution is not based on even rudimentary assessment of the eagles' diet and appetite. Damage to human interests is worst under poor management conditions; for instance, when unfed poultry are on free range or weak lambs live on overgrazed pasture. In rare cases, such as where hatchery trout or reared pheasants are unnaturally concentrated, individual hawks or eagles may have to be controlled when damage is proved; but this is no excuse for wholesale persecution of a species.

Entirely beneficial species include vultures, elanine kites, kestrels and other small insectivorous falcons, most buzzards (*Buteo* and related species), and many small eagles. Neutral species, such as snake eagles and chanting goshawks, can safely be ignored. Objective analysis of the predation situation indicates that diurnal raptors deserve protection except where extensive damage can be proved. Extensive damage is frequently claimed without proof; for instance, in the southwestern United States, where the golden eagle has been persecuted for alleged damage to sheep, improbable in any event and impossible on the scale claimed.

A few falconiform birds have been trained to secure game animals for man, either for sport or to provide food (see FALCONRY).

#### Need for protection

Falconiforms need no protection except from man. Conservation problems, therefore, mean conserving raptors living in or passing through inhabited areas. Undoubtedly the main difficulty is ignorant prejudice against falconiforms by educated, civilized man, which is seldom found, much less effectively exercised, in more primitive human communities. A recent threat, since 1950, is the persistent effect of highly toxic agricultural chemicals (DDT, dieldrin, etc.)—again, the product of civilized man. Positive conservation of falconiforms must include the control of habitat destruction; of active persecution by shooting, trapping, poisoning, and collecting of eggs of threatened species; and of the widespread toxic effects of persistent agricultural chemicals.

Agricultural communities destroy some types of habitat, especially forests, but create others in the process. In Africa, for instance, some forest falconiforms may be eliminated, but much larger populations of adaptable species such as black kites, hooded vultures, and long-crested eagles may move in. The effect of agriculture is not always detrimental, especially when a mixed landscape of forest and open country results. Before the advent of chlorinated hydrocarbons, the peregrine was most numerous in Britain in habitats close to agricultural areas with high populations of avian prey. A sparse population of rural cultivators may have no appreciable effect on a mixed population of falconiforms over long periods of time.

Overcollecting for zoos and museums, and for falconry, has severely affected some species. The behaviour of the few individuals who collect the specimens or eggs of threatened species for commercial purposes must be controlled. In a few instances, chiefly of island species such as the Philippine monkey-eating eagle, this is urgent.

#### Effect of pesticides

Toxic agricultural chemicals are the most difficult of conservation problems because of their subtle and widespread effects (affecting even migrant populations of some hawks that breed in uninhabited areas) and the benefits they confer on human food supplies. The best hope, other than new developments of less toxic substances, is realization of the probably serious overall effect of these long-lasting poisons in contamination of the whole environment. If, as appears likely, the chemicals eventually will adversely affect man himself, control of the use of these chemicals will follow; and the falconiforms will benefit indirectly. (See PEST CONTROL.)

#### FORM AND FUNCTION

The main distinguishing characters of falconiforms are: the hooked beak, used for tearing flesh; taloned feet, used

for piercing, grasping, and killing prey; and large eyes, with very acute vision. The hooked beak and taloned feet are shared with the unrelated owls, which show similar or parallel evolution. In the falconiforms themselves, parallel evolution for scavenging is shown by the New World vultures (Cathartidae) and the Old World vultures (Accipitridae).

Figure 2: Heads of some falconiforms.

A New World vulture, *Coragyps*, with a weak beak for carrion eating; an Old World vulture, *Torgos*, with a stronger beak for tearing at larger animals; a buzzard, *Buteo*, with a simple raptorial beak for killing and eating small mammals; a hook-billed kite, *Chondrohierax*, with a strongly hooked beak for eating snails; a sea eagle, *Haliaeetus*, with a deep, narrow beak of uncertain adaptive value; a falcon, *Falco*, with a toothed beak for shearing and plucking feathers.

**Size and weight.** Most falconiforms are large. Extremes are the Andean condor (ten to 14 kilograms, wingspan three to 3.35 metres) and the tiny eastern falconets (*Microhierax* species; 35 grams or less). Many species range from 400–2,000 grams in weight. Females are normally 20–100 percent larger than males, especially in bird-killing falcons and accipiters. In vultures, however, the male is normally 10–15 percent larger.

**Plumage and molt.** Falconiforms are bulky, heavily feathered birds, lightweight in relation to their apparent size. The first plumage is usually white or gray down, the prepennae. The preplumulae, or second down, grows through the first after days or weeks and is itself superseded by feathers erupting from the prepennae follicles. The latest feathers to develop fully are wing and tail quills, which are large, strong, and often especially adapted.

The immature plumage, presumably representing a primitive type, usually differs markedly from the adult. Adult dress is acquired by a series of molts with, in large species, several intermediate or subadult stages. Immatures usually are brown and streaked or spotted; adults may be more brightly coloured. The sexes usually are alike in plumage. In some island species—e.g., the Madagascar cuckoo falcon (*Aviceda*)—the plumage type found in the immature persists in adult life.

Plumage is replaced by a molt lasting four months to several years, slower and more irregular in larger species. Wing quills are molted in definite sequence. In many Accipitridae molt begins with primary feather number 1 (innermost) and proceeds in regular sequence to number 10 (outermost). In falcons it begins at primary feather 4 and proceeds both ways, outward and inward. Large species tend to replace quills irregularly, perhaps because their greater wing loading would make the lack of several adjacent quills disadvantageous.

**Vision, hearing, and smell.** The eyes are globose and move little in their sockets. To see behind it, a falconiform must rotate its head. The focal length is adjustable by muscles controlling the curvature of the lens. Forward binocular vision is through 35–50° of arc. The proverbially high resolving power of hawks' eyes depends partly on a large image on the retina, partly on the concentration of rods and cones. There are two foveae (areas of high visual acuity), one laterally directed for monocular vision, the other forward, for binocular vision; in each fovea the visual cells are still more concentrated, providing resolving power up to eight times that of the human eye. There is a screenlike pecten, which may cast a latticelike shadow on the retina, permitting good perception of shape of moving objects. The iris in many adults is yellow, red, or orange.

Hearing is good, but not especially acute. The ear apertures are large and in harriers and forest falcons are above average size and surrounded by especially modified feathers, forming partial facial ruffs. The forest falcons live in dense woodlands and are seminocturnal, and the harriers hunt small mammals in long grass, both situations where unusually acute hearing would be advantageous.

Except in the New World vultures, which occasionally use their sense of smell to locate food, the olfactory chambers are poorly developed. The sense of smell is normally rudimentary and less important than sight.

**Feet and bill.** These appendages comprise the main killing and feeding adaptations distinguishing birds of prey. The exact structure of the bill varies according to prey eaten (see Figure 2). Falconidae and some insectivorous kites have notches or teeth on the cutting edge of the beak. In falcons these assist in breaking the necks of prey, but their purpose in kites is obscure. In Old World vultures the bills vary, permitting ecological separation while at food.

Prey is normally killed with the feet. Three toes are directed forward, one behind. The hind toe is usually heavier and longer taloned than the others. In the osprey the outer toe is reversible, for more effective handling of fish. Fish-eating falconiforms have sharp spicules on the soles of the toes to grasp slippery prey. The feet may vary from long, slim toed, needle taloned (bird killing, as in accipiters) to short, thick toed (snake grasping, *Circus*) or heavy toed, with thick, strong talons, capable of paralyzing medium-sized mammals. In Old and New World vultures, which seldom or never kill, the feet lack long sharp talons.

#### EVOLUTION AND PALEONTOLOGY

Falconiforms have no obvious evolutionary links with other birds. Currently they are placed between ducks, on the one hand, and game birds on the other; but they bear no clear resemblance to either, while fossil evidence does not indicate intermediate links. The most obvious physical specializations of falconiforms—the cutting, tearing bill and taloned feet—do not indicate close relationships with owls but are due to similar trends in evolution, though some recent anatomical work indicates that owls and the family Falconidae may be more closely related than was at one time thought.

Rather few fossils of falconiforms have been found, and those that have may repay re-investigation. A generalized type is known from the Eocene (50,000,000 years ago). The oldest known raptorial bird, *Lithornis*, of the upper Paleocene, may have been a cathartid vulture. The Cathartae may have evolved in the Old World, dying out

there and surviving only in the New World. Fossil New World vultures include a large terrestrial species, *Neocathartes grallator*, and a huge vulture, *Teratornis merriami*, from the La Brea tar pits in California. Because of their apparently ancient origin, cathartids may be regarded as primitive survivors.

The secretary bird is thought by some to be a descendant of formidable terrestrial predators, *Brontornis*, *Mesembryornis*, and *Diatryma*. These also may have evolved into the South American Cariamidae, which accordingly may be more closely related to the secretary bird than are the latter to other falconiforms.

Such evidence as there is indicates that the falconiforms diverged from their ancestral types 20,000,000 or more years ago, and that relationships with other groups have since become obscured. Certain evidence suggests that the order is polyphyletic in origin; however, their Mallophaga (feather lice) are similar throughout, and this question must remain unanswered until extensive additional information is available.

Among present-day falconiforms adaptive radiation has led to the development of certain climax types in apparently not very closely related birds. For instance, in Australia, buzzards (*Buteo*) are absent, but certain large kites have evolved to fit this niche. In South America the buzzard-like harpy eagle represents a climax of one line of evolution, filled in the Old World by large booted eagles such as *Stephanoaetus*. There has been much specialization for particular function in unrelated species; for instance, in the bullet-like shape of falcons, the spiculed feet of ospreys and certain eagles, and, perhaps most

Drawing by R. Keane

Figure 3: Specialization of the feet of falconiforms. The moderately powerful foot of the lammergeier (*Gypaetus*); the weak foot of a New World vulture (*Cathartes*); the generalized raptorial foot of a buzzard (*Buteo*); the extremely powerful foot of the harpy eagle (*Harpia*); the foot of a bird-catching accipiter (*Accipiter*), with long toes and talons; the fish-gripping foot of the osprey (*Pandion*), with reversible outer toe and rough spicules on the soles; the foot of the short-toed eagle (*Circus*) for gripping snakes; the foot of the secretary bird (*Sagittarius*) adapted for walking.

Killing of prey

Fossil falconiforms

striking, the auditory specialization of the harriers and the forest falcons.

#### CLASSIFICATION

No entirely satisfactory system of classification of the order Falconiformes has been agreed upon. Two rather different systems have been proposed, and much work is needed before some of the outstanding problems can be elucidated.

**Distinguishing taxonomic features.** The main features of falconiforms include the hooked "raptorial" bill; the basal cere, or bare skin, covering the nostrils; the powerful feet with hooked claws; sustained powers of flight and carnivorous habits; and difference in size between the sexes. Some suborders or families have additional characters; for instance, the Cathartae have pervious nostrils (*i.e.*, the partition between nostrils is incomplete) and a rudimentary hind toe; Pandionidae, a reversible outer toe; Sagittariidae, long legs with short, rather blunt toes; and Falconidae, toothed beak and long, sharply pointed wings, and a noncentrifugal wing molt. Some of these characters may indicate convergent evolution rather than true close relationships.

On the basis of inside eggshell colour, the order may be divided into three rather distinct groupings or suborders: the Cathartae, the Accipitres (with the secretary bird and osprey), and the Falcones. Biochemical analysis of egg-white protein tends to support these groupings and suggest that all are rather more closely allied to one another than to other groups of birds, even though there are some similarities with apparently unrelated orders, such as Procellariiformes. Egg-white proteins also indicate that cathartids are all closely interrelated and that they are related to Accipitridae. The Accipitridae are all rather closely related, though the egg-white patterns of Old World vultures and some kites indicate divergence. The egg-white patterns of Falconidae indicate close relationship within this family, but less close affinities with other falconiforms.

**Annotated classification.** The classification of L.H. Brown and D. Amadon, 1968, which is given below, was based upon that in J.L. Peters' *Check-List of Birds of the World*, modified as necessary in the light of modern knowledge. The main divergent view has been that of E. Stresemann, which was based largely on the sequence of wing molt and departed strongly from the order of Peters and from Brown and Amadon. Those groups indicated below by a dagger (†) are known only from fossils.

#### ORDER: FALCONIFORMES

##### Suborder Cathartae (New World vultures)

Nearctic to Neotropical. Seven existing species; fossils dating back perhaps to Eocene.

##### †Superfamily Neocathartoidea

One family, Neocathartidae. Fossil Nearctic, including *Neocathartes grallator*, differed from other Cathartae in having terrestrial habits.

##### Superfamily Cathartoidea

Pleistocene fossil and present-day species, Nearctic and Neotropical, perhaps formerly Palearctic.

**Family Cathartidae** (New World vultures). Seven present-day Nearctic and Neotropical species and Pleistocene, Nearctic, and neotropical fossils. Pervious nostrils, rudimentary hind toe, large olfactory chambers. Large or medium sized (1.5–14 kg; 1.2–3 m wingspan); do not build nests; inside egg colour yellowish.

†**Family Teratornithidae** (teratorns). Very large-sized fossil Pleistocene species, including *Teratornis merriami* (estimated about 50 lb; 14 ft wingspan) and still larger species.

##### Suborder Accipitres

##### Superfamily Accipitroidea

There are 207 worldwide existing species, small to large, and many fossils.

**Family Pandionidae** (osprey). One species, *Pandion haliaetus*, nearly worldwide, present-day; large, weight 900–1,500 g; wingspan 135–175 cm; resembles some kites in similar sternum and absence of bony eye shield; reversible outer toe, with talons rounded, not grooved; green inside eggshell; squirt droppings; littoral; builds own nest.

**Family Accipitridae** (kites, hawks, buzzards, harriers, eagles, Old World vultures). There are 206 species, worldwide, but some subgroups—*e.g.*, Old World vultures—confined to Europe, Asia, and Africa. Small to very large (100 g to about 10 kg); many adaptive radiations; forest or open country. In all, inside eggshell green; strong hooked talons in all but Old World vultures; squirt droppings; build own nests.

##### Superfamily Sagittarioidea

**Family Sagittariidae** (secretary bird). One species, *Sagittarius serpentarius*, central Africa; present-day, with some doubtful fossils. Large (weight 3.4–3.8 kg; wingspan 1.5–2 m); terrestrial, long legged, short toed; in nesting and display resembles Accipitridae. Inside eggshell green but certain other characters indicate affinity with South American Cariamidae. (See GRUIFORMES.) Usually accepted as falconiform but may not be.

##### Suborder Falcones

There are 61 worldwide species, present-day and fossils. No superfamily designations; the order comprises only 1 family.

**Family Falconidae** (caracaras, milvagos, forest falcons, falconets, and true falcons). Some genera (*Polyborus*, *Daptrius*, *Herpetotheres*, *Milvago*, *Micrastur*) confined to New World, and others (*Microhierax*) only Oriental; very small to medium sized (35–1,800 g). Resemble Accipitridae in hooked beaks, talons, sexual dimorphism, etc.; differ in molt sequence, some anatomical characters, behaviour (droppings fall below perch; head bobbing in some; in all but caracaras no nest made); inside eggshell reddish.

**Critical appraisal.** Stresemann's classification of present-day falconiforms differed from the one given above in being based almost exclusively on the order of wing molt, classified in three ways: (1) beginning with primary number 4 and proceeding inward and outward from there; (2) "descendant," beginning with primary number 1 and working outward to the wing tip; (3) "irregular," with no clear sequence. The third category can again be subdivided into types that molt "descendant" (number 2 above) in juvenile molt and irregularly in adult plumage, and others that molt irregularly in all stages of plumage.

On this basis the order Accipitriformes of Stresemann (*cf.* Falconiformes of most authors) was divided into three suborders, Cathartae, Accipitres, and Sagittarii. The suborder Cathartae contained the New World vultures (*e.g.*, Cathartae of Brown and Amadon); the Accipitres included all those species included by Brown and Amadon in their suborders Accipitres and Falcones, with the exception of the secretary bird, Sagittariidae. Stresemann places the secretary bird alone in a separate suborder, Sagittarii. He thus included all but eight species of present-day falconiforms in the suborder Accipitres. Stresemann divided his Accipitres into two families: Accipitridae, molting "descendant" (number 2 above) or irregularly; and Falconidae, molting from primary 4 (as in number 1 above). Each of these families was divided into a number of subfamilies, and it was in the arrangement and order of these subfamilies that Stresemann's order of classification differed most strongly from the other current systems.

The relative merits of these two classifications are still open to discussion. That of Stresemann has been criticized on the ground that virtually all of the birds that molt irregularly are either large or very large. This applies to all his Cathartae; to all or most of his subfamilies Gypaetinae, Aegypinae, Polyboroidinae, Circaetinae, Haliaeetinae, Machaerhamphinae, and Pandioninae of his family Accipitridae; to the larger and heavier members of his subfamily Accipitrinae; and to the secretary bird. No member of his Falconidae molts irregularly, but then none, except some caracaras and perhaps the gyrfalcon, can be called large and heavy. It appears at least as probable that the order of wing molt is as related to weight, size, and wing loading as to phyletic relationships. No one, however, questions the obvious differences between falcons and hawks, which are more strongly stressed by Brown and Amadon in their suborder Falcones than by Stresemann, who gives the falcons only family rank.

Modern birds usually are classified by the principle of placing the most primitive first and leading successively to the most highly evolved. Brown and Amadon sug-

gested that Stresemann's ordering of subfamilies in his Accipitridae reversed that order by beginning with the rather specialized Old World vultures and ending with the sea eagles, kites, and osprey, which they regard as relatively primitive falconiforms. The position of the osprey remains controversial. Comparison of egg-white proteins indicates that the Old World vultures are closer to the typical eagles and buzzards than to the snake eagles and harriers. Stresemann concluded his large subfamily Accipitrinae with the buzzard-like harpy and monkey-eating eagles (*Harpia* and *Pithecopaga*), which Brown and Amadon considered less highly evolved than the booted eagles with feathered toes, such as *Spizaetus* and *Stephanoaetus*.

The whole subject of the classification of the Falconiformes is, in several respects, in need of thorough critical reappraisal and review. The best of the existing classifications is a compromise that still leaves many questions of precise relationships unanswered.

BENT, "Life Histories of North American Birds of Prey," *Bull. U.S. Natn. Mus.*, vol. 167, pt. 1 (1937), and vol. 170, pt. 2 (1938), a review by species of the natural history of all of the falconiforms and strigiforms (owls) found in North America; L.H. BROWN, *Eagles* (1955; shortened version, 1970), an account of the biology of these impressive birds, written for the layman, and with D. AMADON, *Hawks, Eagles and Falcons of the World* (1969), extensive information on the natural history of every species of the falconiforms; L.H. BROWN, *African Birds of Prey* (1971), an ecological study of falconiforms and strigiforms on the African continent; P.E. BROWN and G. WATERSTON, *The Return of the Osprey* (1962), a detailed account of the natural history of the osprey; J.J. and F.C. CRAIGHEAD, *Hawks, Owls and Wildlife* (1956), a detailed study of the food ecology of raptorial birds and their effect on prey populations; M.L. GROSSMAN and J. HAMLET, *Birds of Prey of the World* (1964), a heavily illustrated work dealing with both falconiforms and owls; J.J. HICKEY (ed.), *Peregrine Falcon Populations* (1969), a report of a symposium to determine the cause of the decline of the falconiform populations, especially that of the peregrine; H.K. SWANN, *Monograph of the Birds of Prey (Order Accipitres)*, vol. 1 (1930), vol. 2 (1945), a classic work on the biology of the falconiforms of the world, with many fine colour plates.

(L.H.B.)

## Falconry

Falconry is the art of employing falcons, other hawks, and sometimes eagles in hunting game, often termed hawking. This article discusses the history and art of falconry, including the birds, falconry terms, and choosing and training the hawk. Representative works on falconry, including reprints of classic treatises, are listed in the bibliography.

**History of falconry.** Falconry is an ancient pastime practiced by man even before he learned to write. There is evidence of falconry in Assyria in the period of Sargon II (721–705 BC). Merchants, adventurers, and crusaders from Europe and England became familiar with falconry in the Orient and on their return home brought falcons and falconers with them. The sport flourished in western Europe and the British Isles in the Middle Ages as the pastime of the privileged classes. During the 17th century, after the advent of the shotgun and after the enclosure of the open lands and numerous social upheavals in the older countries, the noble sport of falconry died out, surviving in Europe largely through the enthusiasm of members of hawking clubs in various countries. In Great Britain the Falconers' Society of England was founded about 1770 but ceased in 1838 with the death of the then manager, Lord Berners. Because of the scarcity of herons (a main quarry of the club's peregrine falcons in East Anglia) and also partly because of the plowing up of the heath land over which the falconers rode, the centre of English falconry moved to The Netherlands, and in 1839 the Loo Hawking Club, an Anglo-Dutch society under the patronage of King William II of The Netherlands, was formed; in the first eight years of its existence, 1,500

herons were taken by its hawks. In 1853 the royal patronage was withdrawn and the Loo Club came to an end. For the next 10 years falconry was kept alive in England by a few amateurs and their professional falconers. Then, in 1864, the Old Hawking Club of England was founded, mainly to hawk rooks on the Wiltshire Downs. It was wound up in 1926 and the British Falconers' Club was founded in 1927. In the second half of the 20th century, the club had a membership of about 250. More than half the members were resident in the United Kingdom, but only about 30 kept and flew hawks. The reduction of the rabbit population by myxomatosis and the placing of many of the traditional quarries on the protected list both had a profound effect on the sport after World War II. All British birds of prey including owls came under the protection of the law, and a license was required from the Home Office before an intending falconer could take a young hawk for falconry.

Falconry clubs exist in other European countries. The French Club de Champagne went out of existence in 1870, but French falconers are organized in the Association Nationale des Fauconniers et Autoursiers Français. In Germany, the Deutscher Falkenorden was founded in 1923 and is a thriving club. Austria has its club, and Italy the Circolo dei Falconieri d'Italia. In the United States falconry is represented by the North American Falconers Association.

Falconry is still practiced in Libya, and sheikhs in Saudi Arabia and the Persian Gulf states still train their saker falcons to hunt bustard. In Indian and Pakistani Punjab and in the Northwest Frontier Province of Pakistan, falconers fly their falcons at duck and their goshawks at partridge. Much-prized hawk bells are made at Lahore and Amritsar. Japan has a few falconers, who fly their mountain hawk eagles at hare and their goshawks at pheasant.

A revival of interest in the sport occurred after World War II, and, with the reprinting of old treatises on the art, together with magazine articles and television programs on the subject, falconry attracted new adherents.

**The birds and the art.** Hawks, owls, and eagles are natural predators and kill in order to survive. With skill and patience, they may be trained by man to kill selected quarry, but none will retrieve game. Some, because of their temperament and flight habits, are more desirable than others. The most popular has long been the peregrine falcon, which possesses all the desirable traits. It can stand the climatic changes of any country, it is strong and swift, gentle and fierce as required, and when caught wild is readily trained by man. Only two groups of hawks (about a dozen species) possess such characteristics—the true falcons, or long-winged hawks, and the accipiters, or short-winged hawks. Among the latter are the goshawk and the European sparrow hawk. Because of the use of agricultural pesticides the hawks together with other birds of prey are on the decline.

Falconers have their own language. The male hawk, which is smaller than the female by one-third, is the tiercel. Only the larger female hawk is properly called the falcon. An eyas is a hawk taken from the nest when fully fledged but as yet flightless. Wild-caught immature birds are called passagers because they often are caught when migrating, and adults are haggards. After capture and until ready to be trained, eyases are "at hack." While being hacked the birds are fed regularly on fresh meat, tied to a board or block, always in the same spot. Eyases are seldom used in India and Africa but are commonly used in Europe and the U.S.

The would-be falconer's choice of hawk depends on the locality and cover conditions in which it will be used. The long-winged hawks are used in open country, while the short-winged accipiters are better equipped to work hedge-rows and woods. Another difference between the two groups of hawks being considered is their method of killing. Falcons usually kill their quarry in the air, cleanly and at the end of powerful dive, or stoop, but they do occasionally cling, or "bind to," their prey. The goshawk may perch in a tree watching intently while man and dogs

Falconry  
terms

beat the cover. When game is flushed, the goshawk dashes fiercely in pursuit, "binds to" its victim, carrying it to the ground, and then pierces the vital organs with its massive talons. Goshawks are used for hunting hares, rabbits, and pheasants. The smaller accipiters are best for starlings and small game such as partridges and quail.

Once the type of hawk is decided upon, the falconer must make another choice: whether to use an eyas or a wild-trapped hawk. The novice usually begins with an eyas—legally obtained. Trapping a wild hawk requires patience and skill. One method is to hide in a blind near a bow net set over a wild hawk's kill. As the hawk returns to its kill, the net is pulled with a cord, and if successful the falconer at once removes the bird, attaches leather thongs called jesses to its legs, and covers its eyes with a ruffer (soft leather hood used on new-caught birds).

Training begins by carrying the hawk on the heavily gloved fist several hours each day while talking to it gently and stroking its plumage with a feather. When the hawk is able to feed from the fist without the ruffer, it is ready to be broken to the hood and to people, dogs, and the like. Then it is trained to feed from the lure, a padded weight with wings of a pigeon or another bird attached and to which meat is tied. The lure is whirled on a cord and the hawk taught to fly aggressively to it over increasing distances. After this manoeuvre is mastered, the bird is trained to kill for itself. Now it is ready for hunting. Eyases are trained in much the same way as wild-caught birds.

**BIBLIOGRAPHY.** J.G. MAVROGORDATO has written two authoritative works: *A Hawk for the Bush* (1960), which specializes in the sparrow hawk as an accipiter, or short-winged hawk, and *A Falcon for the Field* (1966), on the flying of the longwinged hawk, or falcon, at every recognized quarry. M.H. WOODFORD, *A Manual of Falconry* (1960), is the best general work, suitable also for the beginner, with specialist's chapters on game hawking by S. Allen and rook and magpie hawking by J.G. Mavrogordato; a veterinary surgeon, Woodford has written a useful chapter on health and disease. Other useful works are GILBERT BLAINE, *Falconry* (1936, reprinted 1970); and E.B. MICHELL, *The Art and Practice of Hawking* (1900, reprinted 1960), accepted as the best treatise on the merlin. As many of the originals of the recommended books below have become collectors' items, for all practical purposes the works above relating to modern conditions and all the hawks used are to be especially recommended.

J.E. HARTING, *Hints on the Management of Hawk* (1898, reprinted 1970); F.H. SALVIN and W. BRODRICK, *Falconry in the British Isles* (1855, reprinted 1970). Important early works on falconry are the remarkable treatise by the Holy Roman emperor FREDERICK II (1194-1250), first printed in 1596 and translated into English by CASEY A. WOOD and F. MARJORIE FYFE as *The Art of Falconry* (1943); EDMUND BERT, *An Approved Treatise of Hawkes and Hawking* (1619, reprinted 1950).

## Falkland Islands and Dependencies

The Falkland Islands lie northeast of the southern tip of South America, 300 miles (480 kilometres) east of the mainland. Covering an area of 130 by 80 miles, the some 200 islands comprise a land area of approximately 4,700 square miles (15,800 square kilometres). The two main islands, East and West Falkland, account for about 4,300 square miles of the total. The Falklands are a self-governing colony under the British crown. British sovereignty over the group has been contested since the 1760s—first by Spain and then by Argentina, which in the early 1970s still maintained its claim. The capital is Stanley (Port Stanley), on East Falkland.

The Dependencies consist of groups of islands lying from 700 to 2,000 miles to the east and southeast of Port Stanley. They consist of South Georgia, the South Sandwich Islands, and the Shag and Clerke Rocks. British Antarctic Territory is administered from Port Stanley but since 1962 has formed a separate colony.

Capt. John Strong, an Englishman, made the first recorded landing in the Falklands, (1690), naming the

FALKLAND ISLANDS

sound between the two main islands after Viscount Falkland, then the treasurer of the British navy. The name later came to refer to the whole group. The term Las Islas Malvinas is in general use in South America. (See ANTARCTICA; for associated physical features, see ATLANTIC OCEAN; DRAKE PASSAGE.)

**The natural environment.** The main structural elements in the islands are two folds running east-west across the northern parts of the islands and parallel to Falkland Sound on the west. Ranges of hills follow the trend of these folds, occasionally rising to 2,300 feet. The coastal topography is typical of a drowned coastline, with long, winding creeks. The rivers are small and sluggish and occupy broad, peat-covered valleys.

The climate is dominated by the prevailing strong westerly winds; in Stanley the average wind speed is more than 16 miles per hour. Gales are recorded on an average of four times a month, but storm-force winds are almost unknown, though gusts have been recorded above 80 miles per hour. Rainfall, spread evenly throughout the year, reaches maximums in December and January and minimums in September and October. It averages 25 inches annually, falling from 16 to 21 days a month. Light falls of snow, soon melting, occur on about 50 days during the year. Temperature range is narrow, with seasonal uniformity but marked day-to-day variability: the mean average is about 42° F (5° C), with a maximum average of 64° F (18° C) and a minimum average of 25° F (-4° C). The air temperature has never been known to exceed 80° F (27° C) or to fall below 12° F (-11° C). Average daily sunshine is about four and a half hours.

Vegetation is similar to that of the Atlantic heath type, consisting of low, dense, shrubby vegetation in a barren landscape; white grass (*Cortaderia pilosa*) and diddle-dee (*Empetrum rubrum*) dominate the plant associations. There is little variety of species—only about 160, none of which is peculiar to the islands. The banks of peat, typical of the islands, are built up under a light-green carpet of *Astelia prunila* (a kind of lily) and reach 18 feet in depth. Around the coastline and on some small islands, an almost pure strain of tussock grass (*Poa flabellata*) is found; formerly, it was very extensively present. There is no natural tree growth.

There are no longer any land mammals indigenous to the Falklands, the indigenous wild fox being extinct. But unspoiled natural conditions and abundant food supply make the islands and the seas around them a unique area for wildlife. Sixty different species of birds, including the black-browed albatross, are known to breed there. Three main species of penguin breed in the thousands; more rarely, the king and macaroni penguins also breed. Inland are many geese and birds, including the military starling, the black-throated finch, the Falkland pipit, Cassin's falcon, and the red-backed buzzard. Marine mammals to be seen are Peale's porpoise and Commerson's dolphin. Of amphibious marine animals the southern sea lion is still the most abundant of the three major species breeding; fur seals are rare, but the elephant seal is common, and the leopard seal is seen, though it does not breed there.

The absence of trees and the abundance of clouds lend

Climate

Mammal life

an austere aspect to the landscape, which consists largely of moorland and hilly mountainside, scattered with outcrops of rocks and numerous clusters of large, quartzite boulders. But this austere aspect can quickly vanish when sunshine brings colour to the sea and to the lovely, indented coastline, with its graceful, sandy bays, fringed with surf, and countless islets.

**History.** It is not clear who discovered the Falklands. It seems likely that the English navigator John Davis in the "Desire" was the first to sight them, in 1592; Sebald van Weerd, a Dutchman who was in the region in 1600, gave his name to them on maps of the 17th and 18th centuries. The French navigator, Louis-Antoine de Bougainville, in 1764, founded the first settlement on East Falkland. The British, in 1765, were the first to settle West Falkland. They were driven off in 1770, however, by Spanish troops, Spain having bought out the French. War between Britain and Spain was averted only when Spain agreed to return "the port and fort called Egmont" to the British. For economy the British naval garrison was withdrawn in 1774, leaving a plaque claiming full sovereignty over all the Falklands for the British crown. Spain maintained its settlement until 1806, when an uprising against Spanish authority broke out in Buenos Aires province, Argentina. Spain made no further claim to jurisdiction, but in 1816 the United Provinces of the Río de la Plata claimed to succeed Spain in sovereignty over the Falklands and took possession of Soledad in 1820. A local governor was installed in 1828. Four years later the British government reasserted its claims to the Falklands, and in 1833 a British force peacefully expelled the Argentine soldiers and their vessel from Soledad and raised the British flag. The British prime minister said in 1834 that the British were not prepared to permit "any other state to exercise a right as derived from Spain, which Britain had denied to Spain herself."

In 1842 the capital was moved to Stanley. Settlement continued, and by 1885 the community of nearly 1,800 persons was self-supporting. In 1892 the Falklands were granted the status of a colony. In World War I (on December 8, 1914) the Falklands were the scene of a naval battle between British and German fleets.

**The colony.** *The people.* The population—about 2,000 in 1970—is English speaking. Of these, 79 percent were born in the Falklands, and 98 percent have British nationality. Sixty-five percent of the population belong to the Church of England and 23 percent to other Protestant denominations, and 11 percent are Roman Catholic. The population first exceeded 2,000 in 1901, reached a peak of almost 2,400 in 1931, and declined slightly in the 1960s as emigrants sought more varied employment abroad, but this trend was offset by an increase of short-term, skilled contract personnel.

The pattern of living on the islands is sharply divided between that of small, isolated sheep-farming communities and the wide cross section of interests represented in Stanley. In the capital live government officials, professional groups, technicians, artisans, and the personnel of the British Antarctic Survey, the Radio and Space Research Station, and the telecommunications centre.

sheep, producing an average of 4,750,000 pounds of wool annually. This is sold in Great Britain and is the country's only resource. Public financial expenditure is some £450,000, the revenue being obtained from income tax. There is some revenue from customs duties levied on wines, spirits, malt liquids, and tobacco. The island's stamps, of notable philatelic interest, are a source of income from sales to collectors of current issues. While the colony is self-supporting, occasional help from Great Britain is received. The Falkland Islands Company, incorporated by Royal Charter in 1851, has played a notable part in the economic development of the islands.

More than 1,000 motor vehicles maintain land communications, using the 12 miles of concrete roads in Stanley or the unsurfaced tracks elsewhere when weather permits. A government-operated air service, using seaplanes, carries passengers, mail, and medical patients between farm settlements and Stanley on nonscheduled flights. There are no external air communications. A government launch and a ship, the "Darwin" of the Falkland Islands Company, sail around the islands to carry stores and collect the wool clip; the latter vessel goes to the mainland with passengers, mail, and freight, making about 12 trips a year to Montevideo. Four times a year a chartered vessel brings supplies directly from England, returning with the wool clip. External telecommunications are maintained by the government wireless station; internal communications are by landline and radio telephone.

**Administration and social conditions.** The government of the islands is democratic and independent. At its head the governor, appointed by the British crown, is advised by an executive council, the majority of the members of which are elected from and by the elected members of a legislative council. In Stanley there is a town council, empowered to levy property taxes to meet the cost of public services. General social conditions are good; there is no unemployment, and the one trade union negotiates wages and conditions for all employees. Housing is well built and adequate, the average number of rooms being more than seven, compared with an average of under five in the United States and Great Britain. There are systems for old-age pensions, children's and dependents' allowances, and workmen's compensation. Education is free and compulsory to the age of 15, with two schools in Stanley, a boarding school at Darwin, and schools at five other settlements. Children in outlying homes are taught by itinerant teachers, the whole program augmented by the use of radio. There is a free medical service with four doctors, a dental surgeon, and nursing staff and a 32-bed hospital in Stanley.

Cultural life is largely provided by radio, Stanley station relaying London's programs; but many people also directly receive the world's stations. Several social clubs provide a variety of indoor activities, and outdoor sports include football, cricket, golf, and trout fishing. Publications include the government's *Falkland Islands Gazette*, the *Falkland Island Monthly Review*, and the annual *Falkland Islands' Journal*, with items of historical, geographical, and general interest.

**Prospects.** Argentina continues to press its claim to sovereignty over the islands, but the British government rejects any transfer of sovereignty or change in the status quo. Economically, with the price of wool unsteady, the outlook is uncertain, but diversification of the economy is being pursued: commercial use may be made of the very large quantities of kelp around the islands, and tourism is being encouraged.

**BIBLIOGRAPHY.** SIR W.L. ALLARDYCE, *The Story of the Falkland Islands* (1909), provides an account of the discovery and early history. M.B.R. CAWKELL, D.H. MALING, and E.M. CAWKELL, *The Falkland Islands* (1960), presents a general picture of life in the islands. A.F. COBB, *Birds of the Falkland Islands* (1933), and *Wild Life of the Falkland Islands* (1910), are useful accounts of the islands' animal life. C.W. GUILLEBAUD, *Report on an Economic Survey of the Falkland Islands* (1967), is an expert and up-to-date account of the economy. See also the Falkland Islands Colonial Reports, published every two years by HMSO.

**Economic life.** The whole area of the islands, outside of Stanley, is devoted to sheep farming. Half the male population is thus employed. Farms vary in size from 3,600 acres to 161,000 acres. There are over 600,000

(C.J.T.)

## Family and Marriage

Almost all human beings have grown up in some kind of "family," but families have varied considerably in form, not only from one era to another and from one culture to another but also within eras, within cultures. In a culture the form of the family changes or disappears, giving way to others. All these many aspects of the family constitute an important part of social change. The first way to look at the family is as a group, a household.

The article is divided into the following sections:

- I. Forms and functions of families and marital unions
  - Household forms
  - Marriage forms
  - Functions of the family
- II. Historical background
  - Premodern Western families
  - The onset of industrialization and urbanization
  - Modern society and family
- III. Development and organization of the modern family
  - Mechanisms of mate selection
  - Preparations for marriage and the marriage ceremony
  - Marital and familial dynamics: the family life cycle
  - Roles and activities throughout the family cycle
  - Conflict, crisis, dissolution
  - Divorce
  - Remarriage
- IV. Transition of the form and structure of the modern family
  - Security in society and family
  - The effects of technology
  - The drive for female equality
  - The role of ideology

### I. Forms and functions of families and marital unions

#### HOUSEHOLD FORMS

There is no one accepted method of classifying households. The types discussed here are not mutually exclusive. (For a more extended treatment of familial and kinship terminology and of family and marriage in preliterate and agrarian societies, see KINSHIP.)

**Corporate family.** The corporate family is organized around a number of important activities, such as hunting in its territory, cultivating its land, trading its products, performing important rituals and rites, and rearing its children. Though common to preliterate societies, the pattern can also be applied to Western society, for members of Western households do share shelter, food, and resources, as well as activities arising from their use. Industrialization tends, however, to disperse the members of the household among different employers and occupations and to reduce the number and frequency of common rites or activities.

**Extended family.** The extended family includes not only the parents and unwed children but also married children and their wives or husbands and offspring. Among the wealthy, people generally live longer, and extended families of good economic standing may include as many as four generations, at least for a short period of time. Strictly speaking, a small extended family is no longer extended when one of the parents in the older generation dies. An extended family should thus be seen as a stage in the family cycle and as an ideal form that is difficult to attain in such poor countries as India or Iran.

**Conjugal family.** A husband and a wife almost always come from different families (the incest taboo), and therefore their bond, as a conjugal family, is not consanguine, or blood related. But the children in the conjugal family, of course, have consanguine bonds with their parents. This makes the concept of the conjugal family rather clumsy, and so it tends in modern literature to be replaced by the concept of the *nuclear family*.

**Nuclear family.** The nuclear family consists only of parents and their children. This type of family is universal; it forms the nucleus of the corporate as well as of the extended family and, of course, constitutes the first stage in both. The nuclear family is probably the oldest type of family, going back to the earliest ancestors of man, maybe half a million years ago or more. These beings lived in small bands, and their young were born at intervals of

one or, at the most, two years, but it took several years before the young could manage for themselves. The mother must have had help from a husband in caring for them, and these parents and children must have formed rather stable nuclear families, although the best hunters may have taken an extra wife if, for example, a female had lost her husband.

As the cultural level of man rose and was adapted to climate and resources, the pattern of the nuclear family changed. Industrialism and geographical mobility seem to have an unfavourable effect on the formation and maintenance of large families and even on the acceptance of the extended family as an ideal. Thus modern families now tend to remain nuclear families, and family activities and solidarity are reduced not only in the nuclear family but even more between the generations, particularly between young parents and their older kin.

**Experimental family.** Various other familial arrangements have sometimes been tried in new situations not suited for nuclear families. One of these is the *kibbutz* in Israel. There a large number of people from different countries, with different educations and backgrounds, were brought together in collectives, concentrating on the tasks of clearing land, irrigating it, and growing crops. Every member had to work for the collective; most of the women were engaged in making meals, washing and mending clothes, or caring for the children. The rather difficult circumstances in which most *kibbutzim* started allowed the couples only the evenings to see each other and their children in the privacy of their own room, and this evening family produced and consumed very little except emotional, sexual, and social contacts. This or a similar pattern persists in most *kibbutzim*. The younger members often enjoy considerable sexual freedom, but if they decide to form a family, they apply for a room of their own, and if they get it, this generally implies the official recognition of their union. Apparently the intense interaction within the *kibbutz* is able to compensate for the reduced interaction in the family.

Other experimental solutions are possible among modern young people who often try to form small groups, as isolated as possible from society. Mutual interaction among those involved may then be so dominant that a group family seems natural to them, at least for a time.

#### MARRIAGE FORMS

The nuclear family is monogamous by definition; that is, it has only one man with one wife. But in many cultures, the husband is allowed to take more wives in a marriage form called *polygyny*; and in some the wife is allowed to take more than one husband in a form called *polyandry*. *Polygamy* is a broader concept including polygyny as well as polyandry. Some anthropologists formerly believed that their data from a few preliterate cultures demonstrated the existence of *group families*, which included several husbands and wives, but few still believe that this type of family existed.

**Monogamy.** Monogamy is the commonest form of marriage in all cultures. A monogamous culture is simply one in which only monogamous marriages are legally accepted—polygamy being a crime. The ties between husband and wife in a monogamous marriage are strong in some cultures, weak in others. Strong ties may prevent divorce and even the remarriage of widows and widowers; weak ties generally lead to easy and numerous divorces.

**Polygamy.** In polygyny, the husbands are allowed and encouraged to take more than one wife. The famous anthropologist George P. Murdock classified 250 cultures according to the form of the family. Of these, 193 were classified as polygynous. It is doubtful, however, whether such Islāmic countries as Algeria, Tunisia, Egypt, and Pakistan should today be classified as polygynous; public opinion there seems now to favour monogamy.

If cultures with the usual proportions between the sexes are to practice polygyny, it is evident that they must either prevent some of the men from marrying at all or keep the marrying age low for women and high for men,

The modern family as a nuclear family

especially for those marrying for the second or third time. Of course, from the economic point of view, polygyny is easier among the well-to-do.

Polyandry is rare; only two cases are cited in Murdock's sample. It seems to be associated with scarcity of women owing to the practice of infanticide of females. If a tribe is very poor and the wife herself can contribute very little, she will need several husbands to support her and the children—and may still be forced to reduce the number of children.

#### FUNCTIONS OF THE FAMILY

**Personal or individual functions.** *Psychological security.* An important function of the family—especially in Western societies where there is much tension—is emotional or psychic security. Independent nuclear families are especially associated with intimacy and emotional interdependence, either because they originally had this function or because they have taken it over from extended families or from other forms that have broken down. In Western culture, there is particular stress on the companionship between husband and wife, symbolizing the modern equality of sex roles and based on a division of labour that presumes to give the same value to male and female tasks. This companionship and parenthood seem to be the most important sources of psychological security because elsewhere, at work and in other groups, more value is placed on efficiency and matter-of-fact relations.

*Sexual satisfaction.* In all cultures an important marital reward, in addition to companionship and certain social privileges afforded married people, is the gratification of sexual relations. Western culture stresses the importance of sexual satisfaction, but it also keeps sexuality under comparatively strict control. Indeed, few societies have tried, as Western society has done, to restrict sexual intercourse exclusively to married couples. Although a married man in most cultures is forbidden intercourse with a woman married to another man, he may, nevertheless, have affairs with one or more of his female relatives. Premarital liaisons between an unrelated boy and girl are forbidden in only 54 cultures of a sample 250.

Within the family, the husband and wife are always allowed comparatively great sexual liberty with each other, although there may be a sexual etiquette to be followed, such as taboos on intercourse during menstruation, pregnancy, and lactation.

*Physical security.* An individual feels a sense of physical security because of the family's willingness or duty to protect one another, to care for the sick or injured, to provide one another with shelter, warmth, food, and clothes. With the usual distribution of tasks in the family, the husband might hunt game, tend cattle, or work in the fields or in a quarry, while the wife in most cultures remained in the vicinity of the home, carrying water, collecting roots and berries, making, mending, and washing clothes, tending the fire and bringing fuel for it, thus contributing her important share to the well-being and security of the family. Societies with a permanent place of residence as a rule pay more attention to their dwellings; families build houses or huts not only to obtain more comfort but also to realize more security and privacy than can be found in tents or temporary shelters. Physical security also depends heavily on the mores, codes, and legal system of the society.

**Social functions.** *Procreation and child socialization.* Societies that have paid too little attention to procreation have run the risk of extinction; and societies that are unable to educate or socialize their children in traditional fashion undergo change, lose some cultural traits, and probably invent or borrow other traits. In other words, a society cannot be stable unless it has made acceptable provision for procreation and child socialization.

Child socialization in most cultures is not considered a task but rather part of the daily labour—a labour in which children take their allotted part and, in the process, pick up necessary knowledge and lore. The socialization period generally ends in adolescence, but in most pre-

literate cultures the adolescents are given the status and privileges of adults only after dramatic or painful passage rites, often interpreted as the killing of the boy and his rebirth as a young man. The girls generally receive less attention and ill-treatment, although their first menstruation is sometimes considered dangerous and is therefore associated with a period of isolation. Literate societies tend to change the passage rites into festivals.

*Regulation of sexual behaviour.* Because the sexual drive can be very strong and disrupt the regulated behaviour pattern in the family (because of jealousy or whatever), all cultures have found it necessary to control sexual relations between men and women, whether married or not. Murdock listed seven categories of sexual relations: *marital sexuality*, between a married couple; *adultery*, between two persons, at least one of whom is married to someone else; *incest*, between two persons whose bond of kinship, as defined by the culture, bars them from sexual relations; *mismatching*, between members of different classes, castes, or ethnic, national, or religious groups that are not expected to have sexual relations; *status unchastity*, between two persons, at least one of whom has a social position demanding chastity; *incontinence*, between persons whose sexual relation contravenes taboos pertaining to menstruation, pregnancy, etc.; and finally *fornication*, between partners who adhere to all other rules and taboos but are themselves unmarried.

All cultures prefer to prescribe marital sexuality and forbid incest, but the regulations concerning the remaining five classes of sex relations vary considerably. They are forbidden, allowed, or required according to circumstances. Western culture has prohibited even fornication, but only 3 societies in Murdock's example of 115 went as far as that, and so it must be recognized that the Western mode of strict sex regulation is atypical.

The sexual privileges within marriage need not exclude sexual freedom prior to marriage. Murdock found such freedom in about 70 percent of the societies about which he had information. The incest taboo is very rigorous, however—probably because it threatens the ties between husband and wife in the nuclear family and their ties to the children. Incest seems to have been allowed only among some ruling dynasties (Egypt, Hawaii, the Incas).

*Contribution to social and economic life.* The family is the most common economic unit, involving a relatively efficient division of labour between husband, wife, and children. Nowhere, however, do families, normally, live in isolation. They almost always form a part of a larger group, a community, in close contact with one another, probably because such a community makes it easier to produce food, to introduce a more advanced division of labour, to enjoy social intercourse, and to get help when injured, ill, or temporarily without means.

*Contribution to order in society.* The type of family, the social organization, and the sources of livelihood all depend on one another. Hunting, gathering, or herding creates or favours small migratory bands consisting of a few families. Agriculture tends to make the families adopt a more or less permanent place of residence and unite either in scattered neighbourhoods or concentrated villages, such as may also develop in a fishing economy. Bands of hunters or herders generally own their land collectively, whereas the farmers of neighbourhoods or villages with few exceptions own their fields privately, although pastures and woods may remain collective property. Similar communities, in communication with one another, tend to develop a culture together, to create a "we-feeling." Together they tend to develop a common kinship system, a common system of law, and eventually political unification. About half the societies in Murdock's sample had remained at the community level, and half consisted of several communities.

The smaller and the more isolated the community, the more important the family unit. Larger communities tend to organize collective action, to produce specialists, to invest authority in chieftains, and so forth, thus changing faster and often developing stronger social controls over facilities and individuals.

Categories of sexual relations in and out of marriage

## II. Historical background

The following are a few family systems from the past that are representative of Western patterns: the patriarchal pattern from the Bible, the old Roman family, Tacitus' picture of the Teuton family, the medieval family, the European peasant family pattern, and modern varieties.

### PREMODERN WESTERN FAMILIES

The family pattern of the patriarchs, as described in the Bible, still influences present practices. Abraham, Isaac, and Jacob are described as nomad chieftains, owning great herds, married to several wives, allowed to take concubines and to get rid of them. The Old Testament accorded women a lower status than men and, in some respects, so did Christianity.

The  
Roman  
family

The old Roman family gave extreme power to the father (*patria potestas*), who represented the community and had the right even to kill his own sons. He was his sons' guardian as long as he lived; and after marriage, they lived with their families in his household, forming a very extended family. The family was proud of its lineage and anxious to obtain for the sons brides of equally good family who would bring substantial dowries to increase the family fortune. But men were not allowed more than one wife and so officially remained monogamous. In practice the wife had considerable influence; and later, in imperial Rome, the power of the clan and of the father were reduced. Women, however, still had lower status and in fact were not permitted to manage their own affairs. Roman family law influenced all parts of the Roman Empire and lasted far longer than the empire itself, for it was taken over by many of the new nations and, up to a point, by the Roman Catholic Church as well.

The family in the Teuton tribes was described by Tacitus as a contrast to Roman decadence in the 1st century AD.

The marriage tie with them is strict: you will find nothing in their character to praise more highly. They are almost the only barbarians who are content with a wife apiece: the very few exceptions have nothing to do with passion, but consist of those with whom polygamous marriage is eagerly sought for the sake of their high birth. As for dower, it is not the wife who brings it to the husband, but the husband to the wife.

These tribes thus seem to have been monogamous and to have accorded women high regard, inheritance rights, and so forth; among the Heruli, brother and sister shared alike.

The medieval family in the Mediterranean countries tended to retain traits characteristic of Roman family law—representing the power of the father, a dowry, the lower status of women, and the extended family—but it was, of course, also influenced by the Roman Catholic Church and the feudal system. In the northern half of Europe, which was little urbanized and was dominated by the victorious Teuton tribes, the peasant families tended to follow their old family patterns but had to seek protection from the local lord, who was a member of the military aristocracy. Only the church could oppose the feudal lords, but the oath of celibacy prevented the clergy from forming a hereditary class. The concept of celibacy by implication painted women as sinful and unclean, a picture that was counteracted by the sublime idealization of the Holy Virgin and female saints and by the slightly less highly idealized concept of women in the romantic poetry of the minstrel, singing of the lady of his heart's desire.

European peasants up to modern times seem to have followed the same broad family pattern. The farm belonged to the family, but as H.J. Habakkuk has pointed out, the family had two conflicting aims: to keep its property intact and to provide for the younger children. In England the eldest son took over the family farm, but in France and the Rhineland the law stated that all children had the same right to inherit. All the same, there was a tendency to let the eldest son take over the farm,

to represent it in the village, and to be the head of the immediate family to whom members could turn if they got into difficulties. It was his duty to look after them and to provide a bed and food for them. He had far-reaching powers over his children and his farmhands. The pattern was that of a patriarchal, monogamous family concentrating all resources in the hands of the father but also laying all the duties on him. His younger brothers could stay on the farm, but often they did not marry, unless they were able to establish themselves at least on a small scale. The housewife was responsible not only for the household but also for the cattle, sheep, goats, poultry, and kitchen gardens, which were the source of food, leather, cloth, and homemade utensils. This, however, did not give the housewife a strong economic position, because meat, milk, butter, cheese, and eggs in those days were not paid for in cash. Almost the only thing that brought in ready money was the sale of grain, and grain was produced by the men—farmhands working with oxen and horses. When the economy changed and the farms started to sell animal products, milk, and other items, the transports to and the contacts with the dairy-marketing organization were taken over by the men.

The members of the peasant families, it seems, had security but little freedom, and there may have been far more tyranny and restriction than might be imagined.

The families of the craftsmen and merchants in the towns had a similar division of labour, since they too produced crops and raised animals. As a rule, the households also included journeymen, apprentices, and servants.

### THE ONSET OF INDUSTRIALIZATION AND URBANIZATION

The peasant family pattern in England, which stressed the need to keep the family farm in the hands of the eldest brother, seems to have stimulated the migration of the younger ones to the growing industrial centres; and, according to Habakkuk, the same tendency was evident in Germany, where the younger children of peasant families did inherit but got their share in cash and then tried to establish themselves elsewhere. If the children had equal rights, however (as in the regions under the Code Napoléon, they tended to marry and remain in the village, though they might work elsewhere for seasons or short periods to supplement the meagre family income or even to buy land to enlarge their holdings.

Industrialization often started as domestic industry or small workshops in areas where equal inheritance rights had divided the farms and forced the peasants to look for extra incomes. But large-scale industries had to be located in areas to which a reserve of farm hands could be induced to migrate permanently. Low-wage, large-scale industries would obviously have little chance against domestic industries in such countries as Russia, where the extended family was strong enough to keep its members together.

It is evident that industrial centres and towns mainly attracted unmarried and comparatively poor youngsters as permanent residents. These people did not necessarily break off communication with their families, but the family lost its grip on them; and if they managed to adapt themselves to working in town, they had little benefit from their family there. The family's claims and its lack of understanding of their new situation were a disadvantage no longer balanced by any advantages. Moreover, the new class of industrial workers felt freer to marry and have children, and their high rate of fertility soon made migration from the villages less vital for the process of industrialization.

Overpopulation and poor harvests could cause the mechanism to break down, however, and trigger great waves of migrating peasant families, from southern Germany at the beginning of the 19th century, from Ireland in the 1840s, and from Scandinavia later on, all moving to European cities or overseas to such lands as the United States.

The old family pattern in the United States was originally brought by the British colonists, but the transfer to

The family  
in the  
Industrial  
Revolution

the New World added new elements. Women, being fewer in number, achieved comparatively high status (though, as elsewhere, they were excluded from the right to vote). Religious social control was strict in Eastern areas, but on the frontier compromise became necessary.

#### MODERN SOCIETY AND FAMILY

Sociologists, comparing the preindustrial family pattern with the modern Western one, point out that men now work in factories or offices, not at home, that they receive their wages in cash, and that the family is no longer a producing but only a consuming unit. (There is even a trend toward letting industry take over much of the preparation of food.) Nor is it possible for the family to provide adequate care for the old and the sick; society has stepped in, providing hospitals, medical care, and special homes. The difficult task of socializing children is taken over by day nurseries, which are becoming more common as more mothers take work outside the home, and by the school system, which even provides school meals. Finally, recreation has been largely removed from the home by the entertainment industry.

The family has a number of functions left, however; it provides its members with a place where they are met with affection, where, in theory, they are protected from the stress to which they are subjected in their work and in the community, where the devotion between husband and wife can be expressed, and where they can have children and care for them. These functions are becoming more important as the family gives less attention to other things.

Sociological reasoning of this kind is based upon the fact that certain types of behaviour within the family are becoming less common, and others are becoming more common. In other words, there is a change in the functions of the family. But the emotional ties between husband and wife remain, as does their sexual behaviour. Children are still born within the framework of the family and receive within it care and security, something that seems to indicate the survival of the family and its emotional, sexual, and nurturing functions in the future.

This picture is simple only because all complicated data have been excluded. The Western rural family has been regarded as patriarchal and self-supporting, firmly anchored in its kin and its community, taking care of its members and representing the "good old times." Reality must have been considerably more varied and often difficult to stand, even if people did not have the schooling required to verbalize their sense of deprivation as far as consideration, comfort, and privacy were concerned.

### III. Development and organization of the modern family

#### MECHANISMS OF MATE SELECTION

**Customs of dating and courtship.** Today's generation of young people seems to be evolving new patterns of developing contacts leading either to temporary liaisons or marriage. The patterns contrast with the one usually attributed to an earlier generation. In the former system (which is still widespread), *dating* was seen as an initial phase of marking available partners and testing them in standardized situations, which sometimes included sex relations. Once a boy and a girl started going steady and gave up dating others, they had advanced to the second phase, *courtship*, concentrating their attention and expectations on each other, trying to adjust to each other and to be accepted by each other's parents, to get a degree, a job, and so forth—goals often not easy to coordinate. Courtship might be officially recognized as *engagement*, meaning that the partners had given each other promises, exchanged rings, and the like; this ceremony was very important in northern Europe, for instance, because it gave more scope for sex, but its importance is now declining. In this "traditional" system, the success of a courtship is judged solely according to the outcome: did the partners marry? No consideration is given to whether the persons involved used this time really to seek emotional, social, sexual, educational, or

economic adjustments or to find out on what points they differed irreconcilably.

These norms now seem less relevant to many of today's adolescents in their frantic search for emotional experience and contacts, for understanding, fun, and love. In the future, those who study the family may have to find a new design or pattern and study (1) the adolescent "contact pools," (2) the adolescents' peculiar evaluation of traits in dress, music, slogans, politics, and philosophy, and (3) their intellectual, emotional, and sexual partnerships, which are formed, broken, and reformed and in which intellectual factors seem to mean more and sexual contacts less than adults believe, since sexual contacts are often no longer considered the crowning experiences of togetherness. Partners needing security may choose to live together permanently, have children together, marry before or after doing so, leave the contact pool or stay in it notwithstanding. This pool of theirs, however, will soon become more or less segregated from younger pools, and all the time it will be shrinking in size as more hopeful couples or resigned individuals depart and only a small number of them return. In any event, the whole evolving pattern (or patterns) is unclear and difficult yet to systematize for examination.

**Matrimonial agencies and marriage arrangements.** Parents, having made many adjustments before or after their own marriage, are usually eager to hand on this wisdom to their children, who often doubt its relevance. Up to a point, parents are still able to arrange acceptable contacts by giving parties, taking their children with them to the right social gatherings, and so forth. They also use subtle techniques to encourage desirable contacts and discourage less desirable ones. This influence can still be effective, especially when the parents of the desirable partner willingly cooperate in the "matchmaking." In modern society, the choice of marriage partner is still considered one of the big decisions in life, and researchers have therefore studied selection and adjustment in courtship and marriage, pointing out the similarities and differences between partners that they maintain are important. These "prediction data" are then used in lessons on the problems of family life, in social work, and in counselling people seeking advice or contacts. On the basis of such data, official and private agencies give advice about the selection of a partner or about the process of adaptation and may even pair off suitable partners by registering clients and arranging for certain ones to meet.

**Customary factors of selection.** One's own selection of a marriage partner is usually restricted to the people one meets (one's own family excluded), and the more often one meets them the greater chance one has to discover and appreciate their merits, to demonstrate one's own merits, and to succeed in attracting the desirable partners. Casual acquaintances are thus weeded out from the selection process, and those who are left tend to live in the same neighbourhood, to have the same working hours, to work at the same place and in a similar type of job, to be about the same age, and to have the same interests, the same kind of education, and the same religion, ethnic background, friends, and social class; and all these tendencies must emerge according to the distribution pattern of social contacts.

There is, then, a general tendency to select a marriage partner of the same quality and social class, a tendency called *homogamy* (*homos*, "like"; *gamos*, "marriage"). The homogamous tendency, however, is often weak and sometimes even reversed: a man may compensate for his lack of youth by displaying a high income or compensate for a low income by displaying a good social background; girls use their looks for general compensatory purposes. But in some cases "opposites attract": dominating men, for instance, may prefer submissive women rather than willful ones.

In Western cultures the two partners are expected to be in "love" with one another. This is sometimes carried to the extent of believing that everyone has her Mr. Right or his Miss Right waiting somewhere. They are meant for each other, and the moment that they meet their hearts

Romantic  
love

can tell. It is disheartening if only one falls in love, not the other. Romantic love often gives rise to very strong expectations that generally have little to do with reality.

All partners ought to have something like the same opinions on procreation and parenthood. How many children? How shall they be spaced and how educated? These are points that the partners must agree on from the beginning or be able to compromise on—if they are going to be successful partners. If they marry despite differing opinions, they probably run a far larger risk of maladjustment and divorce.

Economic considerations are important and were even more important formerly, when the husband had to be able to bear the financial strain of a wife, home, and children, *before* he was ready for marriage. Now in developed societies the wife often has a job, too, and if necessary she can go on working. Should something serious happen to the family, modern society generally gives considerable assistance, and it is therefore no longer necessary to have financial reserves sufficient to meet all eventualities.

Another aspect to note is that strong social values are vested in the family: "socially valuable" people generally are expected to make a good marriage, and if they are either single or married to the wrong person, this often is taken to show that something is "wrong" with them. People eager to make a career therefore tend to marry with an eye to their partner in utility. The politician, for instance, usually must be a marital model in every respect; his wife, too. They must have the right kind of happy but in no way peculiar life, a nice comfortable home, a reasonable number of children who behave like other children, and so forth. The businessman needs a perfect hostess, either in the bright cocktail-party style or in some other useful area of service. Military officers often need a wife trained in the traditions and helpful as a channel for information and intrigues in the female side of the base. The ambitious female partners, as a matter of fact, sometimes seem to select men whom they can promote by their contacts and abilities, thus promoting themselves at the same time.

But partners may not be selected only because they seem to be good tools or investments; they may be the owners of power to be wielded, money to be used, or social contacts to be enjoyed. These direct advantages are usually evident to both partners, however, and the partner wanting them but lacking them has to compensate with other goods.

**Uncustomary marital trends and patterns.** The pattern of homogamy and marriage during young adulthood is strong, a fact reflecting the strength of the supporting social norms. Thus exceptions are few: young people under the age of 16, for instance, are rarely allowed by law to marry; couples who have passed their 50s are free to marry but are somehow considered overripe, if marrying for the first time. A partner far older than the other is often considered odd (especially if it is a woman), and there is suspicion that one is exploiting the other. Statistical data show that such marriages occur infrequently: in about 2 percent of the marriages in Sweden in 1969, for instance, both partners were under 20 years of age; in 2 percent both partners were over 50; in a little more than 3 percent the bridegroom was at least 10 years older than the bride; and only in rare cases were brides more than 10 years older than their husbands (that is, in only one-fourth of 1 percent of the marriages).

These social norms vary of course from one ethnic or cultural group to another. The Lapps in northern Scandinavia sometimes marry very early, and the law makes provision for them. European Gypsies follow a similar pattern but have to circumvent the law or get individual exemption. (In Europe the trend toward younger marriage partners is very pronounced, and family law has changed in this direction in some countries.)

In countries with several religious, ethnic, and other distinctive social groups, there is a tendency to avoid intermarriage between the different groups when one group

enjoys more esteem in the society than the other. The members of the under-esteemed groups generally do not accept the low evaluation of themselves and are unwilling to compensate for a disadvantage based only on prejudice. They therefore prefer to marry within their own group, where they can get full value for their own marriage merits.

The general disapproval of illegitimate births and unmarried mothers tends to make such phenomena commoner among lower social classes, people in slum areas, underprivileged ethnic groups, younger age groups, and so forth, since all these groups are less restricted by sexual and social norms, feeling or believing that they have little to lose. Many very young brides, for instance, are pregnant, their pregnancy being just the reason why they break the convention about marrying early; among the brides about 20 years of age, the percentage who are pregnant is still comparatively high, but the percentage drops in higher age groups.

Disapproval of pregnancy out of wedlock is directed in the first place at the girl, in the second place at the boy, who has the chance of remedying the situation by marrying the girl. In some Western countries, in spite of the oral contraceptive "pill" and other contraceptive techniques, the number of illegitimate births increased during the 1960s—partly because so many young couples lived together, had children, and brought them up without bothering about wedding ceremonies. More recently, however, the trend has seemed to reverse: the number of births and especially illegitimate births among young girls has been decreasing, probably owing to more regular use of the pill.

#### PREPARATIONS FOR MARRIAGE AND THE MARRIAGE CEREMONY

**Religious factors.** The marriage ceremony and the vows given emphasize the bonds between husband and wife, their duty to share responsibility and to support their family according to their ability. These obligations are not always respected in practice and thus require strengthening by the formality of solemn promises given in front of witnesses.

The status of the marrying couple within the religious community depends to some degree on their ability to satisfy the norms of their church: they should belong to it, look happy, have the right clothes, the right attendants, and behave so as to revive sentimental memories in the married onlookers and strengthen the romantic wedding expectations of the unmarried. Even in a country like Sweden, where status in the congregation means very little, religious factors still strongly influence the image of the happy bridal couple: a very high proportion of marriages take place at Easter and Whitsuntide, important Christian festivals.

**Civil factors.** Traditionally, a wedding not only united the bride and groom, but also brought the two parent families and their kin together. They had to meet, to see one another, and to show that they accepted one another; and so the wedding became a feast, a demonstration of social background and resources in respect of food and drink, of clothes, looks, and *savoir vivre*, whereby the two kins formed two teams in a social game, to appreciate one another but not to be outshone by the other team. As a married couple, the bride and groom had more status than they had when unmarried; and they left their old peer groups, sometimes after send-off parties, to take their place as fully fledged members of society. In the upper classes, the initial difficulties in adjusting to each other were eased by a wedding trip, a honeymoon in a different environment, far from interfering busybodies.

All these civil factors are important only if the bride and groom are both marrying for the first time. There is a tendency to shorten the engagement and cut down on the ceremonies if the bridegroom has been married before, and this tendency is even more pronounced if the bride has been married before. This simplification of the civil ceremonies indicates that those not married before have a higher status on the marriage market.

marriages

**MARITAL AND FAMILIAL DYNAMICS:  
THE FAMILY LIFE CYCLE**

Dating and engagement are said to facilitate adjustment between the prospective husband and wife and should at least allow them to verbalize their expectations vis-à-vis each other regarding house, home, and children and to form their patterns not only of persuasion and compromise but also of conflict and conflict resolution in everyday life. Some of these patterns they have learned at an early age from parents, sisters, and brothers, and such patterns often persist even when they are said to have been given up. Other expectations and patterns the couple take over from society in general: a husband should bring home an adequate portion of his pay, be faithful to his wife, and love his children; a wife must be a good mother, a pleasant and faithful companion, and so on, although such expectations are not easy to live up to in practice and seem old-fashioned when they collide with ingrained bachelor ways or some modern life patterns that, for instance, stress the married woman's duty to be gainfully employed, politically informed, as well as interested in literature or music. But then, most couples, once married, quite quickly fall into the traditional behaviour connected with the home, food habits, and so on—so quickly indeed that these tendencies seem to have been there all the time, although temporarily hidden. The transformation is probably bound up with a change in the forms of social intercourse. Once the couple have acquired a house of their own, they invite people in and expect them to admire it and to pay them back with the same kind of invitations. Because their unmarried friends tend to give them up (and vice versa), they are generally restricted to other young married couples who "share their interests"; adolescent patterns depart, and usually only the new patterns survive that have been adopted by most other couples. Lately, however, young couples seem to maintain better contact with their old friends and to take less interest in the "home"; and consequently there are now more new patterns among young married couples (one of these being, at present, the tendency to form families without getting married).

Psychologically the first period of adjustment in marriage seems to demand more of the wife than of the husband. He has to reduce his personal expenditures, to postpone decisions in order to let his wife take part in them, to bring his expectations regarding sexual satisfaction down to a realistic level, and so forth. His wife has not only to make the corresponding adjustments but also generally to cope with the household, buying and preparing food and using her taste in decorating the home—all behaviour that tends to put the wife in a subordinate position trying to serve, entertain, or influence her husband. Today these traditions are counteracted by strong tendencies toward equality in interaction, not only in the sexual sphere but also in those spheres that have always been considered female monopolies and therefore of little value—repairing clothes, dressing the children, and the like. These tendencies toward equality seem to be far stronger in the higher social classes than in the lower ones and seem to be associated with modern higher education.

Sexual intercourse may lead to pregnancy, but this chance can now be reduced or eliminated by using the pill or other contraceptives. Couples using them are thus able to postpone having a child, to determine the intervals between their having children, or intentionally to stay childless. At the other extreme, couples who desire pregnancy but have problems of sterility or infertility can resort to various drugs to improve or restore fertility. All such choices are influenced by social factors, because most people are eager to behave according to the social norms of their groups—or at least eager to say they do. Thus family planning is generally commoner in cities and among the upper classes. Significantly, though, in Sweden and parts of the United States, the upper classes have tended to plan and have *many* children, whereas the middle classes with their smaller resources have planned

and had fewer children and the working classes still fewer—unless their resources have been so poor that they could not plan at all and had many children.

If a couple do have children, they then face the problem of raising them. Traditionally the father had the role of presumed expert in technical matters, sports, books, and so on, and this gave him an instrumental role as a leader, giving orders, making decisions, showing or telling people what to do and how to do it. The mother's role, on the other hand, was more "expressive," showing sympathy, giving support or consolation, releasing tension, joking. When married women also work outside the home, this gives them rather instrumental roles in their jobs and leaves them so little time at home that they have to adopt an instrumental role at home too, giving orders, making decisions, and having too little time to establish emotional contacts. It may then be that some husbands have more time to establish more expressive roles, reading stories, listening to the children, and so forth. The traditional allocation of roles is thus no longer always applicable.

The roles played by various members of a family change with the development of a child. The baby is closely related to its mother and to hardly anyone else until it needs less physical care, when the father and later its siblings are also able to give and receive affection. But the interaction changes all the time as the infant gets older, picks up new roles, finds its peer groups, goes to school, and then, as an adolescent, starts to take over the same adult role as the parents. At this time the parents should be able to accept the child as a responsible, mature person, although this means that they have to give up their roles of father and mother. Some parents are unable to make this adjustment; mothers, for instance, try sometimes to prevent their youngest sons from assuming this final adult role.

Because people now marry earlier and have children earlier, families tend to see their children leave earlier. Fathers seem able to stand this better than mothers, and mothers who have activities outside the home better than those who do not. But parents may have a married child return to the home, and they may have to look after their grandchildren if the mother in the younger family has a job or becomes ill.

The child-launching stage—when the child goes to college or takes his or her first job and finds a place to live—is not only the end of a role for the parents but also a trial: how should one behave in a new situation with new role expectations? The parents still exercise some control, use the telephone, write letters, expect letters and reports and so on; but this kind of control diminishes, and when the child marries it should disappear, unless an overambitious parent-in-law tries to take command in the new household as well.

By the time the children have left the home, the parents are generally middle-aged or old, their sexual activity and their energy reduced. They tend to give up goals exposing them to too much stress: a new business career, political engagements, and so forth. This pattern of retirement or near retirement is of course convenient for those who feel old and worn out, but it may be very disturbing for those who are—or consider themselves to be—fit for a long time yet. They often are very fit, but modern industrial society, which stresses social mobility, usually favours young, aspiring leadership rather than age and experience.

The retired husband (or wife) generally restricts his (or her) activity to the home and thus might upset the pattern of behaviour there, at least for a while. Old age affects the retired couple, of course, their interests and their health. The children sometimes let their parents live with them, especially when they have become seriously incapacitated. Grandparents seem to adjust more easily to life in the home of a daughter than in the home of a son, where the danger of tension arising between wife and mother-in-law seems to be greater. But grandparents living in a family seem on the whole to affect the family atmosphere favourably. Data seem to show that mothers

are more stable when they have the help of grandparents and that children are treated more affectionately when a grandmother lives in the house. Grandparents and grandchildren seem to have some ground in common: both are centred in the home, away from the bustle of competitive society, which they regard with some fear and suspicion; both have time for and a need for contact.

#### ROLES AND ACTIVITIES THROUGHOUT THE FAMILY CYCLE

**Sexual aspects.** Sexual activity is in part a function of age. Alfred Kinsey, in his measure of male sexual activity, found a maximum number of orgasms at about age 17, after which the rate slowly decreases. The corresponding female curve had a later maximum and dropped more slowly. Kinsey was of the opinion that the drop was due more to the men's declining activity than to the women's.

Married men and women are sexually more active on the average than unmarried, partly because of selection (the active ones are usually more eager to get married), partly because of more frequent opportunity. Probably this difference is now smaller than it once was, because the pill and other contraceptive techniques have made coitus less risky and possibly commoner among unmarried, especially young, people. The average age at which young people make their sexual debut seems to be going down.

Familial  
division of  
labour

**Economic aspects.** Traditionally the husband has been the breadwinner and the wife has taken care of the home, the household, and the children. In the upper classes, a wife, home, and family are often adjuncts to the husband's career. Among those women with academic training in western Europe, however, there is a strong tendency in another direction: the wife considers her own career and salary just as important as her husband's. More women today retain their jobs after marriage and after childbirth. Working wives, moreover, tend to have fewer children, though cause and effect may be confused here, since wives with few or no children have less reason to stop working.

In the lower income classes it has generally been taken for granted that if the husband could not earn enough, his wife would have to take a job. But as living standards have risen, the better-paid workers have been able to afford to keep their wives at home—and have generally wanted them there. Sometimes, however, the trend seems to move in the opposite direction, at least in western Europe. During periods of labour shortage, married women are tempted by high wages to take jobs away from home. Nursery schools and similar social agencies have thus been organized on a large scale to take care of the infants; schools have often taken over the task of providing the pupils' lunch, thus absorbing another maternal task. Besides, the younger generation of wives have often accepted the idea of equality and have acquired an education that makes them almost as useful on the labour market as men. Such wives might feel frustrated if restricted to the home and so are inclined to take work outside the home in order to secure social contacts.

In poor families, children are frequently expected or forced to supplement the meagre income as soon as the law and compulsory school attendance permit. In such families, the youngest child is usually in the most favourable position and may even get an opportunity to acquire a higher education.

As the standard of living rises, a progressively smaller part of the income is spent on food. Recently married couples have to acquire a home with the usual capital goods. This takes time and money. The husbands have to give up their former expensive forms of recreation and adapt themselves to their family obligations, some changing into "experts" on household machinery, house repairs, and the like. If they become householders, they often remain in the "do-it-yourself" pattern for the rest of their lives. Otherwise, this object-oriented phase may pass with diminishing financial difficulties, and they can again turn to recreation, travelling, and fishing.

Many of the younger generation now seem to be ori-

ented toward experiences instead of toward objects. Emotions, new contacts, and ideas are important to them, not expensive clothes, cars, or gadgets.

**Patterns of power distribution.** Decisions in the family depend on the particular behaviour concerned, on the situation, on the traditional leadership in the family, and on other such factors. But the formal decisions made by the leader of the family have very often already been determined by the other members and by the situation. Probably the patterns of "patriarchy" or "matriarchy" are oversimplifications in most modern societies, since most family decisions are made as the result of interaction between members of the family, not as the result of argument; decision making proceeds unconsciously as members demonstrate their own needs and resources and find out one another's needs and resources and so come to a tacit understanding. Even in Japan, for instance, the traditional strict hegemony of the husband and father seems to be slowly eroding under modern pressures.

Traditionally the husband is granted more power or deference in the family, but there are limits to his power, and there are large areas that are closed to him. Should he go beyond them, he would not be obeyed. Similarly, the wife's decisions in the home may give her a dominant position but not for all activities and not contrary to the expectations of the family. In practice, modern society thus tends to reduce the distinction between husband-dominated and wife-dominated families because most families come fairly close to a decision-sharing pattern. On the surface, however, the upper and middle class families seem to have less husband dominance, working class and farmer families more. A large proportion of young families accept the idea of decision sharing.

**Household tasks and their distribution.** Interview data show that husbands are taking over more and more household tasks, especially in young middle class families in towns. Probably the husbands accept their fair share of the household tasks, and this share naturally grows considerably if the wife has a job. (In some countries, such as Sweden, however, wives with just as many working hours as their husbands still tend to do a much larger part of the household tasks.) What are the husbands' new tasks? To begin with, they have taken over such jobs as using household machines, polishing their shoes, making their beds. They also often try their hands at cooking and at buying the food. In modern families, the husband might cope with the baby, changing its diapers and preparing its bottles.

One would expect families with working wives to have more household machines and more rationalized tasks. This seems not to be the case. They spend less time on cooking and washing up, but this is due only to the fact that they seldom have lunch at home. They also spend less time on their children, mending clothes, sewing, sleeping, and so forth as their time is too short.

In large families, the older children are expected to take over some tasks, but evidently this is more an ideal than a reality, at least insofar as the boys are concerned.

**Social activities.** The neighbourhood is important to the pattern of the family's social activities, and families are therefore eager to find the right kind of neighbourhood with a school that suits their children, a church adapted to their need for new contacts, women's activities for municipal reforms, and so on.

Generally, young people moving into a new residential area stick to their old friends in other areas to begin with, although they tend to cultivate their old contacts in the new surroundings. Gradually day contacts may become evening contacts, new acquaintances are picked up in local group participation, and slowly the old contacts outside the area shrink, unless they are fortified by business dealings or strong interests in common. (Housewives, of course, often make contacts with one another during the day, take a cup of tea together, borrow small things, or take care of each other's children. These day contacts need not develop into evening contacts—ones, that is, that include the men in the families.)

The geographical mobility of modern families would

The role of  
the neigh-  
bourhood  
and geo-  
graphical  
mobility

seem to influence their social activities considerably. Upper and middle class families tend to move more than working class families, who are consequently better able to keep their contacts intact, not only with their neighbours but also with relations living in the same area. Working class social life may therefore be seen as a last reminiscence of the former upper and middle class "society life," in which formal dinner parties were given, and relations, neighbours, and business acquaintances were brought together in a home organized for this type of entertainment, with a drawing room, a parlour, and a dining room—the family thus having to live their everyday life as best they could in this show place planned for guests and banquets. The old "society life" pattern disappeared in Europe during World War I.

**Educational aspects.** Education, as noted earlier, is an important factor in mate selection, and thus husband and wife tend to be on the same educational level. Couples on higher educational levels not only provide their children with a more intellectual milieu, more books and so on, but also expect them to get good marks at school and to go on to college or even to graduate studies. Parents seem to consider it a duty to push their children through the same school examinations that they took themselves—or, if possible, better ones. Although this might be taken as a hopeful identification—that one's children should succeed better in life than their parents—it could just as well be regarded as a means of safeguarding the social status of one's children, of making it possible for them to remain in the same social class or to climb a bit higher; for these purposes education is certainly a great help.

Upper class children on the average receive better marks in elementary school than working class children, and consequently a higher percentage of them enter higher schools. Even among children of the same intellectual achievement, judged by their school marks, the upper class children are far more likely than the working class children to enter higher education, partly because of economic factors, partly because of a more ambitious attitude among upper class parents.

**Community aspects.** The family is responsible not only for socializing the children but also for ensuring that all members conform to or share certain basic values. If the family is too divided, with the members openly quarrelling or even fighting, neighbours and friends reduce their interaction with it and avoid giving gifts and kindnesses, since these could be seen as siding with one party against another. Such a family, then, is excluded from the reciprocal exchange of services and obligations. On the other hand, families with so much loyalty among the members that they isolate themselves and withdraw from community activity are not appreciated either. Such families may be forgiven, at least for a time, if they can make an acceptable excuse—an excuse such as a very difficult task to be performed, prolonged illness, or serious family problems. And in the worst cases, the community may intervene and give social support or even therapy to families in need.

#### CONFLICT, CRISIS, DISSOLUTION

No family can escape conflicts, but each family has its own way of handling them. Generally a serious conflict makes the family leader eager to close the ranks of the family and try to persuade the member or members at the centre of conflict *not* to confide in others, especially not to outsiders. Usually only then can some compromise be reached. If outsiders—even counselling agencies, doctors, and so on—are brought in loyalty tends to die. The family leader may then get into difficulties and even lose the position of leader, which in turn may break up the family.

Consequently, social agencies that are trying to protect the rights of weak or very young members of the family sometimes find that instead of uniting a family in conflict, they cause it to break up. Even help in the form of money, however necessary, might dethrone the family leader from the position of breadwinner. Legal help may

do the same if it demonstrates the inability of the leader to cope with the circumstances in which the family finds itself. It seems that only the leader can bring in help from the outside to solve troubles without endangering the family unity.

**Economic problems.** Unemployment, if it hits the male breadwinner, not only threatens his leadership in the family and the family's standard of living but also forces other members of the family out onto the labour market, where they may have a better chance since women and young people are paid less and are more vulnerable to demands for extra service. If the wife has work but the husband has not, the rational solution would seem to be that the husband takes over the household tasks. Modern young couples sometimes adjust in this way, but in older generations it was too degrading to the husband. He left home "to look for a job" and if he could not find one, he might leave the family and not return. Very poor families in the cities often seem to break up this way, if the husband is unable to secure a job.

Even if the male breadwinner has a job, this is no guarantee that the family will be spared quarrels about money. He may keep too much for himself, or the wife may ask for more than he has to give. Most wives are not happy if their husbands have too strict a control of the expenses; thus if squeezed too hard between a tight-fisted husband and nagging children, wives sometimes take a job to obtain money that they may use as they wish. Quarrels about money, in any event, are not only frequent but also difficult to solve.

**Child problems.** One of the reasons why people want children is to have their expectations fulfilled. It is a hard blow, for instance, to get a mentally retarded child who is unable to live up to these expectations and yet is in need of love and care. Most parents react in a very primitive fashion in this situation and try to deny the problem: "If we only wait, everything will be all right!" They often do not dare ask the doctor or bring in experts, because they are unable to accept the truth, in spite of their suspicions. When they finally have to face it, they feel it is unfair. Why should this happen to them? Then comes the suspicion that after all they may have done something to cause this situation. They feel guilty. As few people are able to stand guilt of this kind, they tend to transfer it to others. Perhaps the physician made a mistake. Perhaps one's spouse may have been careless on some occasion. Part of their reaction is directed toward the retarded child, but generally such a reaction is transformed into overprotection. Marriages with retarded children are probably less stable than other marriages, because the strain is far greater.

Maladjusted children also cause feelings of guilt in the parents, and indeed maladjustment in children in many cases is the result of maladjustment in the parents, who may expect unreasonably much from their children or behave asocially themselves at home. In trying to adjust to such pressures, the children may develop symptoms that protect them against violence and impossible demands and that are sometimes even useful in keeping the family together; but it is also possible that these symptoms may destroy the child's chances of adjusting at school, in the neighbourhood, and in society in general. Counselling agencies sometimes find that if the maladjusted child can be cured, or if he is taken away from his parents, the family is unable to survive losing its scapegoat and breaks up, or, alternatively, some other member goes to pieces. Delinquency among children is commoner in slum areas, cities, and lower social classes, but its occurrence in well-to-do families can often be diagnosed as a reaction against a lack of emotional warmth or a reaction to rigid discipline. But these factors are found at all levels of society.

**Individual parent problems.** The home and the family can be used as a repair shop by breadwinners who are subjected to stress at work, but the breadwinner with troubles at home seems to run greater risks of alienation and accidents in the job. Generally, however, work outside the home makes it easier for the breadwinner to

Problems involving retarded or maladjusted children

Problems of husband and wife

survive family troubles, at least so long as they are of moderate proportions.

Housewives and family members who are at home all day tend to be more emotionally involved in the family and therefore more dependent on the interaction there, more vulnerable when members of the family meet with accidents, contract mental or physical illnesses, and so forth. It is then assumed that the housewife will take care of them. If she has a job herself, she will probably have to give it up temporarily or feign illness herself in order to nurse the victim and administer the traditional cures or the doctor's prescriptions. Should a family member die, the wife tends to feel more guilt and generally has less chance of having her attention distracted by other things.

Family members who are chronically ill are difficult to take care of in modern homes, and so the severe cases are placed in institutions. There again the housewife feels more responsibility for keeping contacts alive. This does not mean that the husband evades responsibility, only that he acts in a less emotional, more intellectual manner and that he has to give his support and understanding to his wife if she is to be able to stand her own feelings of guilt and sorrow.

**Husband-wife problems.** Generally, people marry because they have a good relationship and expect that marriage will make it still better, giving them more opportunity to meet, love, help each other, and have children, thus fulfilling their desire for recognition and success. They bring with them from their parental homes, however, a set of expectations and ideals that are scarcely known to themselves, although they are strongly influenced by them in their behaviour in the home, especially toward their children. These expectations can be so impossible to meet that the marriage proves to be a serious disappointment even in the first months. The husband may have a strong need to assert his will in all details, or the wife may want a perpetual courtship with compliments and overwhelming recognition on every occasion, sulking if she does not get it. The partners are seldom able to recognize their own individual patterns but prefer to rationalize, making the other partner responsible, pointing out his or her thoughtlessness, mistakes, or intentional rudeness. Generally at least one partner tries to adapt, but when his or her disappointment becomes sufficiently great, the scenes begin to have an effect and the weaker partner may be forced into desperate resistance, so that a kind of terror balance is achieved.

Most marriages have some tendencies in this direction, at least when one of the partners is depressed or worn out. Children often give rise to new sets of expectations. The unsuspecting father may be disappointed to find that instead of being a convenient plaything, the baby cries, takes a lot of time, and breaks up the former leisure pattern. The husband may even feel neglected and jealous if his wife is completely absorbed as a mother. Later, alliances between one of the parents and the child or children can alienate the other parent. This, of course, is a risk run to greater extent by the father since he has less time to invest in the children and is often forced to make up for this with gifts or money. If the alienation is great enough, the alienated partner may desert the family.

Newly married people often expect an unreasonable amount of sexual gratification. Unsatisfied with the limited amount available or unsatisfied with the personal relationship that they have found in their marriage, they may sometimes establish extramarital associations. Kinsey found in his studies of the U.S. population that about one-quarter of the married men (one-third of the younger married men) turned to other women. Ten percent of married teenagers' intercourse was with other women, a figure that dropped to five percent for those who were 45 years old or more. The corresponding figures for married women were low for wives under 25 but rose to more than 10 percent for wives over 40 years of age. Probably the figures for adultery are higher now in the United States, as elsewhere.

Extra-marital relations

**Separation.** Separation means that husband and wife have agreed to live apart or that one of them has gone to court in order to have an agreement drawn up regarding the financial support of wife and children or the custody of the children. Separation does not allow the partners to remarry and is only a relief from a marriage that demands too much or gives too little.

In some countries, in Scandinavia for instance, separation is a first step toward divorce and is meant to give the partners at least a year to try out the economic and emotional consequences of living apart. If they move together again, the separation is nullified.

#### DIVORCE

**Distribution.** The frequency of divorces varies with the divorce laws of the country concerned and with the attitude toward divorce. Legislation not only affects behaviour but is itself affected by a number of circumstances that the lawmakers have consciously or unconsciously taken into consideration—such things as old customs and usage and, above all, public opinion. (For the legal aspects of divorce, see FAMILY LAW.) People who have been granted divorces must be able to go on living in their communities without being rejected or put in a position in which they cannot make a living for themselves. Industrialization has made it easier for women to support themselves, whether they are single, married, divorced, or widowed. In this connection, it is interesting to note that the Great Depression of the 1930s stopped the rise in the number of divorces in the United States for a time.

The frequency of divorce partly depends on the changing structure of the population. Because people tend to live longer and to marry earlier, marriages are exposed to danger for a longer period. The more people marry, the more marriages are exposed to danger, and a high marriage rate probably brings with it a higher frequency of risky marriages. Divorces are more frequent in cities than in rural areas, and the continuing immigration to cities may increase the frequency.

Public opinion may be more tolerant toward divorce now, but it is still considered a sign of maladjustment and consequently can be expected to be more common in slum areas and lower social classes. This, however, is counterbalanced to some extent by the fact that legal action demands a lawyer and some money, something a family with little economic latitude has difficulty in mobilizing.

Religious groups generally have a more uncompromising attitude toward divorce and thus a lower divorce rate. People in some occupations—clergymen and teachers, for instance—are expected to behave perfectly in their family lives; divorce might force them to change their profession. In the United States, politicians and high military officers have a similar disinclination for divorce, but in western Europe, such professionals deviate hardly at all from the common upper class pattern. Actors, authors, and other groups that have many contacts with the opposite sex and only slight control by colleagues or relatives tend to have a high divorce frequency. Data from Sweden indicates high frequencies for actors and artists (21%), authors and journalists (16%), athletes (14%), and officers (13%), and low frequencies for diplomats (7%), engineers (7%), clergymen's sons (6.5%), farmers' sons (6%), judges and magistrates (5%), teachers (4%), and clergymen (2%). These data, however, hold good only for prominent persons listed in *Vem är det?*, the Swedish equivalent of *Who's Who*, and only for the facts reported by the people concerned. The women in *Vem är det?* form a comparatively small group, dominated numerically by actresses, and this group therefore shows a divorce frequency far above the men's. Younger age groups, finally, tend to have a higher divorce frequency than older ones. Most youthful marriages, it should be remembered, were contracted because the girl or woman was pregnant.

The number of children in the marriage is also influential. Childless couples tend to have a higher divorce

Changing mores regarding divorce

rate than couples with children. But couples who drift apart rapidly are probably careful not to have children. Childlessness can be a cause of divorce, but it can just as well be a consequence of the disharmony that eventually leads to divorce.

**Social and psychological effects.** Emotional ties are nearly always complicated in a marriage and may include such elements as intense aggression or serious masochism. Such elements deeply influence the interaction in the family, creating tension, feelings of guilt, or even open clashes, which, when acted out, bring some relief—at least temporarily—to the actor, but deeply disturb the other members of the family. This may result in threats of separation or divorce being made by both husband and wife, even though the aggressive or masochistic partner making or provoking such threats may be deeply attached to the other partner. If such a marriage breaks up, the more aggressive partner may find it exceedingly difficult to readjust and may feel very guilty, probably trying to put all the blame on the other partner. Most divorced persons exhibit weak but noticeable reactions of this kind and they are apt to act out their emotions, using their relations and friends as listeners or possibly as co-actors.

Socially a divorce generally disrupts the contacts between the former partners and the married couples with whom they formerly associated. Few former partners preserve respect and understanding for each other; generally they take a very negative view of their former partner and feel a need to have their friends share this view. People then feel forced to make a choice between the two and stick to it. Actually, the husband more easily retains the contacts resulting from professional interests; the wife the contacts dominated by domestic interests. (The children, too, are exposed to this competition for loyalty and tend of course to side with the parent who is given their custody, while at the same time they may try to preserve a tacit understanding with the other parent.)

Sexual adjustment after the divorce is likely to be difficult if the husband and wife have had a good sexual relationship that was suddenly broken by the separation. This, however, is unusual. Serious strife between the partners tends to destroy their sexual relations, so that the divorce seldom deprives them of a rewarding sex life. Before the divorce comes up in court, both partners have tended to avoid or hide sexual relationships outside the marriage, in order to improve their case in court. After the divorce, when they are free from such considerations, they often are unable to find acceptable partners whom they can trust and love and introduce to their children.

The divorce affects the children in many ways and may threaten their socialization if they are very young. This, however, may just as well be attributed to the strife leading to the divorce as to the divorce itself. Swedish data from a representative sample of Stockholm boys indicated that divorced families did not show a higher percentage of maladjusted boys than complete families. But, on the other hand, a group of seriously maladjusted boys contained a far higher percentage of boys from divorced families than the representative sample, 42 percent, compared with 13 percent. Probably very disturbed backgrounds were commoner among the seriously maladjusted boys, and divorce was just one of the elements in those backgrounds. It therefore seems that divorce need not increase the danger of maladjustment for the children, but it may be an indicator of serious trouble in the family, resulting in the maladjustment of the children as well.

Courts tend to entrust the mother with the custody of the children, unless there are serious reasons against this. Mothers, after all, are probably more ambitious as parents, but data suggest that boys who grow up with their mothers and without contact with their fathers or with other male behaviour patterns to follow may have difficulty in defining their own roles.

Most families readily accept divorce as a way out of serious conflict; they do not, however, like to think that their own conflicts are serious and they dislike divorce

among their friends. Families react as if divorce were a disease or a threat to their own solidarity. The divorced friends may be shunned or treated as failures in order to neutralize their bad influence. Husbands and wives who behave in this way may be afraid of losing their partners, but there may also be a strong, unconscious desire to get rid of them.

#### REMARRIAGE

A divorce, on the one hand, may be a traumatic experience that makes the divorced person unwilling to risk another marriage; or, on the other hand, it may be the first step toward a new marriage. Generally more than half of those divorced are remarried, with new partners, within a couple of years. This is partly due to the pressure exerted by their married friends—and indirectly by their own children. Divorced people are often treated as undesirably free agents, and at least the members of their own sex seem anxious to neutralize them as quickly as possible in a new marriage, willingly helping to provide acceptable contacts but withholding status and friendship until the scheme has worked. Children may also increase their divorced parents' willingness to remarry because the parent with whom they live has generally less time for them and a lower standard of living than before the divorce; above all, children are accustomed to and need contact in the home with a father as well as a mother.

Widows and widowers are subject to similar pressures to remarry if they are still attractive, if they have children at home to care for, or if they feel a new attachment would help them get over their bereavement.

**Distributional factors.** Remarriage is somewhat more common among widowers and divorcés than among widows and divorcées. Age is obviously an important factor: young people remarry much more frequently than do the old. Clearly, countries or regions with a high divorce rate tend to have a high rate of remarriage, too, because their attitude toward marriage is likely to be less rigid and provide more opportunity for trial and error.

**Considerations in selection.** Statistics on remarriage are not plentiful, and they are difficult to interpret, but one trend can be pointed out. People who remarry choose new partners who themselves have been previously married to a far greater extent than can be explained by chance.

How stable are these new marriages? On the average they run a greater risk of ending in divorce. The reason may be that the people concerned know how to go about getting a divorce, but it may just as well be that people who have found it difficult to live with someone else the first time may find it just as difficult to do so the second time. These two reasons do not exclude each other, of course; on the contrary, they may easily appear in combination.

A third reason for the instability of remarriages is the difficulty involved in marrying a woman who has previous experience of marriage and may also have children. A new husband may be—or may feel as if he is being—compared to the former husband (who seems to come off best in most respects) or, still worse, to the deceased husband (who is often beyond all criticism). The wife and her children sometimes get together and make the new husband an outsider who is allowed to provide for them, although he is never accepted as a member of their family. If he is accepted by the wife but not by the children, the conflict may be harmful to the children's social adjustment. A woman who marries a man who has been married before and has children faces corresponding difficulties and the extra burden of being a stepmother. The role of stepfather seems to be less odious in some way.

**Psychological adjustment.** The rewards of remarriage seem in the first place to be social ones: a person who remarries has fulfilled the expectations of society, relations, and friends, has done his or her duty to the children, and so is given full status again. The emotional

rewards may be just as satisfactory (a courtship, in some cases, may be the best way to forget the old ties and to cure psychological hurts); there is, however, considerable risk that the divorced person will still be emotionally tied to the former partner, not really caring about the new one, who was only accepted for social reasons. Any adjustments, however, may be easily disturbed, especially by children who jealously watch the stepparent, anxious to protect the rights that they have been given or have taken during a period when they tried hard to replace or compensate for the missing parent. In being forced to give up their heightened status, they may feel degraded, and they may put the blame for this partly on the intruder, partly on the parent whom they trusted but who they now feel let them down. The remarried parent in such a situation is caught between two loyalties. Conflicts of this kind are exceedingly difficult to resolve. The new parent is careful not to give open offense to the children but tends to exploit their indiscretions. The children in their turn try to avoid the stepparent and attempt to monopolize their own parent, who tries to play for time, hoping that the children will soon be out of the conflict.

#### IV. Transition of the form and structure of the modern family

##### SECURITY IN SOCIETY AND FAMILY

Reduced tasks or roles of the family

Modern societies try to protect their citizens against violence, distress, ignorance, and maladjustment. People are so anxious for this protection that they find it difficult to believe that exploitation, extermination, hunger, illiteracy, or vice on a grand scale need persist in their own society. But it can be argued that this unsafe world is safer than it has ever been before, thus making individuals in modern societies more independent of the protection and help of class, clan, family and peer groups. Evidently individuals should then be less dependent on the family and able to some extent to experiment with other forms of contact groups, not based on family ties. One possibility would seem to be the local work team, living in a collective, a *kibbutz*, or something similar; another possibility is the peer group forming a "group family," not winning their bread together but eating it together, having intellectual, emotional, and even sexual contacts with several other members. Intellectually such arrangements may have several advantages, but the difficulty seems to be that one's own individual process of growing up, in the overwhelming majority of cases, took place in a family and that one consciously or unconsciously tries to rebuild or recover the same constellation as that in which one advanced from the role of child to the role of adult. One thus finds it exceedingly difficult not to perform the tasks and not to demand the rights that one expects. This is above all the case in connection with the emotional and sexual monopoly of contacts with one's spouse and the role of pattern builder in relation to one's children.

##### THE EFFECTS OF TECHNOLOGY

Technology and society interact in a very complicated manner. Society eagerly accepts some technological innovations and completely disregards others, which often are just as useful. The technological innovations that are accepted may seriously affect or change industrial and agricultural production, consumption patterns, and ways of living.

Once the family was an important production unit; now industrialization and modern society have taken over most of its productive tasks. But efficient sales organizations have found the family a convenient target for their efforts, and mass media have found channels to the family's hearts and brains—or at least to the family's eyes and ears. Perhaps these tendencies can be interpreted as proofs of a new production era in the family; the technology of television, home freezers, washing machines, family cars, "do-it-yourself" kits, and so forth may give the family more tasks to perform together, more chances to survive.

On another level, however, technology often works in the opposite direction. New machinery and new factories generally are located in new areas, forcing employees to move from their families, creating long journeys to work or forcing them to leave the neighbourhood in which their family has lived. New products often replace old ones, causing changes of work or unemployment, and at the very least unemployment seriously affects family life. New technology, such as automation and atomic power, will probably have similar effects on a large scale, unless they are introduced slowly and under efficient social control. Even so, they may influence marriage, fertility, and education because there will be far less need for unskilled labour and far more need for technical know-how or theoretical training. Adjustment to these new circumstances may be difficult for women in higher social classes, who will probably be pushed out by men, in spite of official acceptance of the pattern of equality; and adjustment also will be difficult for lower class men, whose labour will be in less demand, while working class women may find it far easier to find service jobs, which are less well paid.

##### THE DRIVE FOR FEMALE EQUALITY

The democratic ideology was once strong enough to convince the majority of people in Western cultures that all men should have equal civil and political rights. This, however, did not apply to women; and considerable political change was (and still is) necessary before women were (or will be) granted fundamental political and civil rights in the more advanced countries, though they now generally have educational opportunities as good as do the men and access to a number of professions. They generally receive, however, somewhat lower incomes and have smaller chances of promotion. Many married women, for instance, with jobs in workshops, offices, or in the professions, recognize that they will have a lot of housework to do when they get home and that they will have to stay at home on the days that their husband or one of the children is ill in bed. These duties of theirs, although extremely important to the family and society, will be little appreciated by their employers and will reduce their pay as well as their chances of promotion. If modern society has a serious need of married women in jobs outside the home, then the community probably will have to create better facilities for having young children and bedridden members of the family looked after and give women better positions and the same chances of promotion as men with the same formal merits. Shorter working hours, shorter workweeks, and longer holidays also will make it easier for married women to meet the double demands made on them by job and family.

The concept of equality of the sexes seems to irritate some women. This can be interpreted as showing that the pattern is now so established that it can easily stand some criticism. Modern sex technology also lends it support. The problem of having children of the sex desired is theoretically solved. In the future there could be little trouble about securing not only the number of children wanted but also the sex wanted. Then, peculiar ideas that sons are more valuable than daughters can be given free rein; and this may eventually result in sons and daughters being regarded as being of equal value. If people seriously do prefer sons, they will produce a surplus of them and so automatically create a greater demand for daughters. Too unequal a proportion between the sexes, however, will bring other difficulties in its train.

The pill has had a profound effect on sex mores, because it efficiently reduces the danger of unwanted pregnancy and therefore removes one reason for having one set of moral standards for men and another for women. If women can have coitus without risking pregnancy, it is hardly possible to demand that women remain chaste because of a possible child's future. Probably new types of relations between men and women will emerge, but in order to be described they will have to be studied in

terms of contacts—sexual, emotional, intellectual, and otherwise—instead of in terms of contracts—households and families in the classical sense. These contacts should be easier to make and maintain if the partners share the same opinions and value the same things. Differences in background or age tend to raise barriers, and it takes energy, money or intellectual resources to break them down.

#### THE ROLE OF IDEOLOGY

Formerly, social classes or educational groups differed comparatively much from one another and so had little contact. The younger people took over the ideology of their parents very easily, changing it but little. Now most of them take over their more or less organized ideologies from other groups, generally their peer groups. This does not mean that all the members of the younger generation share the same ideology. They do not; there are still large differences between college students and those who have instead gone directly to the labour market. It does mean that there are now far greater differences between the old and the young within each social class or educational group than there were formerly. Even formerly, the ideological differences were large enough to make young people eager to leave their parents and marry, build homes, and have children; but now differences in ideology are even deeper, and they show not only in dress, taste, contacts, and political opinions but also in the forms of social life: some of the younger generation do not accept marriage and do not make homes, although they live with one another and have children together. These ideological differences and the clashes that they create, or are meant to create, can no longer be ignored. They have to be recognized and handled as seriously as class differences or ethnic differences.

**BIBLIOGRAPHY.** J. ALDOUS and R. HILL, *International Bibliography of Research in Marriage and the Family, 1900–1964* (1967), the most comprehensive bibliography available for the period up to 1964; N.W. BELL and E.F. VOGEL (eds.), *A Modern Introduction to the Family* (1968), a selection of excellent readings making use of structural-functional analysis; D.R. BLITSTEN, *The World of the Family* (1963), a good selection of material on the family from different cultures; GUNNAR H.R. BOALT, *Family and Marriage* (1965), a comparison of Scandinavian and Indian family systems with those in the U.S.; H.T. CHRISTENSEN (ed.), *Handbook of Marriage and the Family* (1964), a scholarly volume dealing with the total field of family sociology; N.N. FOOTE and L.S. COTTRELL, *Identity and Inter-Personal Competence: A New Direction in Family Research* (1955), one of the most significant books dealing with the role of the family in the development of its individual members; W.J. GOODE, "Horizons in Family Theory," in R.K. MERTON, L. BROOM, and L.S. COTTRELL (eds.), *Sociology Today* (1959), a good statement of the basic problems in developing theory in family sociology; W.J. GOODE, *World Revolution and Family Patterns* (1963), one of the best family texts on the fundamental theme of industrialization and the family; J. HEISS (ed.), *Family Roles and Interaction: An Anthology* (1968), a selection of readings concerned with the behaviour of persons in different family roles; C. KIRKPATRICK, *The Family: As Process and Institution*, 2nd ed. (1963), a basic text in family sociology; H.R. LANTZ and E.C. SNYDER, *Marriage: An Examination of the Man-Woman Relationship* (1962), a good illustration of social-psychological interpretation of dating, courtship, and marriage; G.R. LESLIE, *The Family in Social Context* (1967), a solid family text; OSCAR LEWIS, *Five Families: Mexican Case Studies in the Culture of Poverty* (1959), important for both the method and content; GEORGE MURDOCK, *Social Structure* (1949), a classic work presenting a social anthropological comparison of sample cultures; D.R. MILLER and G.E. SWANSON, *The Changing American Parent* (1958), a significant work attempting to relate child rearing to occupational structure.

### Family Law

Family law may in general be defined as the body of laws relating to the organization of the family. In the past such law has been closely connected with the law of property and succession, and from the records available, it must have had its principal origins in the economic and property questions created by the transfer of a

woman from her father's family to the power and guardianship of her husband. Even in regard to parent and child, such legal concepts as guardianship, custody, and legitimacy were associated with family power structures and family economic interests. Family law also has to do with matters of personal status—for example, the question whether X is to be considered married or single or whether Y is to be classed as legitimate or as a bastard—although the incidents and importance of these distinctions often lead back to the law of property.

This article is not a treatise on the family laws of the world (which would require at least a volume) but a discussion of the application of law to family relations. It is a consideration of the role of law in regard to the family, an effort to identify the main problems on a comparative basis.

In recent decades, family law has been subject to re-examination in many parts of the world, and the greater legal status and independence acquired by married women has been a catalyst.

#### FAMILY GROUPS

A family group has a certain internal structure as well as relationships between itself and third parties. Family groups in some societies have tended to be complex, as, for example, the Roman paterfamilial group, the Chinese upperclass family, the Indian joint family, the Samurai family in Japan, and many customary family structures in Africa. The family may be a part of a larger group such as the tribe or clan.

**The two-parent family.** At present the dominant form of the family group consists of two spouses and the children they have produced or adopted. The law, therefore, is concerned mainly with the rights and duties of husband and wife and parent and child, particularly in questions of financial support. In a strictly monogamous society, the law will forbid a husband to marry again; while in other societies, it will regulate the number of wives (as does Islāmic law).

In various parts of the world some families are, in effect, matriarchal because the adult male is so frequently absent, as in fishing communities or among peoples with high concubinage rates. Where divorce and separation are common and where welfare programs are available to assist dependents, the one-parent family acquires an importance that is not adequately reflected in traditional law. Some European countries have had significant rates of illegitimacy, and the public services of these and other countries have been sympathetic to the one-parent family. It may be necessary to adapt the law to a greater extent to the needs of one-parent families in such areas as the organization of family and child welfare services and the legal and administrative machinery for family support, employment assistance, day nurseries, and the like. The head of a single-parent household may have difficulty affording the high cost of child care while working or training, especially on a modest or low income.

**The one-parent family.** Traditionally, family law has not concerned itself much with unions that are not commenced by legal marriage, though some systems of law permit the recognition of a "natural" child by a father for such purposes as inheritance or support. The family group based on concubinage has been largely neglected by the law because such unions are often transitory and difficult to define; are considered immoral; occur mainly among poorer or less educated classes (as in some parts of Latin America; or among serfs or slaves); or are associated with an inferior status of the female (particularly in Asian and African countries).

Even where the family is a two-parent group, it may encounter some of the problems of the one-parent family if the woman is employed outside the home. Some European countries, and the People's Republic of China, have probably gone further than most in proportions of women in employment, but many other countries also have changing patterns of female employment. In the poorer classes generally, women have traditionally worked outside the home at unskilled jobs; the new development in recent times is the growing number of middle class

The ways in which law has been applied to families

married women who are employed full-time or part-time for personal satisfaction, increased standard of living, or both.

**Legal consequences of marriage.** Marriage gives rise to certain automatic consequences. But two persons might, for example, produce the economic incidents of marriage by executing appropriate contracts or settlements. On this argument, a marriage provides a technically simple way of achieving what the parties could do for themselves in finance and property matters with greater expense and complexity. In some legal systems, in which agreement on property arrangements is central to the status of a legal wife, a contract in conventional form is the core of the constitution of marriage. The contract may be complex, with a variety of clauses, as in Muslim law or (more so formerly) as in major family unions under French or English law. In most countries today, however, the legal documentation of a marriage is mainly a registration of the event. So basically, in the legal sense, a marriage is the implied creation of certain rights or obligations such as maintenance, marital property and succession rights, and the custody of legitimate minor children.

In modern systems, the parties to a marriage can create the economic incidents of the marriage by a separate agreement. In some early legal systems and in present systems in which customary family law pertains, there is little choice as to the economic incidents of marriage because these are fixed by custom. In legal systems that allow substantial scope for personal independence, as in those of North America and western Europe, the spouses can take up a position of their own as to the economic basis of their family group by a marriage contract or a will.

Status  
and  
contract

According to the English legal scholar Sir Henry Maine legal history shows a movement from "status" to "contract"—meaning that modern private law is less concerned with a person's class (e.g., slave, illegitimate son, serf, freeman, Roman citizen) than it is with voluntary agreements among persons. A maintenance obligation has a different practical significance in a country such as Sweden, where most married women are employed and there are extensive welfare programs, than, for example, in India. Rights of intestate succession will have a different social impact in a country where most people make wills than in one where most die intestate. In many countries there has been a tendency in the law to allow increasing freedom in setting up the family group and establishing its economic base. This is not true of some countries, and generally Communist legal systems impose at least a matrix of mandatory general principles designed to promote the political and social philosophy of the state. The extent of mandatory regulation, as compared with leaving decisions to the spouses voluntarily, is one of the important issues facing family law at the present time.

One feature that distinguishes marriage from a simple contract is that, in many countries, the parties cannot release themselves by mutual agreement. But some recent legislation in North America and western Europe comes close to permitting this; the grounds of divorce have been so widened that the marriage can be terminated, for example, after a period of separation.

**The social environment.** The family group is in some respects a microcosm of society, reflecting within it many facets of the whole social and legal environment. The great religions of the world have taken a special interest in family law, seeing in it opportunities for extending their moral and spiritual influence. Family law has at times been an element in promoting the interests of a particular class; in many countries there have been social hierarchies sustained by marriage and property laws. Practicing lawyers and the courts devoted much of their time to the interests of the dominant class. The family structures of the poor and the peasantry received much less attention in the law; the family law of these classes had more to do with workhouses, charitable institutions, unemployment relief, and welfare services. The 20th-century revolutions in Russia and China had as a main

target the family structures of existing quasi-feudal regimes and consequently made large-scale changes in family law. The introduction of the Meiji code in Japan in 1898 similarly involved basic changes in the traditional family law, marking the emergence of a new society.

The institutions of the village and the commune have a long history in many countries. Such communities may contain a number of families who cooperate in various ways such as in the ownership or management of property; farming and handicrafts; communal help and welfare; religious observances. A significant proportion of the population of Asia, Africa, and Latin America lives in such communities. The administration of the community and the management of its property is usually governed by customary law.

The wide differences in social organization and custom indicate that there can be no universal "best" pattern for family law. The legal regulation of familial relationships should be approached with caution lest the prejudices of a majority be imposed unnecessarily on the private lives of individuals. As the English philosopher John Stuart Mill wrote in his "Essay on Liberty," "There is a limit to the legitimate interference of collective opinion with individual independence; and to find that limit, and maintain it against encroachment, is as indispensable to a good condition of human affairs, as protection against political despotism."

The range of problems falling within the general scope of family law may conceivably increase in the future, and there are legal scholars who predict that, within the next 50 or 100 years, family law may experience some of the most critical events in the history of human societies. First, rising population in some parts of the world may bring profound changes in laws relating to the family. Methods of limiting population and of controlling reproduction and heredity will, to the extent they are put into practice, have an important effect on family relationships and the principles of family law. Second, an increasing life expectancy is itself an important influence on marriage and family structure, because it lengthens the average cohabitation until dissolution of a marriage by death. Third, new dimensions in relations between the sexes could be introduced by a developed biotechnology in the control and management of genes, cells, etc., undoubtedly raising new legal problems. Fourth, the accelerating tendency for people to group in huge urban complexes is a social force bearing on the traditional structures of family law.

#### CHILDREN

It is almost universally the rule that natural or adopting parents have a primary duty to maintain their minor children. In the great majority of cases, the care and upbringing of a child belongs to its biological parents automatically, without regard to their qualification or suitability. No doubt this arrangement was due originally to its convenience and to lack of alternatives, although examples may be found of groups rearing their children in common (usually in tribal societies). The parental system has been justified on religious grounds. Thus, in an Irish case the court declared: "The authority of a father to guide and govern the education of his child is a very sacred thing, bestowed by the Almighty, and to be sustained to the uttermost by human law." A criticism of this system is the inequality of opportunity and upbringing it can offer one child as compared with another. In many modern societies, public services and funds, in particular schools and educational systems, play an increasing part in the raising of children.

**Legitimacy.** By the common law of England, an illegitimate child was a *filius nullius* (without relatives). There may have been two main reasons for this former, discriminatory attitude. First, certain unions between the sexes were designated as lawful marriages, and a man of importance, agreeing to his daughter's marriage, would insist on her having the status of legal wife. Second, paternity, in the legal sense, was easier to establish in the case of a lawful marriage than in the absence of a marriage. The common law of England, for example, pre-

Laws  
relating to  
the care of  
children

sumes in favour of legitimacy when the child is born in lawful wedlock, even if the biological facts may be otherwise. Civil-law systems—those derived from Roman law—have been less absolute than the common law; they provide ways of legitimating a child, such as through subsequent marriage of the parents or through an act of recognition by the father. Modern statute law has brought the positions in different systems closer together and removed some of the worst features of the doctrine of legitimacy. Legitimacy is a concept of diminishing importance in modern law, and even countries that still retain it have usually modified it. They have done so by basing support obligations on parentage rather than on a legally valid marriage and by giving rights of intestate succession (that is, the right to inherit property in the absence of a will) to children born out of wedlock. By the legal devices of legitimation and adoption, and by other means, the difference between the legal status of a legitimate and an illegitimate child has been narrowed. Family laws in all countries seem to be coming generally to the position that an illegitimate child is a member of a family group, albeit perhaps the group is a nonstandard one such as the one-parent family.

Illegitimacy is frequently associated with poverty; a contributing factor in this has been the tendency to exclude the child by law and social circumstances from what the community regarded as a customary and respectable family structure. The bastard has usually lacked the financial support available in the conventional family group. Sometimes the laws have been designed to prevent the cost of support from falling on those not biologically responsible for the birth. Thus, English legislation of 1576 provided that an order could be made on the putative father for the maintenance of a bastard by the parish (the local government). The distinction of legitimacy has been largely removed in some countries, and the thrust of modern law-reform proposals, in general, is that the welfare of all children should be a matter of honest and effective public concern, made mandatory by statutory provisions.

**Adoption.** In modern societies, adoption tends to be associated with illegitimacy because adoption of the children of unmarried mothers has become common in many countries, although in some jurisdictions there is also a nontrivial number of married parents who offer their children for adoption. The ordinary legal principle is that the consent of a natural parent (or guardian) is required for an adoption order by a court. This consent may be dispensed with if the correct person cannot be found or has proved to be an uninterested or cruel parent. Sometimes adoption without consent appears to go further, and an emerging problem for family law in some countries is whether courts or public agencies should be able to effect the transfer of a child away from the custody of its parents on the ground that that is best for the welfare of the child.

Adoption in the older legal systems (as in Roman law) was treated mainly in terms of succession law. It provided a way of introducing an outsider into a family group and so bringing him or her within the scope of the succession rules. In modern systems, succession rights as well as other legal obligations and rights in cases of adoption are usually treated by analogy with those of legitimate children; in some systems there is an explicit equation with legitimate children. Difficulties have been experienced with adoption in private international law because legal rules and procedures vary.

**Education.** The rapid development of education in the 19th and 20th centuries has had dramatic effects upon the family and upon the rights and obligations of family members. Until the latter part of the 19th century, even in highly developed countries, the organized education of children of the poorer classes tended to be casual or nil. Since then, the powers of a father to determine the upbringing of his child have declined before the advance of public education and the complex legislation and financing on which it rests. Today the pattern in some parts of the world is compulsory education up to the late teens, with extensive opportunities for higher educa-

tion into the early 20s and perhaps later. Present tendencies seem to be (in general) toward even longer and further involvement with the educational process. If this trend continues, the educational systems of many countries may become child-rearing systems providing services such as foster homes, boarding houses, children's villages, and various health and welfare facilities. The effect on family law may be to reduce the importance of the biological link between parent and child.

**Decision making.** The older law in many countries regarded decision making in regard to children as internal to the family, an area in which the courts should not intervene except in cases of serious child abuse or the like. In the English common law, for example, there are decisions of the latter part of the 19th century in which this doctrine of the "family veil" was carried to considerable lengths by giving an autocratic position to the father during his lifetime, and even longer, if a testamentary guardian was appointed upon his death. In most primitive societies, customary law gave similar authority to the father, although sometimes the custody and training of girls has been the special province of the mother. In modern law, the power of the father yielded to the principle that the welfare of the child is paramount; but this relaxation has raised important and difficult questions. The prevailing view is that the courts should take jurisdiction and intervene in family decision making in certain circumstances. Generally it may be said that they should intervene when injustice, oppression, or cruelty might result if exclusive private decision making were allowed to prevail—for example, in instances of significant danger to the welfare of the child and in cases of marriage breakdown between the parents. Prevailing theory seems to be that it would be an extreme and undesirable principle to make parent-child relations wholly private and exclude the jurisdiction of the courts, but that it would also be extreme and undesirable to have no private domain of decision making and to bring all family disputes to court. The practical rule lies between the extremes, and the application of such a rule is uncertain and there are bound to be differences of opinion.

A variant of this problem is that of determining the boundaries between private decision making in a family and decision making by public authorities and services, such as child welfare officials. Here the question is to what extent the public authorities ought to share in the bringing up of children. This is a policy issue of great difficulty; in modern times, the courts have tended to intervene more than formerly in cases in which children are neglected, abused, delinquent, and so on. In the Soviet Union and the People's Republic of China, state policy has had a strong influence on the general structure of the family codes and their interpretation by the courts, including the legal rights and duties of parents with respect to custody, guardianship, and child care.

**Questions of custody.** Cases can be cited to show the difficulty of reaching agreement among judges and others as to what constitutes the "best interests" and "welfare" of a child. The Supreme Court of Canada has supported the principle that a natural parent, such as an unmarried mother, should not be denied custody of her child merely because applicants wishing to adopt the child offer better material prospects or a two-parent instead of a one-parent household. Other views maintain that a young unmarried mother is, in general, not a suitable custodian of her newborn child and that therefore public intervention leading to adoption is usually in the child's best interests. Another disputed question is whether a difference of religion between a natural parent and an adoptive parent, or between two natural parents, is against the interests of the child. Various shades of opinion have been expressed: for example, that failure to raise a child in a particular religion may stunt its spiritual development; that a change of religious environment could be upsetting to a child already accustomed for some years to a certain religion.

Questions of custody cannot be determined solely by deduction from a rule of law. They require the exercise of judicial discretion that takes account of all the relevant

circumstances, which may be very complex. Perhaps the child has been for some time previously in the same home; or there has been a long and acrimonious dispute between parents who are divorcing; or there have been conflicts between parents and child-welfare authorities. In divorce cases, the situation is often a *de facto* one: separation of the parents has taken place some time before the legal proceedings, and the child has already been given into the custody of one of them, so that the divorce decree may do no more than regularize in law what has already happened to the child in fact.

#### MARRIAGE

Marriage  
and its  
relation to  
property

The history of marriage is bound up with the legal and economic dependence of women upon men and the legal incapacities of women in owning and dealing with property. In Babylonian law, for example, one characteristic of a "legal wife" was that she brought property to the marriage (as a contribution to the support of the new family). Before there was a developed law of wills, there would be a distribution of property upon the death of a *paterfamilias*. The property taken by a daughter on marriage may have been to compensate for her not being in the family group at the next such distribution. It was also customary for the man to make gifts to his bride, either in property or by giving services to the bride's family, as a token of the seriousness of his intentions.

**Marriage as a transfer of dependence.** In systems in which the females are legally and economically dependent within a family hierarchy, the juridical essence of marriage is the transfer of the woman from control by her own family to control by her husband. Marriage customs of many times, countries, and religions exhibit this principle in a variety of forms: in certain kinds of Roman marriage; in marriages among the Japanese Samurai; in the traditional Chinese marriage; in the Hindu marriage based on the joint family; in Rabbinical law; in Muslim law; and in Germanic and Celtic customary law. The Germanic traditions were imported into England, where they combined with Norman concepts to become the basis of the English common law of marriage. The Germanic law provided, at least in higher class families with property, for a payment by the bridegroom for the transfer of the *mund* (responsibility for, and power over, the woman); for a settlement on the groom by the bride's family; and for a so-called *Morgengab*, which may have represented the completion of the settlement. The giving of a ring had a symbolic role in many kinds of wedding and betrothal ceremonies. The word *wed* derives from the Anglo-Saxon word for security given to bind a promise. The property used as security was not necessarily transferred but given symbolically (*i.e.*, the ring). In a modern Church of England wedding service, the giving of security is reflected in the words, "With this ring I thee wed," and the settlement of property in the words, "and with all my worldly goods I thee endow." The minister has previously asked, "Who giveth this woman to be married to this man?" and, on "receiving the woman at her father's or friend's hands," proceeds with the ceremony. This "giving away" of the woman by her family reflects the transfer of the *mund* to the bridegroom. In some systems the marriage forms may have a "bride purchase" origin, in the sense of compensation to her family (although there are differences of opinion as to the meaning of the customary forms): this was true in certain kinds of marriage in the earlier Roman republic, in Babylonian or Aramaic marriages, in early Arabic marriages, in certain Chinese unions (at least with regard to concubines, in which cases the transaction was more openly a purchase from the girl's parents), in customary marriage in some parts of Africa (*e.g.*, Nigeria, Ghana, Kenya), and in customary marriage among the nomadic tribes of Siberia (*e.g.*, the Kirgiz or Yakuts).

The ancient concept of marriage in many legal systems is that of a transaction between families (and this has sometimes persisted to the present day). Although the consent of the bride and bridegroom was almost always formally required, it may be questioned how real the consent was in the case of a child bride or in marriages

between parties who did not see each other beforehand. Go-betweens and marriage brokers have been part of the marriage customs of many countries, especially in the East; in old Japan and China, for example, the go-between was considered an important person chosen to carry out a responsible task. The go-between and the professional marriage broker still have a substantial following in some countries. Some authorities have suggested that computer "matching" for marriage may become a modern development of the go-between concept.

**Marriage as a voluntary relationship.** The modern idea of marriage, which is becoming almost universal, is a voluntary exchange of promises between the man and the woman. Even though a marriage may involve substantial decisions as to property, these matters now tend either to be automatic (when there is no marriage contract) or to be formalized separately from the marriage ceremony. The ceremony itself is normally an exchange of consents accompanied by religious observances or a civil ceremony (or both). The purpose of the legal formalities is to differentiate the relationship from concubinage and to create certain recognized legal incidents such as maintenance, custody of children, rights under matrimonial regimes, intestate succession, claims under life-insurance policies and pension funds. The legal incidents could doubtless be provided by the execution of specific contracts, settlements, and wills, without a marriage contract.

In earlier legal systems, especially in Asia, the woman's consent was often unnecessary or of minor importance; the marriage negotiations took place between the woman's father and the man or his family. Voluntary consent of the parties became important in Roman times. Roman law during the period of the empire distinguished between an agreement for present marriage and an agreement for future marriage (*sponsalia per verba de praesenti* and *sponsalia per verba de futuro*). This distinction was taken over by Christianity, and a promise for marriage *per verba de futuro* was supported by a guarantee or "deposit" payment or by a penalty clause in a marriage contract.

**Engagement.** The view of the canon law of Christianity was that an engagement incapacitated a person from marriage to a different party and consequently provided ground for annulment of a marriage. This raised an issue that has troubled the civil lawyer but apparently not the common lawyer; *i.e.*, whether penalties, forfeiture provisions, damages, and the like for breach of engagement or betrothal are consistent with the exchange of voluntary consent at the marriage ceremony. Thus, French law has been led to reject an action of breach of promise (while permitting an action in delict—that is, on the charge that one party has been wronged). The common law, on the other hand, allows claims for breach of promise, although the modern tendency is to eliminate this form of action by statute.

**The public interest.** It has been difficult to delineate the boundaries between public and private interest in marriage law. The public interest is involved in the prevention of clandestine marriages; in requiring a license or the publication of banns as a condition precedent to marriage; in requiring parental consent for marriages between persons of certain ages; and in providing for the registration of marriages in a public manner. In practice, however, the marriage laws are often a mixture of functional administrative provisions (such as the requirement for registration, health certificates), old customs, religious ceremonies, and routine administrative precedents. Marriage statutes were introduced in modern times to combat the danger of clandestine marriages, which were possible under the old law in Europe and England by some form of mutual consent. Apart from direct establishment of this consent, it could be done indirectly by: engagement followed by intercourse (*matrimonium subsequente copula*); habit and repute marriage (evidence of acceptance in the community as being married persons). Clandestine marriage was of significance at a time when a man could acquire control over the property of a woman, including absolute ownership of much of it. The

Modern  
marriage  
law

emancipation of women has put an end to the economic advantages of the clandestine marriage, but the legislation to which it gave rise has left an impress on the statute books.

**Age.** For a voluntary consent to a marriage, a party must have reached an age at which he or she is able to give a meaningful consent, and it is also implied that a person may be legally disqualified on mental grounds from having capacity to marry. Marriages of young children, negotiated by their parents, are prohibited in modern societies. Historically, the attitude of the English common law was that a person under seven years lacked the mental ability to consent to marriage, between seven years and puberty there could be consent but not a consummated marriage. At common law, therefore, the marriage of a person between the ages of seven and 12 or 14 was "inchoate" and would become "choate" on reaching puberty, if no objection was raised. Most modern legal systems provide for a legal minimum age of marriage ranging from 15 to 18 years. Many systems require parental consent to marriage when the parties are above the minimum age but below some other age, and failure to obtain this may be a ground for annulment. Parental consent has a long historical tradition, and there have been systems in which the girl's consent was virtually unnecessary. It is difficult to say, therefore, whether modern provisions have a valid social function or are the flotsam of older ideas on marriage.

**Relationship.** Other laws forbid marriage between persons having certain ties of relationship, either of blood or of marriage. "Forbidden degrees" of one sort or another exist in most social groups. The rules against marrying close relatives are sometimes said to be directed against the dangers of inbreeding, but this does not explain the prohibition against unions between persons who are related only by marriage. In classical Chinese society, marriage was regarded as a linking of different families, and the traditional pattern was exogamy (marriage outside the family). In ancient Egypt, on the other hand, where the pharaoh was deified, marriages within the blood were considered desirable in order to preserve its purity. Marriages between cousins are apparently encouraged in some Arab countries, perhaps to strengthen family ties and to keep the property together.

**Religion.** Religion has had a very strong influence on marriage law, often providing the main basis of authority. Hindu family law, which goes back at least 4,000 years (and may be the oldest known system), is a branch of Dharma—that is, the aggregate of religious, moral, social, and legal duties and obligations as developed by the Smritis or Institutes of the law. Islāmic and Jewish family law also rests on spiritual authority. Religious courts have had jurisdiction over family matters in various countries, and in some countries they still possess it. Some modern religious courts retain only their spiritual jurisdiction over marriage and divorce; their judgments have no standing in the secular law. In some Roman Catholic and Greek Orthodox Christian marriages and also in Muslim and Jewish marriages, the application of the religious law is regarded as binding upon persons belonging to the faith. Where religious texts provide the literal authority for legal principles, as in Islāmic law, it may be necessary to reinterpret the texts in order to reform the law. This raises complex issues in those Muslim countries where there are movements for greater equality of the sexes.

#### ECONOMIC ASPECTS OF FAMILY LAW

The comparative legal history of marital property, viewed in broad perspective, consists of a period stretching back for about 4,000 years, during which a husband was generally regarded as a quasi-guardian of his wife, who was dependent upon him economically and legally. The English common law removed the separate legal personality of a woman when she married and merged it in that of her husband, though she regained it if she became a widow. Her husband acquired extensive rights to the administration and ownership of her property, including full ownership (with no obligation even to give an ac-

counting) of any moneys she received from employment or business. Until quite recently, the only property of which a Hindu woman was the absolute owner was her *strīdhana*, consisting mainly of wedding gifts and gifts from relatives. Muslim women have traditionally owned and managed their own property. In Japan, before the Meiji Civil Code of 1898, all of the woman's property such as land or money passed to her husband except for personal clothing and a mirror stand. In early Vietnamese customary law, the property contributions of both spouses formed a common mass that was administered jointly and then divided, together with acquisitions made during their marriage, between the spouses and their heirs. In ancient Burmese law, all of the property of the spouses comprised a common mass that was their joint property but was administered by the husband with extensive powers. In 13th-century France, there was a concept of "community" on the lines of a partnership between the spouses; but by the 16th century, French husbands had secured the *puissance maritale* ("marital power") that gave them power over the disposal of property. In ancient Hungarian law, the bride usually brought property to the marriage, and a regime with a form of dowry persisted until World War II. The law of imperial Russia permitted a wife to own and deal with property independently of her husband—an attitude that differed from its treatment of women in other respects. A Roman wife, in some marriage forms, had a position of independence in regard to her property that was unusual for that era. In Celtic law, the man gave property to the woman's family; according to Brehon law (the ancient law of Ireland), the payment could be made by annual installments over 21 years (the woman's father kept the first installment, two-thirds of the second, half of the third, and so on, the remainder going to the wife).

**The emancipation of women.** The emancipation of women, which occurred in many countries during the latter part of the 19th century and the first part of the 20th, had a profound effect upon family law and marital property. The Scandinavian countries made radical reforms in their marital property laws in the 1920s; they introduced a new type of matrimonial regime in which the spouses retain independent control of their property except for some items for the disposal of which the consent of the other spouse is required, but the combined remaining matrimonial property is divided at the termination of the regime. This has been influential in the reforms of other countries. The Federal Republic of Germany introduced legal equality of the sexes as a constitutional principle in the 1950s, followed by substantial amendments to the civil code with respect to the financial and property relations of spouses; these included a new matrimonial regime on sharing the value of the economic gains of marriage, analogous in broad principle to the Scandinavian reforms, but containing new features. The French civil code received major revisions with respect to the matrimonial regimes in 1965. In 1969 the civil code of Quebec was revised to give full capacity to married women; it also created a new matrimonial regime, described as a partnership of acquests (that is, property acquired by the spouses after their marriage). In 1950 the People's Republic of China enacted a comprehensive marriage law including provisions giving the spouses equal rights with regard to ownership and management of marital property. The Soviet Union's Draft Principles on Marriage and the Family (1969) provide for community of acquests with equal rights of the spouses to possess, use, and dispose of property. The German Democratic Republic introduced a code of family law in 1965 based on principles of equality of the sexes in financial and property matters. Czechoslovakia's code of family law, enacted in 1964, introduced a concept of joint ownership with an equal share in management. Community sharing systems have been introduced by codes in Romania (1954) and Poland (1964). Substantial changes in the property capacity of Hindu women were made by the Hindu Succession Act of 1956. In the 1970s proposals for the reform of marital property were also under study in various other countries: for example,

The variety of approaches to marital property

## Maintenance and support

England and Scotland; Belgium; Israel; and Ontario, Canada.

**Maintenance.** The law of maintenance and support has differed from that of marital property in most countries. A widow, for example, normally receives some share in her husband's estate upon his death. Some systems of law require that dependents receive a compulsory share in the estate or dependent's relief or family provision (that is, financial support out of the estate for a dependent in straitened circumstances). Most systems of law have traditionally regarded financial support as the responsibility of a husband and a father (to which any dowry or property from the wife was considered a contribution). But in a hierarchical structure, such as the Greek or Roman family, the responsibility might rest on the paterfamilias, if different from the husband. In Hindu law, the male members of a joint family, together with their wives, widows, and children, are entitled to support out of the joint property.

*The influence of legislation.* Social welfare legislation and the principle that a child's welfare is paramount have added a dimension and an inconsistency to the traditional principle of paternal responsibility. The new dimension is a public one and implies that society has an ultimate responsibility to see that children receive at least a minimum standard of maintenance. In some countries, including the United States, Canada, Great Britain, and various continental European countries, attempts have been made to combine both parental and public responsibility for the child's welfare.

The enforcement of the legal obligation of a parent to maintain a child runs into a number of difficulties in law and practice. The father may be too poor to support his child, or he may be impossible to locate, or he may already be in prison for refusal to pay. A wife may be reluctant to sue her husband (for personal reasons and perhaps in the hope of a reconciliation), and if she does not do so, the child will be deprived of financial aid and its welfare will suffer. Where there are social welfare programs supported by taxes, efforts may be made to protect the tax revenues by, for example, requiring a deserted wife to sue her husband as a condition of receiving welfare payments. Sometimes the authorities institute criminal or contempt proceedings against the husband. But in the North American and British experience, the payment record of obligants on maintenance orders is generally poor; the money recovered is usually inadequate to provide minimum support; and the cost of enforcement may approach the sums collected. Many people, moreover, wish to avoid getting involved with the law and the courts and will refuse to initiate action for maintenance. It is not difficult to see why a high proportion of one-parent families exist in poverty even in countries with highly developed economies.

*Working wives.* The introduction to the British Census of 1851 stated: "The duties of a wife, a mother, a mistress of a family, can only be efficiently performed by unremitting attention; accordingly it is found that in districts where the women are much employed from home, the children and parents perish in great numbers." Much has changed since then. Most modern countries provide that a husband and wife have mutual obligations of financial support according to their means, aiming at a common standard of living for them both. The older principle was that the husband supported the wife in return for obtaining most of her property or becoming *chef de la famille et de la communauté* in a community-property system. Some common-law systems are a curious mixture of old and new principles. In general it can be said that women tend increasingly to seek employment for other than economic reasons. Thus, in Canada in 1931, 10 percent of the women in the labour force were married; by 1961 the percentage had risen to 50. Two results of this trend are that (1) more married women now own some money and property and (2) on separation, divorce, or widowhood, a woman is more likely to be in employment and so not dependent for support.

**Choice of regime.** Recent reforms in marital-property laws have tended to reflect the wishes of spouses and their

families, rather than traditional customs, religious attitudes, and dogmatic formulas. The French civil code of 1804 began a European pattern of giving spouses a choice of matrimonial regime: the codifiers were confronted with a variety of customary laws in different parts of the country, and, not wishing to impose one of them, they included alternatives in the code, designating one, the Custom of Paris, as the legal regime that would apply if the parties did not select another in their marriage contract. In common-law countries, the tendency has been to favour separation of property—a tendency resulting more by accident than by intention. This has come about because most of these countries adopted married women's property legislation that removed the incapacity of a married woman to make contracts and deal with her property, thus destroying the existing system by which the wife's property passed into the control of the husband. No new matrimonial system was constructed, so that the spouses were placed in the position of separate individuals so far as property is concerned. They can, of course, draw up marriage contracts or settlements to express their own wishes, but such contracts are now rare. The laws of the Communist countries provide only one matrimonial regime, intended to promote the social and political policy of the government.

In countries where the spouses are given a choice of regime, many of them do not exercise their option. A survey made in France in 1963–64 indicated that 76 percent of the couples made no marriage contract and therefore were subject to the legal regime. The figures are probably similar in other countries. In Quebec, on the other hand, before the legislation in 1969 on marital property, more than 70 percent of marrying couples signed contracts for separation of property; part of the explanation for this may be that Quebec is surrounded by jurisdictions in which the common law prevails.

*Separation of property.* Even in modern times, in most cases husbands and wives differ in their potential for acquiring property. In separation of property, husbands and wives owning property and dealing with each other will be in the same position as unmarried adults. There are, however, grounds for distinguishing marital property questions from ordinary property questions because persons who cohabit on a domestic basis share a common standard of living and usually also the benefits of each other's property. A major element in many marriages is the raising of children, and the traditional female role places the married woman at a disadvantage so far as earning money and acquiring property are concerned. It is inconsistent of society to encourage a woman to take the domestic role of wife and mother, with its lower money and property potential, but in property matters to treat her as if she were a single person. It is also inconsistent to place upon the husband the sole responsibility for maintaining his wife and children, if his wife has regular employment outside the home. When the marriage is dissolved, if the wife has not been regularly employed and now enters the labour market on a full-time basis, she may be at a considerable disadvantage as far as salary and pension rights are concerned.

*Community property.* A marital-property system should try to balance two sets of interests: the interests of the spouses and the interests of third parties such as purchasers, creditors, and business partners. Community-property regimes emphasize the first but are less attractive in terms of the second, because the property is tied up in the community and is subject to the interests of both spouses, whereas the third party may be dealing with only one of them. Separation of property gives property independence to each spouse, but it does not provide for sharing unless the spouses place items of property under joint ownership. Consequently, there has been a trend in many countries toward new regimes giving the husband and wife independence in dealing with property but also providing rules for a division of net assets on liquidation of the marriage. The first country in Europe to initiate this type was Sweden, in 1920.

In some common-law countries, certain items of property have received special treatment. Examples are the

Alternatives in marital property law

matrimonial home in English law (under decisions of the courts beginning around 1950) where there has been concern about a wife's being evicted by a purchaser or mortgagee from her husband, and also about division of proceeds of the sale when both spouses have contributed something to the purchase, or where one has done improvements on the other's property, or where the husband's payments toward the purchase have been possible because the wife's money was used for the day-to-day domestic needs of the family, and so on. In parts of the United States and Canada, particularly the West and Midwest, there have been "homestead" laws providing that one spouse cannot dispose of or encumber the home without the consent of the other, that the use goes to the widow or family on the owner's death, and that the home cannot be sold in execution of a will.

**Tort actions between spouses.** In English common law, as amended by the property legislation of the 19th century, a husband could not sue his wife in tort (that is, for a wrongful civil act not arising from contract), and she could sue him only in respect of damage to her separate property. This has been variously explained as stemming from the doctrine of the unity of the legal personalities of husband and wife (so that the plaintiff and the defendant are the same legal person) or from the belief that it would be disruptive to the family to allow damage suits between spouses. The modern tendency is to permit any delict or tort action between spouses. This seems consistent with the fact that many damage suits, such as automobile accidents claims, are covered by insurance, and the litigation in such cases is therefore between two insurance companies with the spouses as nominal parties.

Movements exist in North America and Europe favouring a "no-fault" basis for delict or tort proceedings; this would transfer the emphasis in such actions to securing compensation for the person who suffered the damage, rather than determining whether the plaintiff can establish a cause of action (which usually means proving fault).

**Co-ownership.** Some marital-property systems that are basically separation of property have modifications for the situation in which, for example, an asset has been acquired by contributions from both spouses with the intention that both will benefit from its purchase—as with a home, furnishings, an automobile, a joint bank account, or joint investments. But the attitudes of husbands and wives as to their property after a marriage has broken down may be quite different from their intentions when an asset was acquired. There are decisions of the English courts that imply that in some of these circumstances, at least, the net value of the asset should be divided equally on the maxim that "equality is equity." The boundaries of this principle, however, are not at all certain.

Japanese marital-property law was revised in 1947, and the present legal regime is a modified form of separation of property. Under this regime, property to which only one spouse has title, but in the acquisition of which both have really cooperated during their marriage, is considered substantially co-owned. The civil code has been interpreted to the effect that substantially co-owned property is attributed to the title holder in a question involving third parties and to both spouses in a question between the spouses themselves.

#### DIVORCE

A marriage can terminate as a human relationship before it is dissolved by law. Quite often the court rulings as to property and the custody of children will merely confirm arrangements that have already been made by the parties concerned. In the United States and Canada, 80 to 90 percent of divorce proceedings are undefended; often the parties have made provisional arrangements about property, and one of them already has custody of the children. Before a union can be dissolved by divorce, there must have been a valid marriage. If a marriage has been imperfectly constituted in law, it may be annulled; grounds for annulment include lack of capacity, no real-

ity of consent by the parties, a vitiating defect in the marriage ceremony, or the subsequent discovery of a defect such as inability to consummate the marriage.

**Repudiation.** In old legal systems, marriage was conceived as the transfer of a woman from the power of her family to that of her husband under terms usually specified in the marriage contract. The standard method of dissolving a marriage if both parties were alive was repudiation, resulting usually in the return of the woman to the power of her family. Repudiation has had a considerable history; it has strongly influenced marriage law in Muslim, Jewish, Chinese, and Japanese law. In Muslim law, repudiation can occur without proof of legally designated fault or a breakdown of the marriage. In practice, of course, there are checks on the too facile use of this power by a husband, such as objection from the wife's family, the obligation to repay the value of a dowry, or religious disapproval. In Roman marriage law, unilateral repudiation at will was permitted, and this freedom existed for some time in the early Christian Era. The concern of the Roman law was for solemnity rather than grounds, and unilateral divorce was by a notification of repudiation before seven witnesses.

At the other extreme from repudiation at will is the sacramental view of marriage (as in the teaching of certain Christian churches) that a marriage may not be dissolved during the joint lives of the spouses. Formerly, a Hindu marriage was indissoluble (except by caste custom) and might be eternal.

**Grounds for divorce.** Between the extremes of repudiation at will and indissoluble marriage, there are various divorce formulas: divorce for fault, such as adultery, desertion, cruelty, addiction to alcohol or drugs, or imprisonment; divorce on grounds analogous to frustration of contract, such as incurable insanity subsequent to the marriage or disappearance of the spouse; divorce by mutual agreement; and divorce on the ground that the marriage has broken down. The variety of laws and attitudes with respect to divorce is bewildering. In comparing divorce laws, it should be remembered that the rates of divorce and of marriage breakdown are different; the latter are hard to ascertain, although the breakdown rate obviously exceeds the divorce rate. If the grounds for divorce are widened, then the divorce rate will rise; and if marriage is made indissoluble, the divorce rate will, of course, be zero.

A complicating factor in divorce law is the question of giving recognition to foreign divorces. The divorce laws of countries and states differ, and so do their rules for recognition of divorces elsewhere. A person living in a jurisdiction in which divorce is difficult to obtain may be able to go to another in which divorce laws are more liberal and obtain a dissolution of the marriage that will be recognized in the first jurisdiction. A feature of private international family law is the "limping" relationship—when a person is regarded as married by country X and as single by country Y, and a child as legitimate by country A and as illegitimate by country B. One reason why a country may restrict the recognition of divorces is that there are a number of jurisdictions in which divorce is granted on liberal grounds and with only nominal connections between the spouses and the divorce-granting jurisdiction (sometimes giving the impression of "divorce mills" that are operated for commercial reasons).

Some divorce laws provide for conciliation efforts (as in Sweden, Australia, and Canada), but these do not seem to have had any significant effect on divorce rates. In Chinese law, there is a long tradition of conciliation in many legal areas, including family law. But divorce stems from the desire to end an intimate human relationship that may have existed for some years. It is not an ordinary dispute at law; it has little in common with the interpretation of a business deal, a tax claim, a criminal charge, a wage dispute, or other legal questions that can be presented fairly precisely to a court or a mediator. In a divorce, only the spouses can really know the differences between them, and neglect of this distinction can produce reasoning by false analogy in relation to family law.

Patterns in  
divorce  
law

## FAMILY COURTS

In some countries there are special courts for family matters, set up in pursuit of religious, political, or social objectives; these include the Christian, Muslim, and Jewish ecclesiastical courts. There are also people's courts and conciliation courts, particularly in Communist countries.

Another approach has been to establish social courts that have a functional relation to the legal problems affecting families. Such problems include marriage, divorce, annulment, matrimonial regime, maintenance (of spouses or of children), adoption, custody of children, legitimacy, filiation proceedings, juvenile delinquency, care and protection of children, assault on a spouse or a child, torts between spouses, marriage contracts, and judicial separation. Although these are the problems that produce the largest volume of private law litigation in most countries, family law has not, in many countries, been given a corresponding priority by the regular courts.

Those who favour special courts for family matters argue that family law is concerned with human relationships that require a judicial environment different from that of ordinary civil actions. The facts of the dispute in a family matter may not be as significant as the underlying problems (financial difficulties, health, addiction to drugs or alcohol) that have projected the issue. Another argument favouring family courts is that a high proportion of family proceedings are noncontentious or undefended; for example, proceedings concerning adoption and children in need of care are normally noncontentious and require not so much the application of law as an inquiry into what is in the best interests of the child. In family matters, moreover, the court has need of ancillary services—social workers, probation officers, liaison with various social agencies—and those connected with the court should have some interest and training in this area. Finally, since children and young persons are often involved, there is need of special legal officers to present inquiry material to the court or to represent the interests of the children (which may conflict with the positions taken by their parents).

A number of countries have special courts for cases relating to children and young people (sometimes with lay members), and special procedures for the disposition of such cases. Less progress has been made in the area of comprehensive family courts. One reason may be that family law is unrewarding and time-consuming as compared with more lucrative and prestigious fields of law.

It is sometimes argued that judges should be given a wide discretion in family cases. This seems to have been done in the family codes of eastern Europe and the People's Republic of China, which are loosely constructed with statements of politico-legal principles and leave much leeway in specific matters to the judges or conciliators. In England and the United States the proposal has been made that in a divorce case, for example, the court should have discretion not only as to the custody of children but also as to maintenance and property; the court should do what it thinks just, having regard to the history of the marriage and the behaviour of the spouses. Against this it is argued that such discretion tends to turn tribunals into courts of morals in which the prejudices of judges take precedence over legal consistency.

**BIBLIOGRAPHY.** Naturally the comparative family law of the world relates to an enormous literature. Further, the principal legal writings in each country are in the language of that country, and there has been little translation of law books or articles into other languages. The following are a few suggestions for further reading, the majority of the texts mentioned being in English or French, and a number relate to the complex subject of comparative marital property.

*Comparative law:* W. FRIEDMANN (ed.), *Matrimonial Property Law* (1955); A. ROUAST, J.B. HERZOG, and I. ZAJTAY (eds.), *Le Régime matrimonial légal dans les législations contemporaines* (1957); and the journal *Revue internationale de droit comparé* (1949).

## Faraday, Michael

Michael Faraday, English physicist, chemist, and physical chemist or, as he himself would have said, natural philosopher, was the discoverer of electromagnetic induction, of the laws of electrolysis and of fundamental relations between light and magnetism, as well as being the originator of the conceptions that underlie the modern theory of the electromagnetic field. Faraday was born on September 22, 1791, at Newington, Surrey, which later became part of the borough of Southwark in south London but was then in the country. His father was a blacksmith who had migrated from Yorkshire. The family having moved to north London, Michael, at the age of 14, was apprenticed to a bookseller and bookbinder, in whose shop he read with keen interest books on science that came into his hands. Having heard Humphry Davy lecture at the Royal Institution of Great Britain and conceiving an eager desire to "enter into the service of science," to use his own words, he applied to Davy for employment, sending him as evidence of his interest the notes that he had made of the lectures. As a result he was, at the age of 21, appointed assistant to Davy to help with both lecture experiments and research. He accompanied Davy on a tour in Europe where he had many menial duties to perform but also saw much of the active scientific research and, in general, expanded his view. As the English chemist J.H. Gladstone, who knew him well, wrote:

His University was Europe; his professors the master whom he served and those illustrious men to whom the renown of Davy introduced the travellers.

*Early work.* His first published paper, which appeared in 1816, was of no importance. In 1820 he was devoting much attention to steel, the preparation of a rustless steel being one of his objects, and this work continued for some years, but, beyond finding that small quantities of added metals had a pronounced effect on the properties of steel, no result of importance was obtained. In 1820 Faraday discovered two unknown chlorides of carbon and a new compound of carbon, iodine, and hydrogen. It was in this year that the Danish physicist H.C. Ørsted announced his discovery that a wire conveying an electric current deflected a pivoted magnetic needle brought up close to the wire, a discovery that aroused great interest but was imperfectly understood. Faraday grasped that the force was a circular one surrounding the wire and on this basis made in 1821 the first of his great electrical

Dedication

Discovery  
of electro-  
magnetic  
rotation

discoveries, that of electromagnetic rotation. He set up a simple experiment in which a wire carrying an electric current rotated in the field of a horseshoe magnet. This discovery brought Faraday widespread fame but also some trouble with W.H. Wollaston, who had been unsuccessfully attempting something similar. In the same year Faraday married Sarah Barnard, a union that was happy though childless.

In 1823 Faraday liquefied chlorine, arousing the jealousy of Davy, who considered that he had initiated the work and was entitled to the credit. In consequence, he opposed Faraday's election to the Royal Society, which nevertheless took place in 1824. The next year Faraday made a chemical discovery of the first importance by isolating benzene or, as he called it, bicarburet of hydrogen, from a liquid obtained in the production of oil gas. About the same time he was pursuing research on optical glass, to which he devoted prolonged labour with little result. The "heavy glass" that was one of the products of the research, however, played an essential part in his great discovery of the rotation of the plane of polarization of light in a magnetic field. It was in 1825 that Faraday's position at the Royal Institution was improved by his promotion to the post of director of the laboratory. The next year he began to give formal lectures for the members of the Institution on Friday evenings, a custom that has continued as Friday evening discourses ever since. He also initiated the Christmas lectures for young people, known formally as Christmas Courses of Lectures Adapted to a Juvenile Auditory, of which he himself gave 19 courses. Faraday was supreme as a lecturer and deviser of effective lecture experiments, and there are many contemporary accounts of the interest and enthusiasm that his discourses aroused.

*Major work.* The second period of Faraday's researches may be said to have begun in 1831. He was convinced that the various forces of nature with which physics—always termed by him natural philosophy—was concerned were intimately interconnected. Electric current produced magnetic force, and, conversely, magnets had an effect, as he had shown, on electric currents. He was certain that magnetism could produce electricity: in fact, as early as 1822 his notebook contains the words "Convert magnetism into electricity." From time to time he had tried to produce currents by placing magnets near wires or coils of wire but had no success. In ten days in 1831 he carried out a series of experiments convincingly demonstrating the discovery of electromagnetic induction—the production of electric current by a change in magnetic intensity. These experiments were of such importance that in 1931 their centenary was celebrated at an international conference organized by the Institution of Electrical Engineers in London. The most famous experiment was that of the induction ring, a ring of soft

iron bearing two separate windings of insulated wire, the ends of one of which were connected to a galvanometer (an instrument for measuring electric current). When the ends of the second wire were connected to a battery there was no effect, but when that circuit was made or broken, by closing or opening a switch, the galvanometer indicated that a current was flowing in the first wire. A similar effect was obtained with an iron cylinder that had a wire wound around it in a helix: when, by means of magnets, the magnetic flux in the cylinder was changed, there was a momentary current in the helix. A variation of this experiment was to introduce a magnet into a helical coil of wire or to withdraw it. These experiments all have in common a change of magnetic flux through a circuit that produced a current in the circuit.

Faraday produced what was, in effect, the first dynamo: he placed a rotating copper disk between the poles of a large permanent magnet and showed that a current could be obtained in a wire extending from the axis of the rotating disk to its edge. He soon followed these experiments with others demonstrating that a current in one circuit could induce a current in another without the necessity of an iron core. In discussing these fundamental discoveries Faraday employed the conception of magnetic lines of force to make his ideas clear, for he was no mathematician. Somewhat later, in the course of his researches on static electricity, he developed the analogous conception of lines of electric force whose course and concentration expressed the various effects of electric current. It is in acknowledgment of his fundamental discoveries concerning the functions of dielectrics, or non-conducting materials, that the unit of capacity is named the farad. In this work he discovered the significance of what he termed specific inductive capacity, later called dielectric constant.

Faraday's conceptions of electric and magnetic force and their interrelations, expressed in terms of his lines of force, were fundamental. From them James Clerk Maxwell (*q.v.*) developed the equations that underlie all modern theories of electromagnetic phenomena.

It was shortly after his work on electromagnetic induction that Faraday, once more in search of unity, showed that the five kinds of electricity then distinguished—frictional, galvanic, voltaic, magnetic (induced current), and thermal—were fundamentally the same. "Electricity, whatever may be its source, is identical in its nature." In the same period of his researches he arrived at the basic laws of electrolysis that bear his name and introduced the terms now universally used: anode, cathode, anion, cation, and electrode.

After this succession of epoch-making discoveries ensued a period of exhaustion from which Faraday recovered only gradually. The third, and last, period of his researches began about 1844 and included as the main discovery that of the rotation of the plane of polarization of light in a magnetic field, in which his heavy glass played an essential part. This, again, resulted from his fixed idea that light and magnetism must be connected. In 1850 he tried to show experimentally a relation between gravity and electricity, concluding his paper with:

Here end my trials for the present. The results are negative. They do not shake my strong feeling of the existence of a relation between gravity and electricity, though they give no proof that such a relation exists.

In 1858 he retired to live near Hampton Court, Surrey. At that time he still retained a lively interest in science, but his health and his powers gradually waned and there he died peacefully on August 25, 1867.

Faraday was possibly the greatest experimental genius the world has known. Incessantly he was prompted to believe that certain fundamental relations were waiting to be found, and he was not dismayed by dozens of fruitless experiments from persisting until basic discoveries were finally established. In theoretical physics he provided the fundamental concept—expressed by his lines of force—that the medium was the site of electromagnetic action; at the hands of Maxwell this led to the conception of electromagnetic waves. To all his other gifts he added the ability to describe his ideas in clear and simple language.

## Farm Buildings

The buildings on a farm generally consist of the farm family's house, the dwellings of hired workers, and the various structures and facilities for farming operations. Because farming systems differ widely, there are important variations in the nature and arrangements of farm buildings. This article deals with farmhouses and service buildings that can be classified as follows: livestock barns and shelters; machinery- and supply-storage buildings; buildings and facilities for crop storage, including fodder; and special-purpose structures. (For facilities used in livestock production, see LIVESTOCK AND POULTRY FARMING.)

**History.** Historical knowledge of farm buildings is scant; it is rare for farm buildings more than three centuries old to remain standing. The farmhouses in Europe of centuries ago were simple, with only one floor and, often, a single room. Later, the common room, where the meals were cooked and eaten, was separated from one or several sleeping rooms.

At first a hole in the roof served as chimney for a fireplace in the centre of the house. Then, in countries using masonry construction, large chimneys began to appear; they are still frequently seen in old European farmhouses. Their huge fireplaces were used for heating, cooking, and smoking and curing. In some underdeveloped areas, for example in Africa, single-room huts are still the rule. Shapes differ, and materials employed are found on the spot. In tropical Africa, "banco," a mixture of straw, clay, and animal hair, is used for walls, with the same material laid on boughs or thatch for the roof. Elsewhere, the huts are wood structures that are covered with palm leaves.

The first sedentary breeders kept their animals near their living places, inside natural or handmade fences. At a certain stage, however, it became necessary to have roofs, mainly to facilitate operations such as milking and feeding. Cattle were tied up in the barn and remained so until the 20th century, when the loose-housing system reappeared. In the underdeveloped areas of the world, livestock enclosures still range from simple fences to roofed buildings.

The storage of crops became a preoccupation in the first stage of agriculture. Cereals often were stocked in a loft inside the house. In the 20th century, private and co-operative cereal producers developed grain elevators, and the problem of cereal storage in the farm lost its importance as far as the cash-grain farms were concerned. This soon became true for the other agricultural cash products, such as fruits and potatoes.

**General layout.** The location of the farmstead and the relative position of its different buildings are influenced by several factors, external and internal. Among the external factors, mainly natural, are soil conditions, climatic conditions, and access facilities to the main road and to the fields.

Internal factors depend on the type of business enterprise the farm is suited for. Among general principles that must be taken into account are the necessity of some partition between the farmhouse and service buildings, minimizing of transportation between buildings, the possibility of enlarging buildings, and security against fire. Four general layouts may be defined: large crop farms, large stock farms, farms in underdeveloped areas, and small to medium mixed farms.

**Large crop farms.** Independently owned farms of this type, mainly cash-grain farms, are numerous in North America. The layout is simple, for there are generally two types of service buildings, one for storage and the

other for machinery. The layout is similar in the Communist collective farms mainly harvesting cereals (*kolkhoz* and *sovkhoz* in the Soviet Union; cooperative and state farms in eastern Europe). Large farms specializing in fruit production have a shed for the conditioning and storing of products, the other main building being a machinery and supply shelter. Some large farms specializing in viticulture include buildings that are equipped with wine cellars.

**Large stock farms.** Two types of large stock farms, extensive and intensive, may be distinguished. The extensive type is exemplified by the cattle ranchers of the United States. At the extreme, there are no buildings, only equipment. In Australia and New Zealand, dairy cows are kept without housing. The only building houses the milking parlour and the milk room, in the centre of the pasture. In the western United States, the most important beef ranches have several thousand head, entirely free on the range. The only building is the elevator with the milling and mixing machinery. For the animals there are only troughs and fences. Among intensive stock farms are the big dairy units—with several hundred cows—in the United States, in western Europe (France, north Italy), and in eastern Europe and the Soviet Union. There are three major layouts: parallel buildings; monobloc buildings (Hungary, East Germany); and circular layout, with the milking parlour in the centre (United States, north Italy). The covered feedlots for fattening beef, in the United States Middle West and elsewhere, feed from several hundred to several thousand head and are generally built with a shelter for the animals and with tower or bunker silos. Large units for hog production often have many buildings, partly to reduce disease risks and partly to separate the various animals—e.g., the suckling sows, in-pig sows, fattening pigs, and boars. Some systems, however, use only one or two types of buildings. Large poultry units, specialized either for egg or for broiler production, use large identical buildings, the number depending on the unit size.

**Farms in underdeveloped areas.** In the underdeveloped areas, two types of buildings are found: those of the latifundia, or large plantation-type farms, and those of the small-owner or tenant farms. In these, buildings are generally small and scattered, the construction of a single large building being too expensive.

**Mixed farms.** The small and medium farms, which characterize European agriculture and which exist in many other parts of the world, are managed on the traditional mixed-farming and animal-husbandry system. Consequently, this type of farm normally has several service buildings: one for machinery, one for hay and cattle, another for hogs, another for sheep. In mountain areas, however, there often is a single building, including the house. With the increase of the farms' average size in these areas, there is relative specialization, and the number of buildings in the newly built farms is decreasing.

**Building and enclosure materials and construction.** These include homes (farmhouses), livestock barns and shelters, buildings for machinery and supplies, and crop-storage and special-purpose structures.

**Farmhouses.** The basic requirements for the farmer's family are about the same as those of the urban family, but certain features of the farmhouse depend on the farm-life pattern. Because the farmer generally comes directly from the fields or the service buildings, with soiled clothes and boots, it is necessary to provide a rear entrance with a washroom or lavatory and clothes-storage space. For the same reason, many farmers prefer a dining place close to the kitchen or included in it. The house must include an office and a large food-storage place with ample refrigeration, including a freezer in many countries, as most farm families are large. There are usually three or four bedrooms.

Satisfactory modernization of old farmhouses is difficult in some cases, but if the available surface is important and the main walls strong, renovation can give good results. The cost of a new house must be proportionate to the farmer's income; for this reason, farmhouses in un-

Extensive  
and

stock  
farm types

Early  
housing  
for  
livestock

derdeveloped regions have a smaller surface with a main room (kitchen and dining room), two or three bedrooms, a large washroom, and a storage place.

*Livestock barns and shelters.* These tend to become the most important elements of the farm layout. Two general types of animal shelters may be distinguished: the multipurpose type, a single-story building with clear-span roof construction, useful for feed storage and machinery, as well as for livestock; and the specific type, designed for a particular type of animal.

Types of  
cattle  
housing

There are two major cattle-housing methods, the stall barn (or stanchion barn) and the loose-housing system. In the stall barn, each animal is tied up in a stall, for resting, feeding, milking, and watering. The typical plan has two rows of stalls. In older buildings, hay and straw are stored in an overhead loft, but in modern layouts adjacent buildings are generally used.

In cold and moderate climates the barns need insulated walls and ceilings, as well as ventilation systems, either natural or power-operated. In mild and hot areas the barns are open on one or two sides. The loose-housing system, developed in the United States after World War II, is now employed throughout the world. Basically, it includes a wood- or metal-framed shelter, arranged so that the animals can move freely inside and sometimes also between the shelter and an outside yard. Depending on the bedded areas, four types can be distinguished: loose housing on permanent litter—i.e., straw, corncob, sawdust; loose housing in free stalls or cubicles; loose housing on slatted floors; and loose housing on sloped concrete.

In some countries, in old as well as in new buildings, dairy cows are housed in stall barns that include milk rooms. Milking takes place in stalls, and the milk is carried either in cans or directly by pipeline to a refrigerated tank in the milk room. Modern layouts with loose housing always include a milking parlour, either stationary or rotary. Two types of loose housing are used: loose housing on permanent litter and loose housing in free stalls, either under a clear-span roof or under a narrow lean-to roof. Beef-breeding cows often live on pastures, with only open-front sheds, during the calving period. In France and Scotland, however, they are kept in barns all winter. For fattening steers there are two major housing systems. The first of these is the American system, with very large groups of animals and a wide surface per animal. In the western United States, the open feedlots include only fences, troughs, and alleys for feed distribution. In the Midwest Corn Belt, a shelter is often included. The second, the European system, is characterized by very small groups (10 to 20 animals each) and a very small surface, generally covered. Any of the four loose-housing systems can be used.

For horses and ponies it is customary to use individual stalls, where the animal can move freely, even though this requires more space. Mules may be kept together in large pens. In mild climates, sheep and goats live on pastures without any shelter. The facilities include fences, waterers, corrals, dipping vats, and lambing and shearing sheds. In moderate and cold climates, the flock is wintered in sheds. The trend is toward clear-span buildings, with large alleys so that trailers can distribute feed into racks and troughs. Ewes are housed by groups (50 to 100 each) and special pens are kept for lambs. Feed racks and fence partitions are generally movable. For the dairy ewes there are special milking parlours. Goats are housed either in tie stalls, for small flocks under 50 head, with milking on the spot, or in pens, for larger flocks housed by groups, with milking in a special milking parlour. Pig housing varies for sows and fattening pigs. The sow lives with its litter for four to eight weeks according to the weaning age chosen. During this period there are two types of housing: movable, individual houses (generally of wood) located on or close to pastures and fixed in place, and central farrowing houses. A sow may farrow and live with its piglets in a single pen or farrow in a special stall, to avoid possibly crushing the piglets, or may farrow tied up by a chain or a harness. The pregnant sows live either free in groups of six to 12

or tied up or blocked up inside individual stalls. In cold climates the house is heated; in all modern practice infrared lamps or tubes are used to keep the piglets warm.

Fattening pigs, like fattening beef cattle, may be kept either in a simple feedlot, in large groups with a wide surface per head and a simple open shelter, a system widely used in the United States Corn Belt, or penned in a closed building, isolated and ventilated, each pen holding seven to 15 pigs. This is the most common system in Europe. Size of the pig units varies all the way from five sows or 20 pigs to large farms of up to 100,000 pigs. Poultry is the most industrialized type of animal production. Some of the breeding phases no longer take place in farms but in specialized plants; the farmer buys either chicks for broiler production or young layers for egg production. The typical modern broiler house holds from 10 to 100,000 birds, with automated feeding. Two types of facilities can be used. The broilers can be put on the ground on a deep litter of wood shavings, on wire mesh above a pit, or on a combination of these two floors. Alternatively, the broilers can be housed in metal cages, on three stories, each cage holding three to ten animals. In this case, feeding and cleaning are mechanized and the density is higher. The typical laying house holds several thousand hens. The same facilities as for broilers are used, but use of the cage is more common for layers. There are several types of cages, some of which are mechanized to facilitate feeding, cleaning, and egg collecting. Each cage can hold one to five hens. The density can reach about 23 hens per square metre (0.5 square feet per hen). The main types are cages in two- or three-story batteries (California cages), which are not superposed but rise in tiers; and flat-deck cages, which allow maximum mechanization. The buildings are generally one story, fully enclosed; they have insulated structures with sophisticated ventilation systems. Turkeys and other fowl are housed like poultry but generally on the ground. Rabbit production involves housing by groups in cages, on one, two, or three stories.

Modern  
broiler  
houses

*Buildings for machinery and supplies.* This type of building is designed solely to afford protection from the weather, mainly rain. Machinery storage should have as much surface as possible between the interior posts, without being too deep, so that each machine can be taken out easily. The best solution is a clear-span shed, wood- or metal-framed, eight to ten metres wide (26 to 33 feet), open on one side and 4.5 metres (15 feet) high under the gutter. At the end of the shed, one bay is reserved for repair and maintenance and another for tools. This part is equipped with sliding or overhead doors. The same shed, or another, can be used for storing the fertilizers, seeds, and pesticides.

*Crop storage.* Wheat, barley, shelled corn (maize), and other cereals can be stored in farm bins if the moisture is below a certain limit (from 10 to 15 percent). In some cases artificial drying is necessary before storage, though it is possible to store wet grain, especially shelled corn, in airtight silos for animal fodder. The most common methods of storage of dry grain are (1) in piles of 1.5 to three metres (five to ten feet) on a waterproof floor in a building with reinforced walls; (2) in square or round bins erected within a building, usually of timber, plywood, corrugated steel, or wire mesh lined with waterproof paper; and (3) in watertight bins, often of corrugated metal, with their own roofs, for outside erection. Ear corn is dried by natural ventilation through a crib of limited width, located in a building or outside. Loose or baled hay is stored and sometimes dried by ventilation with fresh or heated air, either under sheds or in special installations called hay towers. Silage is made to conserve moist fodders, such as corn, sorghum, and grass. There are two types of silos. The horizontal silo is a parallelepiped, either cut into the ground (trench silo) or built above ground (bunker silo). The floor is natural earth or concrete. The walls can be concrete, timber or plywood, or sheet steel. The capacity varies but can be large. The tower silo is an above ground cylinder, with a six- to nine-metre (20- to 30-foot) diameter and a 15- to 20-metre (50- to 65-foot) height.

Silos

Ordinary silos, which are only watertight, are of wood, concrete, masonry staves or blocks, or steel. Special airtight silos with steel walls and a fused-glass surface are used for storage of high dry-matter silage, called "haylage." Fruit and vegetable storage for family consumption is usually in caves or cellars. For crops to be marketed, conditioning and storage generally are handled by commercial enterprises, but some large, specialized farms have their own storage. The buildings are insulated, and temperature control is assured either by ventilation with outside air (i.e., for potatoes and onions) or by refrigeration (i.e., for apples).

**Special-purpose structures.** Many secondary farm structures, such as smokehouses and well houses, are a leftover of the past, but some are necessary in specialized farms. A typical example is the tobacco barn, built for static air circulation.

**Table 1: Farm-Building Expenditures in Developed Countries**

	year	expenditure (\$000,000)
France	1960-62*	130
West Germany	1960-62*	300
United Kingdom	1968	240
United States	1960	1,500

\*Average for years given.

**Economic impact.** There are no complete statistics on farm-building expenditures. It is only possible to quote figures for some developed countries. These are given in Table 1. The trend is toward a rapid increase, except in the United States. The statistics given in Table 2 show farm-building values in some developed countries.

**BIBLIOGRAPHY.** ORGANIZATION FOR EUROPEAN ECONOMIC COOPERATION, *Farm Buildings, Including Their Remodelling and Adaptation*, 2 vol. (1958-60), is a survey of farm building practice in the United States and western Europe, including farmhouses. JOHN B. WELLER, *Farm Buildings* (1965), is the most comprehensive technical book on the subject; BIRGER NYSTROM and BERTIL LILLIEHOOK, *Jordbrukets Driftsbyggnader* (1960), also deals with the whole subject, excluding farmhouses, and includes many photographs and legends of figures written in English. Some works on animal housing are: DAVID SAINSBURY, *Animal Health and Housing* (1967), emphasizing physiologic and sanitary aspects; *Pig Housing*, 2nd ed. (1970), with good explanations on the numerous facilities described; and ALBERT MEHLER and WERNER HEINIG, *Bauten für die Rinderhaltung* (1968), the most recent and comprehensive work on cattle housing, including many figures. The ELECTRICITY COUNCIL, LONDON, *Grain Drying and Storage* (1968), provides a short but exhaustive guide on the subject. See also the ORGANIZATION FOR ECONOMIC COOPERATION AND DEVELOPMENT, *Capital and Finance in Agriculture* (1970), one of the very few documents about the national economic impact of farm buildings; and the AGRICULTURAL RESEARCH COUNCIL, LONDON, *A Bibliography of Farm Buildings Research* (1969), including publications on a wide range of subjects related to farm buildings from many countries.

(R.Ma.)

## Farm Management

Farm management normally consists of making and implementing the decisions involved in organizing and

operating a farm for maximum production and profit. Farm management draws on agricultural economics (q.v.) for information on prices, markets, agricultural policy, and economic institutions such as leasing and credit. It also draws on plant and animal sciences for information on soils, seed, and fertilizer, on control of weeds, insects, and disease, and on rations and breeding; on agricultural engineering for information on farm buildings, machinery, irrigation, crop drying, drainage, and erosion control systems; and on psychology and sociology for information on human behaviour. In making his decisions, a farm manager thus integrates information from the biological, physical, and social sciences.

Because farms differ widely, the significant concern in farm management is the specific individual farm; the plan most satisfactory for one farm may be most unsatisfactory for another. Farm management problems range from those of the small, near-subsistence and family-operated farms to those of large-scale commercial farms where trained managers use the latest technological advances, and from farms administered by single proprietors to farms managed by the state.

In Southeast Asia the manager of the typical small farm with ample labour, limited capital, and only four to eight acres (1.6-3.2 hectares) of land, often fragmented and dispersed, faces an acute capital-land management problem. Use of early maturing crop varieties; efficient scheduling of the sequence of land preparation, planting, and harvesting; use of seedbeds and transplanting operations for intensive land use through multiple cropping; efficient use of irrigation and commercial fertilizer; and selection of chemicals to control insects, diseases, and weeds—all of these are possible measures for increasing production and income from each unit of land.

In western Europe the typical family farmer has less land than is economic with modern machinery, equipment, and levels of education and training, and so must select from the products of an emerging stream of technology the elements that promise improved crop and livestock yields at low cost; adjust his choice of products as relative prices and costs change; and acquire more land as farm labour is attracted by nonfarm employment opportunities and farm numbers decline.

On a typical 400-acre (160-hectare) corn-belt farm in the United States with a labour force equivalent to two full-time men, physical conditions and available technologies allow a wide range of options in farming systems. To reach a satisfactory income requires operating on an increasing scale of output and increasing specialization. Corn and soybean cash-crop farming systems have increased in number along with corn-hog-fattening farms and corn-beef-fattening farms. Thus, the choice of a farming system, the degree of specialization to be chosen, the size of operation, and the method of financing are top concerns of management.

For a typical crop-livestock farm in São Paulo's Paraíba Valley, Brazil, large-scale use of hired labour creates a substantial management problem. With 30 to 40 workers per establishment, procuring and managing the labour—keeping abreast of demand and supply conditions for hired labour, working out contractual arrangements (wage rates and other incentives), deciding how to combine labour with other inputs, and supervising the work force—are of critical importance.

A rancher with thousands of acres, whether in the pampas of Argentina, the plains of Australia, or the prairies of the United States, is concerned about the rate of increase of the herd through births and purchases and herd composition—cows, calves, yearlings, steers, heifers. Risks from drought, winter storms, and price changes can be high. Weather, prospective yields, and the price outlook are the constant concern of competent and alert farm managers.

On a collective farm in the Soviet Union with 30,000 acres (12,000 hectares) and 400 workers, major management decisions are made by party-state representatives; the collective-farm chairman responds largely to their directives, though in the 1960s signs appeared to point to greater autonomy for the farm manager. Major manage-

The individual farm

The collective farm

ment concerns are determining optimal size of the collective, improving labour incentives, increasing crop and livestock yields, and reducing unit costs—with emphasis on levels of fertilizer, on pesticide and herbicide use, and on conservation of soil and water in crop production.

Thus, the character of the world's agriculture is shaped as millions of farmers manage the resources under their control in ways to obtain as much satisfaction as possible from their decisions and actions, which are made in a large variety of settings in regard to human, capital, and land resource combinations; technological possibilities; and social and political arrangements. Future agricultural progress depends on improving the quality of management and the environment in which farmers make decisions and on helping them adjust their decisions to the changing environment. In the low-income agricultures of the world in the 1970s, expanded research, improved input supplies and transport facilities, enlarged market opportunities, and an otherwise encouraging environment promise to open up a much wider area for managerial choice and decision making.

#### BASIC FARM MANAGEMENT PROBLEMS

**Land, livestock, and labour.** A good farm manager is familiar with the legal description of the farm property for which he is responsible, location relative to other property, roads, markets, and sources of supply, the details of the field arrangement and farmstead layout, the farm's capital position or relation of debts to assets, and the resources of the farm, such as the capabilities of its soils. Such facts enable the manager to analyze and evaluate his resources and plan their use. To calculate profit potential, the farm manager estimates the yield expected from each acre or hectare of land and from each head of livestock. He then applies money prices to these quantities.

The size of a farm business, an indication of its profit-making potential, is measured by the total number of acres or hectares in the farm, acres or hectares planted to cash crops, productive man-work units (the number of workdays of labour required under average efficiency to care for crops and livestock), livestock units kept, capital invested, and total cash receipts. While total acreage is often used to describe farm size, it is not a very satisfactory measure since it does not specify how much land is hilly, stony, swampy, or otherwise unproductive. Total cropped land, total receipts, invested capital, or productive work units are better measures. Though livestock are counted by the head for the sake of comparison, for management purposes one cow is roughly equal in value to two calves, five hogs, ten young pigs, seven sheep, 14 lambs, or 100 laying hens.

While the amount of land in a farm is more or less fixed, many farmers buy or rent additional acreage to increase their volume of output as a means of reducing unit costs. If such acreage is available within a reasonable distance, then land can often be profitably exploited. Other ways of increasing volume include bringing unimproved pasture and woodland into the cropping plan and shifting either to more intensive methods of cultivation or to more valuable crops. Before making major changes, the farm manager attempts to assure himself that the new crops will grow well and will find a market in his area. Almost all the governments of the world today have departments or ministries of agriculture which have been established for the purpose of advancing agricultural welfare by spreading technological information. Often these agencies perform extensive experimentation with new crop varieties, new cultivation techniques, and improved breeds of livestock, thus reducing the burden of risk upon the individual farm manager contemplating such changes. Considerable experimentation and research are also carried out by private agricultural supply firms that hope to improve their competitive position in the marketplace by developing a valuable new product.

In some of the developing countries, traditional patterns of land tenure and laws of inheritance may result in one farmer holding many quite small plots at some distance from each other. To reduce the resulting labour ineffi-

ciency and low productivity and to spur development of large-scale agriculture, governments in these countries have frequently legislated to permit or compel consolidation of such holdings (see LAND REFORM AND TENURE).

Some kinds of farm work are directly productive, some are indirectly productive, and some are not productive at all. Work such as plowing, planting, cultivating, harvesting, feeding, and milking is directly productive. Maintenance of fences, buildings, and machinery, though often necessary, is not directly productive. Such work as trimming shrubbery and mowing lawns, unless it adds to the market value of the farm, is not considered productive. Similarly, capital can be highly productive, as in the case of livestock; indirectly productive (*e.g.*, tractors, buildings, and supplies); or unproductive, as a large, showy barn or house. Land, too, can be highly productive, moderately so, or waste. Analysis of farm records has shown that farmers often overequip their property, thus using buildings and machinery to less than full capacity. Generally speaking, small farmers have been shown to have a higher proportion of their total investment in buildings than in machinery. In the developing countries, where relatively large quantities of human labour and relatively small amounts of capital are employed, a rather different problem exists. In these areas, farm managers need large numbers of people to work the fields during planting and harvest and far smaller numbers to perform routine cultivation tasks. In consequence, these countries face a problem of underemployment of agricultural labour during much of the year.

**Financial management and large-scale operation.** Among the financial tools a farmer can use to analyze, plan, and control his business are financial statements, profit and loss statements, and cash-flow statements. A financial statement tells the amount of money invested in farm assets, outstanding debts, the owner's equity in the business, and the degree to which the farm is liquid and solvent. Liquidity is the ability to meet financial obligations on time, whereas solvency is the ability to pay all debts if the business is forced to discontinue. A profit and loss statement shows sources and amounts of income and operating expenses. Comparison of profit and loss statements over a period of years tells which resources have been most profitable and whether there has been an advance or decline in net income. A cash-flow statement shows the sources and uses of funds at given periods during the year. Such a statement provides a useful check on the accuracy of the farm's other business records.

For the traditional farmer, land and labour (his own and that of his family) are the major resources. Under favourable conditions, the farmer has changed his role from labourer to operator-manager; much larger farm units with high capital investments have resulted. Such conditions include the existence of a considerable body of applicable scientific knowledge, an opportunity for greater efficiency from large-scale operations, the existence of good markets and transportation, the opportunity to routinize and centrally direct farm work, and an absence of community antagonism to large-scale agriculture.

The trend to the substitution of capital for labour is especially noticeable in the United States, for example, where capital accounts for a steadily increasing proportion of farm inputs. In the United States in 1940, capital comprised 30 percent of farm inputs, labour 55 percent, and land 15 percent; by 1970 capital accounted for 65 percent of farm inputs. By 1980, it is estimated that capital will probably comprise 75 percent of inputs, labour 10 percent, and land 15 percent. Capital typically replaces labour when large machines do the work of several men using smaller implements; when chemicals replace the scythe and hoe for weed control; when milking parlours, pipelines, and bulk tanks replace hand-milking operations; when a mechanized installation replaces the fork and bushel basket in dairy, beef, or hog feeding; when automated sprinklers bring irrigation water to crops; when cisterns and lagoons handle animal waste; when combines and forced-air crop drying speed the harvesting of small grain; and in similar substitutions.

Productive and non-productive farm labour

Calculating farm size

Conditions favourable to large-scale operations

The technical knowledge that a modern large-scale farm manager must possess is frequently held to be far greater than that required of most businessmen with equal investment; the capital required to operate such a farm is beyond the reach of many. In consequence, financial-management techniques resembling those of industry are often employed. Capital is imported from the outside; production is scheduled to meet quantity, grade, and timing requirements; and labour is given specific tasks, as in a factory.

Recognizing the economic benefits of large-scale agriculture, many underdeveloped countries have attempted to create conditions for its existence. National governments, often with outside help, have financed large-scale development programs, involving irrigation or improvement of huge acreages by means of dams, drainage facilities, and canals, and these have revolutionized the lives of many traditional farm managers within the space of a few years. Improvements in crops and livestock, marketing techniques and organization, and transport and power have in some cases increased agricultural productivity and income several times over. Since capital and management have been in the hands of government, the traditional farm manager has, however, often lost some of his independence, and not all such programs have succeeded. Poor planning and management by government authorities and resistance from the farmers themselves have led to some expensive failures.

The commodity market

**Reducing market risks.** The marketplace for agricultural commodities is exceptionally risky for three important reasons. First, no single farm producer can place or withhold enough of a single item on the market to affect the market price; second, the quantity of a commodity taken off the market does not increase in proportion to price declines; third, the farm manager cannot respond to falling prices by quickly switching production from an unprofitable item to a profitable one. To reduce his risks and safeguard profits, the farm manager may specialize or diversify depending on conditions; he may also use the futures market (see below).

A specialized farm manager concentrates his effort on the production of one item such as wheat, cotton, milk, eggs, or fruit. By such specialization he can realize the benefits of large-scale production and can make the most money from an enterprise in which he is highly skilled. On the other hand, the specialist is vulnerable to sudden changes in the market, to plant and animal diseases, and to soil exhaustion resulting from cultivation of a single crop.

Diversification—the spreading of one's talents over more than one farming enterprise—may be accomplished horizontally or vertically. Horizontal diversification means the production of more than one item for sale. In vertical diversification, the farm manager handles raw products after harvest by processing, packaging, transporting, or even selling at retail. A poultry farmer who produces eggs and washes, candles, grades, packages, and markets them at retail is said to be vertically diversified. He has taken on some of the jobs that could have been performed elsewhere, and as a result he generally receives a better return for his efforts.

Programs of agricultural diversification have been carried out by some developing countries, with the government acting as a kind of national farm manager. Upon achieving independence, nations such as Ghana and Nigeria, in West Africa, found their economies highly dependent upon a single raw agricultural export (cocoa for Ghana; palm oil for Nigeria). Sharply falling prices for these commodities or epidemics of plant disease were seen to have disastrous effect on national prosperity. Erosion problems also caused concern. The governments responded by horizontally diversifying into other profitable crops and vertically diversifying in establishment of industries to process these commodities or turn them into manufactured goods before export.

A capable farm manager may use the futures market to try to minimize his risks. In the futures market, the farm manager contracts with some buyer to deliver a given quantity of some commodity at a specified date in

the future for an agreed price. The buyer is often a speculator who hopes that prices will rise, enabling him to sell the commodity or the contract at a profit. Futures markets enable the farm manager to establish in advance a price for a crop or earn payment for holding a crop in storage. Futures markets also permit some farmers to speculate on a price increase without storing a crop, establish in advance the price of livestock feed intended for later use, and establish an advance price for livestock.

#### MANAGING LARGE, SMALL, AND MIDDLE-SIZED FARMS

Farm management specifics vary all over the world; it is possible here to cite only some of the most typical practices in several leading agricultural countries.

**Large-farm management.** Research has shown that large farms produce more efficiently than small farms. In sugarcane production, for example, the most efficient farm may include many thousands of acres or hectares. Yet, a well-managed dairy farm might achieve greatest efficiency with two men and fewer than 100 cows. In the future, as technology advances, the farms that are managed most efficiently will probably be larger than the most efficient farms at present.

Large farms can reduce costs by claiming volume discounts on their purchases. They can negotiate prices on fertilizer, seed, crop chemicals, petroleum products, machinery, and repair services. Large operators also have an advantage in selling their products. Managers of large corn farms, for example, can contract directly with a large processor for an entire year's production of given quantity and quality for a specific date in the future, thus commanding a higher price. The middleman is eliminated, and production, handling, and processing can be prescheduled for greater efficiency. Large farms also have a smaller investment in machinery and buildings per crop acre.

**United States.** The increase in the capital requirements of United States farms has already been described above. These changes in American agriculture are, to a large degree, the result of a revolution in financial management. Up to about 1930, little outside capital was needed to finance farming operations. Today, capital investment has vastly increased; farmers obtain their production goods and services—land, machines, breeding stock, seed, fertilizer, and other necessities—in a variety of ways.

Meeting capital requirements

Renting land is one way. In contrast to earlier days when land ownership was considered the ideal, renting land is now a widely accepted management practice. Large acreages of corn land in the Corn Belt, wheat land in the Great Plains, and cotton land in California and Arizona are operated by renters. Renting land enables farmers to operate on a much larger scale than would be possible under ownership. Specialized rice growers in the Sacramento Valley of California, who own tractors, tillage tools, and harvesters, receive rice-acreage allotments from the federal government. Such growers own no land, renting it instead from owners who have no rice allotment. Growers prepare the ground, irrigate it with water supplied by the landowner, and contract for application of seed and fertilizer. When the crop is ripe, the growers harvest the rice with their own combines and haul it to a warehouse for drying and storage. In upland areas of the valley, other growers raise tomatoes under contract from a canner, renting their land from a general crop farmer.

Farmers who do not wish to tie up capital in high-priced farm machinery can contract for harvesting of such crops as wheat, corn, grain sorghum, and barley. An airplane operator may seed, fertilize, and apply weed spray for a rice grower. Vegetables, fruit, and nuts may be picked under contract by shipper-packers whose crews move from farm to farm. Similar operations in livestock include sheepshearing, dehorning, branding, and artificial insemination.

Rental of machinery is another management device farmers use to obtain the services of equipment too expensive to be owned individually. Rental of livestock is also receiving attention. In the northeastern United States, dairy farmers lease cows. The owner of the cows

may be a contracting firm, a local bank, or an individual investor for whom the bank serves as agent. The scheme is useful both to older farmers who wish to retire but want to retain their interest in dairying and to young dairymen who want to expand but have limited capital.

**Soviet Union.** Following the Bolshevik Revolution of 1917, large landholdings were expropriated by the state and the land was distributed among the peasants. In 1928, collectivization of Soviet agriculture was initiated on a large scale; a three-part structure composed of state farms (*sovkhoz*), collective farms (*kolkhoz*), and private plots emerged. The state farms, or *sovkhoz*, are owned, managed, and operated by the state. Workers on state farms are salaried employees of the state; farm managers are state appointees. During the 1960s state farms increased sharply in numbers and declined in size. Much of the increase in numbers is the result of new state farms being established in the virgin land areas and the consolidation of smaller collective farms into state farms.

The collective farm leases land from the state and is worked by members of the collective under an elected committee that, as the management unit, has the responsibility of organizing land, labour, and capital in accordance with production requirements. Until recently, payment to collective members consisted of their share of the collective's produce or income from its sale. Each individual's share was determined by a workday unit that took into account the time spent performing a job and the level of skill required for the job. Although the system is still used, most collective farms have shifted to a monthly wage similar to that used by state farms.

Private plots up to two acres (0.8 hectares) in size and operated by individual workers occupy only 3.2 percent of the planted area in the Soviet Union but produce nearly half the potatoes, 40 percent of the eggs, 20 percent of the meat, and 13 percent of the vegetables.

The Soviet  
farm  
manager

Though the Soviet farm manager's role has in the past not included primary decision making, which has been done for him, there has been a trend since the 1960s toward more management autonomy in farm production. The Soviet government is promoting greater efficiency in agriculture by increasing the level of inputs and by improving incentives to farm labourers. These measures include financial concessions to farmers and expanded use of fertilizers, pesticides, irrigation, and drainage. The Soviet farm manager has additional functions that in other countries are performed by government and welfare officials, such as providing roads, recreation, education, health, and welfare to members of the collective.

**Israel.** A unique feature of the management of agriculture in Israel is its cooperative settlements, which evolved as a result of the needs encountered by immigrants who were new both to their surroundings and to farming as a profession.

The two basic types of cooperative settlement are the moshav and kibbutz. A moshav is a village containing up to 150 farm family units and supported by a strong multipurpose cooperative organization. Each family is an economic and social unit, living in its own house and managing and working its own fields. Although each farmer is independent, his social and economic security is ensured by the cooperative structure of the village, whose organization markets his produce, purchases his farm and household equipment, and provides him with credit and other services.

A kibbutz, numbering from 60 to 2,000 members, is a true collective based on common ownership of resources and on pooling of labour and income; it functions as a single democratic unit. Under the supervision of a manager, each member performs an assigned task but receives no salary or wages because all his needs are provided by the kibbutz.

Israel's agriculture is highly organized into farm societies. One society, the Farmer's Federation, has a membership of 7,000 citrus growers. There are plantation development companies and associations of wine, fruit, milk, and cotton producers.

Production  
for export

**Australia.** A significant characteristic of farm management in Australia is the emphasis on production for

export markets. Since the production of fine wool is the most important rural industry, grazing of sheep is a leading enterprise. Production of wheat, meat, dairy products, and fruit for export also figures large in the nation's agricultural economy. Australian export production is highly organized through statutory marketing authorities. Ten such authorities supervise the marketing of wheat, dairy products, meat, eggs, canned fruits, dried fruits, apples and pears, wine, honey, and wool.

Getting started in almost any farming venture in Australia requires substantial amounts of capital.

**Management of small and middle-sized farms. Canada.** Canadian agriculture consists largely of family farms, managed and operated by the owners. Less than one farm in 100 has hired management. A Canadian farm may vary in size from a factory-type broiler chicken plant of an acre or two (up to one hectare) to a cattle ranch that includes several townships. On a mechanized grain farm a farmer may operate 1,000 acres (400 hectares) or more with very little hired help. While most farmers in Canada own the farms they operate, there is a growing tendency to rent additional land. Current management trends also include increased use of commercial fertilizer and chemicals for pest control.

Farm management practices vary widely. Some farmers who rent land pay cash rent. In other cases the landlord takes a share of the crop or a share of the income from the sale of livestock or milk. On farms where most of the income is derived from the sale of grain, it is common for the tenant to give the landlord one-third of all grain produced. The landlord supplies the land, pays the taxes and fire insurance on the buildings, and provides materials for maintaining buildings and fences. Integration, the management of two or more stages of production and marketing, is spreading, with the trend most noticeable with sugar beets and canning crops.

**United Kingdom.** British farmers are well known for their efficient management and use of mechanical aids. Milking machines are employed on all but the smallest farms; electricity is widespread; grain combines are common; and there is one tractor for every 35 acres (14 hectares) of arable land. British farmers also use great quantities of commercial fertilizer per acre, the cost of which is subsidized by the government. The government also subsidizes the cost of lime, eradication of tuberculosis, construction of silos and other capital equipment, and pays part of the cost of voluntary consolidation of small farms into more efficient commercial units.

Several agricultural commodities are subject to the authority of government marketing boards: some buy produce, others control producer-buyer contracts, and still others maintain broad control over marketing conditions. Cereals, potatoes, eggs, sugar beets, and wool are the principal products governed by marketing bodies.

**Denmark.** In Denmark, successful farmer cooperatives play a major management role, extending credit and controlling production, marketing, import, export, purchasing, and sales. Through these cooperatives, Danish farmers enjoy the benefits of large-scale production and distribution despite the small size of individual farms. About 90 percent of Denmark's output of pork and milk and about 50 percent of egg output is marketed cooperatively. The number of farms in Denmark has been declining in recent years, but those remaining are becoming larger. Average size in 1967 was 40 acres or 16 hectares. The family farm predominates.

Coopera-  
tives in  
Denmark

**Farm management in developing countries.** Many of the problems of the farm manager in developing countries have been described above. For further information, see AGRICULTURAL ECONOMICS; ECONOMIC DEVELOPMENT; and LAND REFORM AND TENURE.

**India.** Farm management practices in India range from the modern and sophisticated to some that have been in use for centuries. Illiteracy, inadequate water, unreliable power supplies, poor transportation and communications, making the timely acquisition of supplies and marketing of produce difficult—all hamper the development of modern farm management practices. For example, many farmers are unable to read the directions on a

sack of fertilizer, to write an application for a production loan, or to calculate their profit and loss. Where progress has been made in introducing improved farm management techniques, visual and oral methods of instruction and training are being used successfully. Training techniques include on-farm demonstrations, farmer exchange programs, tours, short courses, literacy classes, exhibits, and audio-visual vans.

*Republic of Zaire.* Shifting cultivation is the typical method of farming in the Republic of Zaire, formerly known as the Democratic Republic of Congo. The native farmer clears two or three acres (about one hectare) in the forest or savanna, crops it until the fertility of the land declines, then moves on to another area. Fertilizer, insecticides, and fungicides are not generally available.

A land-settlement plan, called the *paysannat* system, in which strips of cultivated land were alternated with bush and grassland, was introduced in the 1930s to increase production. This system, however, has disintegrated since independence due to the lack of management personnel, government extension services, and disruption of marketing channels. Often side by side with traditional farms are large modern plantations owned, managed, and operated by individual Europeans and corporations. Plantation crop yields are two to ten times those of indigenous farms, probably pointing the direction of future development.

**BIBLIOGRAPHY.** In *Principles of Farm Management*, 2nd ed. (1960), H.C.M. CASE and PAUL E. JOHNSTON describe the scope and principles of farm management, the technique for achieving a coordinated farm plan, and the procedures to follow to achieve success. In *Profitable Farm Management*, 2nd ed. (1963), JAMES E. HAMILTON and W.R. BRYANT set forth the principles of efficient farm management and explain the ways to apply these principles to gain more profit and a better living from farming. DON PAARLBERG, *Future of the Family Farm* (1971), discusses the changes taking place in farming in the United States and current trends that indicate future developments in the management of American farms. D. HOWARD DOANE, *Vertical Farm Diversification* (1950), discusses the financial advantages of performing services beyond production of raw farm products, such as storing, processing, packaging, transporting, and retailing. TRIMBLE R. HEDGES, *Farm Management Decisions* (1963), outlines the principles and procedures for making intelligent farm management decisions and improving the skills used in the decision-making process. I.F. HALL and W.P. MORTENSON, *The Farm Management Handbook*, 4th ed. (1963), explains the principles of farm organization, planning, management, and operation used by successful farmers. ELTON B. HILL and MARSHALL HARRIS, *Family Farm-Operating Agreements*, rev. ed. (1963), explains a sequence of agreements through which young farmers can acquire equity in the family's farming enterprises. *Economic Principles in Financial Management* by WEIGLE and RIECK (1971), points out the role of good farm business management in profitable farming. TRIMBLE R. HEDGES and GORDON R. SITTON, *Farm Management Manual* (1956), shows how to inventory farm resources, plan for their best use, and analyze farm operations to achieve maximum efficiency. G.W. FORSTER, *Farm Organization and Management*, 3rd ed. (1953), treats farm management in both theory and practice with emphasis on the use of approved management techniques. FRANK P. KING and L.S. HARDIN, *Better Farm Management* (1956), is designed to help young men prepare for a career in farming as a business and provide guidance in making wise management decisions. The UNITED STATES DEPARTMENT OF AGRICULTURE, *Yearbook of Agriculture* (1970), includes a summary of developments in new farm management practices. *Managing Our Financial Future* by extension economists at the University of Minnesota, the University of Wisconsin, and the United States Department of Agriculture (1971), cites the adjustments that are taking place in the resource mix in modern farming, especially the rapid increase in inputs of capital and management relative to land and labour and the greater skill needed to manage farm finances successfully. The *Use of Future Markets* by DOBSON and WEIGLE (1971), describes the use of future markets as a tool that can be used to help reduce the risk from unexpected price changes. J.H. SITTERLEY, *Opportunities in Commercial Farm Management* (undated, Ohio State University), presents a background for those who are considering farm management as a career. L.L. JONES, *Soviet Union Agriculture with Emphasis on Cotton Production and Distribution* (1970), describes the organizational structure of present-day Soviet agriculture and the developments that led to the present management system. *Farming in Canada*, published by the CANADA DEPARTMENT OF AGRICULTURE (1970),

outlines the physical and social conditions under which farming is carried on in Canada. Current worldwide agricultural developments that reflect the farm management practices being followed are reported in *Foreign Agriculture* (weekly) and in various publications of the United States Department of Agriculture.

## Farnese, Alessandro, Duke of Parma

Alessandro Farnese, duke of Parma and regent for the Netherlands under King Philip II of Spain, played a crucial role in the maintenance of Spanish possessions there. First as a general and brilliant strategist and later as an equally gifted diplomat and political administrator, he succeeded in winning back the Catholic southern Netherlands from the control of the rebellious United Provinces and defending them against the Union's Protestant leader, William the Silent, prince of Orange.

alle Gallerie de Parma, Italy

Alessandro Farnese, duke of Parma, oil painting by Frans Pourbus the Elder (1545-81). In the Galleria Nazionale, Parma, Italy.

The family of condottieri (chiefs of bands of mercenaries) into which Alessandro Farnese was born obtained its high position in the 15th century in the service of the popes, as well as through a custom of contracting politically useful marriages. A Farnese even became pope in 1534, assuming the name of Paul III; he set up the papal states of Parma and Piacenza as a duchy in order to award them to his illegitimate son Pier Luigi. A son of Pier Luigi, Ottavio (duke of Parma from 1547 to 1586), married Margaret of Austria, the illegitimate daughter of the Habsburg emperor Charles V; and from this union twins were born on August 27, 1545, only one of whom, Alessandro, survived.

The lineage of his mother and the quarrels of his father with the Emperor determined Alessandro's destiny. When still a child, he was sent to the court of Philip II of Spain, another member of the Habsburg family, as a guarantee of Duke Ottavio's loyalty to the Habsburgs. Philip was then in Brussels, in the Netherlands, and Alessandro stayed there from 1556 to 1559, becoming acquainted with men who would be the principal actors in the dramatic religious and political conflict soon to tear the Netherlands asunder. In 1559 he went to Madrid, where he became a friend of the royal family. He next returned to the Netherlands, in 1565, where his mother, Margaret of Parma, had been regent for six years. In the same year, at the age of 20, he married the Portuguese infanta Maria after protracted matrimonial negotiations. He did not meet his betrothed until two days before his marriage, and the household that established itself at Parma in 1566 was not particularly happy, since the chief interests of the young husband remained hunting, riding,

Early  
career

and warfare. Alessandro's correspondence of this period is filled with complaints of his enforced idleness.

The opportunity for action that he had so long awaited arrived unexpectedly in 1571, when, appointed as a lieutenant to Don John of Austria, he fought brilliantly against the Turks in the Battle of Lepanto. The following year, however, Alessandro returned, not without resentment, to Parma. Religious disturbances in the Netherlands soon freed him from inactivity when, in 1577, Don John, by then the Spanish governor general, charged with suppressing the revolt, appealed for his support. In 1578 Alessandro fought energetically in the Battle of Gembloux, in which the rebellious Dutch forces were routed, and punished a number of towns with a harshness that contrasts with his subsequent attitude.

Governor  
general  
of the  
Nether-  
lands

Don John died October 1, 1578, and a few days later Philip II appointed Alessandro as governor general of the Netherlands. For the first time the sovereign had made a fortunate choice. Farnese, Italian on his father's side, had all the intellectual flexibility of that nation, which in the Netherlands contrasted favourably with the Castilian severity and sectarianism. He was a great soldier, with a fundamental knowledge of his profession. A sociable man, gifted with considerable natural attraction, he rejected all fanaticism. In many ways he resembled his foe William of Orange, who had also, for the first time, encountered an adversary of his own stature.

Thus, Alessandro began, at the age of 34, a brilliant career, which ended only with his death. He immediately showed the full measure of his astuteness by undertaking a diplomatic reconciliation with the Dutch states that had Catholic majorities, while continuing military operations against the Union of Utrecht, the alliance of rebellious provinces, mostly Protestant, led by William of Orange. Although seriously ill, Alessandro conducted the difficult siege of Maastricht and captured the town on June 29, 1579, thus delivering a heavy blow to the prestige of his adversary. His negotiations with the southern, largely Catholic, provinces, in the meantime, were concluded by the Treaty of Arras in May 1579. One of the main achievements of his administration was accomplished in this treaty, which restored peace in the southern provinces. The agreement was reached at the cost of certain Spanish concessions, which included the removal of foreign troops and Farnese's own departure within six months. An expert politician, Farnese succeeded, however, in keeping himself in the Netherlands as commander and regent, going so far as to enter into conflict with his mother, whom the King had initially appointed to the position in order to attain his purpose.

The removal of foreign troops and the organization of a "national" force left Farnese with only 15,000 poorly trained soldiers, the majority of whom were of the same nationality as their opponents. It was a pitiful band that he led to the sieges of the next two years. Unable to attempt long sieges, Farnese negotiated as quickly as possible and granted honourable surrenders. He captured the city of Tournai in November 1581 and permanently established his government there. He succeeded in forcing another surrender the following year, but his army was at the end of its strength and could no longer undertake extensive operations against the Union of Utrecht, which continued under the leadership of William.

Farnese, using all of his talents of persuasion, then succeeded in obtaining from the King, and from the Spanish-controlled provinces, the recall of Spanish troops and the dispatch of Italian units into the Netherlands. Finally, with sufficient reinforcements, he switched to the offensive at the end of 1582. Heading an army of 60,000 men, with full powers to act, he devised and carried out an excellent strategy.

Toward the middle of 1583, by conquering the towns of Diest and Westerlo, he endangered communications between Antwerp and Brussels. He subdued several coastal towns and tentatively planned to encircle the United Provinces by capturing the county of Zutphen. In the first half of 1584 he conquered three more strategic positions, thus cutting off Antwerp from the sea. Ypres and Bruges surrendered in turn.

Without further delay, Farnese launched the siege of Antwerp. In order to isolate the city, Farnese built fortlets and a pontoon bridge across the lower Scheldt River and succeeded in frustrating all attempts of the beleaguered forces to leave the city. The city surrendered at the end of 13 months, on August 17, 1585, concluding one of the most celebrated sieges of military history.

The  
capture of  
Antwerp

The capture of Antwerp was the climax of Farnese's career: the construction of a solid line of defense against the United Provinces consolidated the union of the Catholic Netherlands, which later became Belgium. The assassination of William of Orange at Delft on July 10, 1584, moreover, relieved Farnese of a redoubtable adversary. On the death of his father in 1586, Alessandro became duke of Parma.

Farnese undoubtedly would have pressed the war northward if Philip II had not compelled him to participate in his scheme for the conquest of England. He was instructed to concentrate his forces on the Channel coast preparatory to invading England, but the defeat of the Invincible Armada in 1588 ended that dream. In Spain part of the responsibility for the disaster was laid on Farnese, and his popularity underwent a serious decline.

Last years

At this point Alessandro fell ill and was tended at Spa, while his lieutenants were left to face the Dutch army, reconstituted by Maurice of Nassau, as well as they could. Exhausted by illness, he died at Arras on December 3, 1592, at the age of 47, just in time to avoid learning of his intended disgrace at the hands of Philip II.

Of all the regents for the Netherlands during the reign of Charles V, none could rival Alessandro Farnese, either as strategist or as diplomat. His great achievement was the restoration of Spanish rule in the southern provinces and the secure perpetuation of Catholicism there.

## Fascism

Fascism comprises a political attitude and a mass movement that tended to dominate political life in central, southern, and eastern-central Europe between 1919 and 1944. Common to all fascist movements was an emphasis on the nation (race or state) as the centre and regulator of all history and life, and on the indisputable authority of the leader behind whom the people were expected to form an unbreakable unity. The word fascism itself was first used in 1919 by Benito Mussolini in Italy; in the following years the influence of Fascism made itself felt in countries as far away as Japan, Argentina, Brazil, and the Union of South Africa, its specific aspects varying according to the country's political traditions, its social structure, and the personality of the leader. The Italian word *fascio* (derived from the Latin *fascēs*, a bundle of rods with an ax in it) symbolized both aspects: the power of many united and obeying one will and the authority of the state, which was the supreme source of law and order and all national life.

### THE PHILOSOPHICAL BASES OF FASCISM

Fascism rejected the main philosophical trends of the 18th and 19th centuries, the "spirit" of the American and French revolutions with their emphasis on individual liberty and on the equality of men and races. The message of the Enlightenment had served to enhance the dignity of the individual and had emphasized openness in a secularized society. In contrast, fascism extolled the supreme sovereignty of the nation as an absolute. It demanded the revival of the spirit of the ancient *polis* (city-state), above all of Sparta with its discipline and total devotion to duty, and of the complete coordination of all

intellectual and political thought and activities against modern individualism and scientific skepticism. The Italian slogan "to believe, to obey, to combat" was fascism's antithesis to "liberty, equality, fraternity," and to the prophetic and Christian messages of peace. The combination of an unquestioning faith and of a virile combativeness was to transform the nation into a permanently mobilized armed force to conquer, maintain, and expand power.

In its beginnings fascism was not a doctrine and had no clearly elaborated program. It was a technique for gaining and retaining power by violence, and with astonishing flexibility it subordinated all questions of program to this one aim. From the beginning it was dominated by a definite attitude of mind that exalted the fighting spirit, military discipline, ruthlessness, and action and rejected all ethical motives as weakening the resoluteness of will. Stressing the irrational and instincts and activism, fascism insisted that the strong will always prevail over the weak, the more resolute over the irresolute. Ultimately everything depended upon the decisions of the leader, decisions to be blindly obeyed and immediately executed. Fascism returned to an authoritarian order, based upon the subordination of the individual and the inequality of caste and rank.

**The reliance on power.** Power is, of course, an element present in all political life. The first major writer to abandon the moral and normative approach to politics in favour of pure power was the Florentine man of letters Niccolò Machiavelli (1469–1527). A man of the Renaissance, he looked to the people of pre-Christian antiquity as the original possessors of *virtù*, the civic virtue necessary to the modern ruler; he believed that Christianity was, unfortunately, "true," but that its stress on meekness and humility would damage political man, weakening and at the same time fanaticizing him. Machiavelli's methodology involved the empirical observation of human nature and behaviour, which he believed to be changeless. His deep feelings about the degradation and corruption of Italy at his time led him to put his hope into the daring and the violence of a great man who would exercise power ruthlessly but with prudence. Power, Machiavelli apparently believed, legitimized the state, if rationally applied, as *raison d'état*, by a man able to manipulate the people and use the army for his own purposes. In his quest for a "new prince" and a new principle of policy he knew that he was opening "a road as yet untrodden by man." The road led to the absolute sovereign state.

**The emphasis on sovereign-state power.** In the bitter and protracted religious conflict of 16th-century France, the French jurist Jean Bodin (1530–96) stressed the importance of the sovereign, but by no means unlimited, power of the state in effective government. During the constitutional crisis of 17th-century England philosopher Thomas Hobbes (1588–1679), saw sovereign power as more absolute, unlimited by the subjects who have authorized it and responsible only to God. For Machiavelli the state was a work of art, created by the skill of the prince whom Machiavelli wished to teach the rules of conduct; for Bodin and Hobbes the state was a rational contrivance to lift central authority above religious and civil disputes. The peace treaty of Westphalia in 1648, in an attempt to end over a century of religious warfare, gave the secular sovereign, generally a hereditary absolutist monarch, the right to determine the religious beliefs of his subjects. The maintenance of law and order became the highest guiding principle, but even at this stage the state had not yet become the object of awe or emotional veneration.

The state became such only after the French Revolution, and above all in the emotional teaching of German Romantic philosophers, such as Johann Gottlieb Fichte (1762–1814) and Georg Wilhelm Friedrich Hegel (1770–1831). For these men the national collectivity assumed, morally and politically, an absolute rank. Fichte's utopian "closed state" was authoritarian, anti-individualistic, and economically self-sufficient.

But Fichte did not endow the state with the sacral aura

that Hegel gave it. For a century, German historiography was to accept the Hegelian concept of the absolute-power state that acts in its own self-interest without consideration for humanitarian principle or for the rights of individuals or of other states. Hegel's followers, like those of Fichte, overlooked the complexity and ambiguity of his philosophy and concentrated on his exaltation of the state as an end in itself, as the "actuality of the ethical idea," as "absolutely rational," and as the source of all "concrete freedom." Only as a subject of the state (specifically, for Hegel, the Prussian monarchy) does the individual gain objective reality and an ethical life. The state's unconditional sovereignty reveals its nature above all in war.

**The integrally autarkic state: the Dreyfus Affair.** In the first part of the 19th century Hegel was, then, the philosopher of a militaristic monarchy opposed to the growing strength of 19th-century middle class liberalism. At the end of the century another antiliberal, anti-individualistic, and authoritarian movement made its influence felt, this time in the middle class democracy of the French Republic. Its leader was Charles Maurras (1868–1952), who repudiated the disunity and verbosity of parliamentarianism. He admired the Roman Catholic Church (but not Christianity, which in his opinion glorified universalism, social unrest, and pacifism), but for the virtues of hierarchic discipline and traditionalist order. The supreme norm of political life was to Maurras the absolute primacy of France and this meant action in France's interest instead of hesitation, parliamentary discussion, and consideration of world opinion.

In 1894, a military tribunal convicted Capt. Alfred Dreyfus, the only Jewish officer in the French general staff, of pro-German espionage. Dreyfus insisted on his innocence, and his case became the centre of a bitter dispute involving questions of the precedence of national interest over objective justice. If Dreyfus were innocent, then the French army command on which France depended was dishonoured and stood accused of intrigue and worse. Antiliberal forces saw in the dispute an opportunity to overthrow the parliamentary republic, in which many high army officers and the church saw something fundamentally un-French, the work of Freemasons and Protestants, Anglo-Saxons and Jews. Whereas Maurras, in his struggle against democracy, pleaded for a return to the ancient monarchy, his compatriot, Maurice Barrès (1862–1923), saw the remedy in a leader who, being in close touch with the masses, would be the embodiment and the effective will of their thought and feeling. Against the rational cosmopolitanism of the "uprooted" intellectuals (a term that he made the title of his most famous novel in 1897), Barrès extolled the close community of a nation with its deep roots in past generations and in the ancestral soil (the "blood" and "soil"—*Blut and Boden* of Hitler). To Barrès the individual was merely a link in the chain of generations, inevitably determined by the blood of common forefathers.

**Vitalism and elitism.** The beginning of the 20th century felt the influence of Friedrich Nietzsche's (1844–1900) contradictory and often misunderstood work. Not a forerunner of fascism, Nietzsche despised German nationalism, anti-Semitism, and the authority of the state. He was, in fact, an extreme individualist, in revolt against all uncritical obedience by believers or followers and against the traditional values of church and fatherland. But he also despised the common man and democracy; he believed in great personalities and their exclusive rights. He found his time lacking in greatness and heroism, and he glorified the courage of warriors, though he meant first of all warriors of the mind, strong enough to overcome their own pettiness and their acceptance of faith or belief that came to them from second or third hand.

Oswald Spengler (1880–1936) shared Nietzsche's feeling of the decadence of Western civilization, brought about by Christianity and democracy, and his faith in the need for an aristocratic elite. Writing during World War I, Spengler insisted that all history is struggle among nations and that each nation's future will be decided by

Maurras and Barrès: the state can do no wrong

The state in German Romanticism

Spengler and Sorel: the struggle of peoples

its power relationships to other peoples. Each people must be "in condition" for inevitable struggle and must trust its leaders; what is significant is not the victory of truth but the triumph of the will-to-power.

The French radical antiliberal Socialist Georges Sorel (1847–1922) in his revolutionary syndicalism emphasized the dynamism and new vitality of a heroic proletariat against an effete bourgeoisie. In his *Reflections on Violence* (1908) Sorel claimed that the working-class movement needed irrational myths to carry out its role in history. This idea influenced many Socialists in Latin countries, especially in north-central Italy, at the time Benito Mussolini was growing up. Violence, Sorel declared, was "sublime" when it was exercised by a movement with a historical mission. In Sorel, radical socialist theory of the left fused with a radical conservatism of the right in common rejection of bourgeois "mediocrity."

Among Italian pre-1914 social philosophers, other more conservative forerunners preached an elitist doctrine of vitality and the competitive power struggle. They turned from Count Cavour's liberal faith in parliamentarianism, which had established the unified Italian kingdom of 1861, to a quest for new elites and new rationales. Among them was Gaetano Mosca (1858–1941). Mosca's *Elementi di scienza politica* (1896; Eng. trans. *The Ruling Class*, 1939) owed much to the Austrian professor of public law Ludwig Gumplowicz (1838–1909), whose fundamental work *Der Rassenkampf* ("Racial Struggle") in 1883 established the "group" as the fundamental unit of sociology, which he interpreted as the science of the interaction of groups. Material need was to Mosca the prime motive of human conduct; conquest and the satisfaction of the conqueror's need by the labour of the conquered, the fundamental essence of history.

Mosca and Vilfredo Pareto (1848–1923) argued that there had always been a ruling class of a few men who held power over the majority; that society is, thus, hierarchically organized, though the elites may change and, in fact, the change of elites is as much the essence of history as are wars between ethnic groups. The new elites carry with them their own values, expressed in social myths that can neither be proved nor disproved and that serve as a call and inspiration to action. The collective psychology of Scipio Sighele (1868–1913) and Gustave Le Bon (1841–1931) hypothesized that crowds obey collective subconscious emotions rather than the rational individuality of their single members, and, therefore, that crowds are highly susceptible to manipulation by leadership that can arouse in them heroism or savagery of which the individual alone would be incapable. Endlessly reiterated statements rather than rational thought influence public morality.

#### THE CONDITIONS FOR THE EMERGENCE OF FASCISM: POLITICAL PREREQUISITES

The troubled state of Europe in the years before 1914 was greatly intensified by the pressures that World War I put on societies that were not yet socially and politically modernized. This was true in varying degrees of Germany, Italy, and Japan, all of whom had entered the war in the expectation of great gains in territory and status, and of acquiring full equality with the older societies of the West. The deep moral depression and confusion which the defeat of 1918 produced in Germany was due to the apparently inexplicable difference between expectations and final failure.

The discrepancy between Germany's advanced industry and her semifeudal-state structure, with its traditional authoritarian basis, had weakened her war effort. The failure on the battlefield led to a deeply emotional nationalism which ascribed the shortcomings not to Germany's backward political structure but to enemy plots and domestic "enemies." Thus, the authoritarian militarist elite was not discredited by the defeat of 1918; on the contrary, the fear of Bolshevism brought support for the defense of the traditional structure.

Though Italy was to be among the victors in World War I, the relative backwardness of its political, social, and economic structure in 1914 put an immense strain on all

aspects of Italian society and life. The failure of expected gains from the war to materialize led to a weakening of the country's insecure liberal foundations. Those who, like Benito Mussolini, had agitated for Italy's entrance into the war in 1915, tried to direct the discontent and fear of the population against the victorious democracies who, unlike Italy, had emerged strengthened from the war. Social unrest frightened the propertied classes, the major landowners, and the church. Instead of carrying through long overdue reforms, they sought for a strong man who could sway part of the masses, war veterans, and lower middle class and turn them against the threat of Bolshevism. Fascism was, thus, regarded as a bulwark against the modernization of Italy. Though this was an underestimation of the syndicalist and radical aspects of Mussolini's original position, he was able to achieve, more than Hitler did later, an accommodation with the old ruling class, the monarchy, the army, and the church.

Fascist movements, wherever they have arisen, have frequently been inspired by national feelings of disappointment, and by the assumed need to close ranks in order to reach often fantastic goals (e.g., the revival of Roman glory). Japan's fascist movement was linked to its attempt in World War I to establish a protectorate over China, which was frustrated, largely, as Japan felt, by the United States. Similarly, the strength of the fascists in Hungary owed much to the bitter national resentment at the loss of its non-Magyar subjects to new or enlarged nation-states created at the end of the war. These new states were not politically strong, and, as in Spain or Latin America, traditional right-wing conservatism, backed by the church and the pre-1914 oligarchy, found itself in conflict with the dynamism of fascism and its contempt for traditional ideas. Later, both were to enter into uneasy alliances in their fear of Bolshevism.

#### SOCIAL AND ECONOMIC CONDITIONS THAT ENCOURAGE THE DEVELOPMENT OF FASCISM

Politically and socially the modern, industrial middle class societies that developed in Britain, Scandinavia, Switzerland, the Low Countries, and France in the 19th century showed a great power of resistance to fascism, which was, on the whole, confined to fringe movements. Even in Germany, with her bitter resentments accumulated from her failure in World War I, which Hitler masterfully manipulated and fused with older resentments, fascism would probably not have come to power had it not been for the inflation crisis of 1923 and the widespread unemployment of the early 1930s. Finally, the rise of fascism in Germany owed much to the weakness of civilian democracy in that country. Germany had originated as a nation-state in 1871, thanks almost entirely to the military-authoritarian tradition of Prussia and the victories achieved by its army without the aid of any other power. The new *Reich* was proclaimed at the gates of Paris, the capital of the defeated enemy, and the German middle classes and German scholarship all willingly accepted the traditional values of the efficient ruling class, though by 1900 these values were insufficient to support an expanding modern industrial society.

Neither a capable semimilitary bureaucracy nor a scientific technology existed in Italy, Spain, Portugal, Greece, or Romania, where low urban and rural productivity during the early 20th century constantly widened the gap between these countries and the modern West and provided a basis for the growth of fascism.

In Italy, the farthest advanced of these countries, it was estimated in 1900 that half the population could neither write nor read. Though the north of Italy made great progress in the first 15 years of the present century, the fact is that even in 1914 the per capita income of the country, measured in standard gold units, was only 105 compared with 237 for Britain and 182 for France. Southern Italy's peasant population lived, according to one account, "in conditions of utmost destitution, illiteracy was the rule. Afflicted with gross dietary deficiency, accustomed to deprivation, and muddled by ceaseless toil, whole regions were innocent of the most elementary education and were consequently not equipped to participate

in the challenge" offered by modern civilization. Archaic traditions and authoritarian religion preserved in Italy and Spain, in Romania, Greece, and Hungary a social system that was outside the modern world.

Fascism was an effort to employ anti-individualism and authoritarianism in modernizing economically backward societies. Arturo Labriola (1873–1959), an early syndicalist, spoke of Italy as a colony of "plutocratic Europe." The leader of an aggressive Italian nationalism, Enrico Corradini (1865–1931), influenced by Nietzsche and Maurras, saw the future as a conflict not between workers and capitalists but between proletarian and plutocratic nations. It was in that sense that fascism may have influenced the new African nations as they tried to organize themselves in the 1950s and 1960s. Despite its reactionary view of man, fascism regarded itself as representing youth against senility, the wave of the future against the effete heritage of the 19th century, biological vitality against the craving for peace and comfort.

#### THE ITALIAN EXPERIENCE

It has been shown that fascist movements arose where traditions and social structures favoured them. Unlike democracy, fascism demands a charismatic leader, a "new prince" as Machiavelli called him, who can gather all the prefascist emotional and social strains into one persuasive philosophy and will appeal to the masses. In Italy Benito Mussolini (1883–1945) was such a leader. From 1902 to 1914 Mussolini wrote many articles in the spirit of a radical Marxist. In this Marxist period of his life he became in 1912 editor of Italy's leading socialist daily, *Avanti!*, in Milan, a position of great influence for such a young man. He was then an extremist in his Marxist views, stressing revolutionary idealism and militant antimilitarism but deprecating dogmatism.

Whereas Marx's conception of history was based on 19th-century humanism and rationalism, Mussolini's was influenced by an early 20th-century emphasis on vitality and biological vital force, on a synthesis of Nietzsche and Sorel with Marx. This inclination to a heroic and active life-force made him, together with Gabriele D'Annunzio (1862–1938), the poet and glorifier of action, the chief propagandist of Italy's entrance into the war on the side of the Allies. It was over this issue that he broke with the Socialist Party, resigned from his editorship, and founded his own paper, *Il Popolo d'Italia*.

**Mussolini's philosophy.** Mussolini's philosophy, which developed slowly as his struggle for power and for a powerful state progressed, was officially presented in his article on the *Dottrina del fascismo* ("Doctrine of Fascism") in the *Enciclopedia Italiana* (1932). It reveals the pragmatic beginnings of the movement with complete frankness: "Our program is simple. We wish to govern Italy. They ask us for programs, but there are already too many. It is not programs that are wanting for the salvation of Italy but men and will power." By 1932 he had found a traditional philosophical garb for his vitalistic doctrine in the neo-Hegelian idealism of Giovanni Gentile (1875–1944), which saw the state as the source of all ethics and all individual life.

For Mussolini, all theoretical considerations were subservient to the "inexorable dynamics" of the factual situation. It is, he insisted, the role of the leader to master this dynamic process: he knows that the "iron logic of nature" will make the strong prevail over the weak. In contrast to Marxism, which asserts a rational logic of history that it claims will bring about the final triumph of the weak in an act of universal salvation, there is no fulfillment of history in Fascism. Instead, all history is incessant struggle, and the struggle itself is welcomed for its own ethical value. For

war alone brings up to their highest tension all human energies and puts the stamp of nobility upon the peoples who have the courage to meet it. Fascism carries this antipacifist struggle into the lives of individuals. It is education for combat . . . War is to the man what maternity is to the woman. I do not believe in perpetual peace; not only do I not believe in it but I find it depressing and a negation of all the fundamental virtues of man.

**Triumph and decline of Italian Fascism.** From 1922, when he first seized control of the Italian government in Rome, until 1927, Mussolini progressively consolidated his dictatorship, and the Fascist state took form (see ITALY, HISTORY OF). State and party became monolithic instruments in the hands of Mussolini, the *capo di governo* (head of the government) of the state, the *duce* (leader) of the party. The *legge fascistissime* (most Fascist laws), drafted by the leading Fascist jurist Alfredo Rocco, turned Parliament into a party congress, practically fused legislative and executive power, and made the Grand Council of Fascism an instrument of the *duce*, who alone could summon it and determine its agenda.

With this success Mussolini began to look farther into the future. Until 1930 he had emphasized the long overdue modernization of a backward country by a strong and efficient government and a new dedicated elite that could communicate a sense of vitality, virility, and energy to the whole people. But on Oct. 25, 1932, Mussolini assured a Milan audience of the world leadership of fascist Italy. "Today, with a fully tranquil conscience, I say to you, that the twentieth century will be a century of fascism, the century of Italian power, the century during which Italy will become for the third time the leader of mankind." In 1934 Mussolini claimed that Fascism, an Italian movement in 1922, had "since 1929 become not merely an Italian phenomenon but a world phenomenon." To achieve his ends, Mussolini demanded the transformation of Italy into a *nazione militarista* and *guerriera*. In this goal he succeeded even less than in that of Italy's modernization.

In his earlier stages Mussolini regarded Fascism as a development within Western civilization and looked with distrust generally upon Germany and specifically upon Hitler's National Socialism, which he recognized as "one hundred percent racism: Against everything and everyone: Yesterday against Christian civilization, today against Latin civilization, tomorrow, who knows, against the civilization of the whole world." But his imperialism and his overestimation of the power of Fascism drove him into the arms of National-Socialist Germany.

The conquest of Ethiopia (1935) opposed Italy to the West and the League of Nations. In the following year, dazzled by German success, Mussolini began to speak of a Rome-Berlin Axis and celebrated it during his visit in Berlin in 1936 and Hitler's return visit in May 1938. Hitler's sincere admiration for him as "the leading statesman in the world, to whom none may even remotely compare himself" increased Mussolini's self-delusion. The intervention for Fascism in Spain's Civil War and the Munich accord with England in September 1938 seemed a crowning success in Mussolini's policy; in reality they masked, with Italy's acceptance of German anti-Semitic laws, the fall of Italy to the position of Germany's satellite. As such, but also out of desire for glory and booty, Italy in June 1940 entered the war started by Germany in September 1939. The war revealed Italy's backwardness and inefficiency, until three years of warfare brought the fall of Mussolini and his party.

#### THE GERMAN EXPERIENCE

Hitler found a much better prepared soil in the antidemocratic traditions of the German *Reich* than Mussolini did in the tradition of the Italian Risorgimento, the 19th-century movement for Italian unity. Like Maurras and unlike Mussolini, Hitler had never been a Socialist or a man of the left. He was entirely unknown even in 1919 when as an agitator for the *Reichswehr* (army) he attacked the Western and German democrats, moderate Socialism, and Russian Bolshevism. He was, unlike Mussolini, the man of the one idea, which in him assumed demonic or maniac dimensions, but he was in tune with older currents of German thought and emotionalism.

**Hitler's "Mein Kampf" and German anti-Semitism.** Hitler grew up as a subject of the multi-ethnic Catholic Habsburg monarchy. He shared with the Austrian Georg von Schönerer (1842–1921) a virulent hatred for the

Hitler's  
racial  
myths

Habsburgs, the "inferior" Slavs, for Catholicism as un-German, and above all for Jews and Judaism as non-Aryan. Hitler's propaganda methods were influenced by another Austrian, Karl Lueger (1844–1910) who, though a supporter of the dynasty and church, became a popular mayor of Vienna by opposing capitalistic liberalism and Marxian Socialism and appealing to the emotions of a lower middle class that felt threatened by both. In the restless years after 1918 Hitler took up this appeal. His anti-Semitism went far beyond Lueger's, becoming an obsession with him; the Jewish problem was no longer political, religious, or economic but the all-explaining theme of history. Hitler regarded the Nordic Aryans as the only creative race on earth, the only source of human greatness and progress. He believed that its end would mean the end of all civilization. Since he saw the German *Reich* as the highest expression of Aryanism, he proclaimed that it was necessary, not only for Germany but for the salvation of mankind, to secure the victorious survival of Germany by maintaining the purity of German "blood" against contamination by inferior races.

The total rejection of all miscegenation was one of the two fundamental pillars in Hitler's two-volume *Mein Kampf*, which he wrote in 1924 and 1926, and which became the bible of the new faith. The other was the absolute necessity of conquering a vast land base in eastern Europe, which was to become German by the ejection and enslavement of the "inferior" though white Slavic peoples. Germans would settle the immense and fertile plains and thus create a geopolitically unassailable *Reich*. The existing (and any future) Slav leadership class was to be exterminated to secure German domination. To these two fundamental ideas Hitler remained faithful from the very beginning of his agitation until his death. They had no parallel in Mussolini's writings, which glorified war and its spirit but presented no plan of a great aggressive war or any racial fanaticism. When Hitler dictated his last will shortly before his suicide, he repeated once more his fundamental interpretation of history: "Above all, I demand of the nation's leaders and followers scrupulous adherence to the race laws and to ruthless resistance against the world poisoners of all peoples, international Jewry," which he identified with the despised liberalism of Western capitalism and the socialism of Russian Marxism. His last words in 1945 expressed the same ideas that had guided him in 1919.

**Hitler's persuasion of the Germans.** From the beginning, Hitler served the fascist movement by his understanding of the potential of the spoken word and the psychology of the masses. His appeal to the Germans as the most exalted race in the world counteracted the disillusionment and inferiority complex of a people believing itself surrounded by a hostile world. Hitler wrote in *Mein Kampf* that all propaganda must hold its intellectual level at the capacity of the least intelligent of those at whom it is directed and that its truth is less important than its success. "The slighter its scientific ballast, and the more exclusively it considers mass emotions, the more complete will be its success." In 1937, moreover, at the ninth party congress in Nürnberg, Hitler declared that "Germany has experienced the greatest revolution in the national and racial hygiene which was undertaken for the first time on an organized basis in the country. The consequences of this German race policy will be more decisive for the future of our people than the effects of any other laws. For they are creating the new man."

Many Germans believed in the reality and the superiority of this new man. Thus the racial interpretation of history and the fascist contempt for democracy lured Germany into war against communism and democracy at the same time. By 1942 Germany had challenged the whole world and seemed at that point to have a good chance of emerging victorious from this total ideological war. Three years later it collapsed.

#### OTHER FASCIST MOVEMENTS IN EUROPE

The defeat of German fascism sealed the future of many other fascist movements that had come to power or

grown in importance in many European countries partly with Germany's help or protection. In some of them, radical revolutionary fascism, eager for the modernization of the country, found itself in conflict with the authoritarian, semifeudal structure with which it often made common cause against Western liberalism, represented by a generally weak domestic middle class, and against an often exaggerated threat of Bolshevism from the outside. Yet reactionary authoritarianism and fascism fused in different ways in different countries, and with Italy's and Germany's defeat, the merely authoritarian reactionary regimes survived more easily than did the outright fascist ones.

In most European countries there were a number of competing small fascist parties with no strong leader. Some of these came to power by National Socialist military success. In other cases (Britain, Switzerland, Sweden, or Denmark) the liberal parliamentary forces proved to be strong enough to keep the fascist movements within narrow bounds, and in others reactionary elements were able to use fascist movements as their support. The only one of these movements that could claim world attention on the international scene was the originally very radical Falange Española under the leadership of José Antonio Primo de Rivera (1903–36). The Spanish republican regime was established in April 1931, and Rivera was elected a deputy of the right in 1933. But in the next year he broke with it and united the Falange with the Juntas de Ofensiva Nacional Sindicalistas (Committees of Nationalist Syndicalist Offensive), "a movement steeped in true Spanish frenzy, launched by the young and dedicated to combatting . . . the irresponsible hypocrisy of the bourgeoisie" (Eugen Weber, *Varieties of Fascism*, D. Van Nostrand Co., Inc., Princeton, New Jersey, 1964, p. 117). The Falange was ultranationalist and eager for a thorough reform of Spain's antiquated social order. But in the election of 1936, won by the popular front of leftist moderate and radical parties, the Falange was unable to elect even a single deputy.

When civil war broke out in Spain in 1936, the republican government outlawed the Falange, which sided with General Francisco Franco; and in 1937 Franco united it with the military formations of the deeply reactionary Catholic Carlists, the Requetés, and made it an instrument of his personal leadership. But whereas in Italy and Germany fascism had absorbed the state, in Spain the victorious conservative oligarchy absorbed fascism.

In a similar way the authoritarian and traditionalist oligarchy in António de Oliveira Salazar's Portugal kept fascist movements within very narrow limits, while using some of Mussolini's conservative slogans, as did the clerical semi-fascism in Austria under the two chancellors Engelbert Dollfuss (assassinated by the National Socialists in 1934) and Kurt von Schuschnigg and the Slovakian independence movement under Father Josef Tiso.

Radical fascist movements developed in some Balkan countries—most prominently in Croatia, Hungary, and Romania. They shared with the conservatives the bitter hostility to Marxism and the Soviet Union, but they were obsessed by an extremist spirit of terroristic violence in a strange union with religious fanaticism. As a result of German victory the Croatian Ustaše, a party under the leadership of Ante Pavelić (1889–1959), turned Croatia into a state on the model of the most extremist National Socialist Party formation, the SS, or Schutzstaffel, into which only the most dedicated and racially pure Germans were admitted. The Ustaše persecuted and killed many thousands of Orthodox Serbs, Jews, and Muslims. Catholic monks and other priests are alleged to have taken an active part in this struggle for the "purity" of the Croatian land and faith, and the Ustaše envisaged the revival of the Great Croatian kingdom as it had existed under Peter Krešimir (1058–74) and Dimitrije Zvonimir (1076–89). The dream was destroyed first by Fascist Italy's occupation of Croatian Dalmatia and of Slovenia and finally by the collapse of Italy and Germany. Pavelić escaped to Argentina, where he died.

Fascism ruled in Croatia only four years; an even more

The

Falange

Fascism  
in the  
Balkans

violent fascism disturbed the political life of Romania for almost 25 years. Independent of the rise of Italian or German fascism, the fascism of Corneliu Zelea Codreanu was rooted in older traditions of the Romanian Orthodox Church and the Romanian peasantry. As a student at the University of Iasi, Codreanu organized fellow students, sons of poor priests and peasants, into a National Christian Anti-Semitic League, which indulged in murder and a strange fanatical morality. In 1927 the movement was reorganized as a Legion of the Archangel Michael, characterized not by a flag but by an icon and by its members' dedication to a frugal ascetic life. The Iron Guard, as the Legion called its armed branch, represented an attempt at a fundamental reform of Romanian life. But the attempt to build a new life was made on the basis of wild blood sacrifices, one of whose victims in 1938 was Codreanu himself. In 1940, after the abdication of the King, a civil war within a coalition of the conservative Army under Gen. Ion Antonescu and the Legion under Horia Sima, Codreanu's successor, ended with the Army crushing the Legion in January 1941. Antonescu's Romania actively participated in Germany's war against Russia, but the Romanian fascist movement remained, after orgies of death, crushed, and its surviving leaders found refuge in National Socialist Germany.

In a similar way the fate of fascism and of reactionary circles was intertwined in Hungary. The Hungarian government under the regency of Miklós Horthy (1868–1957), the last commanding admiral of the Austro-Hungarian Navy, dreamed of the restoration of the former nine-centuries-old Great Hungarian realm. The suppression of the short-lived communist regime in Budapest in 1919 combined with the fascist hatred of Bolshevism to produce, what was for that time, an unprecedented "white" terror. But Horthy himself was a moderate conservative and even when Hungarian extreme nationalism led him to form a profascist government under Gyula Gömbös in October 1932, Horthy followed a moderate course. Gömbös died suddenly in October 1936. Meanwhile a Hungarian National Socialist Workers Party had been formed with an arrow cross as its symbol. In 1935 it found its leader in Ferenc Szálasi, who had been a capable general staff officer in the army but now developed a fanatical racial faith in Hungarianism, which in some ways recalled Hitler and Codreanu. After Hungary's entry into the war, the Germans in 1944 occupied Hungary and interned Horthy. Szálasi was finally the head of a state, which he planned as the "Corporatist Order of the Working Nation." But the war was soon lost after a bloody winter of massacres of Jews and political opponents. Szálasi was executed; Horthy found refuge in Portugal.

Fascism outside Italy and Germany suffered from the lack of charismatic leaders who could embody a nationalist myth and yet be adroit political tacticians. In Nordic Germanic Europe, which, according to racial doctrine, should have shown a strong penchant for National Socialism, except for Norway few sympathized with German fascism—much fewer than among the eastern and southern Europeans. In Norway the great writer Knut Hamsun (1859–1952) and Vidkun Abraham Quisling (1887–1945), former minister of war in the farmers' party administration and son of a rural clergyman, took a pro-Nazi stand based on their opposition to Western "plutocracy" and their fascination with peasant rootedness, the opposition of the "natural" countryside to the "corruption" of urban civilization. Quisling founded, in 1933, the Nasjonal Samling, with the cross of St. Olaf as a symbol and the restoration of the greatness of Viking Norway as a goal. Under the German occupation Quisling became prime minister, but his following remained insignificant in his native land.

Stronger than in northern Europe was the fascist movement in Belgium. This was partly due to the fact that the Belgian nation was divided into a dominant French-speaking minority and a Flemish-speaking majority that struggled for complete equality. In 1931 Flemish extremists formed the Verbond van Dietsche Nationalisten, the Union of Dutch National Solidarists, who

dreamed first of a Great Netherlands, later of a Great Burgundy, both times avoiding a close cooperation with German National Socialism. A more important fascist group originated in French-speaking Belgium and found in Léon Degrelle an energetic demagogue and leader who strove for an agreement with the Flemish and showed understanding for modern social developments. Degrelle had grown up as a Catholic and in his young years had been influenced by Charles Maurras. He called his organization Rex and virulently attacked the parliamentary system. After a rapid growth his party lost its influence and Degrelle himself was defeated in a by-election in 1937 by a typical representative of the Belgian upper middle class with the approval of the Catholic primate. Degrelle's Flemish adherents joined the radical wing of the Flemish nationalists, the Vlaamsche National Verbond, and Degrelle formed a Walloon legion for the German SS and fought in the war against Russia. The confused character of the Rexists was symbolized by its red flag with a crown and a cross on it. In Belgium, as in Switzerland and The Netherlands, the parliamentary system of the conservative middle class was too strong to allow the success of a fascist party, and any threat of communism was too remote and improbable. In these countries terroristic violence so characteristic for the regimes of Mussolini, Hitler, Codreanu, or Szálasi remained unknown.

Of a very different nature was the short-lived fascist movement in England, where Sir Oswald Mosley, a member of the aristocracy, formerly a member of the Conservative Party, and later a member of the Labour government, founded in 1932 under the impact of the economic crisis the British Union of Fascists. The Union's plan was to replace the "old gang" of politicians by a new young elite, in tune with the new time. The paramilitary form of his party meetings and its "defence force" ran so deeply counter to Britain's centuries-old civilian tradition, that in spite of Mosley's undeniable rhetorical and intellectual gifts the English masses resisted him, and the strong British Conservative government of the period offered little foundation for arousing fear of a domestic "Bolshevik" threat. The Conservative government was intelligent enough to forbid, after some street fighting in 1936, all paramilitary uniforms. By 1938 Mosley, perhaps the most intelligent and rational of all fascist leaders, ceased to be a figure of public importance.

The picture offered by France in the critical years was more complex. But there, too, fascist movements were diffuse and short lived. One of the followers of Charles Maurras, George Valois, disappointed with Maurras's lack of active interest in social reforms, founded in 1925 the Faisceau, composed largely of war veterans; but only the crisis of the 1930s produced a number of groups, all nationalist, anticapitalist, and anti-Marxist. The largest of them, the Croix de Feu (Fiery Cross) of Col. François de La Rocque, rejected dictatorship and most of the fascist rhetoric. Characteristic for French fascists were the "proletarian" anti-Communists, led by former Socialists and Communists like Marcel Déat, the founder of the Rassemblement National Populaire, and Jacques Doriot, the former Communist mayor of Saint-Denis, a Parisian "red" suburb, who founded the Parti Populaire Français. More than in other countries, these French fascist groups were joined by some intellectuals who were disenchanted with the apathy of French life and yearned for revolution and action. The most prominent of them, Pierre Drieu La Rochelle (1893–1945), summed up the nihilism, which is fundamental to all fascism, when he wrote in 1934: "Liberty is exhausted. Man must seek new strength in his black basic nature. I say it, an intellectual, the eternal libertarian." (From *Socialisme Fasciste*, Gallimard, Paris, 1934, p. 102.)

#### FASCIST MOVEMENTS OUTSIDE EUROPE

Like nationalism, socialism, and communism, fascism was a European movement. But in the 1930s, when economic crisis seemed to reveal weaknesses of the liberal tradition, in general, Fascism spread to Asia and Latin America, adapting itself to the social conditions of the

Reaction  
and  
fascism  
in Japan

Fascism  
elsewhere  
in Europe

countries there. Only in two cases did it become significant and assume an official role. The first instance was Japan, where fascism resembled German National Socialism in its reassertion of ancient models of life. On Feb. 26, 1936, the army took control of Japan and supported a national or tribal mysticism that bore a close resemblance to that of Germany's. Young "patriotic" officers tried to assassinate a number of leading Japanese statesmen, aristocrats, and high officers who seemed to them to represent the influence of foreign "dangerous thought," of the West, of liberalism, and of individualism, which threatened the traditional military spirit and absolute dedication to the cult of the emperor. In a number of cases the young officers were able to kill their victims. "The massacre was immensely popular in the army. The army acted as though the revolt was the work of the whole body and had succeeded. In its new orders the army said that it could not tolerate liberalism, that internationalism and individualism must be banished, and nationalism and the Japanese principle be promoted." (A. Morgan Young, *Imperial Japan 1926-1938*, William Morrow and Co., Inc., New York, 1941, p. 34.)

Different from other fascist countries, Japan saw the embodiment of its national ideal, not in a popular leader but in the emperor. The national destiny was to be fulfilled by observing the duty to the throne and thus attaining the highest pinnacle of morality. The imperial will was to fix standards of justice and injustice, of right and wrong. Philosophy was regarded as good only when it was in conformity with the imperial will. Except for Germany, Japan was then the only nation that thought itself strong enough to extend its national ideal over the five continents. In the late 1930s Japanese professors and writers, similar to their German colleagues, demanded the rejection of rational and universal ethics and the return to the ancient tribal gods in order to make the nation the most perfect instrument for its mission of conquest. The war in China was "not presented as one of conquest and exploitation but rather as a holy crusade to rid the land of unjust rulers [Chiang Kai-shek, red communists] and inaugurate there a regime of peace, righteousness and prosperity." (Harley F. MacNair, *The Real Conflict Between China and Japan*, The University of Chicago Press, Chicago, 1938, p. 193.) Later Japan spoke of a coprosperity sphere of a new Japan-led Asia.

Perón's  
fascistic  
populism

Less ambitious were the aspirations of fascism in Argentina, where the movement resembled that of Italy rather than of Germany. The initiative in Argentina came, however, not from former socialists and syndicalists but from officers, the Grupo de Oficiales Unidos (Group of United Officers), who seized power in 1943. The initials of the group's name stood for *gobierno* (authoritarian government), *orden* (order), and *unidad* (national unity). The officers believed that as a result of its relative wealth and its ethnically purely Caucasian population, Argentina was to assume the leadership in the struggle against "Yankee imperialism" and in the modernization of the continent. Among the officers, Juan Perón assumed a leading role and turned the movement into one of national socialism. With the help of his wife, Eva María (1919-52), he sought the support of the poorer masses, the *descamisados*, or shirtless ones. His attack on the traditionally ruling oligarchy brought him wide popular support, so that he was twice elected president of Argentina, 1946 and 1951. Perón organized the workers into a Confederación General del Trabajo, which was devoted to him, and claimed to have replaced "plutodemocracy." He created a mass party standing for "justicialism," a middle way between communism and capitalism. But his own inconsistent policies and the accusation of widespread graft provoked a revolt of the armed forces in September 1955, as a result of which Perón left the country and settled in Spain.

By 1970 fascism seemed to have lost the attractions it had exercised in the 1920s and 1930s. Communist Russia and China seemed in 1970 less conquerable than in 1940. After the fall of fascism in Germany and Japan both nations experienced a wave of great prosperity, which weakened, especially in the young generation, the

formerly strong appeal of a militant nationalism. The conquest of a "living space," which Germany, Japan and Italy before World War II thought indispensable for the growth of their national economy, not only revealed itself as unachievable even to a broad anticommunist coalition, such as the three leading fascist powers established in 1937, but as a superfluous fancy, for the loss of empire brought misery neither to Britain nor Germany, the Netherlands or Italy, France or Japan. An unexpected industrial and agrarian productivity raised the living standards of the masses in the democracies, which could now concentrate upon the necessary domestic reforms and abandon the lure of military glory. By 1970 fascism seemed a trend characteristic of the recent and yet faraway past. Except for small marginal movements, most elements were seeking to secure what fascism had denied, the cooperation of peoples of various civilizations and ideologies and the condemnation of war.

## Fatigue

Fatigue, like anxiety, relatively permanent impairment, and illness or disease, is a form of human inadequacy. All of these everyday terms lack precision and distinction, and definition is, therefore, a fundamental problem.

Fatigue was once used as the name for an ostensibly identifiable complex of inner feelings thought to be descriptive only of people and taken to be the result of some kind of taxing activity (such as work). The not particularly rigid concept was applied to specific parts of the body as well as to the person as a whole. If major discomfort was felt in a leg, it was said that the limb was fatigued or tired, just as at other times the person might say that he was tired. Such usage eventually became generalized so that even inorganic materials were said to be "tired": structural steel broke down under "fatigue"; i.e., became brittle through crystallization. Such broadening of the meaning of the word fatigue added many connotations. Seriously accepting all the meanings that the word fatigue has would make it a meaningless synonym for inadequacy in general.

Fatigue  
and work

The once-held belief that work was the cause of fatigue led to efforts to use the work output of factory workers, for example, as direct measures of fatigue. Early studies by industrial psychologists and engineers failed to show a close connection between how an individual worker said he felt and the amount of work he accomplished; production-oriented investigators were even led to attribute no significance at all to inner feelings of fatigue, and their attention shifted from the inner condition of the worker to external phenomena not related to the worker at all. In the process it was forgotten that work output is a product of, rather than a description of, the worker. For other researchers who retained an interest in the worker himself, study was typically directed to specific, observable body processes rather than to the overall internal state of the worker as manifested in how he said he felt. Studies of body processes disclosed, among other things, that oxygen and glucose (sugar in the blood) were consumed during work and that waste products such as carbon dioxide (excreted from the lungs) and uric acid (in the urine) were produced. Hence, for some investigators fatigue came to mean a bodily state in which waste products were present in high concentration. All such studies clearly revealed specific results of exertion and disclosed evidence for the burning of food materials (metabolites); taken by themselves, the data provided a picture of the human organism as an energy-converting system and showed a definite relation of this process to energetic (work) performance. Such studies are a part of basic physiological research and apply most closely to what may be expected of people under heavy exertion in the workaday world (*e.g.*, strenuous labour) and in sports and athletics. Feelings and other signs of fatigue can arise suddenly and disappear equally suddenly, and the onset, duration, and termination of fatigue symptoms may appear to bear little relation to exertional (work) activity. When fatigue arises in nonexertional situations, there is a temptation simply to say that the fatigue is "psychological" or "motivational" (see MOTIVATION). Relatively little research has been devoted to fatigue as descriptive of the person himself and of the full range of demands he has to meet, although many of these demands lie outside the simple energy requirements of more-or-less arduous work. Accordingly, understanding fatigue involves determining the ways that the human organism is related both to his internal states and to his external environment; potentially fatiguing demands on the individual may arise from both within and without.

Man is able to—and may—respond to any situation in more than one way and at more than one level of behavioral complexity. The most readily observable ways are grossly physical and chemical; but these, in turn, underlie other levels of response such as primitive sensory activity (becoming aware of stimuli), and still higher levels such as perceiving (*e.g.*, evaluating the nature and objectives of work activity). At the highest level of activity the relationship often is spoken of as existing between the whole person and the environment. Since most investigative attention in industrial or other production situations has been directed toward what man can do in terms of his being only a machine that converts food energy into useful work, an understanding of the fine details of the relation between fatigue and physiological body processes has preceded experimental efforts to specify the role of personal attitudes (such as the individual's own evaluation of his abilities). Such self-evaluations (*e.g.*, a worker's judgment that he cannot continue activity) rather than any exhaustion of the energy available within the body result in the termination of activity. Often when such changes in performance are attributed to motivation, or to any of a number of factors called psychological, one's allegiance to ancient views of the nature of man may tempt him to think of mental factors disjoined and unrelated to any physical, energistic description of the organism. Yet, a fully useful definition of fatigue would require that all relevant factors be considered. Indeed, modern efforts to achieve a unified, integrated definition of fatigue rest on studies in which higher-order mental processes (such as thinking, perceiv-

ing, and emoting) are investigated to find whether they seem to stem from physical body processes (*e.g.*, see EMOTION).

Fatigue as it is applied to the whole person involves an individual's feelings of discomfort and aversion, his inner awareness of making mistakes, and any changes in observable signs of effort required to carry on the performance involved. These aspects are found to be related in various ways to measurable variations in work output. Investigators who typically focus primarily on work output are apt to be concerned with the applied, practical view of the person as a productive worker; interest is more likely to be concentrated upon the worker himself by those scientists who wish to study fatigue even if their findings are not directly productive of work output. The worker himself is interested in how he feels and what makes him feel as he does.

At any rate, in accounting for fatigue, it is useful to make distinctions between what pertains to the man as a whole and what pertains only to some part or organ of the man. That the total man's behaviour is spoken of as personalistic, or psychological, is not simply because self-awareness (inner feeling of fatigue) is involved but because at this level, resources are directed toward ends that go beyond the limited function of any one body part. This situation is illustrated by a simple example in muscular activity. When muscle activity is described in itself (at a given subpersonalistic level), it is simply called muscle contraction. Muscle contraction occurring as an integrated part of more complex personalistic behaviour may be called reaching; this action is an integral part of grasping a pencil, which is part of the more personalistic act of writing to one's friends.

While fatigue is one consequence of grossly observable activity, it can occur in the absence of manifest muscular exertion. It can develop, for example, as a rather immediate response to a socially exercised demand (such as that of a nagging supervisor), of which the person suddenly becomes aware but may not like. The feeling of fatigue produced in the absence of productive work seems to be essentially the same as that produced by goal-directed labour. Some components nevertheless are different, such as aching muscles in the one case and not in the other, but the factors that give fatigue its identity and differentiate it from other states of inadequacy are present in both. In each case conditions exist that can even result in one's total inability to carry on, whether his muscles contain high concentrations of waste products or not.

Muscular exertion does, however, produce biochemical changes in the body that are quite complex and that differ in various tissues and organs such as the heart or the brain. The consequence almost invariably is to produce secondary effects, perhaps muscular stiffness, and these in turn give rise to higher level effects such as one's sensory awareness of pain and discomfort. At a more personalistic level, the individual may develop a change in attitude with regard to the task or activity in progress; *e.g.*, he may begin to feel aversion for the work. The whole process, in effect, yields the individual's self-generated assessment of his own ability to carry on. If he continues his exertions under his personal assessment that such activity will produce more pain or will become more nearly intolerable or even impossible, the anticipated consequences include less efficient work performance. As the worker becomes preoccupied with his discomfort and with his waning production, the effect typically is to produce still more inefficient work. Thus fatigue defined as muscular inability to carry on and fatigue defined as a kind of felt aversion for exertion and as feelings of inability to carry on are all produced.

Performance may be observed to deteriorate (among factory workers, for example) even when there are no signs of the feeling state and of the aversive, pessimistic self-assessment defined here as personalistic fatigue. Indeed, often enough one may be "fatigued" without knowing it, indicating the predominance of relatively subpersonalistic factors at work. Such factors can be lumped under the term impairment, mentioned originally as one

Pain and  
fatigue

Fatigue  
without  
physical  
exhaustion

of the major forms of human inadequacy. While transient impairment and personalistic fatigue generally have not been distinguished from each other by many psychologists, in numerous studies impairment, rather than the feeling of fatigue, has been the point of interest.

Impairment of this sort reflects alterations in the chemical processes that occur within the cells of the body. That the alterations are reversible is illustrated in alcohol intoxication and oxygen lack (hypoxia). When such transient impairment incapacitates the individual for energetic activities without greatly affecting his brain processes, he is likely to feel tired and weak. Thus, it can be said that transient physiological impairment and personalistic fatigue are closely related, one being a basis for the other. When brain processes are so sharply affected as to reduce perceptual or attitudinal awareness, impairment may produce marked behavioral consequences without associated feelings of fatigue. In such cases, feelings of weakness and tiredness may not be reported by the individual since his abilities for self-evaluation have been dulled. The failure of people to have feelings of fatigue as a consequence of physiological impairment is characteristic of some forms of hypoxia, which can be brought on in several ways. One of these is by a fairly abrupt reduction in atmospheric oxygen pressure, as would occur in one's being deposited atop a mountain by helicopter. Feelings of fatigue are much more likely to set in when oxygen reduction is gradual and associated with exertion (as in mountain climbing). Along with lack of oxygen, other factors of the climber's task play their roles, and the climber's own awareness of the negative factors that are developing produces the full syndrome of fatigue, including both the inability to carry on and the aversive attitude.

In contrast to this, oxygen lack can be produced much more quickly in a decompression chamber in a laboratory, without any associated muscular exertion. It is possible to reach levels of hypoxia that abruptly reduce the subject's efficiency in exercising self-assessment, and personalistic fatigue in such cases fails to develop.

#### ENVIRONMENTAL FACTORS IN FATIGUE

**Limiting conditions.** In considering what it is in the environment that promotes fatigue, those conditions, such as lack of oxygen, that limit physiological function act directly at subpersonalistic levels. Other examples of limiting conditions are temperature extremes and lack of salt, water, or sugar. Regardless of one's personalistic attitudes, these factors limit physiological function and eventually can make the person unable to carry on.

High environmental temperatures put excessive demands upon the heat-regulating mechanisms of the body and soon can become seriously incapacitating. This incapacitation stems, in part, from the kind of immediate sensory feeling of being overheated that the person does not like and, in part, from physiological derangement and failure of the body regulating processes involved adequately to reduce the rising temperatures within the person. Man is not passive to thermal (heat) conditions, some of which make excessive demands upon the internal processes that generate, release, and dissipate body heat. There are special temperature-regulation centres in the human brain. Depending upon whether heat needs to be generated to keep the body from becoming chilled or to be dissipated to forestall overheating, various patterns of activity (e.g., shivering) are initiated (see HOMEOSTASIS). When the load on any of the body mechanisms involved becomes great, various symptoms of distress begin to emerge. Fatigue is one of the earliest symptoms, appearing even when physiological distress is not extreme, long before prostration occurs.

Salt depletion (hyponatremia), water lack (dehydration), and sugar loss (hypoglycemia) and other limiting conditions bring on complex bodily imbalances that produce changes in sensory function (such as distortions in perceptual processes), in thinking, and in emotional behaviour. Sugar lack not only impairs the individual for exertion but results in feelings of fatigue. Muscular exertion requires blood sugar as its chief fuel. The symptoms of

low blood-sugar level (hypoglycemia) are signs of bodily weakness, headache, and other distress. In a study of industrial workers in which diet was investigated in relation to physical efficiency, it was noted that at particular times of the day, work output dropped and complaints of fatigue and irritability arose. It was hypothesized that there might be a direct relation between these vocal complaints, worker blood-sugar level, and the daily pattern of food intake among these employees. When the number of meals was varied over a range of two to five per day and the effects of fasting on blood-sugar level were studied, it was found that by spacing meals closer together, thus permitting workers to eat more often, blood-sugar levels remained desirably high for greater periods of the work day even when the total food intake was held practically constant. With widely spaced meals, the amount of blood sugar fluctuated between feedings, reaching lower levels than those observed when meals were eaten closer together. Other measures of bodily function were found to be similarly related to differences in the daily distribution of food intake; that is, respiratory (breathing) and muscular efficiency remained higher when meals were closely spaced. Although the apparent impetus for carrying on the investigation derived from personalistic complaints of tiredness and weakness, the research centred on physiological factors in the situation. Apparently, it was taken for granted that when blood-sugar level, respiratory activity, and muscular efficiency were well maintained, feelings of fatigue would be minimized.

**Occupational demands.** Aside from the general, physiologically pervasive limiting factors, there are conditions specifically imposed by occupational situations; e.g., poor ventilation, presence of toxic fumes, poor design of working equipment, conditions inherent in keeping up the rate of worker performance (e.g., in keeping pace with machines). Rest periods, coffee breaks, and background music are often introduced in work situations in efforts to reduce fatigue.

Beyond the limiting conditions noted above, there are, from the standpoint of occupational demand, several other classes of fatigue-producing situations. These include conditions of work calling for the expenditure of considerable energy; work assignments that require paced performance; those demanding prolonged uninterrupted activity; emotionally frustrating situations; and work demands that exceed the competence of the individual. Although fatigue most directly stems from a specific set of bodily conditions, the classes of occupational factors just given can be distinguished as environmental precursors of fatigue that can be altered in seeking to mitigate internal sources of distress.

While energy expenditure produces bodily waste products, the fatiguing effects are not limited to such clearly biochemical changes. Subtler, less grossly physiological factors such as familiarity with the task are also found to be related to one's fatigability. Thus, performing different tasks supposedly with the same parts of the body still can produce differing fatigue responses. An unfamiliar task that involves new patterns of movement may be experienced as unusually taxing even though it seems to require no more exertion than does a better learned, habitual performance. This situation seems to occur because the new task typically involves a unique set of muscle fibres, and because learning to perform efficiently involves a reorganization of activity among the active fibres. Older, habitual muscle patterns of activity that serve to accomplish a task tend to be more streamlined than do newly formed or temporary modes of behaviour. The overall result of coping with an unfamiliar set of work movements may include soreness and aching of muscles, as well as general discomfort (malaise).

While the greatest transformation of bodily energy occurs in the muscles themselves, slowdown in production (work decrement) is not all accounted for on an exertional, muscular basis; not all activity is muscular—there is, for example, neural activity in the brain. Many studies of fatigue thus face the problem of specifically accounting for how fatigue, exhaustion, or whatever it is

Temperature extremes

called, occurs while one is waiting for a bus but may not occur while he is busily engaged in an absorbing conversation; or how it is that people get tired from lying in bed. Obviously the pattern of fatigue symptoms is somewhat different from case to case or from situation to situation.

Paced performance is typified by the kind of worker activity involved in keeping up to a factory machine. This situation occurs when one is feeding pieces of metal into a continuously operating stamping machine, the action demanding the repetitious performance of some pattern of movements. The tendency of people ordinarily is to vary their activity even when maintaining their performance to repeatedly achieve the same end. Hence, the requirement of going through the same motions over and over again is often difficult to meet and brings on bodily discomfort. This discomfort is one of the bases for feelings of fatigue.

Prolonged activity involves some of the same factors as does paced performance. Various negative conditions, such as improper posture, though inconsequential in short tasks, build up to levels of considerable importance when performance is prolonged. Frustrating situations, those in which intended activity is blocked, are exemplified among sprinters or swimmers plagued by a series of false starts in a race. This blockage is reflected in muscle tensions and other internalized activities such as feelings of impatience and of being thwarted. Under prolonged frustration, the experiential (attitudinal) result often is fatigue, enhanced by considerable alterations in underlying bodily processes.

Visual  
fatigue

Demands too extreme for specific bodily mechanisms to meet are well illustrated in challenges placed on the activity of the sense modalities (*e.g.*, vision and hearing). Seeing, for example, is a muscular function as far as the initial processes in the eye are concerned. Some visual tasks require tiny sets of muscles within the eye to contract in changing the shape of the lens to accommodate shifts in looking at near and far objects. Other muscles rotate the eyeballs within the skull. These demands often can be met comfortably for short periods, but feelings of fatigue that develop after a few minutes disclose the task inadequacy of the visual mechanisms involved. With proper eyeglasses, the occupational demands may be met more effectively, so that performance (seeing) can continue for much longer periods without discomfort or work decrement. The fatigue that arises in visual tasks is not the decrement; it is the discomfort and task aversion that accrues, sometimes to the point of becoming intolerable.

Visual "fatigue" is a common complaint made to physicians or optometrists. This complaint may simply mean that after a short period of reading the print appears to blur. In such cases, the "fatigue" is a self-diagnosis that suggests sensory impairment rather than a direct description of a feeling of being visually "tired" or fatigued. When, however, the person means that for some reason or other he develops discomfort and task aversion after reading for a short time, he indeed might be said to suffer visual fatigue. The same principle applies to what is called "mental" fatigue, feelings of aversion or malaise that arise in an intellectual task, such as creative writing. The adjective (*e.g.*, visual or mental) that modifies the word fatigue refers to the task situation and does not imply that fatigue is essentially different from one situation to another.

While the class of unfavourable circumstances called limiting conditions (*e.g.*, extreme temperature) contribute to fatigue by directly affecting vital processes, some potentially limiting conditions also act upon man in subtler ways, for example, in sound stimulation (*e.g.*, noise). Auditory stimuli can be so violent (*e.g.*, a jackhammer for breaking pavement) as to damage sensory mechanisms, and such stimuli would belong in the class of limiting conditions. The role of less intense noise in producing fatigue, however, is highly variable from person to person. Some people seem to be habituated to high-intensity auditory stimulation in the form of rock and roll music. A teenager may be able to perceive the

sounds as music in apparent comfort for hours; his father may develop severe auditory fatigue after hearing it as gross noise for a minute or so.

Social factors that can affect fatigability and output in work situations include competition, prestige, and even the feeling of being watched. Various environmental factors that mean much to some may have little effect on others; social aspects of the environment are among those that vary this way. A notable series of studies in industry demonstrated the effect of allowing employees engaged in telephone manufacture to participate in planning their daily activity. The study showed that worker involvement in planning was more effective in raising work output than was the introduction of improvements in lighting and other ostensibly beneficial conditions of work.

#### PERSONAL ASPECTS OF FATIGUE

**State of health.** Fatigue is a condition of the organism as a whole, and to understand it the underlying bodily conditions of the individual must be taken into account. These include infectious diseases and other acute afflictions as well as more chronic, general conditions such as nutritional deficiencies and the lowered energy states characteristic of old people. Acute disease often generates fatigue that may persist throughout and after convalescence; many people remain especially fatigable for months after recovering from the active (acute) phase of influenza, for example. Other disturbances notable for producing fatigue include disorders of the thyroid gland, diabetes, emphysema, arthritis, rheumatism, and anemia.

Symptoms of an underactive thyroid gland (hypothyroidism) are seen in the sufferer's inability to keep awake, his intolerance for low environmental temperatures, his muscle weakness and various discomforts, all of which make the person prone to task aversion and feelings of fatigue. Emphysema makes it difficult to breathe easily and obviously hampers the victim during even minor exertion. Myasthenia gravis, a chronic disease in which muscles become pathetically weak, can readily be seen as a potent basis for fatigue. Arthritis and rheumatism with their pervasive aches and pains can deter the individual from energetic activity, making everyday activities miserably fatiguing. All of these disorders involve definite tissue and organ abnormalities that are directly treated in the attempt to relieve fatigue.

Effects  
of an  
under-  
active  
thyroid  
gland

Metabolic difficulties become increasingly frequent fatigue factors in old age, and efforts to relieve the tendency toward quick and easy exhaustion include the administration of substances that stimulate body metabolism (*e.g.*, so-called anabolic agents such as compounds derived from a chemical called aspartic acid). When fatigue arises from nutritional deficiencies appropriate dietary changes are indicated. Sometimes nutrients such as calcium and vitamin B<sub>12</sub> are injected to hasten recovery; injections of substances containing iron often have spectacular effects in dissipating fatigue associated with some forms of anemia.

Indeed, some substances can benefit almost anyone who complains of undue fatigue. These may help by alleviating bodily discomfort; by improving muscle activity; and by elevating the sufferer's mood.

A common drug helpful in the alleviation of fatigue is aspirin, which is genuinely effective in dispelling a substantial range of general bodily discomforts. Much indisposition among people at any age stems from relatively minor, but general, aches and pains; and aspirin tends to relieve this common aspect of fatigue. While it might be supposed that aspirin's analgesic (pain-relieving) power might also dull one's sensory activity, alertness tends to be enhanced rather than impaired.

Caffeine, known for centuries in tea, coffee, and cocoa (it is also added to many cola beverages), is popularly used for its favourable effects on mood and feelings of tiredness. Among these influences is an effect on muscle activity that forestalls fatigue. When used to excess, caffeine may also contribute to fatigue by producing restlessness, sleeplessness, and irritability. Many other drugs

for elevating mood also tend to relieve fatigue, but a number of them are addictive and easily overused. These include such psychic energizers or antidepressants as the class of chemical compounds called amphetamines (in slang sometimes called "speed" or "uppers" or "ben-nies"), which, used without careful medical supervision, represent a genuine hazard.

Some factors that predispose people to fatigue represent the interacting effects of bodily afflictions and difficulties that seem to be psychiatric or emotional. One of these is a transient form of low blood pressure called orthostatic hypotension (or postural hypotension). A relatively normal, extremely brief episode of postural hypotension may develop when one in suddenly standing after a train ride experiences such momentary symptoms as dizziness and blurred vision. Some people are abnormally susceptible to the problem. Others, possibly men more often than women, exhibit signs of orthostatic hypotension in very specific, apparently emotionally unpleasant situations. The person may begin to have the feeling, after being called upon to stand for awhile, that he is going to collapse; he feels weak and unsteady. Some men report that such symptoms specifically arise when they have to wait while their wives shop. In such cases, there is little for the husband to do that interests him, and he frequently may feel upset about being in the way of the other customers. As blood pressure sharply drops, these men begin to feel so exhausted, weak, and unable to stand that some are driven to call for help. Under less distressing circumstances, the symptoms fail to appear. Some of the same individuals who find themselves experiencing fatigue while with their shopping wives do not reach this state under other conditions in which erect posture also is maintained for considerable periods.

**Psychiatric factors.** Fatigue can be a most persistent accompaniment of a number of psychiatric disorders, including depressions of all kinds, a neurotic disturbance once popularly called neurasthenia, and what is known variously as the effort syndrome, Da Costa's syndrome, irritable heart, soldier's heart, anxiety neurosis, and neurocirculatory asthenia. (There is some controversy whether all of the latter terms actually refer to exactly the same cluster of symptoms.) At any rate, the term soldier's heart or irritable heart seems first to have been used to describe soldiers serving in the Crimean War while Da Costa's syndrome was a popular diagnostic label during the U.S. Civil War. In both cases, one of the first symptoms to appear was diarrhea followed by rapid pulse (which typically outlasted the digestive upset), headaches, and disturbed sleep. About the same kinds of cases began to show up quite frequently in World War I, during which time the cluster of symptoms was labeled the effort syndrome, or shell shock. Fatigue was a prominent complaint in all these cases, which by World War II came to be called combat fatigue or flight (pilot) fatigue. Similar cases arise in civilian life; one curious difference reported is that difficult, rapid breathing in the civilian cases fails to subside during sleep, whereas among soldiers the respiratory signs abate with the onset of slumber. In all of these fatigue-ridden disorders (no matter what they are called), exertion appears to be the essential precipitating feature. Exertion seems to manifest its results in a cluster of consequences, some digestive, some circulatory, and on top of this, a set of personalistic manifestations not to be expected from mere exertion. In military combat, some individuals show signs of personalistic upset (*e.g.*, terror and hate). The effort syndrome may be said to be one expression of personalistic inadequacy. The cause is ordinarily not as obvious in civilian life; nevertheless, there seems to be a class of individuals who express the results of exertion (*e.g.*, the tensions even of sedentary work) in the curious diffuse fatigue pattern just described rather than primarily in some kind of muscular tiredness.

The syndrome nowadays is seen as a psychogenic one, and various causes for it have been suggested. Be all this as it may, this is one pattern of context and response in which fatigue and work insufficiency show up.

Hypochondriasis, a neurotic tendency to be preoccupied

with and to exaggerate the significance of even the slightest signs of bodily ailment, is another very fertile basis for fatigue. Hypochondriacs are expected to be among the first to become tired. Hypochondriacs are so focussed on how they feel that they tend to tolerate much less discomfort than do people generally. Thus what ordinarily are perceived as minor discomforts by most people are readily taken as deterrents to effort in hypochondriasis, and the experience of fatigue arises sooner than in other persons. In this connection, it appears that people vary over a wide range with reference to the degree of discomfort they will tolerate before giving up a task; hypochondriacs tend to fall at the low end of this range.

Almost all individuals suffer from what is commonly called depression, sometimes only rarely and briefly. Among others the depression may persist or may come and go; many of these people seem almost always inclined to be pessimistic. Whatever the origins of depression (and there are many), it is a state in which fatigue is likely to be prominent. According to some authorities, about 85 percent of the patients seen in general medical practice suffer mild, chronic (prolonged) depression of some sort; important complaints among these people include easy fatigability and frequent headaches. Depressed individuals often display enough malfunction of body process (*e.g.*, some have mild thyroid deficiencies) to make them appropriate candidates for medicines used in treating physical disorders. Favourable response to the medication, however, need not be taken to indicate that the patient's trouble is solely a matter of gross physiological disturbance. A number of components that underlie the complaints must be recognized; malfunction in terms of treatable disease combines with personalistic difficulty involving the person's attitudes, interpretations, and motivations.

**Chronic fatigue.** Some people are puzzled and disturbed to find themselves almost always fatigued. Physicians are most likely to be called upon to treat this form, called chronic fatigue. Various drugs have been administered, such as mood elevators, sedatives, and tranquilizers, often enough with unsatisfactory results. Insufficiency of the adrenal glands and vitamin deficiency sometimes have been identified as factors in the trouble, but neither adrenal hormones (corticosteroids) nor vitamin therapy have proved invariably satisfactory.

It has been suggested that chronic fatigue patients are of two sorts—the physically depleted person (*e.g.*, someone with chronic anemia) who is exhausted by very slight effort, and the psychogenically (mentally) tired person who begins to feel fatigue from the mere anticipation of effort. The latter person, however, is sometimes benefitted from the very activity he anticipates with aversion and may actually brighten up nicely after some mild stair climbing, for example. Other chronically fatigued individuals are those persons who start out well in the morning only to tire and quit easily; by contrast, there are others who take considerable time during the early part of the day to get started but by evening are feeling very good and perform at their best. Careful study of such groups remains to be carried out.

Chronic fatigue also is to be considered from the standpoint of the environment of the sufferer. There have been brutally simple circumstances (such as leaking gas pipes in the home) that, when corrected, have led to "miraculous" cures. Alternatively, chronic fatigue sometimes seems to be the result of one's having learned an unfortunate, gloomy way of looking at life, perhaps from childhood disappointments and frustrations. If this is a sizable factor, medicines may be of less avail than are efforts to retrain the individual emotionally (*e.g.*, by widening his opportunities for social success and gratification).

In general, it may be said that fatigue is one of the overall responses people make to demands placed upon them. Sometimes the demand is an industrial or other occupational situation; sometimes it is any one of the countless tasks one imposes on himself (*e.g.*, his efforts to "win friends and influence people"). At other times,

Hypochondriacs

Types of chronic fatigue patients

the demand arises from one's chronic attitude of pessimism or hopelessness that may extend to mere routine activities in which none of the usual exertional demands exist.

Various conditions can be manipulated in formal work situations to minimize the need for effort and to allow for rest and relief from monotony (e.g., pleasant music in a factory). Certain aids for the relief of fatigue involving bodily discomfort or disease can be supplied in drugs and other treatment. In all cases, fatigue seems best regarded as a personalistic outcome arising from any combination of physical, biochemical, social, or personal causes.

**BIBLIOGRAPHY.** S. HOWARD BARTLEY, "Some Things to Realize About Fatigue," *Journal of Sports Medicine and Physical Fitness*, 4:153-157 (1964), a description showing what some may erroneously expect to hear from psychologists about fatigue, *Fatigue: Mechanism and Management* (1965), a short monograph for the physician and athletic coach, indicating the role of drugs in alleviating feelings of fatigue and inadequate performance, "What Do You Mean 'Tired'?" *Today's Education*, 58:40-41 (1969), a description of fatigue in a form adapted for teachers and others in education, and with E. CHUTE, *Fatigue and Impairment in Man* (1947, reprinted 1969), a technical description of fatigue and syndromes confused with it, with many references; D.A. and E.C. LAIRD, *Tired Feelings and How to Master Them* (1961), a nontechnical treatment of various forms of inadequacy, loosely labelled fatigue, with some practical advice.

## Fātimids

The Fātimid dynasty, which ruled an empire in North Africa and then in the Middle East from AD 909 to 1171, tried unsuccessfully to oust the 'Abbāsīd caliphs as leaders of the Islāmic world. It took its name from Fātima, the daughter of the Prophet Muḥammad, from whom it claimed descent (see also NORTH AFRICA, HISTORY OF; CALIPHATE, EMPIRE OF THE; ISLAM, HISTORY OF).

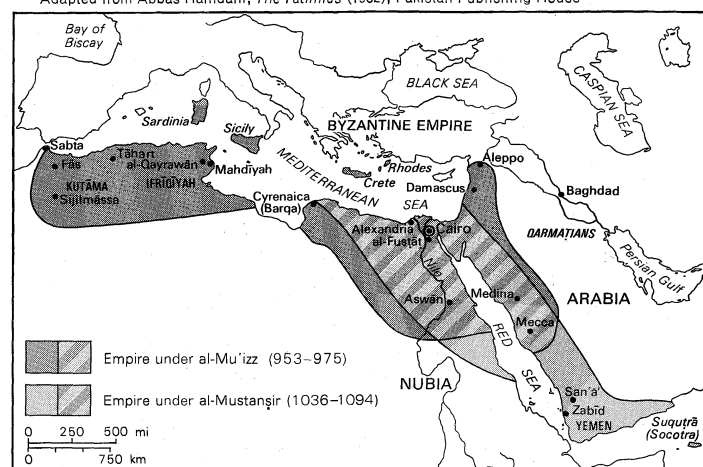

Before the Fātimids, there had been other rulers in North Africa and Egypt who had succeeded in making themselves virtually independent of the 'Abbāsīd caliphs in Baghdad; but they had been loyal Sunnī Muslims, willing to recognize the token suzerainty of the caliph as head of the Islāmic community and to content themselves with lesser claims and titles. The Fātimids, however, were moved by more than personal or dynastic ambition; they were the heads of a great religious movement—the Ismā'īlī branch of the Shī'ah sect—and as such aimed at nothing less than the overthrow of the existing religious and political order in all Islām. Unlike their predecessors, they refused to offer even nominal recognition to the 'Abbāsīd caliphs, whom they rejected as usurpers. They themselves—as Ismā'īlī *imāms* (spiritual leaders), descendants of the Prophet through his daughter Fātima and his kinsman 'Alī—were, in the eyes of their followers, the rightful caliphs, both by descent and by divine choice the custodians of the true faith and the legitimate heads of the universal Islāmic state and community. Their purpose was not to establish another regional sovereignty but to supersede the 'Abbāsīds as the 'Abbāsīds had superseded the Umayyads and to found a new caliphate in their place.

A regional sovereignty was, in fact, all that they succeeded in creating, despite an immense effort—at once political, religious, military, and economic—to overthrow their 'Abbāsīd rivals. The effort began during the 9th century, when Ismā'īlī missionaries in many parts of the Islāmic empire preached a doctrine of revolution against the Sunnī order and the 'Abbāsīd state. Their cause was symbolized in the person of the hidden *imām*—a descendant of 'Alī and Fātima and thus of the Prophet—in whose advent they believed with messianic fervour. Several generations of *imāms* remained hidden as a precaution against persecution. After a number of unsuccessful risings, the Ismā'īlīs were able to establish a firm base in the Yemen; from there they sent emissaries to North Africa, where they achieved their greatest success. By 909 they were strong enough for their hidden *imām* to emerge from hiding and proclaim himself caliph, with the

significantly messianic title of al-Mahdī (the divinely guided one). This marked the beginning of a new state and dynasty.

**The Fātimid dynasty.** For the first half-century the Fātimid caliphs ruled only in North Africa and Sicily, where they had to deal with many problems. Most of their subjects were Sunnīs of the Mālikī school; others—

The Fātimid Empire.

a substantial minority—were Khārijites. Neither group was well disposed toward the Ismā'īlī doctrines of the new rulers, and they offered stubborn resistance to them. Even among the Ismā'īlīs themselves, a conflict soon arose between the state and the revolution—that is, between the caliph al-Mahdī (reigned 909-934) and the missionaries who had brought him to power. The necessary adaptation of the Ismā'īlī doctrine and mission to the needs of the Fātimid state and empire was carried out at the cost of bitter struggle and much bloodshed. There also were political problems with fractious Berber tribes and neighbouring Muslim rulers, as well as a war against the Byzantines in Sicily and Italy that the Fātimid rulers had inherited from their North African predecessors.

While coping with these difficulties, the Fātimids never lost sight of their ultimate aim, expansion to the East, where the centre of 'Abbāsīd strength lay. The first step was the conquest of Egypt, and for this the Fātimids prepared for half a century. The first caliph, al-Mahdī, established his capital at Mahdiyyah (founded 920) on the east coast of Tunisia. His successors al-Qā'im (reigned 934-946), al-Manṣūr (reigned 946-953), and al-Mu'izz (reigned 953-975) ruled from there. In 913-915, 919-921, and 925 unsuccessful expeditions were sent against Egypt. Finally, in 969, under the caliph al-Mu'izz, the first stage in the advance to the East was completed. Fātimid troops conquered the Nile Valley and advanced across Sinai into Palestine and southern Syria. Near al-Fustāt, the old administrative centre of Muslim Egypt, the Fātimids built Cairo, which became the capital of their empire, and in it a new cathedral mosque and seminary, called al-Azhar, after Fātima az-Zahrā (the resplendent), the ancestress of the dynasty (see also EGYPT, HISTORY OF).

The Fātimid challenge to the Sunnī caliphate was now closer and stronger and was maintained by a great power—for a while the greatest in the Islāmic world. For more than a century the Fātimid rulers in Cairo pursued their aim of establishing the universal Ismā'īlī imamate. At times they were compelled by other problems—war on the frontiers, trouble in the Mediterranean, unrest at home or in the provinces—to reach some agreement with their Sunnī rivals; but such arrangements were always temporary, and subordinate to the grand objective.

The Fātimid caliphate was a regime at once imperial and revolutionary. At home, the caliph was a sovereign, governing a vast empire and seeking to expand it by normal military and political means. Its heart was Egypt; its provinces at its peak included North Africa, Sicily, the

conquest  
of Egypt

Red Sea coast of Africa, Syria, Palestine, the Yemen, and the Hejaz, with the two holy cities of Mecca and Medina. Control of these was of immense value to a Muslim ruler, conferring great religious prestige and enabling him to exploit the annual pilgrimage to his advantage.

The caliph was not only an emperor; he was also an *imām*—the spiritual head of the *Ismāʿīlīs* wherever they were and, according to *Ismāʿīlī* doctrine, the embodiment of God's infallible guidance to mankind. As such he was the archenemy of the *Sunni* 'Abbāsid order and the hope and refuge of those who wished to overthrow it. In all the lands still under 'Abbāsid suzerainty, he commanded a great network of missionaries and agents, and he used them to gain converts for the *Ismāʿīlī* faith and workers for the Fāṭimid cause; their task was also to preach and, where possible, to practice subversion against the *Sunni* order and the regimes that supported it. The mission was elaborately and secretly organized under the supreme direction of the chief missionary in Cairo. In the Fāṭimid state the mission became in effect a third branch of the government, together with the traditional military and bureaucratic establishments; it thus approximated to something otherwise lacking in the medieval *Islāmic* world—an institutionalized state church.

The mission had a number of functions. One of these was what is now called ideology; *i.e.*, the organized and exclusive system of ideas adopted by the movement and the regime. This was necessarily expressed in religious terms. *Ismāʿīlī* theology supplied the arguments by which the Fāṭimids denied the 'Abbāsid claim to the caliphate and asserted their own, and was thus a powerful weapon in their armoury. First in Tunisia and then in Egypt, a series of distinguished theologians wrote what became the classical formulations of *Ismāʿīlī* doctrine. Most of these authors had served in the mission; some had been its chiefs. Their task was not without difficulty. From the beginning of the Fāṭimid caliphate in North Africa, the conflicting needs of government and of revolution led to disputes between radicals and conservatives. Sometimes these were no more than arguments between colleagues; sometimes they led to defections, schism, and even armed conflict.

The primary tasks of the mission were thus the formulation and dissemination of *Ismāʿīlī* doctrine. These included much that in modern terms might be considered education and propaganda. The Fāṭimids founded great libraries and colleges, whose functions were to train missionaries to go out into the field, and to provide further instruction for the converts sent to Cairo for this purpose.

The work of the mission was only a part—albeit an important one—of the Fāṭimid grand strategy against the *Sunni* Empire; in this strategy, the universal aims of the *Ismāʿīlī* faith and the imperial purposes of the Fāṭimid state met and merged. Linked with these actions was a great commercial expansion and an economic policy aimed at developing the Red Sea trade between Asia and the Near East, to the detriment of the alternative route through the Persian Gulf, which was controlled by the *Sunni* powers. In the course of this effort, the Fāṭimids extended their rule down both shores of the Red Sea, established their supremacy in Yemen, and sent missionaries to eastern Arabia, to Central Asia, and to India.

**Beginning of Fāṭimid decline.** The high-water mark of Fāṭimid expansion to the East was reached in 1057–59, when a dissident general in Iraq changed sides and proclaimed the Fāṭimid caliph in Mosul and then, for a year, in Baghdad itself. The Fāṭimids were unable to provide support, however, and the general was driven out of Baghdad by the Seljuq Turks. This proved to be a turning point and the beginning of the decline of both Fāṭimid power and *Ismāʿīlī* influence.

Several reasons may be adduced for the failure of the Fāṭimid bid for *Islāmic* leadership. One was their adoption and retention of a religious doctrine that was ultimately unacceptable to the *Sunni* majority. Fāṭimid *Ismāʿīlism*, as a theology, represented a great spiritual and intellectual achievement; but it was remote from the central consensus of *Islām*, and with the *Sunni* revival of the 11th and 12th centuries its rejection became certain. The

coming of the crusaders indirectly sealed its fate, for in the great 12th-century contest between *Islām* and *Christianism* there was no room for a schismatic caliphate on the Muslim side.

In their ventures abroad, the Fāṭimids achieved many successes, the most notable being the conquest of Egypt itself. They suffered repeated setbacks, however, in Palestine and Syria; these difficulties, on the Fāṭimids' very doorstep, contributed in no small measure to their ultimate failure. Despite the sympathies of important elements in the population, they were never really able to control Syria, where, in addition to local opponents, they also had to face major attacks from outside—by the Byzantines, the Turks, and then the European crusaders. It was in Syria that the great Fāṭimid advance to the East was delayed and halted; and it was in Syria that a new power arose that in time destroyed them.

These troubles abroad no doubt fed, and were fed by, the growing discontents in Egypt. At first the caliphs retained full personal control of affairs, presiding over an essentially civilian government. The army's importance increased, however, and it was there that the first signs of trouble appeared. At first the army was largely Berber. Berber troops conquered Egypt, and for a while the Berber garrisons in Cairo, Damascus, and other cities—as well as the Tunisian merchants and officials who followed the caliphs to Egypt—maintained the character of the Fāṭimid caliphate as a North African ascendancy in the Middle East. But this did not last; during the reign of al-'Azīz (reigned 975–996), the second caliph in Egypt, Turkish and other Mamlūks were recruited and quarrels broke out between them and the North Africans. Later, a third force was added to the racial conflict, with the formation of regiments of black slaves from Nubia and the Sudan. Fights between the different groups first became a factor during the reign of al-Ḥākim (reigned 996–1021), in whose time, partly because of his own highly eccentric behaviour, the personal authority and religious prestige of the caliph began to decline. His successors became little more than puppets in the hands of their viziers and their generals. During the long reign of al-Mustanshir (reigned 1036–94) factional strife brought Egypt into a vicious circle of anarchy and tyranny, made worse by recurring famine and plague. The provinces, in east and west, were lost to local dynasts or invaders; even the Hejaz, vital to the religious claims of the caliphate, refused to share the Egyptian famine and turned instead to Baghdad. Finally, in 1073, an able soldier, Badr al-Jamālī, went to Cairo at the invitation of the caliph and seized power; in one night his officers rounded up the leading generals and officials and put them to death. He assumed the titles of commander of the armies, director of the missionaries, and vizier, symbolizing his control of the military, religious, and bureaucratic establishments; it is by the military title that he is usually known.

Badr al-Jamālī restored order and, for a while, even brought some measure of prosperity. Egypt was now ruled by a military regime, headed by the commander of armies and maintained by his troops. The office became permanent; Badr was succeeded by his son and then by a series of military autocrats who kept the Fāṭimid caliphs in tutelage. The later commanders were not even *Ismāʿīlīs*.

**The end of the Fāṭimid state.** Badr and his successors saved the Fāṭimid state from collapse and postponed its end for nearly a century. At first Badr retained and even tried to revive the aims and claims of the Fāṭimids to universal dominion, but it was too late. Responding to the Seljuq challenge from the East, he pursued an active policy in Syria, Arabia, and elsewhere, using both religious and worldly weapons. In Syria, however, the armies of the Fāṭimids suffered repeated defeats; in Arabia their following was reduced to insignificance. Badr's son and successor al-Afḍal in effect renounced the claims of the Egyptian Fāṭimid dynasty to the universal caliphate. On the death of al-Mustanshir in 1094 it was al-Afḍal who chose the new caliph. Al-Mustanshir had nominated his elder son, Nizār, who had been accepted by the *Ismāʿīlī* leaders; the younger son, Aḥmad, was a youth without al-

Badr  
al-Jamālī  
and his  
successors

Extension  
of Fāṭimid  
rule

lies, who would be entirely dependent on his sponsor. It was no doubt with this in mind that al-Afdal married his sister to Ahmad and, on al-Mustansir's death, proclaimed his brother-in-law as caliph with the regnal name al-Musta'li (reigned 1094–1101); in doing so, al-Afdal split the sect from top to bottom. Even in Egypt there was some opposition; in Persia, Iraq, and Central Asia the Isma'ili mission, now led by the redoubtable Hasan-e Sabbah, refused to recognize the new caliph and broke off relations with the Fātimid authorities in Cairo. Hasan-e Sabbah's new Isma'ili movement, known after its Syrian branch as the Assassins, proclaimed Nizār and his descendants as rightful imāms and condemned the caliphs in Cairo as usurpers. Even those Isma'ilis, chiefly in the Yemen, who had accepted al-Musta'li broke away in 1130 when al-Musta'li's son al-Āmir (reigned 1101–30) was murdered by the Assassins and was succeeded by his cousin al-Hāfiz (reigned 1130–49). Claiming that al-Āmir had left an infant son who was now the hidden imām, the Yeménites refused to recognize al-Hāfiz or his successors in Cairo. The divergence between empire and revolution, discernible from the accession of the first Fātimid caliph, was now complete.

The end of the dynasty came in 1171. The last four caliphs were no more than a local Egyptian dynasty, without power, influence, or hope. In 1171, as the last caliph lay dying in his palace, Saladin, who as nominal vizier had become the real master of Egypt, allowed a preacher to recite the bidding prayer in the name of the 'Abbāsid caliph of Baghdad. The Fātimid caliphate, already dead as a religious and political force, was now formally abolished. After more than two centuries, Egypt had returned to the Sunni fold.

**BIBLIOGRAPHY.** A useful account of the Fātimid caliphate, with full bibliographical guidance, is given by M. CANARD in the article "Fatimids," in the *Encyclopaedia of Islam*, 2nd ed., vol. 2 (1965); see also the article on Fātimid art by G. MARCAIS. The Fātimid period may be studied within the larger context of Islāmic history in the *Cambridge History of Islam*, vol. 1 (1971); and in general works on medieval Egypt. S. LANE-POOLE, *A History of Egypt in the Middle Ages*, 2nd rev. ed. (1914), is in many ways out of date, but still useful. The contributions of GASTON WIET to two general histories of Egypt present a more modern view; they are the anonymously edited *Précis de l'histoire de l'Égypte*, vol. 2 (1932); and GABRIEL HANOTAUX (ed.), *Histoire de la nation égyptienne*, vol. 4 (1937). There are only two monographs on the Fātimid caliphate in Western languages: F. WUESTENFELD, *Geschichte der Fatimiden-Chalifen* (1881); and DE LACY E. O'LEARY, *A Short History of the Fatimid Khalifate* (1923). Both are superseded, but the former retains some value. Particular aspects of Fātimid religion and history are discussed in P.J. VATIKOTIS, *The Fatimid Theory of State* (1957); and B. LEWIS, *The Assassins* (1967). Articles on Fātimid history are listed in J.D. PEARSON, *Index Islamicus 1906–1955*, pp. 479–480 (1958, and supplements).

(B.Le.)

## Faulkner, William

Imagination is the simple quality that assures Faulkner's place among the major novelists of his time. Never at home in the literary world, he projected a little world of his own: Yoknapatawpha County, "William Faulkner, sole owner and proprietor," as he lettered on a map drawn for one of his books. He peopled the county with extraordinary characters, white, black, and red, all living intensely, almost convulsively; then, as their story developed from novel to novel, he made it a fable of the real American South in history and, beyond that, of human destinies everywhere.

**Youth and first writings.** The oldest of four brothers, he was born September 25, 1897, in New Albany, a county seat in northern Mississippi. His parents were Murry C. and Maud Butler Faulkner; it was the novelist himself who later added a "u" to the name. Soon the Falkners moved to Ripley, in the adjoining county, and then 50 miles southwestward to Oxford, where the novelist was to spend most of his life. In Oxford his father owned and lost a livery stable and a hardware store before he became business manager of the state university. The family was proud of its Southern heritage and re-

Faulkner.  
Robe Capa—Magnum

vered the memory of the boys' hot-tempered great-grandfather, Col. William C. Falkner, who had served with distinction during the Civil War. Later, besides building a railroad from Ripley into Tennessee, he had written a romantic novel, *The White Rose of Memphis*, popular enough to be reprinted 36 times. When Billy Faulkner was in the third grade, his teacher asked what he wanted to do when he grew up. He rose from his seat and answered, "I want to be a writer like my great-granddaddy."

Billy, or "Memmie"—as he was called by the family and also by a devoted servant, Caroline Barr, who told him stories remembered from slavery days—was an imaginative boy, always leading his brothers into scrapes. His imagination was fed by haphazard reading. There was no public library in Oxford then, but the house was stocked with books, including Dickens and many other English classics. He was not interested in formal studies and dropped out of the local high school after his second year. At the time, he was in love with a girl in the same block, Estelle Oldham. Dreaming of marriage, he went to work in his grandfather's bank. Meanwhile, another neighbour, Philip Stone, soon to enter the family law office, took charge of his reading and provided him with books unknown in Oxford, many of which were in the Symbolist or Modernist tradition: Charles Baudelaire, Paul Verlaine, and Stéphane Mallarmé (Faulkner taught himself to read French). These men and others in the same tradition, such as Oscar Wilde, James Joyce, T.S. Eliot, and Conrad Aiken, appeared a little later in lists of his favourite authors.

Estelle married another man and went to live in the Orient. Faulkner enlisted in the Royal Air Force Canada and was sent to Toronto as a cadet pilot. That was in the summer of 1918, and the war ended before he had finished his basic training. Home again in Oxford, he was admitted to the University of Mississippi—"by special dispensation for returned troops," he said in a letter—but he stayed there only long enough to join a fraternity and contribute poems to the literary magazine. During the years that followed, he engaged in a series of occupations to earn enough for "paper, tobacco, food, and a little whiskey" while he was learning to write. Thus, in the fall of 1921, he worked as a clerk in a New York City bookstore. For the next three years he was postmaster of the university station, just outside of Oxford—"the damndest postmaster the World has ever seen," Phil Stone wrote of him. It was Stone who put up most of the money for the publication of his first book, a cycle of pastoral poems, *The Marble Faun* (1924).

The first half of 1925 he spent in New Orleans; perhaps it was the only time when Faulkner moved in a talkative literary circle, though he did little of the talking. It was

Early  
literary  
influences

## First novel

also the time when he wrote his first novel, *Soldiers' Pay*, about the return to Georgia of a fatally wounded aviator. The novelist and short-story writer Sherwood Anderson was then the great man of the New Orleans circle, and he recommended the novel to his own publisher. In July Faulkner sailed for Italy on a slow freighter; soon he made his way to Paris, partly on foot. He was living there alone, on the Left Bank, when he heard that the novel had been accepted for publication the following spring. The advance against royalties of \$200 paid for most of his passage to New York and his railroad ticket to Oxford, where he arrived before Christmas. In Oxford (and, during the summers, in Pascagoula, on the Gulf coast of Mississippi) he continued for some years to support himself by odd jobs: by working as house painter, carpenter, golf professional, deckhand on a shrimp trawler, and, by his own account, rum smuggler on a speedboat that dodged through the Louisiana bayous. Meanwhile he was writing furiously, mostly at night.

His second novel, *Mosquitoes* (1927), was a heavily satirical picture of the New Orleans literary circle. It was also, in effect, a rejection of the circle and of others resembling it. He was to do his future work in something close to isolation. Besides novels and poems, he was producing a great number of stories, each of which was handed over to Phil Stone, typed by his secretary, and sent off to several magazines. The stories always came back, and, at one time, Stone reported that a drawer of his filing case was nearly full of rejected manuscripts. A third novel, *Flags in the Dust*, finished in the autumn of 1927, was refused by the publisher of the other two. Faulkner became persuaded that his work would never again appear between hard covers. "Now I can write," he said to himself before starting *The Sound and the Fury*. A translation of the remark might be, "Now I can forget the public and live in my imagination."

*Flags in the Dust* was given a new title, *Sartoris*, and was finally accepted by another publisher, after changes in the manuscript by an unknown hand; it appeared in January 1929. Disproportioned and sometimes emotionally overwrought, it is the last of his apprentice works, but also the first to deal with his imagined community and to state many of the themes he would later develop at length. *The Sound and the Fury*, accepted by still another publisher, appeared in October of the same year. Describing as it does the decay and fall of the aristocratic Compson family—and, implicitly, of a social order—from four different points of view, it is extraordinary for its technical and psychological range and is the first of his masterworks.

Estelle Oldham came back from China after the failure of her first marriage, and she and Faulkner were married in June 1929. During the spring of that eventful year he had written a draft of *Sanctuary*—"the most horrific tale I could imagine"—and had sent it to his new publisher, Harrison Smith. "Good God, I can't publish this. We'd both be in jail," Smith reported, but without returning the typescript. During the late autumn, Faulkner wrote *As I Lay Dying* while he worked as night fireman at the university power station. Reviews of *The Sound and the Fury*, more impressive than its sale, were persuading editors to take a second look at his short stories. "A Rose for Emily" was the first to appear in a national magazine (April 1930), and it was soon followed by others. Faulkner took the risk of buying a big, dilapidated house—which he called Rowanoak—built shortly before the Civil War.

**Mature works.** He was now well along in what later came to be known as his major phase. The sheer number of his books was becoming impressive. In the years from 1930 to 1942 he published two collections of stories, a second and last book of poems (*A Green Bough*, 1933) and nine novels—all this besides working on movies in Hollywood and making repairs on Rowanoak with his own hammer and saw. The novels are *As I Lay Dying* (1930), about a poor-white family and its journey through fire and flood to bury the mother in Jefferson, the county seat of Faulkner's Yoknapatawpha County; *Sanctuary* (1931), his one popular success—the publisher had

changed his mind about it and Faulkner had rewritten it in proof, without softening the horror; *Light in August* (1932), with its portrait of Joe Christmas, who may or may not be a mulatto and can live in neither the white world nor the black world; *Pylon* (1935), about barnstorming aviators, published in the same year that his youngest brother, Dean, was killed while piloting the plane that Faulkner had bought two years earlier, when he had been working for the movies; *Absalom, Absalom!* (1936), a fable of the old South that is one of his best books but was the most scathingly reviewed, so that his readers began to drop away; *The Unvanquished* (1938), about the Sartoris clan in and after the Civil War; *The Wild Palms* (1939), two separate stories counterpointed in alternate chapters; *The Hamlet* (1940), first volume of a projected trilogy about the rise of the unscrupulous Snopes family; and *Go Down, Moses* (1942), about the Mississippi wilderness and the white and the black descendants of a planter who lived on the edge of it. Except for *Pylon*, all these novels contribute to the Yoknapatawpha cycle.

That cycle was not something planned in advance, as Emile Zola's *Les Rougon-Macquart* series had been. Faulkner started with his own countryside, his own kinfolk, his own memory of stories told him by Caroline Barr—Mammy Callie—or overheard on Saturday afternoons in the Oxford town square; but the stories grew in his imagination, where he sublimated, as he liked to say, "the actual into the apocryphal." Sometimes his version of an incident or his judgment of a character changed from novel to novel, but he was not disturbed by such inconsistencies: "I know these people better now," he used to explain. In the end the novels are even more remarkable for their unity than for their diversity. They all have in common three qualities that, before their time, were somewhat exceptional in American fiction: a sense of place, with events partly determined by their background in nature; a sense of history—that is, of the living past; and a sense of community. Often, Faulkner's narrator is the imagined voice of the community.

Unified as they are in their essential subject, the novels are extremely diverse in their approach to it. Each of them adopts a new method or a number of methods to solve a particular problem that the author had set himself. Sometimes the novel had started with a mental picture—Faulkner says, for instance, that *Light in August* started with the picture of a pregnant woman walking barefoot on a dusty road, and the problem was to explain how she got there and what happened next; the author himself didn't know when he was writing the first chapter. The case was different with *As I Lay Dying*, where the whole story existed in Faulkner's mind before he set the first word of it on paper (writing very rapidly, he says, on the back of an upturned wheelbarrow). Three other books—*The Unvanquished*, *The Hamlet*, and *Go Down, Moses*—first existed as magazine stories, and the problem was to bring the stories together into a novel. Each of the three provides a completely different solution. Among the methods that Faulkner adopted were some he had learned from his reading of Symbolist or Modernist authors—for example, the interior monologue as developed by Joyce and others—but he also acquired and applied the principle that every author should invent his own methods and, if possible, push them further in each new book. Thus, his interior monologues were sometimes those of idiots or of persons on the edge of insanity. A technique he made peculiarly his own was that of delayed meaning, so that he circled round the subject of a novel as if it were a hidden city in the jungle. In matters of style, he set the modern against the traditional, the simple against the involuted or sometimes the needlessly obscure, and mingled Shakespearean grandiloquence with Southwestern humour. "Take chances!" was the motto he chose for himself. Some of his experiments were monumental failures, but others succeeded so well that in later years they were to change the tone and scope of American fiction.

His widespread influence, however, was still in the future. During the early 1940s, Faulkner seemed close to

Faulkner's  
methods  
of writing

being forgotten—not in France, where his novels had been ably translated; not by his fellow American novelists, some of whom admired his work intensely; but by the American public at large. Although *The Hamlet* and *Go Down, Moses* contain some of his best writing—including a superb story, “The Bear”—they had gone almost unnoticed. In 1945 his novels were effectively out of print, except for a few copies of *Mosquitoes* in his first publisher’s warehouse. Faulkner himself, unable to live by writing fiction, had accepted a long-term contract to write movie scripts in Hollywood at a modest salary.

**Rediscovery as a writer.** His second rise to fame, steeper than the first, began with the publication in 1946 of *The Portable Faulkner*. It presented his Yoknapatawpha legend as a whole, with extracts from most of his books arranged in historical order. Some of the novelists who admired his work—notably Robert Penn Warren—seized the opportunity to write illuminating essays about it. The public began to take notice, and Random House, his final publisher, put the books back into print, one after another. In 1948 Faulkner published a new novel, *Intruder in the Dust*, about a white boy who saves a proud Negro from being lynched. It was the first of his books since *Sanctuary* to have even a modest popular success. *Collected Stories*, published early in 1950, won the National Book Award. At the end of the same year Faulkner was awarded the Nobel Prize (for 1949) and accepted it in an address famous for his prediction that man would survive in a world on the brink of self-destruction. Academic critics had gone to work on his books, which were providing the raw material, sometimes transformed beyond recognition, of a thriving industry.

Work for  
U.S. State  
Department

Much against his private inclination, Faulkner had become a public figure. He travelled abroad for the State Department: to Peru and Brazil in 1954; to Japan (where he had enthusiastic readers), the Philippines, and western Europe in 1955; to Greece in 1957; and to Venezuela in 1961. He was happier as writer in residence at the University of Virginia (1957 and 1958), because his only daughter and his grandchildren were living nearby. Meanwhile, he had taken a stand on at least one public question, that of the Negroes in Mississippi. Faulkner profoundly sympathized with the Negroes, but he had a strong residue of Southern nationalism and believed that the South should integrate for itself, without Northern interference. His opinions irritated the extremists and even the liberals of both races.

It was known that Faulkner drank heavily at intervals, but most of the time he kept hard at work, as is shown by the record of his publications. In 1951 his book was a three-act play, *Requiem for a Nun*, with a narrative prologue to each act that gave it the effect of a novel. (Although staged in several European countries, its production in New York was not a success.) In 1954 Faulkner published his longest novel, *A Fable*, on which he had been working for nearly ten years; its hero is Christ incarnated in a French corporal during World War I. Turgid and apocalyptic, the book leaves its readers uncertain of what the author is trying to say. In other novels of his last period, Faulkner was rounding out the Yoknapatawpha story, which continued to grow in his imagination; the county became a kindlier place as he looked back on it. Some of the demonic fire had gone out of his writing, which now expressed a more tolerant view of human nature. *The Town* (1957) and *The Mansion* (1959) are the concluding volumes of the Snopes trilogy. There is much high-flown talk in both of them, but *The Mansion* is redeemed by the story of Mink Snopes and how he returns from prison to kill the head of his clan. *The Reivers*, Faulkner’s last book, is a nostalgic comedy of boyhood that appeared, to great acclaim, only a month before he died in a hospital near Oxford (July 6, 1962). His death followed that of Hemingway by a year and marked the passing of a generation that had invented new shapes for American fiction.

#### MAJOR WORKS

NOVELS: *Soldier’s Pay* (1926); *Mosquitoes* (1927); *Sartoris* (1929); *The Sound and the Fury* (1929); *As I Lay Dying*

(1930); *Sanctuary* (1931); *Light in August* (1932); *Pylon* (1935); *Absalom, Absalom!* (1936); *The Unvanquished* (1938); *The Wild Palms* (1939); *The Hamlet* (1940); *Go Down, Moses* (1942); *Intruder in the Dust* (1948); *Requiem for a Nun* (1951), part novel, part play; *A Fable* (1954); *The Town* (1957); *The Mansion* (1959); *The Reivers* (1962).

SHORT STORIES: *These 13* (1931); *Dr. Martino and Other Stories* (1934); *Knight’s Gambit* (1949); *Collected Stories* (1950); *Big Woods* (1955).

POEMS: *The Marble Faun* (1924); *A Green Bough* (1933).

**BIBLIOGRAPHY.** More books and scholarly articles have been written about Faulkner than about any other American writer of the 20th century. As yet there is no bibliography that includes all the biographical and critical studies. JAMES B. MERIWETHER, *William Faulkner: A Check List* (1957), is complete for Faulkner’s published writing to that time.

By far the largest collection of Faulkner manuscripts, including many preliminary drafts, is on deposit at the Alderman Library of the University of Virginia. After most of the collection was displayed at Princeton, Meriwether described it in an admirable book-length catalog, *The Literary Career of William Faulkner* (1961).

There is no collected edition of Faulkner in English (there is one in Spanish), but his books are faithfully kept in print. MALCOLM COWLEY (ed.), *The Portable Faulkner* (1946, rev. 1967), is a selection based on the Yoknapatawpha County cycle.

The authorized record of his life, abundantly detailed, is by JOSEPH L. BLOTNER, *William Faulkner: A Biography*, 2 vol. (1972). There is firsthand information about the man and his background in JOHN FAULKNER, *My Brother Bill* (1963); in a book by another brother, MURRY C. FALKNER, *The Falkners of Mississippi* (1967); and in JOHN B. CULLEN and FLOYD C. WATKINS, *Old Times in the Faulkner Country* (1961). ROBERT COUGHLAN, *The Private World of William Faulkner* (1954), is largely anecdotal. Almost all the interviews with Faulkner, including those in Japan, are collected in JAMES B. MERIWETHER and MICHAEL MILLGATE (eds.), *Lion in the Garden* (1968). MALCOLM COWLEY, *The Faulkner-Cowley File* (1966), contains 26 of Faulkner’s letters.

Many critical studies of Faulkner’s work have elaborated the symbolic elements to the neglect of the sense and the structure. A better balanced treatment of all the novels is MICHAEL MILLGATE, *The Achievement of William Faulkner* (1966); an earlier one is IRVING HOWE, *William Faulkner: A Critical Study*, rev. ed. (1962). CLEANTH BROOKS, *William Faulkner: The Yoknapatawpha Country* (1963), is unsurpassed for the novels and stories in the Yoknapatawpha cycle. Other critical books that contribute to a full picture are WILLIAM VAN O’CONNOR, *The Tangled Fire of William Faulkner* (1954); OLGA W. VICKERY, *The Novels of William Faulkner: A Critical Interpretation* (1959); H.H. WAGGONER, *William Faulkner: From Jefferson to the World* (1959); WARREN BECK, *Man in Motion: Faulkner’s Trilogy* (1961), about the Snopes novels; and JOHN LONGLEY, JR., *The Tragic Mask: A Study of Faulkner’s Heroes* (1963). Shorter critical essays are collected in FREDERIC J. HOFFMAN and OLGA W. VICKERY (eds.), *William Faulkner: Three Decades of Criticism* (1960), which also contains a selective bibliography by Vickery; and in ROBERT PENN WARREN (ed.), *Faulkner: A Collection of Critical Essays* (1966), which is notable for Warren’s introduction.

(Ma.C.)

## Feast and Festival

Throughout the history of human culture, certain days or periods of time have been set aside to commemorate, ritually celebrate or re-enact, or anticipate events or seasons—agricultural, religious, or socio-cultural—that give meaning and cohesiveness to an individual and to his religious, political, or socio-economic community. Because such days or periods generally originated in religious celebrations or ritual commemorations that usually included sacred community meals, they are called feasts or festivals.

The terms feast and festival usually—though not always in modern times—involve eating or drinking or both in connection with a specific kind of rite: passage rites, death rites, sacrificial rites, seasonal observances, commemorative observances, and rites celebrating the ending of fasts or fast periods. Fasting, the opposite of feasting, has often been associated with purification rites or as a preparatory discipline for the celebration of feasts and associated rites. Festivals often include not only feasting but also dramatic dancing and athletic events, as well as revelries and carnivals that at times border on

the licentious. Depending upon the central purpose of a feast or festival, the celebration may be solemn or joyful, merry, festive, and ferial.

Another term associated with the events and activities of days of sacred significance is "holy day," from which is derived the word holiday. This term has come to mean a day or period of special significance not only in religious calendars (e.g., the Christian Christmas and the Jewish Hanukka) but also in the secular (e.g., May Day in the Soviet Union and Labor Day in the United States and Canada, both of which holidays celebrate especially the accomplishments of the working class).

This article, though it will concentrate on feasts and festivals in the history of religions, will also give attention to the holidays of what has been termed the secular (or profane) sphere. Most secular holidays, however, have some relationship—in terms of origin—with religious feasts and festivals. The modern practice of vacations—i.e., periods in which persons are "renewed" or participate in activities of "recreation"—is derived from the ancient Roman religious calendar in a reverse fashion. More than 100 days of the year were feast days dedicated to various Roman gods and goddesses. On the days that were sacred festivals, and thus holy days, persons rested from their routine daily activities. Days that were not considered sacred were called *dies vacantes*, vacant days, during which people worked. In modern times, however, vacations (derived from the term *dies vacantes*) are periods of rest, renewal, or recreation that may be sacred or secular holidays—or simply periods of time away from everyday work allowed by modern business or labour practices.

Feasts and festivals, originating in the dim past of man's social, religious, and psychic history, are rich in symbols that have only begun to be investigated in the 19th and 20th centuries by anthropologists, comparative folklorists, psychoanalysts, sociologists, historians of religion, and theologians. Such investigations will not only elucidate mythological, ritualistic, doctrinal, aesthetic, and psychic motifs and themes but will also provide educative insights to modern man, who has been caught up in social and religious forces that he has found difficult to understand. Feasts and festivals in the past have been significant informational and cohesive devices for the continuity of societies and religious institutions. Even when the feasts or festivals have lost their original meanings in doctrinal or mythological explanations, the symbols preserved in the rites, ceremonies, and arts (e.g., pictorial, dramatic, or choreographic) have enabled persons in periods of crisis or transition to preserve an equanimity despite apparent evidences of disintegration within their cultures or societies. Thus, the scholarly investigations of the many and various facets of feasts and festivals will provide different forms of information that will be of help to modern man in achieving an understanding of his origin, identity, and destiny.

#### NATURE AND SIGNIFICANCE

**Concepts of sacred times.** By their very nature, feasts and festivals are special times, not just in the sense that they are extraordinary occasions but more so in the sense that they are separate from ordinary times. According to Mircea Eliade, a Romanian-American historian of religion, festival time is sacred; i.e., it participates in the transcendent (or supernatural) realm in which the patterns of man's religious, social, or cultural institutions and activities were or are established. Through ritualistic re-enactment of the events that inform man about his origin, identity, and destiny, a participant in a festival identifies himself with the sacred time:

Religious man feels the need to plunge periodically into this sacred and indestructible time. For him it is sacred time that makes possible the other time, ordinary time, the profane duration in which every human life takes its course. It is the *eternal present* of the mythical event that makes possible the profane duration of historical events.

In religions and cultures that view time as cyclical—and this applies to most non-monotheistic religions and the cultures influenced by them—man understands his

status in the cosmos, in part, through special times (e.g., New Year's festivals) celebrating the victory of order in nature over chaos. New Year's festivals have been celebrated in recorded history for more than five millennia. In ancient Mesopotamia, for example, Sumerians and Babylonians celebrated the renewal of the life-sustaining spring rains in the month of Nisan—although some cities of Mesopotamia retained an ancient custom of celebrating a second similar festival when the rains returned in the month of Tishri (autumn). Sacrifices of grain and other foods were dedicated to the gods Dumuzi (or Tam-muz) or Marduk, major fertility deities, at a ziggurat (tower temple), after which the people participated in feasting, dancing, and other appropriate ritualistic activities.

In the 20th century, the view that New Year's Day is a time significant in the victory of order over disorder has been celebrated, for example, in areas influenced by Chinese religions. In order to frighten the *kuei* (evil or unpredictable spirits), which are believed to be dispersed by light and noise, participants in the New Year's festival light torches, lanterns, bonfires, and candles and explode firecrackers. In 1953, when the first day of the lunar New Year coincided with a solar eclipse, the government of the People's Republic of China (which has been anti-religious in its propaganda and official activities) expressed an anxiety that the repressed "religious popular superstitions" might encourage some form of anti-government activity. According to the views of Confucius (6th–5th centuries BC) and Mencius (4th–3rd centuries BC), two of China's great religious teachers, whose social and ethical influences have extended into the 20th century, a solar eclipse during the New Year's festival is a sign of a coming disaster and of a lack of favour by Shang Ti, the Heavenly Lord, who sends omens to indicate his disapproval of man's evil activities.

In religions and cultures that conceive of time as linear, progressing from a beginning toward an end time, when the whole cosmos will be renewed or changed, man understands his status (i.e., his origin, identity, and destiny) in relationship to particular events in history that have a significance similar to those expressed in the myths of people who view time as cyclical. The Jew understands his status as a member of the "people of God," who were "chosen" during the Exodus of the Hebrews from Egypt in the 13th century BC to be witnesses to the liberating love of Yahweh (their God). His being one of the chosen "people of God" is celebrated especially during the Passover festival—in which the Exodus is ritually re-enacted and commemorated—in the month of Nisan (spring). Similarly, the Christian understands his status as a member of the "new people of God." He believes that he has been chosen by Christ, who was crucified and resurrected by God in the 1st century AD, to work for the Kingdom of God that was inaugurated in the first advent of Christ and will be consummated at the Parousia, the Second Coming of Christ as king and judge. The festival of the Resurrection, or Easter, is ritually re-enacted every year in order that the believer might participate in the present and future kingdom of peace. The eucharistic feast (the Holy Communion), though celebrated at many and various times during the year, originated in the event (namely, the Lord's Supper on Holy Thursday preceding Christ's Passion) that has been interpreted as a commemoration of the crucifixion and Resurrection. Just as the New Year's festivals of the religions that interpreted sacred time as cyclical incorporated both remorse and joy in their celebrations, so also the feasts of the Passover and the Resurrection include sorrow for the sins of the individual and of mankind and joy and hope for the salvation of man and the world (see also CALENDAR; JEWISH RELIGIOUS YEAR; and CHURCH YEAR).

**Times of seasonal changes.** The significance of seasonal renewal in prehistoric times. Before the development of agriculture, with its associations with solar and lunar calendars, ritual feasts were probably celebrated by hunters and gatherers of tubers and fruits. Paleolithic (Old Stone Age) peoples from about 30,000–10,000 BC and those living in what are called "Stone Age" cultures

Man's view of himself in cultures that see time as cyclical

Man's view of himself in cultures that see time as linear

The value of studies of feasts and festivals

in the 20th century, such as the Aborigines in Australia and New Guinea, have celebrated various rites in which feasts have assumed positions of significance. Seasonal variations—important in the maintenance of the food supply—were associated with the migrations and fertility of animals and the growth and decay of tubers and fruits upon which the clan or tribe depended for its very existence. Thus, out of an acknowledgment of seasonal change, rituals—often including ceremonial feasts—most likely developed in relationship to beliefs that the continuance of the food supply depended on the sacred or holy powers that controlled various aspects and facets of nature: *e.g.*, animals, vegetation, the change in climatic conditions, weather phenomena, mountains, and rivers.

Access to the sacred or holy powers was obtained and maintained by certain religious personages (*e.g.*, shamans, or persons having healing and psychic transformation powers, priests, clan or tribal leaders, and other persons having special learned or inherited powers). Though interpretations by scholars vary and the evidence is still subject to much speculating, Paleolithic cave paintings—such as that of the “sorcerer” (a bearded figure wearing a mask on the top of which were antlers of a deer) at Les Trois Frères in France—and rock paintings of the Aruntas of central Australia—such as totemic animals (symbolizing clan and animal relationships) or mythological nature heroes (*e.g.*, Katuru, the “lightning man”)—may indicate that fertility of animals and vegetation has been a primary concern (though not the only concern) in the ritual control of the food supply. Rituals connected with controlling the food supply generally centre on a feast in which eating, drinking, dancing, and the chanting of efficacious formulas play important symbolic roles.

At some point in human history (about 8,000–6,000 BC in the ancient Near East), when calendrical seasons were associated with planting and harvesting, special days or periods most likely were set aside for fasting (because of a paucity in the food supply) or for feasting (because of an increase in the food supply). Thus some calendrical periods inspired feelings of discouragement and remorse (when the food supply was low) or feelings of encouragement or joy (when the food supply was sufficient to meet immediate and future needs). Certain days were set aside during these periods for special rituals (often including feasts) that celebrated seasonal renewal, later interpreted in terms of individual spiritual or social renewal. In Zoroastrianism and Parsiism, for example, the annual seasonal renewal festival of Nōrūz (New Year) in the spring, dedicated to Rapithwin (the time of the midday meal), is at the same time a solemn and joyful celebration of new life in nature and the anticipated resurrection of the body when the world will be restored to its original and intended goodness—after the defeat of Ahriman (the spirit of evil and chaos) and his demons.

*The significance of seasonal renewal in ancient Egypt.* Seasonal-renewal motifs in ancient Egypt were often incorporated into other aspects of sacred times—such as times of passage rites (*e.g.*, ascension of the pharaoh to the throne), of death rites (*e.g.*, the transformation of the dead person into a glorified person, a *ḥu*), and of commemorating certain historical events (*e.g.*, military victories in which the pharaoh preserved *ma'at*—*i.e.*, order, truth, and justice—which was active in the realms of nature and society).

In Egypt during the 5th millennium BC, astronomers in the Nile Delta region associated the annual inundation of the river—which covered wide areas with fertile soil—with celestial movements, especially that of the star Sirius (*i.e.*, Sothis) and the sun. From such observations the Egyptians developed a solar calendar of 365 days, with 12 months of 30 days each and five festival days at the end of the year. Though priests assumed important functions at the festivals centred about the fertility of the soil irrigated by the Nile and the life-giving warmth of the sun, the pharaoh, the sacred king, embodied the continuity between the realm of the sacred (*i.e.*, the transcendent sphere) and the realm of the profane (*i.e.*, the sphere of time, space, and cause and effect). The pharaoh

was believed to be the son of the sun god Horus of the Horizon (Harakhte), symbolized by the falcon; the sun god was also known as Re, among other names. The eastern horizon (*ḥt*) was viewed as the meeting point of the underworld of the dead and the world of the living. The sun god also was known as Atum, which means “to be at the end,” or the west. Osiris, the god of the afterlife (the world of the dead) was believed to be embodied in the recently deceased pharaoh, who passed on his sacred powers and position to the new pharaoh, his son. At the *šd* festival, the new pharaoh, as the son of Horus and of Re, as well as of Osiris, was invested with both kingly and priestly powers. At his coronation festival the pharaoh was believed to gain the power to restore *ma'at* after the death of the previous pharaoh, and also to restore economic prosperity.

During the royal festivals—*i.e.*, ascension to the throne, the coronation, and the *šd* festival—feasting presumably occurred. Festivals associated with seasonal renewal, however, involved sacrifices, eating, drinking, and sometimes dramatic or carnival-like events. Some scholars hold that the Egyptian terms for festival, however, contain concepts that became extremely significant in later Hellenistic (Greco-Roman) religions—*e.g.*, the mystery, or salvatory, religions, such as those of Mithra, Isis, and the Eleusinian mysteries—and Semitic-based religions—*e.g.*, Judaism, Christianity, and Islam. According to this view Egyptian terms for festival, such as *ḥb*, *ḥ'*, and *pr.t*, all contain concepts of resurrection and epiphany (*i.e.*, the manifestation of a god). In Eastern Orthodox Christianity, for example, the festival of the Epiphany (January 6) celebrates Christ's manifestation to the Magi of the East (presumably followers of Zoroaster, a 6th-century BC Iranian prophet) and his Baptism in the Jordan River. The usual Greek designation for Epiphany is “the day of the light” (*hē hēmera tou phōtou*), in reference to the words in the Bible, in John 1:4, that Jesus is the “light of men.” Under the influence of the Christian Catechetical school at Alexandria (led by Clement and Origen in the 2nd and 3rd centuries AD), the earlier religious speculations of the Egyptians concerning their festivals were enhanced by further mystical and spiritual interpretations that affected Christian worship, piety, doctrine, and iconography, especially in Eastern Christianity.

The Egyptians celebrated many festivals that were connected with seasonal renewal, some of which became elaborated into sacred times of cosmic significance. Among their more popular festivals were those dedicated to Osiris, Amon-Re (the sun god), Horus, and Hathor (the sky goddess, represented by a cow).

Of special interest is the festival dedicated to Min, celebrated during the harvest month of Shemou (April). A statue of Min, represented as an ithyphallic god of fertility in iconography, was placed on an inclined pedestal, which was the symbol of *ma'at*. This pedestal represented the primordial mountain, a symbol of resurrection, renewal, and rebirth. During the processional honoring Min, hymns were sung and ritual dances and perhaps other types of dances were performed. The pharaoh and his queen entered the shrine and presumably enacted a sacred marriage rite. After the pharaoh's enthronement at the harvest Festival of Min, four arrows were shot toward the north, east, south, and west; and birds also were released in the directions of the four cardinal points of the compass. The releasing of the birds and arrows announced the harmonious union of man—both as an individual and as a corporate being—with the divine powers of nature inherent in the pharaoh as “Horus son of Min and Osiris.” Though the pharaoh was symbolically significant in the feasts and festivals of ancient Egypt, the priests of the various cults officiated in the rituals and sacrifices to the many gods and announced the proper times for the differing forms of celebrations (see also SACRED KINGSHIP).

*The significance of seasonal renewal in ancient Mesopotamia.* In ancient Mesopotamia, in Babylon, where the king was viewed not as the son of a god but as a god's agent, or representative, on earth, the New Year's festival (Akitu), in the spring month of Nisan, contained not

The pharaoh in Egyptian feasts and festivals

The Festival of Min

Probable reasons for feast and fast days

The  
New  
Year's  
festival

only seasonal renewal motifs but also themes centring on the renewal of man and his community. The *Enuma elish*, the epic of creation, was read at the festival in order to remind the participants that cosmos (order) arose out of chaos by means of a struggle between Marduk, the god of heaven, and Tiamat, the goddess of the deep and the powers of chaos. The New Year's festival was sometimes celebrated over a period of 10 to 12 days in Babylon. On the fifth day, a sheep was beheaded; the body of the sheep was thrown into the river, and the head was taken into the wilderness. This ritual act, in which an exorcist (*mashmashu*)—one who casts out demonic powers—participated, symbolized the ridding of the community of the powers of chaos. (It was similar to the scapegoat ritual of the ancient Hebrews, in which the sins of the community were ceremonially transferred to a goat, which was later led to a wilderness area to wander about far from the community.)

Before sunrise of the third day following the scapegoat ceremony, the Babylonian king, as the representative of a sinful people as well as the agent of the god, had to submit to ritual acts of humiliation: his symbols of power were removed, and the priest (*urigallu*) hit him in the face and enjoined him to pray for the forgiveness of his sins and the sins of his people. After a profession of innocence, the priest absolved the king, restored his regal insignia, and performed ceremonies with the king to ensure the continuous support of the powers of order in nature. During the three days between the sacrifice of the sheep and the reinvestiture of the king, the populace of the city engaged in chaotic activities, perhaps of a carnival-like nature, to symbolize the presence of chaos in nature and society during this period of the apparent absence of the king and the god. When the king reappeared to his people, with his royal symbols of office and in the presence of the statue of Marduk, a procession of statues of the various gods together with their adoring devotees then took place, leading to a sanctuary (*bitakitu*) outside the city. On the 10th day, a banquet involving the king, priests, temple functionaries, and the gods was held to celebrate the renewal of nature, man, and society.

*The significance of seasonal renewal in areas of other religions.* Among the pre-Columbian Maya, the first month (*uinal*), Pop, of the New Year—which would be July in the presently used calendar—became a time for several renewal ceremonies. Old pottery and fibre mats were destroyed, and new clothes were put on. The temple was renovated to meet the needs of the god that was especially venerated during a particular year (the annual god changed from year to year). New wooden and clay idols were made, and the portals and implements of the temple were reconsecrated with blue paint, the sacred colour. The god of the year entered the sacred precincts according to the cardinal point of the compass that he represented (and thus there were only four New Year's gods). The purpose of the processional rite was to ward off the forces of evil that might prevail against the people of the area. Dances by old women and sacrifices of live dogs (by throwing them down from the temple pyramid) were some of the activities that occurred during the Maya New Year's festival.

In Japan, among those engaged in agriculture, the *ta-asobi* ("rice-field ritual") festival is celebrated at the beginning of the year to ensure a plentiful harvest. Dances, songs sung with a *sasara* (musical instrument), sowing of seeds, and feasting play important roles in securing the aid of the *kami* (gods or spirits). Divination by means of archery, in which the angle of the arrow on the target is significant, has been used in shrines to help determine the methods that should be used in securing a good crop. In Hinduism, the Makara-Samkrānti, a New Year's festival in the month of Māgha (January–February), is celebrated with a fair that continues for a month's duration, with much rejoicing. The Śrī Pañcamī, a festival (*utsava*) of seasonal renewal on the fifth day of Māgha, symbolizes the ripening of crops. Feasts and festivals centring on seasonal renewal can be found among all peoples of the world, both past and present. Rogation festivities (Days of Asking), originally held by the ancient Romans to

counteract the effectiveness of the deity (Robigus) of red mildew on wheat, were reinterpreted by early medieval Christians of the West from the 5th century on as litanies for the blessing of the seed. Rogation Day, the fifth Sunday after Easter, is still practiced in the 20th century in rural Roman Catholic, Anglican, and Lutheran churches.

**Other sacred times.** *Crucial stages of life.* Birth, puberty, marriage, and death have been times of sacred significance for peoples of all races from time immemorial. They signify changes in the status of a person's being in terms of a person's relationship with fellow members of his or her society and the realm of the sacred or holy that informs the person of the practical and symbolic ramifications of the new status. These times of change, therefore, have become occasions for feasts and festivals. Some are very elaborate and of long duration; others, especially under the influence of modern secularization, have been abruptly shortened or eliminated.

Birth, a most sacred time in the religions of the world, is celebrated by rites and festivities that appear to be incongruous or inconsistent in many religions. Mothers of newborn children are considered both as participants of the sacred by having brought forth a new being into the world and as persons who are ritually unclean (e.g., among the Israelites and Zoroastrians), probably because of the presence of blood at birth, the loss of which may symbolize the loss of some of the life-sustaining force. Among Brazilian Indians, however, both the father and the mother participate in a ceremony of seclusion for five days (eating only certain foods) in order to protect the sacredness and health of the new mother and child. Seclusion, thus, need not be interpreted negatively. Among the Kikuyu of eastern Africa, seclusion is a symbol of death and resurrection. The mother and child symbolically die and rise again during and after a ceremony of seclusion, after which a feast is held in which a goat is sacrificed and prayers are said. The whole community rejoices that a new child has become a part of the family of man.

The Christian celebration of birth culminates in the sacrament of Baptism, a symbol of the death of the old person and the rebirth of the new person in Christ. As such, it is a rite of purification, using water and the words of institution by Christ. After the sacrament has been solemnized, Christians in many areas have engaged in much feasting to emphasize the joy inherent in the "new birth."

Among the ancient pre-Christian Norsemen, baptism by means of water was believed to impart divine and eternal life to men and even to preserve men from death—so that they "will not perish in war" nor "fall before any sword." Thus, when St. Boniface baptized members of Germanic tribes in the 8th century, he was ordered by Pope Gregory III to do so only according to the formula "in the name of the Father, and of the Son, and of the Holy Spirit." Because whole tribes became Christian en masse during this period, the feasts celebrating the incorporation of the tribe into the church often lasted for several days and included folk customs of which the church did not especially approve, such as those connected with merrymaking (e.g., the drinking of mead).

Puberty, the transition into adulthood, has been celebrated since ancient times by various rituals and festivals. In the secular sphere, it is celebrated in democratic countries by the granting of the right to vote to persons upon the attainment of a certain age. In ancient Greece, young men of the ages of 16 or 17 were admitted as full members of the city-state; but before they were granted voting privileges, they had to swear allegiance to the religion of the city; this made them religious citizens and subsequently adults. After he had attained adulthood, a young Greek could participate in military service and could marry. In the United States in the early 1970s, citizens having attained the age of 18 were granted the right to vote; but the ceremony commemorating this right has been a secularized de-emphasis of this important rite of passage: the mere signing of one's name on a registration certificate.

Puberty rites are celebrated in various ways according

Rites and  
feasts  
connected  
with birth

Rites and  
feasts  
connected  
with  
puberty

to the prevailing religious and social customs. Among the Masai of eastern Africa, youths pass from childhood to adulthood by the rite of circumcision. After various preliminary activities, the boys (12 to 16 years of age) are circumcised and the blood released from the operation is later placed on their heads. After four days of seclusion and a period during which they are dressed in female attire, their heads are shaved and they attain the status of adults and thus can become warriors. Girls attain adulthood by means of similar practices: the cutting or piercing of sexual organs. Among the Akambas of eastern Africa, who perform similar puberty rites of passage, those initiated into adulthood are given presents, and offerings are made to the ancestors. A significant aspect of the festival celebrating the rite of passing from childhood to adulthood is the return from seclusion; this return to their communities symbolizes a type of resurrection and renewal as new persons—adults.

Among the churches of the 16th-century Reformation, the rite of confirmation in the Anglican and Lutheran churches has been a type of puberty rite. The child, who had been a baptized member of the church, became, in effect, an adult, assuming personal responsibility and the privilege of participating in the Eucharist. In the early 1970s, however, the instructional aspect of confirmation—important in almost all pre-puberty practices—has been diminished, especially in some Lutheran churches in the United States, thus de-emphasizing the importance of confirmation as a rite of passage. As the church has become increasingly influenced by secularization processes in the 20th century, the customary feasting to celebrate the rite of confirmation has decreased in practice.

Rites and  
feasts  
connected  
with  
marriage

Marriage, the rite of passage from the single to the united state, has been celebrated with many forms of feasts and festivals. Connected with the *hieros gamos* ("sacred marriage") of the Mesopotamian Akitu (New Year's festival), and of the Israelite Sukkot (Feast of Tabernacles)—during the month of Tishri (the first month of the year)—which had both sexual and covenantal overtones, the rite of marriage developed into a legal and religious act in Judaism and into a sacrament in Roman Catholic and Eastern Christianity. In most religions the married state is considered superior to the single, though tensions between these two states of existence exist in most religions. Monks and nuns who vow to live in a celibate state often celebrate a symbolic marriage to the founder of their religion (e.g., to Christ) or to a religious institution (e.g., the church). In the Talmud, a compendium of Jewish law, lore, and commentary, the statement is made that "He who does not marry is like a murderer and he mutilates (violates) the image of God." In the Avesta, the sacred book of Zoroastrianism, a similar statement is made: "The man who is married stands above him who is not married." Thus, the wedding has become the most significant domestic festival in both the secular and religious realms, in spite of the ascetic tendencies that exist in certain sectors of Christianity, Buddhism, and other religions. The wedding ceremony has often been accompanied by feasting and gift-giving to express the concern of the community for a successful participation within the community and an extension of the community through the procreation of children. Among African religions, marriage as a rite of passage is incomplete if procreation is avoided or not accomplished. After a wedding among the Batoro of Uganda in Africa, dancing and feasting last until the following morning. Later on, gifts are given to the bride's family in order to show gratitude, to compensate for her absence, and to legalize the marriage agreement.

Rites and  
feasts  
connected  
with death

The final rite of passage, death, has brought about numerous festival customs, all the way from the ritual sacrifice of the widow in Hinduism (until the 19th century) to the commercialization of death rites in Western societies. Just as the early Hebrews believed that life passes on to death when the breath (*ruah*) leaves the body, so also do Eskimos in the 20th century believe that death occurs when breath (soul) leaves the body and that death may be a moment when one is translated into another form of life. Among the ancient Greeks, Thanatos

(death) is the twin brother of Hypnos (sleep), and from this conceptional relationship may come the view that death is merely a sleeping state in the passage from this life to an afterlife. Festivities surrounding rites include the customs of playing mournful (and, sometimes, joyful) music, speaking eulogies, performing sacramental acts (e.g., extreme unction in the Roman Catholic Church), performing elaborate or simple embalming practices (e.g., the lengthy procedural techniques of the ancient Egyptians and the rapid techniques of modern morticians), utilizing appropriate and expected bodily gestures and vocal expressions, and feasts of varied elaborateness, depending on the economic or social circumstances of the deceased or his next of kin. Flowers often play important roles in the festivities connected with death rites. In the 20th century, a change from mourning to joyful expectation has occurred in the funeral rites of some Christian churches. Among some African tribes, such as the Ndebele of Rhodesia, funeral processions, sacrifices, ceremonial washings, and protective medicine are included in the festivities that symbolically celebrate man's conquest over death (see also PASSAGE RITES; DEATH RITES AND CUSTOMS).

*Times of commemoration and remembrance.* Festivals of commemoration are among the most important of the sacred times. Some festivals commemorate important events in mythology or the birth, inauguration, or victory of a founder of a religion, a god, or a hero. In Hinduism, for example, the Vaikunṭha-ekādaśī festival in December-January commemorates the victory of the goddess Ekādaśī Devī in her killing of a demon; and the Gaṇeśaturthī commemorates the birthday of Gaṇeśa, the elephant-headed god of fortune. Another major Hindu festival, Navarātri, commemorates the victory of the goddess Durgā over the buffalo-headed demon Mahiṣa; and Rāma-navamī commemorates the birth of Rāma, the hero of the *Rāmāyana*, one of India's great epics. In Chinese Buddhism, the birthdays of Kuan-yin (or Avalokiteśvara), Amitābha, and Śākyamuni (the first two being *bodhisattvas*, or buddhas-to-be, and the last being the Buddha himself) were celebrated before the 1950s with much ceremony. The nativity of Christ (or Christmas) is the most widely celebrated "birthday" of a divine being, though in the 20th century it has been subjected to a wide variety of secular influences.

#### TYPES AND KINDS OF FEASTS AND FESTIVALS

**National and local festivals.** Feasts and festivals vary greatly in types and kinds. Though most are religious in background and character, other types have flourished for various lengths of time in cultures and civilizations of the world, both ancient and modern. Included among such types are social and cultural festivals: e.g., New Year's Day in the 20th century, sword-dance festivals in Scotland, the Olympic festivals in ancient Greece and the modern world, the Great Dionysia of ancient Greece during which dramatic contests took place, and May Day celebrations. National festivals in the United States include Thanksgiving Day (in November), which commemorates the survival of the Pilgrim colony in New England in the early 17th century; Independence Day (July 4), which commemorates the Declaration of Independence of the American colonies from the British crown; St. Patrick's Day (March 17), celebrated mainly in Chicago and New York City as a secular-religious feast; Mother's Day (in May); Memorial Day (in May), commemorating those who have died, especially in war; Flag Day (June 14); and others. National or local festivals in other countries include: Bastille Day (July 14), commemorating the beginning of the French Revolution in 1789; Dominion Day (July 1) in Canada; and independence days in many countries. Birthdays of national founders or heroes are also types of commemorative festivals. In some Protestant countries, Reformation Day has assumed the position of a holiday either nationally or locally. In Israel, Holocaust Day—commemorating the systematic destruction of European Jews by Nazi Germany in the 1930s and 1940s—has been placed on the national calendar of events to be remembered.

The relationship of secular holidays and festival activities to religious festivals

**Secular modernist festivals.** Secular modernist festivals are often mixed with previous religious festivals. May Day, once mainly a springtime fertility festival that can be traced back to the Magna Mater (Great Mother) festivals of Hellenistic (Greco-Roman) times, has become a festival of the labouring class in Socialist countries. Saturday and Sunday football games in the U.S. have all the external trappings of religious festivals. A person from a preliterate culture would see a large congregation gathered together to witness a ritual combat, conducted according to precise ritualistic rules. The participants are dressed in appropriate identifiable garb, or costumes, as they engage in their ritual combat—one side representing evil and the other good, depending upon the viewpoint of the members of the audience. Leading the congregation are priestesses (cheerleaders) dressed in appropriate garb, participating in ritualistic dances, and chanting various formulas that are supposedly efficacious. Operating on the principle of sympathetic magic, the priestesses attempt to transfer the enthusiasm of the crowd to the appropriate combatants. The fact that lay participation in congregational worship in the United States and other Western countries has—for a long time—been little more than a spectator sport, according to some critics, may well have contributed to the festival character of weekend sports activities.

**Carnivals and saturnalias.** Some feasts and festivals provide psychological, cathartic, and therapeutic outlets for persons during periods of seasonal depression. The Holi festival of Hinduism during February–March was once a fertility festival. Of early origin, the Holi festival incorporates a pole, similar to the maypole of Europe, that may be a phallic symbol. Bonfires are lit; street dancing accompanied by loud drums and horns, obscene gestures, and vocalized obscenities are allowed; and various objects, such as coloured powders, are thrown at people. Various interpretations have been given for such activities.

One of the most well-known festivals of ancient Rome was the Saturnalia, a winter festival celebrated from December 17–24. Because it was a time of wild merry-making and domestic celebrations, businesses, schools, and law courts were closed so that the public could feast, dance, gamble, and generally enjoy itself to the fullest. December 25, the birthday of Mithra, the Iranian god of light and the contract and the day devoted to the invincible sun, as well as the day after the Saturnalia, was adopted by the church as Christmas, the nativity of Christ, to counteract the effects of these festivals.

Carnival-like celebrations were held on Shrove Tuesday, the day before the Lenten fast began, in England until the 19th century. Originating as a seasonal renewal festival incorporating fertility motifs, contests involving ball games were held that often turned into riots between opposing villages, feasts of pancakes and much drinking following the contest. The tradition of merrymaking continues in the United States in the Mardi Gras festival on Shrove Tuesday in Louisiana.

#### CONCLUSION

Feasts and festivals, whether religious or secular, national or local, have served to meet specific social and psychological needs. They serve a function of providing cohesiveness to institutions of society: e.g., church, state, and esoteric or socially nonaccepted groups. The cohesiveness engendered in the celebration of feasts and festivals of minority groups (e.g., Christians in the early Roman Empire) often provides a position of strength to the minority group in influencing the institutions of the society and culture of the majority. When a particular religion becomes triumphant in its contest with other religions, it often incorporates elements from the feasts and festivals of the previously predominant religions into its own religious calendar. This has been an important practice of all the world religions, both ancient and modern, in their attempts to bring about social solidarity, order, and tranquility. Similarly, individuals can find cohesiveness psychologically by their participation in feasts and festivals.

During periods of crisis in society, feasts and festivals may lose some of the impact of their interpretive and cohesive functions. Just as the sacraments of the medieval Western Church lost some of their earlier interpretive values during the 16th century under the impact of the Reformation and as the month of fasting before the Feast of Bēma ("judge's seat")—a Manichaean festival commemorating the death of Mani, a 3rd-century AD Iranian prophet who founded the syncretistic Manichaean religion—probably became the prototype of the Muslim fast month of Ramaḍān under the impact of the Islamic invasions of the 7th century AD, so also can persons living in the 20th century expect reinterpretations of the feasts and festivals to which they have become accustomed. Reinterpretations of feasts and festivals may thus provide impulses for institutional changes, which generally occur in times of crisis and transition.

**BIBLIOGRAPHY.** E.O. JAMES, *Seasonal Feasts and Festivals* (1961), is a classic work on feasts and festivals of seasonal renewal and on folk festivals and customs of the Western world from prehistoric times to the early 20th century. MIRCEA ELIADE, *The Sacred and the Profane* (1959), is a classic treatment of the concept of sacred time. W. BREDE KRISTENSEN, *The Meaning of Religion* (1960), treats feasts and festivals from the point of view of the phenomenology of religion in various sections of his book. C. JOUCO BLEEKER and GEO WIDENGREN (eds.), *Historia Religionum: Handbook for the History of Religions*, vol. 1, *Religions of the Past* (1969), and vol. 2, *Religions of the Present* (1971), incorporates feasts and festivals into the general framework of the particular religions. WALTER KRICKBERG *et al.*, *Die Religionen des alten Amerika* (1961; Eng. trans., *Pre-Columbian American Religions*, 1968), treats the various feasts, festivals, and associated rites in the general coverage of the religions of the particular Indian peoples. JOHN S. MBITI, *African Religions and Philosophy*, pp. 110–165 (1969), provides an excellent coverage of the feasts and festivals associated with African passage rites. JEAN HERBERT, *Aux Sources du Japon: le Shintō* (1964; Eng. trans., *Shinto*, 1967), covers the feasts and festivals of Shintō in detail (pp. 147–224). JOHN B. NOSS, *Man's Religions*, 4th ed. (1969), is the best one-volume work that covers the feasts and festivals of the various religions of the world within the general framework of the history, teachings, and practices of the religions.

(L.F.)

#### Federalism

Federalism is today one of the most widespread principles of political organization. Federal systems were at least nominally operative in 17 counties in 1971, and at least 18 others utilize federal principles to incorporate a measure of decentralization into their systems of government. Federalism is, in every case, a means of organizing power and the relationships that flow from it. Most particularly, it is a means for sharing power in political and social systems. Conceived in the broadest sense, federalism looks to the linkage of people and institutions in lasting yet limited union by mutual consent, without the sacrifice of their respective integrities, as the ideal form of social or political organization.

As a basis of political association, federalism may be defined as the mode of political organization that unites separate polities within an overarching political system in such a way as to allow each to maintain its own fundamental political integrity. Federal systems do this by requiring that basic policies be made and implemented through negotiation in some form, so that all the members can share in making and executing decisions. The political principles that animate federal systems emphasize the primacy of bargaining and negotiated coordination among several power centres; they stress the virtues of dispersed power centres as a means for safeguarding individual and local liberties.

The very terminology of federalism is characterized by a revealing ambiguity. The verb federalize is used to describe the unification of separate states into a federal polity and also the permanent diffusion of authority and power within a nation among general and subnational governments. In this ambiguity lies the essence of the federal principle: the perpetuation of both union and noncentralization.

Union and noncentralization

Federalism is more than simply a structural arrangement; it is a special mode of political and social behaviour as well, involving a commitment to partnership and to active cooperation on the part of individuals and institutions that at the same time take pride in preserving their own respective integrities.

#### HISTORY OF FEDERALISM AND THE FEDERAL IDEA

Federal institutions have developed in response to two different situations. On the one hand, federalism has been used as a means to unite a people already linked by bonds of perceived nationality or by common laws; in such cases, the polities that constitute the federal system are unalterably parts of the national whole, and federalism invariably leads to the development of a strong national government operating in direct contact with the people, just as the constituent governments do. The United States is a good example of this form.

On the other hand, federalism has been used as a means to unify separate peoples for important but limited purposes, leaving the individual polities a considerable degree of autonomy. Yugoslavia is one example of this form.

**Precursors and prototypes.** The principles of strong national federalism were first applied by the ancient Israelites, beginning in the 13th century BC, to maintain their national unity by linking their several tribes. The record of and rationale for their effort is presented in the Bible, particularly in the Books of Joshua, Judges, Samuel, and Ezekiel. It was to have a profound influence on the political principles of later generations, particularly at the time of the revival of federal ideas in the 16th and 17th centuries.

The Greek cities experimented with federal-style institutions as means for the promotion of intercity harmony and cooperation, primarily for defensive purposes, through such associations as the Achaean League (280–146 BC). These came close to what are today defined as confederations. But the Greek political philosophers ignored federalism as a political principle, because the very idea contradicted their conception of the small, unified polis as the basis of the good society. A modified form of the Greek view was developed by the 16th-century theorists of international law, who held that a federation could be no more than a permanent league of states that delegated limited powers to a common governing council while retaining full internal sovereignty.

When the American federal system was created in the late 18th century, its architects developed a conception of federalism much like that of ancient Israel, a conception already rooted in American soil as a result of earlier experiments. American federalism was adapted to serve a people with a single national identity who desired a strong national government. In advocating ratification of the Constitution, the authors of *The Federalist* felt it necessary to describe the system as “partly national and partly federal” in deference to the accepted view. But in their usage the term federalist soon came to mean the older conception of federalism as a noncentralized national union having a general government superior to the governments of the constituent states.

As the American system became the prototype for other modern federal systems, the American conception of federalism became the generally accepted one in the modern world. The other conception deriving from the Greek experience came to be called confederation. These different terms correspond roughly to the German terms developed in the mid-19th century: *Staatenbund* (“confederation”) and *Bundesstaat* (“federation”). In French and Spanish, however, the meaning of the terms is often reversed.

Though the American conception of federalism as a strong national union has become the conventional meaning of the term, the idea of confederation remains a living and legitimate aspect of the federal idea in its largest political sense. Confederation is advocated by certain proponents of European political union (the European Economic Community, or Common Market, is confederally organized) and by many “world federalists.”

**Cultural home rule and feudalism.** Two major forms of government, both of ancient origin, utilize what seem to be federal principles but actually are not.

Several great empires, notably the Persian and Roman, structured their political systems around a principle that may be described as cultural home rule, a pattern followed today by the Soviet Union and China. Political life was closely involved with religion and culture in the ancient world, and imperial recognition of local ways implied a measure of contractual devolution of political power. Such home rule was not a matter of local right but represented a conditional grant subject to revocation.

The political system of feudalism is often seen as a manifestation of certain federal principles because of its emphasis on contractual relationships. The Holy Roman Empire came to be the exemplary embodiment of quasi-federal feudalism. The hierarchical character of those relationships, however, and the lack of practical mechanisms to maintain the terms of the contract prevented them from being truly federal. The federalism of some Latin American states is a contemporary manifestation of feudal arrangements because the constituent states are often governed by local military leaders (*caudillos*) who resemble feudal barons.

**The Middle Ages.** More genuinely federal were the leagues of medieval commercial towns in central Europe, formed for mutual defense and assistance. In their corporate form of internal organization, these cities paralleled the Jewish communities of Europe and the Mediterranean world that had always organized themselves on federal principles. All Jewish communities were considered partnerships in Jewish law, created by *askamot* (articles of agreement). Beginning in the 12th century, these Jewish communities frequently joined in leagues similar to those of the new non-Jewish cities.

In 1291 the Swiss cantons formed a confederation for mutual aid in defense of their independence. While it has since undergone several reconstitutions, the Swiss Confederation remains essentially intact, the oldest continuing federal system in the world. It succeeded partly because it was rooted in popular government from the first.

The Christian states on the Spanish peninsula created a political system that ultimately came very close to authentic federalism. During the reconquest of Spain from the Moors, most of the peninsula was reorganized under the *fuero* system, which established local governments with relatively liberal political institutions to encourage resettlement. Three new states arose that joined in a quasi-federal arrangement under the crown of Aragon, each of them (plus several in Italy added later) retaining its own constitution and governing institutions as well as acquiring representation in the overall Aragonese government. The union of Aragon and Castille (a unitary state) under Ferdinand and Isabella undermined the evolution toward federalism in Spain.

In the 16th century, the ideas of the Protestant Reformation (particularly its Calvinist and Zwinglian elements) and the example of the Spanish system of political organization led to new applications of federal principles. The Habsburg heirs to the Spanish crown had applied Spanish principles to organize their other European possessions. In the Netherlands they laid an organizational basis for the subsequent federation of the United Provinces in the late 16th century, influenced in part by Calvinist ideas. When the country gained its independence it established a political system that, while failing to solve the technical problems of federalism, maintained itself in federal style for 200 years. Even after Napoleon put an end to the republic, a residue of noncentralization remained; The Netherlands is now a constitutionally decentralized unitary state.

The Reformation gave impetus to the development of federalism as a social principle in Switzerland, Scotland, The Netherlands, England, and parts of France and Germany. The assumptions of the Puritan, Presbyterian, and Reformed churches were manifested in the formation of communities of the saved; these covenanted together to create congregations (and, in some cases, states) that they could govern as partnerships. The Swiss and the Dutch

Pseudo-federal systems

Antecedents of modern federalism

The ancient Israelites and Greeks

created federal states; the Scots re-established their national identity through the Scottish national covenant; and the Puritans organized their New England colonies and churches on federal principles. The French term for the Protestants, Huguenot, was a corruption of the German *Eidgenossen*, which meant confederates bound together by oath.

**Modern approaches.** The Dutch and Swiss precedents stimulated the first serious efforts to formulate federal theories based on modern political principles. The French political philosopher Jean Bodin analyzed the possibilities of federation in the light of the problem of sovereignty, concluding that the necessity of maintaining sovereignty indivisible within states rendered federalism in the modern sense impossible, though Greek-style leagues for defensive purposes were not incompatible with national sovereignty. The Dutch jurist Hugo Grotius and the German writer Samuel Pufendorf examined federal arrangements as aspects of international law. Grotius, with the Dutch experience before him, concluded that closely knit leagues could prove viable, but Pufendorf held that federalism and sovereignty were so incompatible as to make leagues of any kind infringements upon sovereignty.

The German jurist Johannus Althusius, analyzing the Dutch and Swiss constitutions, perceived that federalism was really concerned with problems of national unity. The first systematic theorist of federalism, he was also the first to connect federalism with popular sovereignty and to distinguish among leagues, multiple monarchies, and confederations. His retention of hierarchical principles and his emphasis on the corporate organization of society reflected the realities of his time.

The application of federalism to the problems of unifying the new nation-states of the 16th and 17th centuries encountered three problems: (1) the difficulty of reconciling a traditionally hierarchical society with the need for fundamental social equality in the sharing of power; (2) the conflict between local autonomy and the need for a strong central government; and (3) the problem of executive leadership and succession, which was not solved until the American federalists invented the elected presidency.

It was the British who created the requisite popular institutions in their colonization of North America and the biblically influenced colonists who established the social basis and the theoretical justification for those institutions. The Americans assumed that their relationship to the British government was federal, even though London entertained no such notion. The Americans' response to the imperial system led them to develop the federal ideas they were later to use so creatively.

In transforming the principles of federalism into a practical system of government, the Americans had the advantage of working with an entirely modern, postfeudal society that was not weighted down with traditional social hierarchies having differential political rights. Being a relatively isolated nation, they escaped the foreign entanglements that create a demand for the centralization of power. Even so, the internal problems of applying the federal principle eventually led to a major civil war.

Almost every other nation attempting the federal solution to the problems of popular government in pluralistic, civil societies has attempted to imitate either the forms or the principles of federal organization worked out in the United States. The theoretical framework for those principles was developed in the debate over ratification of the Constitution. At its core was the classic formulation of the principles of modern federalism in *The Federalist* by Alexander Hamilton, John Jay, and, principally, James Madison. Equally important were the arguments of the "antifederalists," those who wished to preserve even greater state autonomy; many of their arguments remained alive and worked to promote extraconstitutional decentralization in the United States during the 19th century.

The French Revolution, for all of its democratic ethos, was essentially hostile to the spirit and institutions of federalism. Jacobin democracy drew its inspiration from

Rousseau's concept of the general will as interpreted by the revolutionary leadership. Unlike federal democracy, which views the constitutional sharing of power among multiple centres (noncentralization) as the keystone of popular government, Jacobin democracy is committed to centralized majority rule whereby a single elite guides the state by interpreting the general will of its citizens as seen in "public opinion"—whether expressed or manipulated. The immediate heirs of the French Revolution endeavoured to destroy federal institutions in western Europe in the name of democracy, and subsequent generations have proved equally hostile to federal ideas—except insofar as some of them have equated federalism with decentralized government. The minority tradition among the French that endorsed federalism was later to emerge as an intellectual force in the works of Alexis de Tocqueville and as a political movement in the moderate Socialism of Pierre-Joseph Proudhon and Claude-Henri Saint-Simon.

In the 19th century, several of the new Latin American nations experimented more or less successfully with federalism. The three largest Latin American nations, Argentina, Brazil, and Mexico, retain federal systems of varying political significance, as does Venezuela; federal principles are also included in the political systems of Colombia and the Central American Common Market (established in 1958). Latin American federalism, however, has remained primarily a modern manifestation of feudalistic federalism, with *jefes* and *caudillos* replacing counts and dukes.

In the mid-19th century, some Europeans turned to federalism as a form of democratic political organization. They were stimulated by necessity, the American example, and the very influential studies of Tocqueville. Numerous works were written, primarily in the German-speaking countries, where federal or quasi-federal solutions to the problems of political integration were highly regarded and widely used. The most important of these works were the theoretical formulations of the Swiss jurist J.K. Bluntschli, based on his observations of federal reorganization in Switzerland, and the historical studies of the German jurist Otto von Gierke. Federal principles were used in the unification of Germany (1866–71); and Switzerland adopted a modern federal constitution. The Netherlands, Sweden, Belgium, and the Austro-Hungarian Empire adopted quasi-federal institutions to meet particular problems of unification and decentralization.

Later in the century, a school of British theorists and men of affairs emerged advocating the transformation of the British Empire into an imperial federation. Canada and Australia were given federal constitutions and dominion status in 1867 and 1901, respectively; the foundations were laid for the federal unification of India; and an attempt to give New Zealand a federal form of government was abandoned only at the request of the New Zealanders. Theorists such as James Bryce and E.A. Freeman, interested in imperial unity and internal devolution, made their own contribution to federal theory.

Federalism was also taken up in the 19th century by ethnic groups seeking national unity and political autonomy but not in a position to achieve them in any other way. This was the case in Austria-Hungary and in the Balkan countries. In the 20th century, federalism has been used as a means to unify multi-ethnic nations. Several of the ethnically heterogeneous nations created or reconstructed after World War I, including the Soviet Union and Yugoslavia, have formally embraced federalism as a solution to their nationality problems. The British added a federal dimension to accommodate the Ulster Irish. The emergence of new independent countries in Asia and Africa, where ethnic diversity is even greater than in Europe, has led to a further application of federal principles—in India and Malaysia, federalism has been used to secure political and cultural rights for large ethnolinguistic groups; in Africa, federalism has been applied in several nations, including Nigeria and Cameroon, as a device primarily for sharing political power.

Mention should be made of certain experiments in con-

federation since World War II that have sought to link independent countries for mainly economic purposes: the European Economic Community, or Common Market; the East African Community, linking Kenya, Tanzania, and Uganda; the Central American Common Market, established by Costa Rica, El Salvador, Guatemala, Honduras, and Nicaragua; and the Confederation of Arab Republics comprised of Egypt, Libya, and Syria.

#### FEDERAL PRINCIPLES

The use of federal principles in non-federal systems

In addition to full-fledged federal systems, there are other forms of political order that make use of certain principles: multiple monarchies, legislative unions, empires, decentralized unitary systems, and unions of nonterritorial units.

The multiple monarchy is a union that exists only in the person of the sovereign and is maintained only through the exercise of executive power in his name. There is no common legislature, no common legal system, nor much of any common political substructure. Each constituent polity maintains its own political system, which the monarch guarantees to support.

Multiple monarchies have historically been somewhat incompatible with democratic government, and this has been a source of their instability. Attempts to transfer sovereignty away from the monarch are likely to destroy the union. Thus, the Austro-Hungarian Empire disintegrated when the Habsburgs ceased to rule. The dual monarchy of Sweden and Norway ceased to function when democratic government was introduced. In Spain, on the other hand, where circumstances required some form of peninsular union, the multiple monarchy was replaced by something approximating a unitary state.

One method of better integrating multiple monarchies while preserving decentralized government is by legislative union. This was used in the United Kingdom, uniting England, Wales, Scotland, and Northern Ireland. The 17th-century dual monarchy linking England and Scotland was stabilized through a legislative union of the two nations in 1707. Legislative union resembles federal union at several crucial points. It is created by a perpetual covenant that guarantees the constituent parties their boundaries, representation in the national legislature, and certain local autonomies in such matters as municipal law. In the United Kingdom, the Cabinet has acquired a supremacy not foreseen in 1707; but, within the framework of cabinet government, Northern Ireland has been granted its own Parliament with substantial local autonomy, Scotland has acquired a national ministry of its own with a separate administrative structure for most of its governmental programs, and Wales has gained a Welsh Office with growing administrative powers.

Federal principles in empires and unitary states

Some empires make limited use of federal principles through grants of cultural home rule. The Persian and Roman empires did so in the ancient world, and the U.S.S.R. may well be the modern counterpart. In both cases, highly centralized political authorities possessing a virtual monopoly of power decide, for reasons of policy, to allow local populations with different ethnic or cultural backgrounds to maintain a degree of home rule provided that they remain politically loyal to the imperial regime. Efforts to transform such home rule into serious political power are invariably suppressed by the central government.

The use of federal principles is also found in decentralized unitary states. These guarantee their local governments considerable autonomy in some areas, limited to matters determined by the central authorities to be local. Such local powers are subject to national supervision, restriction, and even withdrawal. The central government may hesitate to take such action in areas where local privileges are well established, but, as the English experience has shown, even powerful traditions supporting local autonomy have been overridden by democratically elected parliaments with the support of a national majority.

Some apparently centralized states are actually quasi-federal unions of ethnic, religious, or ideological groups

that, while not organized territorially, have acquired corporate characteristics of their own and have been able to secure constitutional arrangements designed to preserve their respective integrities within a common polity. Belgium, with its linguistic communities, Lebanon, with its religious communities, Cyprus, with its ethnic communities, and Israel, with its ideological parties, exemplify this arrangement. In most of these cases, domestic services and responsibilities are shared by the subcommunities, which are responsible for serving their adherents under the general aegis of the state.

Federative and confederative arrangements are widely used outside the governmental realm to unify or integrate religious, labour, commercial, and cultural organizations. Federative organization is particularly common in the Calvinist and Reformed churches, ranging from the fully federal Presbyterians to the loosely confederated Baptists. Labour unions and business groups are frequently functional federations. Liberal democracy, with its emphasis on pluralism, is highly conducive to such arrangements.

#### CHARACTERISTICS OF FEDERAL SYSTEMS

The various political systems that call themselves federal differ in many ways. Certain characteristics and principles, however, are common to all truly federal systems.

**Basic elements.** *Written constitution.* First, the federal relationship must be established or confirmed through a perpetual covenant of union, usually embodied in a written constitution that outlines the terms by which power is divided or shared in the political system; the constitution can be altered only by extraordinary procedures. Every existing federal polity possesses a written constitution, as do most of the other systems incorporating elements of the federal principle. These constitutions are distinctive in being not simply compacts between rulers and ruled but involving the people, the general government, and the polities constituting the federal union. The constituent polities, moreover, often retain constitution-making rights of their own.

Diffusion of power

*Noncentralization.* Second, the political system itself must reflect the constitution by actually diffusing power among a number of substantially self-sustaining centres. Such a diffusion of power may be termed noncentralization. Noncentralization is quite different from decentralization, which is the conditional diffusion of specific powers by a central government to local governments subject to recall by unilateral decision. It is also more than devolution—the unilateral grant of powers to subnational units by a central government, not normally rescindable. Noncentralization is a way of insuring in practice that the authority to participate in exercising political power cannot be taken away from the general or the constituent governments without common consent.

*Areal division of power.* A third element of any federal system is what has been called in the United States territorial democracy. This has two faces: the use of areal divisions to ensure neutrality and equality in the representation of the various groups and interests in the polity and the use of such divisions to secure local autonomy and representation for diverse groups within the same civil society. While seemingly contradictory, both faces are closely related to the purposes of federalism, and manifestations of both are frequently found side by side within the same federal system. Territorial neutrality has proved highly useful in societies that are changing, allowing for the representation of new interests in proportion to their strength simply by allowing their supporters to vote in relatively equal territorial units. At the same time, the accommodation of very diverse groups whose differences are fundamental rather than transient by giving them territorial power bases of their own has enhanced the ability of federal systems to function as vehicles of political integration while preserving democratic government. Examples are Yugoslavia, where each constituent republic is organized around a different nationality group, and Canada, where the province of Quebec contains a population of French descent.

Territorial democracy

Historically, constitutionally fixed areal divisions of

power have been necessary to maintain noncentralization. In modern democratic theory, the argument between federalists and pluralists has frequently revolved around the respective values of areal and functional diffusions of power. Those who have argued the obsolescence of federalism while endorsing its values have generally based their case on the argument that the areal division of powers is unnecessary to preserve liberty and, indeed, may interfere with its protection. Proponents of the federal-areal division argue that the deficiencies of territorial democracy are greatly outweighed by the advantages of a guaranteed power base for each group in the political system, arguing further that any other system devised for giving them power has proved unable to cope with the complexities and changes of a dynamic age.

**Other elements of federalism.** Other supportive elements supplement the three basic ones. They can be grouped according to their primary impact on the systems they serve.

*Elements maintaining union.* Modern federal systems generally provide direct lines of communication between the citizenry and all the governments that serve them. The people may and usually do elect representatives to all the governments, and all of them may and usually do administer programs that directly serve the individual citizen.

The existence of those direct lines of communication is one of the features distinguishing federations from leagues or confederations. It is usually based on a sense of common nationality binding the constituent polities and people together. In some countries this sense of nationality has been inherited, as in Germany, while in the United States, Argentina, and Australia it had to be at least partly invented. Canada, Switzerland, and Yugoslavia have had to evolve this sense in order to hold together strongly divergent nationality groups. In the newly formed federal systems of India, Malaysia, and Nigeria, the future of federalism is endangered by the absence of such a common national sense.

Geographic necessity has played a part in promoting the maintenance of union within federal systems. The Mississippi Valley in the United States, the Alps in Switzerland, the island character of the Australian continent, the mountains and jungles surrounding Brazil have all been influences promoting unity; so have the pressures for Canadian union arising from that country's situation on the border of the United States and the pressures upon the German states generated by their neighbours to the east and west. In this connection, the necessity for a common defense against common enemies has stimulated federal union in the first place and acted to maintain it.

*Elements maintaining noncentralization.* The constituent polities in a federal system must be fairly equal in population and wealth or else balanced geographically or numerically in their inequalities. In the United States, each geographic section has included both great and small states. In Canada, the ethnic differences between the two largest and richest provinces have prevented them from combining against the others. Swiss federalism has been supported by the existence of groups of cantons of different size categories and religiopolinguistic backgrounds. Similar distributions exist in every other successful federal system.

A major reason for the failure of federal systems has often been a lack of balance among the constituent polities. In the German federal empire of the late 19th century, Prussia was so dominant that the other states had little opportunity to provide national leadership or even a reasonably strong alternative to the policy of the king and government. In the Soviet Union, the existence of the Russian Soviet Federated Socialist Republic occupying three-fourths of the area and containing three-fifths of the population would severely limit the possibility of authentic federal relationships in that country even if the Communist system did not.

Successful federal systems have also been characterized by the permanence of their internal boundaries. Bound-

ary changes may occur, but such changes are made only with the consent of the polities involved and are avoided except in extreme situations. The United States divided Virginia during its civil war, Canada enlarged the boundaries of its provinces, and Switzerland has divided cantons—but these have been exceptions rather than the rule, and in every case the formal consent of the constituent polities was given. Even in Latin America, state boundaries have tended to remain relatively secure; one of the major bulwarks of Latin American federalism has been the coincidence of state boundaries with major social and economic interests or ethnic-cultural groups.

In a few very important cases, noncentralization is given support through the constitutionally guaranteed existence of different systems of law in the constituent polities. In the United States, each state's legal system stems directly and to a certain extent uniquely from English (and, in one case, French) law, while federal law occupies only an interstitial position binding the systems of the 50 states together. The resulting mixture of laws keeps the administration of justice substantially noncentralized, even in federal courts. In Canada, the existence of common-law and civil-law systems side by side has contributed to French-Canadian cultural survival. Noncentralized legal systems are a particularly Anglo-American device, based as they are on traditional common law. Federal systems more often provide for modification of national legal codes by the subnational governments to meet special local needs, as in Switzerland.

The point has often been made that in a truly federal system the constituent polities must have substantial influence over the formal or informal constitutional-amending process. Since constitutional changes are often made without formal constitutional amendment, the position of the constituent polities must be such that serious changes in the political order can be made only by the decision of dispersed majorities that reflect the areal division of powers. Federal theorists have argued that this is important for popular government as well as for federalism.

Noncentralization is also strengthened by giving the constituent polities guaranteed representation in the national legislature and often by giving them a guaranteed role in the national political process. The latter is guaranteed in the written constitutions of the United States and Switzerland. In other systems, such as those of Canada and Latin America, the constituent polities have acquired certain powers of participation, and these have become part of the unwritten constitution.

Perhaps the most important single element in the maintenance of federal noncentralization is the existence of a noncentralized party system. Noncentralized parties initially develop out of the constitutional arrangements of the federal compact, but once they have come into existence they tend to be self-perpetuating and to function as decentralizing forces in their own right. The United States and Canada provide examples of the forms that a noncentralized party system may take. In the two-party system of the United States, the parties are actually coalitions of the state parties (which may in turn be dominated by specific local party organizations) and function as national units only for the quadrennial presidential elections or for purposes of organizing the national congress. Party financing and decision making are dispersed either among the state organizations or among widely divergent nationwide factions.

In Canada, on the other hand, the parliamentary form of government, with its requirements of party responsibility, means that on the national plane considerably more party cohesiveness must be maintained simply in order to gain and hold power. There has been a fragmentation of the parties along regional or provincial lines. The one or two parties that function on a nationwide basis are subject to great shifts in popular support from one election to another. They are also divided internally along provincial lines, each provincial organization being more or less autonomous; at the same time, individual provinces are frequently dominated by parties that send only a few representatives to the national legislature. The

federal  
principle

party victorious in national elections is likely to be the one able to expand its provincial electoral bases temporarily to national proportions.

Federal nations with less developed party systems frequently gain some of the same decentralizing effects through what the Latin Americans call *caudillismo*—in which power is diffused among strong local leaders operating in the constituent polities. Caudillistic noncentralization apparently exists also in Nigeria and Malaysia.

Ultimately, however, noncentralization is maintained through respect for the federal principle. Such respect requires recognition by the decision-making publics that the preservation of the constituent polities is as important as the preservation of the nation as a whole. As the American chief justice Salmon P. Chase said, federalism looks to "an indestructible Union, composed of indestructible States" (*Texas v. White* [1869]). This recognition may spring from loyalty to particular polities or from an understanding of the way federalism functions. Those who value a politics of conciliation and local autonomy are most likely to have respect for the federal principle.

The historical record indicates that federal systems have arisen out of the dual purpose implied in Chase's dictum at least as often as from a desire for political unification. The Canadian confederation was formed not only to unite the British North American colonies but also to give Ontario and Quebec autonomous political systems. Similarly, a guiding purpose in the evolution of the Swiss confederation has been to preserve the independence of the cantons both from outside encroachment and from revolutionary centralism. A good case can be made that similar motivations also played a part in the creation of most other federal systems.

*Elements maintaining the federal principle.* Several of the devices commonly found in federal systems serve to maintain the federal principle itself. Two of these are of particular importance.

The  
sharing of  
power and  
responsi-  
bility

The maintenance of federalism requires that the nation and its constituent polities each have substantially complete governing institutions of their own, with the right to modify those institutions unilaterally within limits set by the compact. Both separate legislative and separate administrative institutions are necessary. This does not require that all governmental activities be carried out by separate institutions on each plane. The agencies of one government may serve as agents of the other by mutual agreement. But each government must have enough of its own institutions to function in the areas of its authority without depending upon the other and the structural wherewithal to cooperate freely with the other's counterpart agencies.

The contractual sharing of public responsibilities by all governments in the system appears to be a central characteristic of federalism. Sharing, broadly conceived, includes common involvement in policy making, financing, and administration. Sharing may be formal or informal; in federal systems, it is usually contractual. The contract is used as a legal device to enable governments to engage in joint action while remaining independent entities. Even where there is no formal arrangement, the spirit of federalism tends to infuse a sense of contractual obligation.

There is likely to be continued tension in any federal system between the federal government and the constituent polities over the years, with different balances between them at different times. The existence of this tension is an integral part of the federal relationship. The questions of intergovernmental relations that it produces are perennially a matter of public concern, because they are reflected in virtually every political issue that arises. This is particularly true of those issues that affect the very fabric of society. The race question in the United States, for example, is a problem of federal-state relations, as is the cultural question in Canada and the linguistic question in India.

Federal systems or systems strongly influenced by federal principles have been among the most stable and long lasting of polities. But the successful operation of federal systems requires a particular kind of political environ-

ment, one that is conducive to popular government and has the requisite traditions of political cooperation and self-restraint. Beyond this, federal systems operate best in societies with sufficient homogeneity of fundamental interests to allow a great deal of latitude to local government and to permit reliance upon voluntary collaboration. The use of force to maintain domestic order is even more inimical to the successful maintenance of federal patterns of government than to other forms of popular government. Federal systems are most successful in societies that have the human resources to fill many public offices competently and the material resources to afford a measure of economic waste as part of the price of liberty.

**BIBLIOGRAPHY.** Comparative discussions of federalism in various countries include: KARL W. DEUTSCH *et al.*, *Political Community and the North Atlantic Area* (1957); IVO D. DUCHACEK, *Comparative Federalism* (1970); CARL J. FRIEDRICH, *Trends of Federalism in Theory and Practice* (1968); URSULA K. HICKS *et al.*, *Federalism and Economic Growth in Underdeveloped Countries* (1961); ARTHUR W. MACMAHON (ed.), *Federalism, Mature and Emergent* (1955); WILLIAM H. RIKER, *Federalism: Origin, Operation, Significance* (1964); B.M. SHARMA, *Federalism in Theory and Practice*, 2 vol. (1951); and K.C. WHEARE, *Federal Government*, 4th ed. (1963).

Theoretical works on federalism are: JOHANNES ALTHUSIUS, *Politica methodice digesta*, ed. by CARL J. FRIEDRICH (1932), reprinted from the Latin text of 1614, including the preface of the 1603 edition and an English introduction; MARTIN DIAMOND, "The Federalist," in LEO STRAUSS and JOSEPH CROPSY (eds.), *History of Political Philosophy* (1963); OTTO FRIEDRICH VON GIERKE, *Das deutsche Genossenschaftsrecht*, vol. 4 (1913; Eng. trans., of 5 subsections, *Natural Law and the Theory of Society, 1500 to 1800*, 2 vol. 1934); ALEXANDER HAMILTON, JAMES MADISON, and JOHN JAY, *The Federalist* (1788); YEHEZKEL KAUFMANN, *The Religion of Israel, from its Beginnings to the Babylonian Exile* (1960), an abridged translation of an 8-vol. Hebrew work; ARTHUR MAASS (ed.), *Area and Power: A Theory of Local Government* (1959); PERRY MILLER, *The New England Mind: The Seventeenth Century* (1939); and SOBEI MOGI, *The Problem of Federalism*, 2 vol. (1931).

Numerous books and articles treat federalism in specific countries, including: WILLIAM ANDERSON, *The Nation and the States: Rivals or Partners?* (1955), a description of the U.S. federal system; VERNON V. ASPATURIAN, "The Theory and Practice of Soviet Federalism," *Journal of Politics*, 12:20-51 (1950); A.H. BIRCH, *Federalism, Finance, and Social Legislation in Canada, Australia, and the United States* (1955); JOAN BONDURANT, *Regionalism Versus Provincialism: A Study in Problems of Indian National Unity* (1958); GEORGE ARTHUR CODDING, *The Federal Government of Switzerland* (1961); ZELMAN COWEN, *Federal Jurisdiction in Australia* (1959); DANIEL J. ELAZAR, *The American Partnership: Intergovernmental Co-operation in the Nineteenth-Century United States* (1962) and *American Federalism: A View from the States* (1971); J.H. ELLIOTT, *Imperial Spain, 1469-1716* (1964); EDWARD A. FREEMAN, *History of Federal Government in Greece and Italy*, 2nd ed. (1893); W. BROOKE GRAVES, *American Intergovernmental Relations: Their Origins, Historical Development, and Current Status* (1964); MORTON GRODZINS, *The American System* (1966); RICHARD H. LEACH, *American Federalism* (1970); AMERICAN ACADEMY OF POLITICAL AND SOCIAL SCIENCE, *Intergovernmental Relations in the United States*, ed. by HARRY W. REYNOLDS (1965); R.L. WATTS, *New Federations: Experiments in the Commonwealth* (1966); R.H. WELLS, *The States in West German Federalism: A Study of Federal-State Relations, 1949-1960* (1961); and AARON WILDAVSKY (ed.), *American Federalism in Perspective* (1967).

## Feeding Behaviour

The living cell depends on a virtually uninterrupted supply of materials for its metabolism. In multicellular animals—single-celled members of the Protista are discussed in the article PROTOZOA—the body fluids surrounding each cell are the immediate source of nutrients. The contents of these fluids are kept at a relatively constant level in spite of tolls taken by the cells, primarily by mobilization of nutrients stored in the body; in vertebrates, for example, glucose is stored in the liver, fats in the fat tissues, calcium in the bones. These stores, however, will become exhausted sooner or later, unless the

animal takes up nutrients from outside. Movements performed for this purpose are termed feeding behaviour.

#### NUTRITIONAL REQUIREMENTS OF HIGHER ANIMALS

Cells use nutrients as fuel for energy production (catabolism) and as material for processes of maintenance and growth (anabolism). Multicellular animals derive energy solely from the breakdown of complex organic molecules, mainly carbohydrates and fats. Because the fuel for the maintenance of animal life comes only from other living organisms or their remains, animals are known as heterotrophic organisms. All animal life depends ultimately on the existence of organisms (largely green plants) that can use inorganic sources of energy, of which solar radiation is by far the most important; some micro-organisms, however, obtain energy from oxidation of simple inorganic compounds.

For anabolic purposes, food must provide adequate amounts of all chemical elements needed by the cells. Of the approximately 35 elements now known to occur in animal cells, four (oxygen, carbon, hydrogen, and nitrogen) make up about 95 percent of the cell weight; another nine (calcium, phosphorus, chlorine, sulfur, potassium, sodium, magnesium, iodine, and iron) contribute about 4 percent. All of these elements have indispensable functions. The remaining 20-odd, together constituting less than 1 percent of cell weight, are called trace elements, because they occur in minute quantities. Although some of them may become incorporated into cells by accident, many fulfill vital functions (see NUTRITION).

It is important to note that animal cells cannot synthesize from simple compounds certain necessary complex molecules. Instead, certain large organic molecules must serve as building blocks; such so-called essential dietary components include the vitamins, some amino acids, and certain fatty substances. In general, higher animals appear to have more restricted synthetic powers than lower ones and to require a correspondingly greater number of essential foodstuffs. Micro-organisms in the intestines of vertebrates may synthesize materials essential for the host, so that the food of the latter need not contain these substances.

#### TYPES OF FOOD PROCUREMENT

Because much of animal evolution, as regards behaviour, as well as anatomy and physiology, involves adaptation for the procurement of food, the extent of the meaning of the term feeding behaviour is not clear. Migratory habits of birds, for instance, no doubt evolved in part as a result of seasonal food shortages; individual birds now, however, start migration before food becomes scarce. Migration, therefore, important though it may be in the feeding ecology of a species, is not considered in this article (see MIGRATION, ANIMAL), which concentrates on food-directed activities that are enhanced by a need for nutrients in the body of an individual. For similar reasons, host finding and acceptance by internal parasites for themselves or their offspring also are excluded.

Even with these restrictions, the diversity of feeding patterns is bewildering. A useful classification has been put forward by British zoologists C.M. Yonge and J.A.C. Nicol, based on the structural mechanisms utilized, although, as Nicol observed, "many animals make use of a variety of feeding mechanisms, conjointly, or separately as occasion demands":

- I. Mechanisms for dealing with small particles.
  - A. Pseudopodial (e.g., many protozoans). Pseudopods consist of fingerlike projections of the cell membrane and its contents (cytoplasm) that surround and engulf food.
  - B. Ciliary (e.g., sponges, bivalve mollusks). Cilia are minute hairlike projections of cell membranes that, by concerted beating in wave rhythm, set up water currents or physically move food particles.
  - C. Tentacular (e.g., certain sea cucumbers). Tentacles are slender, flexible organs on the head. They may function in sensory perception and in actually securing food.
  - D. Mucoid (e.g., many snails, such as *Vermetus*). In this case, the food particles become attached to a sticky

mucous sheet secreted by special cells.

- E. Muscular (e.g., certain coelenterates). In the jellyfish *Rhizostoma*, pulsations of the bell-shaped body draw water and food in through perforations in the arms, then expel the water after the food is removed.
- F. Setous (e.g., many small crustaceans, such as copepods). Setae are bristlelike projections of the cuticle and are found on the appendages of many invertebrates.
- II. Mechanisms for dealing with large particles or masses.
  - A. For swallowing inactive food, such as bottom deposits (e.g., many polychaete worms, some fishes).
  - B. For scraping and boring (e.g., some gastropod and bivalve mollusks).
  - C. For seizing prey.
    1. For seizing and swallowing only (e.g., *Hydra*, many polychaete worms, many lower vertebrates).
    2. For seizing and masticating (e.g., Crustacea, mammals).
    3. For seizing followed by external digestion (e.g., some starfishes, spiders).
 In such cases, the secretory and absorptive surfaces of the digestive system may be applied to the food by everting (i.e., turning inside out) the stomach, a method employed by starfish. Alternatively, digestive enzymes may be injected into the prey, liquefying the tissues, which may then be ingested by the predator. This mechanism is found in spiders.
- III. Mechanisms for taking in fluid or soft tissues.
  - A. For piercing and sucking (e.g., leeches, mosquitoes).
  - B. For sucking only (e.g., many flies, butterflies).
  - C. For absorption through surface of body (e.g., various invertebrates feeding on decaying organic matter, internal parasites such as tapeworms, which lack a digestive tract).

A different classification, often used, rests on the nature of the behaviour for procuring food:

- A. Filter feeders strain food from the surrounding medium more or less indiscriminately.
- B. Selective feeders analyze the environment with their sense organs before aiming feeding responses at chosen items.

Some feeding patterns, however, cannot be easily fitted into either of these classes alone; spiders, for example, sieve prey from the air with webs but perform directed responses to the insects trapped. Class I of the Yonge-Nicol system comprises mainly filter feeders; most members of classes II, IIIA, and IIIB are selective feeders. Selective feeding requires good sensory and nervous equipment and, in most cases, considerable mobility. It is therefore found mainly among higher animals. Yet the primitive sea anemones are selective feeders in that, capable of paralyzing relatively large prey with their stinging cells, they do not discharge them until informed by chemical and tactile senses that prey is present. At the other extreme, whalebone whales are filter feeders, even though they are highly evolved mammals. Swimming at the surface with mouth open, they filter off large plankton (krill) using several hundred horny plates with hair-like fringes hanging down from the roof of the mouth; availability of a rich food source has caused the evolution of their feeding patterns to diverge widely from that of most other mammals.

In all cases, the feeding patterns adopted by species are the result of evolutionary interplay between (1) structural properties inherent in their phylogenetic line and (2) the ecological situations to which they have been exposed. These interactions are too complex to make generalizations profitable. The best approach is to study each species as a separate case in the light of its entire biology. A few examples are given below.

Filter feeders occur among sponges, coelenterates, polychaete worms, echinoderms, brachiopods, mollusks, arthropods, protochordates, fish, birds, and several other groups. As might be expected, filtering devices are diverse.

In the oyster, constantly lashing cilia drive a water current—up to 34 litres (about 36 quarts) per hour—through the openings of perforated gill plates. Particles only two microns (0.002 millimetres) in size are wrapped in mucus and transported by other cilia to special food

A classification of mechanisms of food procurement

Evolutionary forces and limits on feeding pattern

grooves, along which they pass to the mouth by the action of yet further cilia; particles that are too large, too heavy, or capable of producing irritation are sorted out and rejected by various mechanical means.

The polychaete worm *Chaetopterus* uses a bag of mucus, secreted by special body appendages, to strain the water it pumps through its burrow. The mesh openings of the bag, about 40 angstroms ( $4 \times 10^{-7}$  millimetres) wide, can even trap single molecules of large proteins. Every 20 minutes the food-laden bag is taken to the mouth, consumed, and replaced by a new one.

The sessile marine snail *Vermetus gigas* secretes mucus strings up to 30 centimetres (12 inches) long that extend away from the shell and entangle fine plankton. At intervals the strings are drawn back toward the mouth and swallowed.

#### Various methods of feeding on bivalve mollusks

Selective feeders, found among major animal groups, including coelenterates, annelids, echinoderms, mollusks, arthropods, and vertebrates, show even greater diversity of feeding patterns than do filter feeders. One striking point is that different groups deal in different ways with the same food in accordance with special capacities. Animals feeding on bivalve mollusks provide one example. The starfish *Asterias* forces the valves apart by the relentless pull of its sucker tube feet and then everts its stomach through its mouth to digest the soft tissues inside the shell. The snail *Sycotypus* attacks an oyster by stealth: waiting until the valves open, it thrusts its shell between the valves and pushes its tubular feeding organ, or proboscis, into the soft parts. Another snail, *Natica*, supports the scraping action of a filelike structure called a radula with chemical dissolution by sulfuric acid, which is secreted by a gland on the proboscis, and drills a neat hole in a clam. Another snail, *Fulgur*, cracks a clam shell against its own shell by contracting its columellar muscle. Among birds, the oyster catcher (*Haematopus ostralegus*) adroitly cuts the closing muscles of a cockle with its chisel-shaped bill; herring gulls (*Larus argentatus*) break a shell by dropping it onto a rock. A sea otter (*Enhydra lutris*) cracks a clam on its chest, while floating on its back, by pounding it on a stone held between the forepaws.

A few additional examples further illustrate the wealth of adaptations in selective feeding. The sluggish praying mantis (orthopteran insects of the family Mantidae) stalk insect prey until within reach, then carefully orient themselves and accurately and rapidly extend forelegs adapted for grasping. For detecting prey in murky habitats, bats use an ultrasonic echolocation system; some fish use electric pulses in a somewhat comparable manner. Anglerfish dangle a baitlike appendage of the first dorsal spine (luminous in deep-sea species) to lure the fish on which they feed toward their enormous mouths. Certain labroid fishes, which eat parasites off the bodies of other fish, induce their hosts to submit to treatment by a dancing approach; certain blennies treacherously mimic this behaviour and then rapidly bite the fin of the unsuspecting victim. Shrikes perform special wiping movements to remove the sting from certain prey, even without previous experience of stinging insects. The peregrine falcon (*Falco peregrinus*) dives at birds at speeds above 160 kilometres (100 miles) per hour; and the cheetah, or hunting leopard (*Acinonyx jubatus*), pursues antelope at more than 95 kilometres (60 miles) per hour. More than a thousand cormorants may join in a single fish drive. Instead of hunting, some species rob food collected by members of other species; among these robbers are the marauding skuas and jaegers (*Stercorariidae*) and man-of-war birds (*Fregata*), which force weaker cousins to disgorge already swallowed prey, and various tropical flies that take up positions along the line of march of army ants and rob the passing workers.

The driving force for the evolution of each of these adaptations is the survival value to the species of selecting the food sources for which it can successfully compete. For the same reason, closely related species living in the same area may tend to exploit separate parts of the environment; e.g., woodland titmice (*Parus*) forage in different parts of the trees, and the larvae of different spe-

cies of the moth genus *Eupithecia* prefer different food plants. The result of such evolution may be that a species becomes specialized to one kind of food, as have many internal parasites and phytophagous (plant-eating) insects. Such food may be exotic, as is that of the larva of a moth (*Galleria*) that feeds on beeswax. In other species, such as the herring gull, on the other hand, each individual exploits a broad range of foods, thereby lessening the risk of starvation, as it is unlikely that all types of food will become exhausted at the same time.

#### REGULATION OF FOOD INTAKE

Metabolic expenditure cannot exceed food intake for very long if an animal is to survive. One way to equalize the two processes is to decrease metabolism to a level sustainable by maximum intake, which may be limited by the ability to extract food from a meagre habitat. Data for filter feeders suggest that, in certain cases, continuous filtration at maximal rates may be barely sufficient to support normal growth and maintenance. Selective feeders have been found to undergo a more or less drastic reduction of metabolism during temporary starvation. Secondly, the capacity of the digestive system may set a limit on nutrient supply to the body. There is evidence that this is so in the minute filter-feeding crustacean *Daphnia magna*. Such limitations are known to play a role in human feeding behaviour.

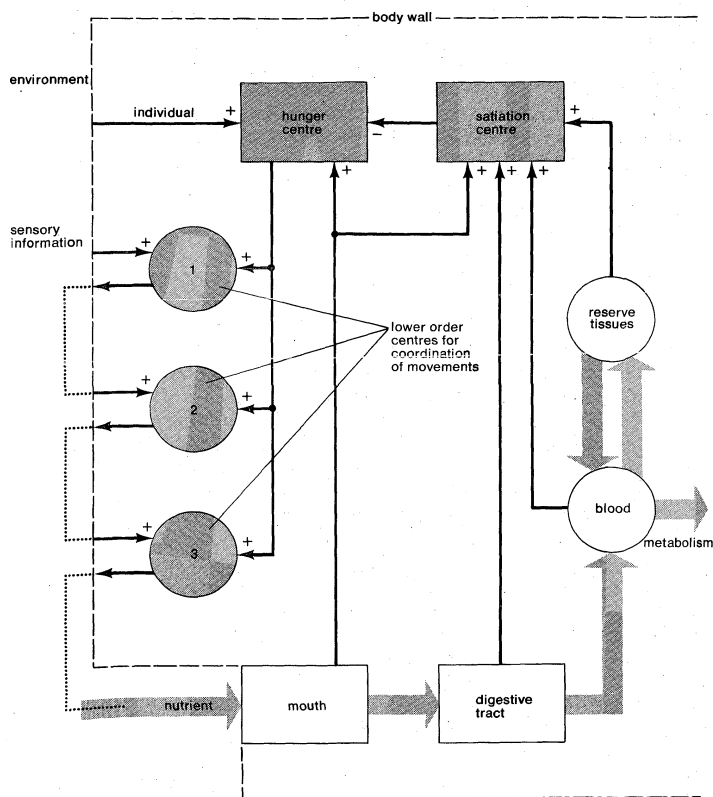

In man and many other selective feeders, nevertheless, the capacities of food-gathering and digestive systems exceed all but the most extreme demands of metabolism. To maintain nutritional balance, feeding must then be geared to metabolic rate. Information on the mechanisms and even on the existence of such regulation of intake is scanty, except for mammals and some insects.

**Vertebrates.** Most information on the control of feeding behaviour in vertebrates has come from studies of mammals, but the general patterns found in mammals appear to be present in fish, amphibians, reptiles, and birds. Food intake requires a well-ordered sequence of searching, food getting, and ingestive activities. Sometimes the behaviour is elaborate. The following elements are distinguished in the various cats: stalking, spying, pouncing, thrusting down with the head, biting the neck, carrying into cover, plucking, and devouring. In grazing animals, the pattern is much simpler. In any case, the movement a feeding animal performs at a given moment depends largely on external stimuli; search and pursuit, for example, are unnecessary when prey is within reach. In this sense, any feeding act is a response to the environment, but it is not a simple "reflex." On repeated presentation of the same food situation, the individual sometimes shows the appropriate response but at other times will fail to do so. These fluctuations in responsiveness are roughly parallel in all elements of feeding behaviour. Responsiveness tends to be higher with increasing lack of food in the body. It appears that responsiveness of the brain mechanisms for feeding is governed by messages reporting the nutritional state of the body. The contents of these messages, in other words, are primary determinants of the level of feeding motivation (for other influences see below *Relation of feeding to other functions*). High and low levels of feeding motivation are the objective counterparts of the everyday concepts of hunger and satiety. Regulation of food intake, then, must hinge on the physiological mechanisms of the feeding motivation.

**Specific hungers.** Lack of any nutrient with a specific anabolic function, such as vitamins or minerals, must be redressed by increased uptake of the particular substance. Little is known thus far of the specific hunger mechanisms that ensure increased uptake, but good evidence exists that a nutrient deficiency causes a specific rise in responsiveness to food containing the substance needed. In the case of thiamine (vitamin B<sub>1</sub>), a learning process is involved. The deficient animal tries various kinds of food and concentrates on those that remove the deficiency. Specific appetite for salt in a sodium deficient subject, on the other hand, appears to rest on a genetically determined increase in reaction to the taste of sodium chloride and does not require any learning.

#### Elements of feline feeding behaviour

Diagrammatic representation of feeding control in a generalized mammal. Thin black arrows represent information flow; shaded arrows the flow of nutrients. The hunger centre is stimulated by general sensory information (e.g., environment suitable for feeding behaviour). It, in turn, activates lower order brain mechanisms for food searching (1), food getting (2), and eating (3); performance of each of which prepares the animal for the next. Ingested food passes through the various compartments of the body, each of which sends messages to the satiety, or satiety, centre, which inhibits the hunger centre correspondingly. In addition, taste messages from the mouth stimulate the hunger centre.

**Caloric regulation.** Lack of fuel in the body can be corrected by intake of any of a variety of possible substances that provide energy. Most natural food contains a mixture of such substances. Energy deficiencies can be alleviated by increased responsiveness to food in general. Ingested food (*i.e.*, calories) passes from (1) the mouth to (2) the digestive tract to (3) the bloodstream; if not needed at once for catabolic processes, the digested food passes to (4) storage sites, of which the fat tissues are the most important. These four regions are continuously monitored. A considerable amount is known about the monitoring roles of the organs for taste, smell, and touch in the mouth region; in addition, distension receptors in the digestive tract monitor the volume there, and chemoreceptors monitor the nature of the contents. Information concerning the availability of glucose (the most commonly utilized sugar) and possibly other fuels in the blood is recorded by cells located probably both in the brain itself and elsewhere (*e.g.*, in the liver). Finally, circumstantial evidence suggests that the contents of fat tissues are also monitored. All food that passes through the body contributes to each of these four messages in succession, until it is eventually catabolized.

The signals converge on the brain mechanisms for the feeding motivation over nervous and, possibly, humoral (chemical) pathways. Here they have effects of two kinds: (1) if signals from the four regions report increased fuel contents, the feeding motivation is lowered (satiety is raised), and (2) if taste (and perhaps other, *e.g.*, visual) receptors are stimulated by palatable food, the feeding motivation is increased. Intake stops when accumulation of signals of the first kind, overriding those of the second kind, causes hunger to drop below a

critical level. Feeding is resumed when hunger surpasses this level as a result of fuel depletion by catabolism and emptying of the digestive tract by digestion and absorption. Once started, intake is enhanced by the positive effects of the food stimulus. The net result of this interplay of positive and negative feedbacks from food responses is that caloric intake, observed over a sufficiently long period (at least several days), is equal to energy output over that period, so that body fuel content (body weight in fully grown individuals) remains constant.

The brain mechanisms involved in vertebrate feeding motivation consist of a complex network, not yet well understood, encompassing, among other areas of the brain, the limbic system (the marginal zone of the forebrain) and the hypothalamus. The lateral hypothalamus ("hunger centre") facilitates feeding responses. Electrical or chemical stimulation of this area elicits voracious feeding in satiated subjects, and its destruction causes more or less prolonged noneating (aphagia). If the subject is kept alive by artificial feeding, however, other brain areas may take over and reinstate more or less normal feeding. In contrast, the ventromedial (lower central) nucleus of the hypothalamus appears to be a clearinghouse for satiety signals. Subjects with lesions in this area stop feeding only at an abnormally high level of energy content (obesity) and grossly overeat (hyperphagia) until this level is reached.

**Invertebrates.** One of the few invertebrates in which the physiology of feeding behaviour has been extensively studied is the blowfly *Phormia regina*. Sucking is elicited by food stimuli on taste organs of the tarsi (the terminal sections of the legs) and proboscis. The meal continues until adaptation of these receptors causes their signals to decrease below the threshold of the sucking-response mechanism. This threshold is modulated, in the following manner, by food present in the digestive tract and in body fluids. As long as food is present in the foregut, the threshold is raised by signals from distension receptors in that area. The foregut is kept filled after a meal by release of food from the crop, where food taken up at the meal in excess of the capacity of the gut is temporarily stored. The threshold will remain high, therefore, until the crop is completely voided. The rate of crop emptying is directly related to the nutrient concentration of body fluids. The latter depends on the balance between absorption from the gut and uptake by the metabolizing tissues. The harder the fly works, therefore, the sooner sucking will be resumed, with the result that food intake is kept equal to caloric expenditure through appropriate spacing of meals.

#### SELECTION OF FOOD ITEMS

Most natural habitats offer a diversity of food objects, and most selective feeders are more or less euryphagic—*i.e.*, they ingest a variety of different foods; strict monophagy is less common. On the other hand, no euryphagic species includes in its diet all potential food objects present in the habitat, nor are those that it does eat taken in proportion to the amounts in which they are available. On what grounds, then, are diets selected?

**Vertebrates.** A plant species constituting only a fraction of 1 percent of a pasture may make up the greater proportion of the diet of a sheep. Insectivorous birds also take a highly biased selection from the insect menu offered by the habitat. Although the relative abundance of different kinds of food is reflected in diets to some extent, this does not usually go so far that a single kind of food, however attractive and abundant, will become the sole constituent. Most vertebrates appear to take a varied diet whenever possible.

**Responses to encountered food.** Diet selection in adult vertebrates proves to be largely the result of individual learning processes that guide the genetically determined response potentialities of the newborn individual into certain definite channels.

Innate responsiveness appears to be broad in species that forage for themselves from birth and thus must deal with many different food situations. The pecking of newly hatched chicks of domestic fowl at all kinds of small ob-

Control of feeding behaviour in the blowfly

Instinctive feeding in young animals

jects, edible or not, is an example. Yet these chicks have certain innate preferences for colour and other features. Such preferences may foreshadow the composition of adult diets. In newly hatched snakes, for instance, feeding responses are more easily elicited with extracts of the natural food of adults of the same species than with preparations of food of closely related species. In contrast, colour preferences of ducklings of different species are similar, although the adult diets differ.

Innate responsiveness may be narrow, however, in young vertebrates for whom the parent is the only source of food. Herring-gull chicks beg for food in response to a few "sign stimuli" provided only by the parent's head among all objects in the natural habitat. Sucking behaviour of newborn mammals is a somewhat comparable example. In such cases, responsiveness must be profoundly reorganized when the individual forages on its own.

Responsiveness is channelled into the adult pattern through experience of taste, nutritional value, and possible noxious properties of various objects. In this way the individual is able to attach a definite palatability rating to each type of food regularly encountered and to associate this with visual or other characters by which it recognizes objects from a distance. As demonstrated in experiments, insectivorous birds may discriminate precisely among as many as 40 different prey species in this manner.

In addition to palatability, detectability of food objects is a factor in diet selection. This has been studied in detail in visually foraging vertebrates. Detectability of an object depends on its degree of contrast with the background as to colour, shape, and movement. The individual predator can learn to detect prey that it finds only with difficulty at first; such "searching image formation" occurs only if the prey is palatable and encountered often.

Finally, responses to encountered prey also depend on (1) the hunger level of the individual and (2) its experience regarding the general food situation. Hungrier predators have lower palatability requirements and may take greater risks to secure prey. At one and the same hunger level, a prey of slight palatability may be rejected if the predator "knows" that further search will probably bring better food but accepted if it "knows" that nothing tastier is available. As a result of these two influences, animals concentrate during scarcity on food scorned in times of plenty.

**Food searching and diet.** The general type of food taken is often determined by the innate search method of the animal and the section of the whole habitat being exploited. A fish-eating bird, such as the osprey (*Pandion haliaetus*), which secures prey by diving into water (but not swimming), is limited in its diet to fish species that are active near the surface. The much discussed question of whether food searching is random is relevant here, for certain kinds of nonrandomness can influence diets. No simple answer can be given. Search must be random in the sense that oriented reactions to food objects can be made only after detection; at the same time, however, the search may be systematic in that (1) places not recently traversed are favoured over those just unsuccessfully explored, and (2) the locality where a prey has just been caught or seen may be searched with special attention. Further, (3) it is most common for individuals to restrict their foraging to parts of the home range where ample food has been previously found, although exploration of other parts is interspersed and may change the destination of further trips if successful. In all, food searching appears to have sufficient nonrandomness to influence diets provided that different kinds of food concentrate in different parts of the home range, as is often the case.

To sum up, vertebrate diet selection is largely molded by learning processes. Insofar as their course depends on chance experiences of individuals, differences in diet may develop even among members of one population of a species. On the whole, however, patterns of food selection are typical of the species, as all its members have similar genetic makeup and live in broadly similar ecological situations.

**Invertebrates.** Learning processes appear to play a relatively small role in food selection by invertebrates. Diets are largely, though not entirely, determined by genetically fixed preferences. Intensive studies have been made of host-plant selection by phytophagous insects. Here, as in host selection by animal parasites, the question is one of the choice of a place to live rather than of food alone, and the selection criteria may be largely a matter of compromise between nutritional requirements and other ecological functions. Leaving aside these complications, the factors leading to selection of a particular plant as food are predominantly chemical, although other properties, such as structure, also play a role. The chemicals involved in part are the nutrients themselves, but often the feeding responses are largely elicited by token substances that are not nutritionally essential but are characteristic of the species or family of plants that provide the natural hosts for the insect concerned.

#### SPECIALIZED ASPECTS OF FEEDING BEHAVIOUR

**Relation of feeding to other functions.** In principle, feeding must proceed throughout life at a pace equal to that of metabolism, but in many cases intake does not closely follow expenditure. It is permissible for intake to lag when there are reserves in the body. In some cases it is clear that large reserves are present in anticipation of increased metabolic demands or predictable food shortage—e.g., hibernating mammals store large amounts of tissue fat before the onset of dormancy; migrating birds do the same before departure. Insect larvae store nutrients to last them through the pupal stage. Adults of many insects, such as mayflies, do not eat at all and have reduced mouthparts. Other species, such as the hamster, solve similar problems by laying in extracorporeal hoards of food.

Discrepancies between intake and expenditure, whether large or small, amount to distortion of the basic pattern of caloric regulation for the benefit of other functions.

Like most biological processes, feeding has a diurnal periodicity; i.e., depending on the species, the active period may fall in daylight or during the night. Only in filter feeders is the activity often continuous.

Priority claims of other functions may lead to suppression of feeding even in hungry animals. Thirsty mammals or birds eat much less than normal because food intake would aggravate water shortage in the body in various ways. The same is true of mammals in a hot environment—i.e., food intake increases heat production in the body and would thus intensify the heat stress—and of female mammals during estrus (periods of fertility). In all these cases, more or less marked loss of body weight results.

Social facilitation is a further cause of discrepancies as here considered. Individuals often start feeding when they observe other members of the same (or other) species doing so. Both timing of feeding and choice of food are affected in this way. Unfamiliar food is accepted more readily by individuals observing others eating it. Such phenomena have been noted in mammals, birds, and fish.

**Food-directed activities in social situations.** A further complication is that food-directed activities may be performed for the benefit of other individuals. This may serve their nutrition or some other function. Marked weight loss may occur in songbirds as they feed most of the prey to their nestling young. Courtship feeding in many birds (and insects), in which the male gives food to the female, strengthens the pair bond rather than having a role in nutrition.

Remarkably intricate is the behaviour by which individuals of social-insect species—honeybees, for example—ensure nutrition of the colony. Tropical honey ants store nectar collected by the workers of the colony in the crops (stomachs) of certain workers that remain inside the nest and become so gorged that they are hardly more than storage bins. They disgorge droplets upon solicitation by other ants in the nest. "Dairying" ants keep aphids as suppliers of honeydew, a sugar- and protein-rich secretion. They milk the aphids by gently stroking them and, in return, protect them against enemies. The aphids may

Deter-  
mination  
of search  
area by a  
predator

even be carried to the nest at the approach of winter and returned to a plant the following spring.

A number of ants and termites cultivate fungi for food. Workers of tropical leaf-cutting ants carry pieces cut off the green leaves of trees to the nest, where other workers use them for making a bed on which the fungi grow. When a queen sets out to start a new nest, she carries a pellet of mycelium (the "root" system of the fungus) in a special pocket on her head during her nuptial flight and subsequent burrowing. After depositing it in the new nest, she manures it with a special secretion until the first workers start bringing in leaf fragments.

The motivational background of behaviour as discussed above has not yet been sufficiently analyzed. Much remains to be done in the more intricate—and even in the more straightforward—cases before satisfactory insight into the functions and causes of the behaviour of animals toward their food is achieved.

**BIBLIOGRAPHY.** R.A. HINDE, *Animal Behaviour: A Synthesis of Ethnology and Comparative Psychology*, 2nd ed. (1970), is an excellent survey of the modern approach to the analysis of behaviour in general, and contains valuable material on several aspects of feeding behaviour. J.A.C. NICOL, *The Biology of Marine Animals* (1960), gives a good introduction to the classification of feeding patterns with typical examples. W.C. ALLEE *et al.*, *Principles of Animal Ecology* (1949), a classical survey of the entire field, is still useful as an introduction to the relations of animals to their food environment and gives many examples. The best review available of the physiology of feeding behaviour is C.F. COPE (sect. ed.), "Control of Food and Water Intake," in *Handbook of Physiology*, sect. 6, vol. 1 (1967), which is largely though not entirely restricted to vertebrates. A more recent, but much more specialized, volume on the same subject is P.J. MORGANE (ed.), "Neural Regulation of Food and Water Intake," *Ann. N.Y. Acad. Sci.*, 157:531–1216 (1969), which is completely restricted to vertebrates. A methodologically important systems analysis of the behaviour of vertebrate and invertebrate selective feeders may be found in C.S. HOLLING, "The Functional Response of Predators to Prey Density and Its Role in Mimicry and Population Regulation," *Mem. Ent. Soc. Can.* 45 (1965), and "The Functional Response of Invertebrate Predators to Prey Density," *ibid.* 48 (1966). C.B. JORGENSEN, "Quantitative Aspects of Filter Feeding in Invertebrates," *Biol. Rev.*, 30:391–454 (1955), discusses the effectiveness of filter feeding mechanisms in relation to the food particle content of natural waters. An introductory survey of the relations of insects to their food plants (and feeding behaviour of insects in general) is presented by v.g. DETHIER in P.T. HASKELL (ed.), *Insect Behaviour* (1966). More detailed and specialized material on this point is contained in J. DE WILDE and L.M. SCHOONHOVEN (eds.), *Insect and Host Plant* (1969). Selective food responsiveness in newly hatched snakes is described in G.M. BURGHARDT, "Comparative Prey-Attack Studies in Newborn Snakes of the Genus *Thamnophis*," *Behaviour*, 23:77–114 (1969). A recent study of the role of searching images in avian feeding behaviour is H.J. CROZE, "Searching Image in Carrion Crows: Hunting Strategy in a Predator and Some Anti-Predator Devices in Camouflaged Prey," *Z. Tierpsychol.*, suppl. 5 (1970).

(L.deR.)

## Feldspars

The feldspars comprise an important group of aluminum silicate minerals of widespread occurrence in nature. It has been estimated that feldspars constitute nearly 50 percent of all rocks exposed at the Earth's surface. Upon weathering they yield clay minerals and therefore can be considered to make up an appreciable fraction of all soils, marine clays, and other unconsolidated sediments as well. The feldspars are principal elements in systems of rock classification, are widely used in the glass and ceramics industry, and certain of them provide ornamental stone and semiprecious gems.

Characteristic of the feldspar group of minerals are solid solution series—i.e., a single crystalline phase whose chemical composition can vary between finite limits that are called end-members. There are three such end-members in the feldspar group, namely, orthoclase, a potassium aluminum silicate ( $\text{KAlSi}_3\text{O}_8$ ); albite, a sodium aluminum silicate ( $\text{NaAlSi}_3\text{O}_8$ ); and anorthite, a calcium aluminum silicate ( $\text{CaAl}_2\text{Si}_2\text{O}_8$ ). At temperatures

above  $700^\circ\text{C}$  ( $1,300^\circ\text{F}$ ) there is complete solid solution between orthoclase and albite. The minerals involved have compositions that vary between pure potassium feldspar and pure sodium feldspar; these constitute the alkali feldspar series. There is also complete solid solution at high temperature between the end-members albite and anorthite. These minerals theoretically vary between pure sodium feldspar and pure calcium feldspar and are called the plagioclase feldspar series. There is commonly a certain amount of potassium in the plagioclase feldspars and some calcium in the alkali feldspars. This is, however, generally not greater than 10 percent of the feldspar molecule. Other elements that enter the feldspars in appreciable amounts are barium, rubidium, and strontium. The barium feldspar ( $\text{BaAl}_2\text{Si}_2\text{O}_8$ ), known as celsian, is very rare, and minerals with compositions intermediate to celsian and potassium feldspar are known collectively as hyalophane.

The importance of the feldspars in the classification of igneous rocks (those rocks that have crystallized upon the cooling of silicate melts known as magma) is such that the alkali and plagioclase series of minerals are further subdivided. The plagioclase series is designated in terms of the fraction of the albite (Ab) component and anorthite (An) component in each intermediate mineral. Because Ab plus An must total 100 percent in each mineral, the content of only one of the end-members need be specified. That is: albite (Ab = 100–90), oligoclase (Ab = 90–70), andesine (Ab = 70–50), labradorite (Ab = 50–30), bytownite (Ab = 30–10), and anorthite (Ab = 10–0).

In the alkali series the feldspar names are related to the structural state as well as to chemical composition. At temperatures above  $700^\circ\text{C}$  ( $1,300^\circ\text{F}$ ) there is complete solid solution from albite through anorthoclase to high sanidine. At lower temperatures intermediate members of the series consist of intimate intergrowths of a sodium-rich and a potassium-rich feldspar; these intergrowths have the general name perthite. Perthites are subdivided according to their size: those called perthites are visible to the naked eye; micropertthites are visible only under the microscope; and cryptopertthites are invisible under the microscope. It may seem from this that the name cryptopertthite would be of little use; an optical effect observed in moonstone, however, is sufficient to indicate that the mineral is a cryptopertthite. In addition, X-ray-diffraction analysis will indicate the occurrence of a sodium-potassium feldspar consisting of two phases intergrown on a submicroscopic scale.

Feldspars find wide application in the glass and ceramics industry mainly because of the lack of colour of some varieties and relatively low melting temperatures. Because they make up the large bulk of many pegmatites (very coarse-grained igneous rocks), relatively pure feldspar can be obtained in large amounts. Cheap glass for bottles is made from granite without removal of the impurities, and, in consequence, the glass is green or brown in colour.

In recent years feldspar has replaced varieties of silica in scouring powders because of the health hazard caused by some varieties of silica in the manufacturing process.

China clay, which is used for making good quality china, is mainly composed of the clay mineral kaolin [ $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$ ], a decomposition product of feldspar.

Feldspar-bearing rocks have been used as decorative stones, the most spectacular being the larvikite (from Norway) and anorthosites containing labradorite, which show pronounced iridescence. Many building stones depend on pink feldspars for their beauty, and some feldspars are used as semiprecious gemstones. The chief varieties are moonstone, a cryptopertthite showing pronounced pale-blue iridescence; and aventurine feldspar, or sunstone, plagioclase or orthoclase containing oriented flakes of hematite that produce a copper-coloured lustre called schiller. Orthoclase and labradorite that exhibit a pale-yellow colour because of the presence of small amounts of iron are also used in jewelry.

This article treats the crystal structure, chemical composition, and physical properties of the feldspars, as well

Economic use and importance

General identification of the feldspar minerals

As noted above, the different distribution of the aluminum and silicon atoms in these tetrahedral sites is the cause of the difference between high sanidine (the highest temperature potassium feldspar) and maximum microcline (the lowest temperature potassium feldspar). In high sanidine, the silicon and aluminum atoms are completely randomly distributed between  $T_1$  and  $T_2$  types of sites, whereas, in microcline, the aluminum atoms are almost all concentrated in the  $T_1(o)$  sites, and the silicon atoms occupy the  $T_1(m)$ ,  $T_2(o)$ , and  $T_2(m)$  sites. All degrees of ordering exist, from high sanidine through low sanidine, orthoclase, and intermediate microcline to maximum microcline. The transition from monoclinic to triclinic symmetry occurs when the  $T_1(o)$  and  $T_1(m)$  sites have different statistical aluminum contents.

A similar relationship holds between high albite and low albite except that, because both are triclinic, the nomenclature for the tetrahedral sites of the highest temperature and lowest temperature forms are the same. Because of the smaller size of the sodium atom compared with the potassium atom, there is a tendency for the framework partially to collapse. The elongation of the sodium atom may be due to random occupation of two sites and is greater in the high-temperature form.

Although the alkali feldspars form a complete solid solution at high temperatures, natural feldspars of composition near  $Ab_{50}Or_{50}$  (one-half albite and one-half orthoclase) are invariably unmixed (*i.e.*, have separated upon cooling) to some extent; the degree of unmixing depends on the rate of cooling. There is some evidence that feldspars that have cooled rapidly are initially homogeneous but will unmix gradually even at temperatures as low as 150° C (300° F). Feldspars that have cooled slowly to low temperatures consist of almost pure low albite and pure potassium feldspar in an intimate intergrowth. Between these two extremes there are all intermediate stages in degrees of unmixing. It should be noted that, whereas the sodium-rich phase is highly disordered in the case of high-temperature perthites and highly ordered in the case of low-temperature perthites, the same is not true of the potassium-rich phase, wherein there are all possible gradations in the degree of order.

**Plagioclase structures.** Structural variation with composition of the plagioclase feldspars is shown in Figure 3. Although the phase diagram of the plagioclase feldspars usually shows complete solid solution between albite and anorthite at high temperature, pure anorthite has a 14 Å  $c$  axis even at the highest temperature, whereas albite has a 7 Å  $c$  axis. In the case of pure anorthite, the aluminum and silicon distribution is completely ordered; this is primitive anorthite. With the substitution of sodium for calcium and the accompanying replacement of some of the aluminum by silicon, the primitive anorthite structure gives way to body-centred anorthite (a structure with atoms at each corner and one in the centre) that also has a 14 Å  $c$  axis. The intermediate plagioclases are briefly described under *Iridescence*.

The peristerite structure occurs in low-temperature feldspars in the composition range  $An_2$  to  $An_{16}$  (see Figure 3). This structure results from an intimate intergrowth of two phases, one being pure albite with the low albite structure, the other of oligoclase composition but with a lower concentration of aluminum in the  $T_1(o)$  site than in low albite. It seems fairly certain that this structure results from exsolution of an originally homogeneous phase, but the precise nature of the reaction has not yet been determined. The iridescence shown by peristerites is caused by the intergrowth of the two phases, but all specimens having this structure do not show iridescence.

#### TWINNING IN FELDSPARS

Twinning is the intergrowth of two or more grains of a given crystalline material according to some definite pattern or arrangement called a twin law. The twin laws common in feldspars can be divided into those that apply only to the triclinic crystals (in which the axis or plane of twinning corresponds to the symmetry axis or symmetry plane in monoclinic crystals) and those that apply either to the monoclinic or triclinic crystals.

Figure 3: Plagioclase system, showing structural variations with compositional change within the system.

From J.V. Smith and P.H. Ribbe, "Atomic Movements in Plagioclase Feldspars: Kinetic Interpretation," in *Contr. Mineral. and Petrol.*, Bd. 21, S. 157-202 (1969); Berlin-Heidelberg-New York: Springer

**Twinning in monoclinic and triclinic crystals.** The twin laws that commonly are found in both monoclinic and triclinic crystals are called Carlsbad, Manebach, and Baveno (see Figure 4). The twins result from the zigzag

Figure 4: Common feldspar twins. (A) Interpenetrant Carlsbad twin. (B) Manebach twin. (C) Baveno twin.

chains of one part being joined to those of the other part by the oxygen atoms, which provide the linkages between the chains of a single untwinned crystal. In the case of Carlsbad twinning, the twin-axis lies in the plane perpendicular to the  $b$  axis and is described as a parallel twin. The Manebach and Baveno twins, in which the twin-axis is perpendicular to the twin plane are normal twins.

**Twinning restricted to triclinic crystals.** Twin laws that occur only in triclinic crystals are very numerous, but many of the laws are of rare occurrence. The two most common types are according to the so-called albite and pericline laws, and these are frequently found in the same crystal. The albite twin is a normal twin, whereas the pericline is a parallel twin that occurs in an irrational plane containing the  $b$  axis. Albite twinning represents an attempt on the part of the crystal to retain the plane of symmetry, and pericline twinning is an attempt to retain the axis of twofold symmetry of the monoclinic crystals. In two varieties of alkali feldspar, namely, microcline and anorthoclase, there is no doubt that the symmetry of the crystals was originally monoclinic; but the crystals subsequently inverted to triclinic symmetry, and, in doing so, twinning occurred according to both twin laws. This condition has been described as

Peristerite structure

Carlsbad, Manebach, and Baveno twins

Albite and pericline twins

M-type twinning to indicate the origin in a monoclinic crystal; this type of twinning is readily detected by single crystal X-ray studies. It also is recognized optically because of the crosshatched, or tartan, appearance of the crystals when viewed in thin section.

In plagioclase feldspars the original symmetry of the crystals was triclinic, and the twinning may be primary (formed during crystallization), or it may be secondary (formed subsequent to crystallization, perhaps by deformation). The appearance of the twinning is different from that shown by M-type twinning in that lamellae (thin layers, seen as lines in thin sections) of one twin are frequently cut off by twin lamellae approximately at right angles, and so the tartan effect is not produced.

In the plagioclases the position of the pericline twin lamellae depends both on the chemical composition and on the structural state. It may indicate a relict structural state in certain instances.

#### PHYSICAL PROPERTIES

**Hardness.** In general, feldspars are quoted as having hardness 6 to 6.5 on the Mohs scale of hardness (on the Mohs scale talc is 1, orthoclase is 6, and diamond is 10). Thus, feldspars are just softer than most minerals that are used as gemstones. Albite is just slightly harder than orthoclase, and, in the plagioclase series, there is a very slight decrease in hardness from albite to anorthite. Detailed study of indentation hardness of the plagioclase feldspars reveals two inflections in the curve of hardness plotted against composition; these inflections occur at  $An_{25-30}$  and  $An_{45-55}$ . It has been tentatively suggested that these may be correlated with structural breaks in the plagioclase series. Hardness is a property that is not easy to measure accurately and consequently has very limited value as a means of identification of individual feldspars.

**Specific gravity.** The densities of the feldspars are dependent on both chemical composition and structural state, but, toward the anorthite end of the plagioclase series, the differences in structural state gradually disappear, and so also do density differences.

Table 1: Densities of Feldspar Group End Members

	high form	low form
$KAlSi_3O_8$	high sanidine 2.558–2.560	microcline 2.560–2.564
$NaAlSi_3O_8$	high albite 2.606	low albite 2.624
$CaAl_2Si_2O_8$		anorthite 2.760

Accurate measurements of density are difficult to make because inclusions and flaws in crystals are common. Consequently, densities usually are calculated from the unit cell volume and molecular weight. Unfortunately, small errors in the cell volume may result in noticeable errors in density. The densities of the two forms of potassium feldspar are roughly the same because the cell vol-

umes appear to be nearly identical, whereas, in the case of sodium feldspar, there is a significant difference in cell volume. The relation between density and composition for the two series of feldspars is, as far as can be determined, linear.

**Cleavage.** Feldspars have two perfect cleavages along the crystallographic planes (001) and (010); the (001) cleavage is the most pronounced. Parting (*i.e.*, the tendency to separate) parallel to a number of faces is reported, and lamellae of sodium feldspar in a perthite may produce an apparent direction of parting.

**Colour.** The feldspars are commonly milky white in colour; indeed, the name albite is derived from the Latin word *albus*, meaning "white." Many of the feldspars are

By courtesy of The American Museum of Natural History, New York; photographs, E. Javorsky—EB Inc.

(Left) Microcline, Pikes Peak, Colorado. (Right) Albite, Amelia Court House, Virginia.

transparent with a yellowish or green colour, and sometimes they are translucent. Feldspars frequently are reddish brown in colour due to staining by iron, more commonly in potassium-rich feldspars. Some have a small amount of iron in their structure and occur as transparent yellowish crystals. The latter are either iron-bearing orthoclases or iron-bearing labradorites, both of which are used as semiprecious gemstones. Their perfect cleavage is a disadvantage in this connection. Feldspars that are green in colour are called amazonite. When transparent they are used as gemstones and when cloudy as decorative stones.

**Iridescence.** The property of iridescence is shown by different types of feldspars. Moonstones, which are alkali feldspars that are made up of a submicroscopic intergrowth of potassium-rich and sodium-rich feldspar, usually have a very attractive pale-blue iridescence and are used as semiprecious gemstones. Plagioclases in the albite-oligoclase composition range (peristerites) that

Play of colours

(Left) Moonstone showing pale-blue iridescence, origin unknown. (Top right) Polished slab of labradorite showing iridescence colors and polysynthetic twinning, from Labrador. (Bottom right) Aventurine feldspar showing schiller produced by flakes of hematite, from Bjordammen, Norway.

consist of submicroscopic lamellae of two phases, one of which is almost pure albite, also show iridescence. The name is derived from the Greek word *peristera* in allusion to the resemblance of the iridescence colour to that of a pigeon or dove.

Somefeldspars in the labradorite composition range show a play of colours that varies through red, gold brown, yellow, blue, and green. Although there is some overlap, the colours are related to the bulk composition of the sample: blue may be shown by samples of composition  $An_{48.5}-An_{52}$ ; green to yellow, by  $An_{52}-An_{55.5}$ ; and orange to red, by  $An_{55}-An_{58.5}$  (Figure 3). The potassium content apparently is critical as to whether iridescence is produced or not, because all specimens that lack iridescence have less than 2.1 mole (gram-molecular weight) percent of orthoclase. Although many workers have tried to explain this effect, there is no consensus of opinion as to its cause. If it is caused by an intergrowth of two phases, then these are extremely similar in structure. Recent work on this topic suggests that unmixing into two phases appears to be the most likely explanation of this phenomenon.

The property of schiller is shown by a type of feldspar known as aventurine, sometimes known as sunstone. The feldspar is usually of oligoclase composition but is sometimes potassium feldspar. The appearance is that of a copper-coloured schiller due to oriented hematite lamellae. When the specimen is heated above 1,200° C (2,200° F), these lamellae disappear, presumably due to solid solution in the feldspar, and they may reappear on annealing at 1,000° C (1,800° F).

**Crystal form and habit.** The feldspars have fairly strong pseudosymmetry, and in the triclinic feldspars this is the cause of polysynthetic (multiple) twinning. This is in some instances hexagonal pseudosymmetry, with the *c* axis serving as the sixfold axis (*i.e.*, one that reveals the same crystal relations with each 60° rotation).

Orthoclase and microcline commonly have prismatic habit, whereas sanidine is frequently tabular (see Figure 5). Albite in pegmatites forms very thin tabular crystals parallel to (010)—a plane parallel to  $a$  and  $c$ ; this is

From A. Deer, R. Howie, and J. Zussman, *Rock-Forming Minerals*, vol. 4 (1963); Longman Group Ltd.

Figure 5: Common feldspar habits. (A) and (B) prismatic habit of orthoclase, microcline, and plagioclase; (C) tabular habit of sanidine; (D) adularia habit.

called cleavelandite. Pericline is a variety of albite found in low-temperature veins. Pericline is characteristically elongated along the  $b$  axis and has simple pericline twinning. The pericline twin law is named from this variety of feldspar.

The feldspars of some volcanic rocks in Norway are rather unusual in that, like adularia, they have a rhomb-shaped outline.

**Optical properties.** Optical properties of minerals require specialized knowledge both for determination and understanding. Although there are other optical properties of significance with regard to the feldspars, only refractive index—the ratio of the velocity of light in a vacuum (in air, as commonly measured) to that in the mineral—will be discussed here.

**Table 2: Optical Properties of Feldspar Group End Members**

	refractive indexes			optic axial angles	extinction angles	
	$\alpha$	$\beta$	$\gamma$		(001) section	(010) section
High sanidine	1.518	1.522	1.522	(-) 64°	0	(+) 2°
Orthoclase	1.519	1.524	1.526	(-) 32°	0	(+) 5°
Microcline	1.522	1.526	1.529	(-) 70°-80°	(+) 5-15°	(+) 5°
High albite	1.527	1.532	1.534	(-) 45°-55°	(+) 0°-2°	+ 9°
Low albite	1.529	1.533	1.539	(+) 78°	(+) 3°	+ 20
Anorthite	1.575	1.584	1.589	(-) 77°	(-) 43°	(-) 39°

Refractive indices of feldspars depend on chemical composition and, to a lesser extent, on the structural state. A graph of refractive indices and composition of alkali feldspars clearly indicates that the substitution of potassium for sodium has a small effect on the refractive index. Measurements must be very accurate to have any value for determining chemical composition. Minor elements such as calcium, strontium, and barium also affect the plot, so that little useful information on alkali feldspars can be obtained by measuring approximate refractive indices except to indicate whether they are potassium- or sodium-rich compositions. In the plagioclase series, on the other hand, measurements of refractive indices have long been recognized as having useful determinative value, but, unless the structural state is known, the accuracy is not as great as might be desired, particularly for sodium-rich compositions.

An alternative method, very useful for relatively unzoned crystals, consists of fusing the crystals to a glass and then measuring the refractive index of the glass. A curve relating chemical composition to the refractive index of the glass for synthetic feldspar glasses may then be used for analysis. Because feldspars are frequently chemically zoned, sometimes in a very complex manner, it may be desirable to determine the composition of the separate zones, a distinction usually made by optical determinations; but, because this measurement depends on both structural state and chemical composition, an accurate knowledge of one of these must be obtained by some other method. A large number of optical techniques for determining the compositions of feldspars are available. These methods were becoming largely outdated in the 1970s, however, with the increasing availability of the electron microprobe.

## PHASE EQUILIBRIA OF FELDSPAR SYSTEMS

**Alkali feldspars.** At atmospheric pressure pure potassium feldspars and compositions from pure orthoclase (Or) to about Or<sub>50</sub>Ab<sub>50</sub> melt incongruently (*i.e.*, they react with the liquid to produce a new solid phase) and yield leucite plus liquid (see Figure 6). The

system is not binary for those compositions above the beginning of melting. For all temperatures below the beginning of melting, however, the relations can be represented in a temperature–composition diagram. There is a minimum melting relationship, and the minimum is near  $\text{Or}_{35}\text{Ab}_{65}$ , as shown in Figure 6.

Figure 6: The alkali feldspar system, showing the liquidus, solidus, and subsolidus relations (see text).

From N. Bowen and O. Tuttle, "The System  $\text{NaAlSi}_3\text{O}_8$ - $\text{KAlSi}_3\text{O}_8$ - $\text{H}_2\text{O}$ ," *Journal of Geology*, vol. 58 ©1950; the University of Chicago Press

Importance of the solvus

The most important feature of the diagram is that it is dominated by a solvus (a boundary between a homogeneous field of solid solution and a field of two or more solid phases derived from the homogeneous one), whose crest lies at some temperature above  $700^\circ\text{C}$ . The experimentally determined solvus has a crest at about  $690^\circ\text{C}$  at a water pressure of two kilobars, but this was determined using completely disordered feldspars: it is likely that some aluminum-silicon order is present in the crystals stable at this temperature, and the effect is to raise the crest of the solvus. The exact location of the solvus cannot be determined precisely because there will be an infinite number of metastable solvi, depending on the

degree of aluminum-silicon order in the specimens used to define the solvus. Thus, the solvus shown is drawn only approximately, on the assumption that its crest is above  $700^\circ\text{C}$  and near  $\text{Or}_{50}\text{Ab}_{50}$ , and in the knowledge that low albite and maximum microcline show a limited solid solution of potassium and sodium, respectively.

The dashed line sloping from  $930^\circ\text{C}$  at albite composition and intersecting the solvus represents the non-quenchable monoclinic-triclinic inversion in sodium-rich alkali feldspars; below the solvus this is denoted by a dotted line to indicate that it is metastable in this region.

Temperature ranges for the stabilities of the various forms of sodium and potassium feldspars cannot be shown because the various forms are not accurately defined, there being a gradual transition from the highest to the lowest temperature form (see Figure 6). The boundary between anorthoclase and sanidine is at  $\text{Or}_{40}\text{Ab}_{60}$  because single-phase crystals of a composition more sodium rich than this are triclinic when observed at room temperature, and compositions more potassium rich are monoclinic at room temperature.

At a water pressure of five kilobars, the melting curves on this system are lowered considerably because of the incorporation of water in the silicate melt, and the minimum is replaced by what appears in projection to be a eutectic (*i.e.*, the lowest melting point possible in mixtures of components that do not form solid solutions). The degree of aluminum-silicon disorder in the two feldspars in equilibrium with the liquid at the temperature of this pseudo-eutectic is likely to be very high; hence the stable solvus close to the melting curves might be expected to be that determined experimentally. The effect of pressure on the solvus is to raise it slightly. (See Figure 8.)

**Plagioclase feldspars.** At high temperature the plagioclase feldspars form a solid solution series with no maximum or minimum. At lower temperatures the phase diagram is extremely complex and not yet fully understood, but the latest ideas are incorporated in Figure 3. The form of sodium feldspar stable at the melting point is monoclinic albite, but, with increasing calcium this quickly gives way to a triclinic form with a  $7\text{ \AA}$   $c$  axis, which extends across the diagram to near anorthite, where the body-centred form with a  $14\text{ \AA}$   $c$  axis is the stable form. The relations at the anorthite end of the series are extremely complex, and recent studies suggest a possible solvus for bytownite compositions. At the albite end of the series, where the peristerites are found in the composition range  $\text{An}_2$ - $\text{An}_{16}$ , it is likely that these represent a solvus, although it has not been proved experimentally, nor has the temperature of the crest of this possible solvus been determined. At high water pressures the solidus and liquidus are lowered, but the shape of the plagioclase loop is not greatly changed.

The melting relations also have been determined in the absence of water at pressures of one bar and 10 and 20 kilobars (Figure 7). At ten kilobars anorthite melts incongruently to corundum + liquid, and at higher pressures the corundum + liquid field extends to more sodium-rich compositions. At 26 kilobars congruent melting occurs only between pure albite and  $\text{Ab}_{88}\text{An}_{12}$ . At pressures above 32 kilobars albite melts to jadeite + liquid, so that above this pressure no plagioclase of any kind can crystallize from a melt.

**Ternary system.** Phase relations in the ternary feldspar system (*i.e.*, the sodium-potassium-calcium feldspar system) have not been completely determined experimentally, mainly because of the viscosity of the melts and the difficulty of attaining equilibrium. At atmospheric pressure only the liquidus surface has been determined, and, because of the incongruent melting of potassium-rich compositions, the system is quaternary.

Crystallization in this system is exceedingly complex because the two solid phases are ternary solid solutions, and with falling temperature these solid solutions approach each other in composition. For certain bulk compositions it can be shown that, at some stage during equilibrium crystallization, one of the feldspars present may be dissolving while the other is precipitating. Different bulk

Plagioclase solid solution series

Figure 7: Melting relations in the system  $\text{NaAlSi}_3\text{O}_8$ - $\text{CaAl}_2\text{Si}_2\text{O}_8$  at one bar, 10 kilobars, and 20 kilobars (see text).

Figure 8: Phase relations in the system  $\text{NaAlSi}_3\text{O}_8$ - $\text{KAlSi}_3\text{O}_8$  at atmospheric pressure and at  $P_{\text{H}_2\text{O}} = 5$  kb, showing the effect of  $P_{\text{H}_2\text{O}}$  on the melting point (see Figure 6) and the solvus.

compositions behave differently, and a detailed discussion of the variations in crystallization paths is beyond the scope of this article.

**BIBLIOGRAPHY.** W.A. DEER, R.A. HOWIE, and J. ZUSSMAN, *Rock-Forming Minerals*, vol. 4, *Framework Silicates* (1963), a standard work on the common rock-forming minerals, giving chemical analyses of representative samples, crystal structures, optical properties, and paragenesis—includes an extensive, well-illustrated section on the feldspars; T.F.W. BARTH, *Feldspars* (1969), a good modern text on the mineral group; H.V. ## Feldspathoids

The feldspathoids are a group of aluminosilicate minerals that contain the alkali metal sodium and, in some varieties, potassium and calcium. Because extensive chemical substitution occurs in natural feldspathoids, their compositions and crystal structure vary widely and, hence, their physical properties show great variation. Nevertheless, they are often identifiable in the field on the basis of colour, crystal form, and geological environment. Chemically, the feldspathoids lie between the feldspars, the structure of which contains no extraneous molecules (*i.e.*, water, sulfate, or carbonate) and permits slow chemical sub-

stitution for the metal ion present, and the zeolites, the structure of which has relatively large spaces that may contain a large number of extraneous molecules and readily permits the exchange of its metal ions—a characteristic that lends water-softening ability to the zeolites. The distinction between feldspathoids and zeolites is somewhat arbitrary, however, and is based more on historical custom than on strict scientific rules (see also FELDSPARS; ZEOLITES).

The most important feldspathoids are nepheline (nephelinite), which is the most abundant mineral of the alkaline rocks, and leucite. Others, including analcime, sodalite, lazurite, noselite (nosean), hauynite (haiüyne), and cancrinite, are relatively rare. The feldspathoid group is of minor economic importance; nepheline, however, is mined in large quantities in Ontario and the Kola Peninsula as a source of soda, silica, and alumina for glass and ceramic products. It also is used in the Soviet Union in the production of alumina and cement. Leucite has been used in Italy as a fertilizer and as a source of alum.

Lazurite-rich rock formerly was crushed to provide ultramarine, an intense blue pigment long used in painting, printing, and colouring of ceramics, but since the synthesis of ultramarine in 1828, synthetic ultramarine of various shades of blue has replaced the rare and expensive natural product. Blue sodalite and massive lazurite are used as ornamental stones and inlays; the latter rock is called lapis lazuli when it is of gem quality.

The feldspathoids have a crystal structure that is a continuous framework of linked silicate tetrahedra ( $\text{SiO}_4^{4-}$ , the basic building block of silicate structure), in which a silicon atom is surrounded by and bonded to four oxygen atoms arranged at the corners of a tetrahedron; aluminum replaces silicon in some of the tetrahedrons. Each oxygen atom is part of two tetrahedrons and provides the linking necessary for a continuous structure. Alkali metals and other large atoms and molecules occupy the holes (spaces) between the oxygen atoms. It is the open framework that permits extensive chemical substitutions in the feldspathoids.

The feldspathoids are characteristic of rocks that are relatively poor in silica and rich in alkalis and aluminum. In these rocks they form as a substitute for the more common feldspars (the German name for the group, *Feldspat Vertreter*, "feldspar substitute," reflects this), which require a higher silicate to alkali ratio. Thus, the feldspathoids can never occur in rocks that contain free silica (quartz;  $\text{SiO}_2$ ) as an original constituent. They occur in a variety of alkali-rich rocks, including volcanic, plutonic, metamorphic, replacement, skarn (lime-rich silicate rocks), and precipitated varieties. Analcime, nepheline, and leucite, for example, occur as phenocrysts (sin-

gle crystals in a finer matrix), and analcime is also precipitated in saline lakes and occurs on the sea floor.

This article treats the crystal structure and physical and chemical properties of the feldspathoids, as well as their occurrence in nature and laboratory synthesis. For further information on crystal structure, see CRYSTALLOGRAPHY, and for associated minerals and mineral groups, see MINERALS and SILICATE MINERALS. Ornamental varieties are treated in the article GEMSTONES.

CHEMICAL COMPOSITION AND CRYSTAL STRUCTURE

Because extensive chemical substitution occurs in natural feldspathoids, a wide range of compositions and associated crystal structures is represented by members of this mineral group. Classification of the feldspathoids, therefore, is best accomplished by grouping members on the basis of chemical composition and structure. Such a classification is presented in the Table, which lists mineral composition, crystal system, and unit cell dimensions. It should be noted that the compositions of most feldspathoids range widely about the ideal formulae that are listed.

The reasons for this classification of feldspathoids will be apparent from consideration of the several feldspathoid groups, the first of which is the nepheline group.

Classification of the feldspathoids

Classification of Feldspathoids According to Composition and Structure			
	idealized composition	crystal system*	unit cell dimensions†
Nepheline	Na <sub>3</sub> KAl <sub>3</sub> Si <sub>3</sub> O <sub>16</sub>	hexagonal	a 10.0, c 8.4
Kalsilite	KAlSiO <sub>4</sub>	hexagonal	a 5.1, c 8.7
Kaliophilite	KAlSiO <sub>4</sub>	hexagonal	a 26.9, c 8.5
Carnegieite (high)	NaAlSiO <sub>4</sub>	isometric	a 7.3
Carnegieite (low)	NaAlSiO <sub>4</sub>	triclinic?	?
Leucite (high)	KAlSi <sub>2</sub> O <sub>6</sub>	isometric	a 13.4
Leucite (low)	KAlSi <sub>2</sub> O <sub>6</sub>	tetragonal	a 13.7
Analcime	NaAlSi <sub>3</sub> O <sub>8</sub> · H <sub>2</sub> O	isometric	a 13.7
Sodalite	Na <sub>4</sub> Al <sub>3</sub> Si <sub>3</sub> O <sub>12</sub> Cl	isometric	a 8.9
Hydroxysodalite	Na <sub>4</sub> Al <sub>3</sub> Si <sub>3</sub> O <sub>12</sub> OH	isometric	a 8.9
Noselite (nosean)	Na <sub>5</sub> Al <sub>3</sub> Si <sub>3</sub> O <sub>14</sub> (SO <sub>4</sub> )H <sub>2</sub> O	isometric	a 9.1
Häuyne (häuyne)	Na <sub>5</sub> Ca <sub>2</sub> Al <sub>6</sub> Si <sub>6</sub> O <sub>24</sub> (SO <sub>4</sub> ) <sub>2</sub>	isometric	a 9.1
Cancrinite	Na <sub>5</sub> Ca <sub>2</sub> Al <sub>6</sub> Si <sub>6</sub> O <sub>24</sub> (CO <sub>3</sub> ) <sub>2</sub> 3H <sub>2</sub> O	hexagonal	a 12.7, c 5.1
Natrodavynite	Na <sub>10</sub> Al <sub>6</sub> Si <sub>6</sub> O <sub>24</sub> (CO <sub>3</sub> ) <sub>2</sub> · xH <sub>2</sub> O	hexagonal	a 12.7, c 5.1
Vishnevite	Na <sub>5</sub> Al <sub>6</sub> Si <sub>6</sub> O <sub>24</sub> (SO <sub>4</sub> )3H <sub>2</sub> O	hexagonal	a 12.7, c 5.1
Scapolite	(family name)		
Marialite	Na <sub>4</sub> Al <sub>3</sub> Si <sub>3</sub> O <sub>12</sub> Cl	tetragonal	a 12.1, c 7.6
Meionite	Ca <sub>4</sub> Al <sub>3</sub> Si <sub>3</sub> O <sub>12</sub> CO <sub>3</sub>	tetragonal	a 12.2, c 7.6

\*In the isometric system crystals are referable to three mutually perpendicular crystallographic axes of equal length. Tetragonal crystals also are referable to three mutually perpendicular axes, two of which are of equal length and the third longer or shorter. In the hexagonal system three axes of equal length intersect at angles of 120° and are perpendicular to a fourth axis that may be longer or shorter. The three axes of triclinic crystals are inclined relative to each other and are of differing lengths. †The unit cell is the smallest volume that contains a complete sample of the atomic or molecular groups that comprise a particular mineral. Dimensions are given in angstrom units (one angstrom equals 10<sup>-8</sup> centimetres), and the letters a and c refer to directions along the crystallographic axes. In the isometric system all axes are of equal length and only one value (a) is given. Similarly, in the tetragonal system a refers to the two axes that are of equal length and c to the third, and in the hexagonal system a represents the cell dimensions along each of the three axes of equal length and c represents the fourth.

**The nepheline group.** Nepheline, kalsilite, and kaliophilite have structures similar to that of the high-temperature form of silica called tridymite, and the structure of carnegieite is similar to another form of silica called cristobalite (see SILICA MINERALS).

The idealized structure of kalsilite has potassium atoms occupying the centres of the large voids in a framework that contains sheets of tetrahedra. The vertices of these tetrahedra are oxygen atoms, and at their centres are silicon and aluminum atoms. Alternate tetrahedra point up (U) like an Egyptian pyramid and share one oxygen (at the tetrahedron's base) with each of three tetrahedra pointing down (D), as shown in Figure 1. The next higher

Figure 1: Crystal structure of kalsilite (see text).

sheet is joined to the first sheet by sharing of oxygen atoms at the top of U tetrahedra so that, in projection, U of the first sheet is under D of the next higher sheet. D of the first sheet comes over U of the next lower sheet. In this structure the oxygen atoms are arranged in the stacking pattern called hexagonal close packing. When smaller sodium atoms substitute for the potassium atoms, the framework buckles to reduce the size of the cavities. For ideal nepheline, there are three small holes for sodium and one large hole for potassium. The expanded kalsilite is able to accommodate only a few sodium atoms before it buckles to the nepheline structure, which can accommodate an extremely large range of compositions. The cell dimensions (see the Table) change with the chemical substitution, and the chemical composition can be estimated from X-ray diffraction data (see CRYSTALLOGRAPHY). Not only does nepheline permit sodium-potassium substitution but it also permits substitution of silicon for aluminum with corresponding absence of alkali atoms to adjust the charges. Kaliophilite and other rare minerals have different degrees of distortion. The relation between tridymite and cristobalite frameworks is analogous to hexagonal and cubic close packing of equal spheres; in

hexagonal close packing, every second layer is oriented the same as the original layer, whereas in cubic close packing every third layer has that orientation. At high temperatures, nepheline of composition  $\text{NaAlSi}_3\text{O}_8$  changes to carnegieite, the cristobalite-like framework of which consists of identical sheets of U and D tetrahedra, but every third sheet is rotated by  $60^\circ$  with respect to the ideal tridymite structure. Upon cooling, the high-order, isometric (cubic) symmetry of carnegieite changes discontinuously at  $690^\circ\text{C}$  ( $1,275^\circ\text{F}$ ) to low-order symmetry as a result of framework collapse. The crystal system of this carnegieite may be triclinic, as indicated in the Table.

Nepheline that has been annealed in metamorphic (altered) rocks shows complex X-ray patterns that indicate a special arrangement of atoms. Nepheline from volcanic rocks typically deviates considerably from the composition  $\text{Na}_3\text{KAl}_3\text{Si}_4\text{O}_{16}$ , whereas nepheline from low-temperature environments is much closer to this ideal formula. Calcium commonly substitutes for sodium and iron for aluminum.

**Leucite and analcime.** Leucite has an aluminosilicate framework that is too complex to describe here: four-, six-, and 12-membered rings of tetrahedra occur in the framework. Above  $625^\circ\text{C}$  ( $1,150^\circ\text{F}$ ) leucite has isometric symmetry, with potassium atoms vibrating at the centre of the large cavities; below  $625^\circ\text{C}$  the framework buckles sharply, producing a one-sided distortion and reduction of size of the cavities occupied by the potassium atoms. The mineral pollucite, a cesium-bearing hydrated aluminosilicate ( $\text{CsAlSi}_2\text{O}_6 \cdot \text{H}_2\text{O}$ ), remains isometric at all temperatures because the cesium atoms are large enough even without thermal vibration to hold the framework in a regular configuration.

#### Modifications of analcime

Analcime has the same structural framework as leucite, but the smaller sodium atoms are each accompanied by a water molecule, thereby precluding structural distortion. Analcime occurs in three modifications, which probably result from different arrangements of aluminum and silicon atoms among the tetrahedra. Synthetic analcime has a random (disordered) distribution of aluminum and silicon atoms, but the atoms in some natural analcimes that were slowly annealed have a regular arrangement.

Analcime and leucite have incomplete sodium-potassium substitution. Analcime commonly contains some calcium, but there is a major gap between its composition and that of the zeolite mineral wairakite ( $\text{Ca}_{0.5}\text{AlSi}_3\text{O}_8 \cdot \text{H}_2\text{O}$ ). Synthetic analcimes range in composition from  $\text{Na}_{1.2}\text{Al}_{1.2}\text{Si}_{1.8}\text{O}_6 \cdot 9\text{H}_2\text{O}$  to  $\text{Na}_{0.76}\text{Al}_{0.76}\text{Si}_{2.24}\text{O}_6 \cdot 1.1\text{H}_2\text{O}$ ; natural analcimes cover about half of this composition range. Analcimes formed at higher temperatures approach more closely the ideal formula; silica-rich analcimes form by reaction of volcanic ash with salt water. Analcime technically may be classed as a zeolite mineral because the water is removed reversibly by heating up to  $150^\circ\text{C}$  ( $300^\circ\text{F}$ ) and because the alkali atoms can be ion exchanged reversibly (for these properties of analcime see ZEOLITES).

**The sodalite and cancrinite groups.** The sodalite and cancrinite groups have aluminosilicate groups related in an elegant way (see Figure 2). In sodalite the aluminum and silicon atoms lie at the corners of imaginary truncated octahedra (the Archimedean semiregular polyhedron, which has eight hexagonal faces formed by truncating the six corners) close packed on the hexagonal faces to fill the space completely. Although the symmetry is isometric, it appears to be hexagonal when viewed perpendicular to one set of imaginary faces; there are three sets of parallel hexagonal faces that are so stacked one behind the other that in projection they appear to have a hexagonal orientation around a central hexagonal face. The centres of the hexagonal faces in sodalite have positions that are analogous to the cubic close packing of spheres.

In cancrinite, two sets of hexagonal faces are stacked one behind the other so that in projection they form a hexagonal pattern around a rather large 12-sided void. The centres of the hexagons in this case have positions analogous to hexagonal close packing of spheres.

Figure 2: Two-dimensional projections of three-dimensional aluminosilicate frameworks of cancrinite and sodalite. The Si and Al atoms occur at the line intersections and oxygen atoms at the middle of the line segments. In cancrinite (A), there are hexagonal rings superimposed so that they lie either at heights 0,2,4, etc., or at 1,3,5, etc. The edges of the rings form tilted squares. In (B) a perspective diagram shows the unit formed from the labelled intersections of (A). In sodalite (C), the hexagonal rings superimposed at 0,3,6, etc., 1,4,7, etc., and 2,5,8, etc., forming truncated octahedra as shown by the perspective drawings of (D). Corresponding intersections are labelled. The upper hexagonal face of a truncated octahedron is emphasized in (C), and descending lines are shown by the arrows.

In sodalite all of the cavities between the oxygen atoms (which lie nearly at the centres of the edges of the truncated octahedron) are near spherical and are connected by apertures in the six-membered rings. In cancrinite there are much larger cavities connected by 12-membered rings, and, in addition, there are smaller cavities. The large cavities and channels permit easy movement of atoms. In the sodalite group, the large chlorine, sulfate, or sulfide units fit nicely in the truncated octahedra, while the sodium atoms lie close to the six-membered rings of oxygen atoms. In cancrinite the carbonate group lies at the centre of the large cavities, while the sodium atoms and water molecules occupy other convenient positions.

**The scapolite group.** The aluminosilicate framework of scapolite, sometimes also called wernerite, is composed of two types of four-membered rings of tetrahedra. One type has alternate tetrahedra pointing upward (U) and downward (D), and the other type has tilted tetrahedra ( $T_1$ ,  $T_2$ ), each of which has an innermost edge that is horizontal and an outermost edge that is vertical; the rings of  $T_1$  and of  $T_2$  tetrahedra are at different levels (see Figure 3). These four-membered rings are so linked that each U tetrahedron has a D tetrahedron above it and a  $T_2$  tetrahedron below it and to the side, whereas each D tetrahedron has a U tetrahedron below it and a  $T_1$  tetrahedron above it and to the side. This arrangement forms vertical five-membered rings composed of two U, two D, and one T tetrahedra.

Chlorine atoms or carbonate groups lie in the large cavities between the T rings. Calcium atoms occur in the elongated cavities bonded to oxygen atoms and to chlorine atoms or carbonate groups.

The distribution of aluminum and silicon atoms in

Structures of the scapolite group

Figure 3: Scapolite structure shown as two-dimensional projection. (See text for explanation of U, D, and T.) Chlorine atoms lie in cavities marked Cl, while Ca atoms occupy in projection the places marked by heavy dots.

scapolite is complex. In all framework structures, the best electrostatic stability results when not more than one aluminum atom is attached to each oxygen. In marialite, each aluminum atom alternates with three silicon atoms in conformity with this rule. In pure meionite with one aluminum atom for each silicon atom, this rule would be violated because no more than two aluminum atoms would be placed in the five-membered rings. Indeed, few if any scapolites closely approach the meionite composition. The relatively low-order symmetry of at least some scapolites is probably caused by special ordering patterns of the aluminum and silicon atoms and perhaps by special orientations of carbonate molecules.

#### PHYSICAL PROPERTIES OF FELDSPATHOIDS

Identification of feldspathoids

The physical properties of feldspathoids are rather variable because of the extensive chemical substitutions. Visual examination of hand-sized specimens or microscopic study of thin sections often permits qualitative identification of feldspathoids, but X-ray diffraction and chemical analysis, especially with the electron microprobe, are desirable for quantitative identification. Simple chemical tests also are useful. Feldspathoids decompose in weak mineral acid because of the high aluminum content, and this serves to distinguish them from feldspar. The hardness of all feldspathoids is 5–6 on the Mohs scale (in which talc, the softest, is 1 and diamond, the hardest, is 10).

Nepheline has a specific gravity of 2.56–2.66, is usually white or gray, has a greasy lustre, and is shapeless in plutonic rocks; simple hexagonal prisms are the predominant form in volcanic rocks. Basal and prismatic cleavages (mineral surfaces that parallel crystallographic planes, along which the mineral tends to split) are poor, and the mineral rarely exhibits twinning—*i.e.*, intergrowths of two or more grains in accord with some preferred crystallographic surface or orientation.

Kalsilite is similar to nepheline, but the specific gravity is 2.59–2.62 and its optical properties differ. The most distinctive property for diagnostic purposes is the potassium/sodium ratio, which can be determined by X-ray diffraction.

Leucite and analcime are white, gray, or pink and usually have trapezohedral forms. Leucite shows intimately twinned crystals on the dodecahedron faces when viewed in thin section, and analcime exhibits very poor cleavage. Specific gravity ranges from 2.45–2.50 for leucite and from 2.24–2.29 for analcime. The minerals are best distinguished optically.

Sodalite, noselite, and hauynite can occur in almost any colour when in hand-specimen size, but they are colour-

less or pale blue in thin section. Specific gravities range from 2.3–2.5, and dodecahedral or shapeless forms are characteristic. Members of the sodalite group are best differentiated chemically because all are isometric with similar optical properties.

Cancrinite and vishnevite also exhibit almost any colour. In thin section these minerals are usually colourless, and perfect prismatic cleavage is characteristic. Specific gravities range from 2.3–2.5, and their perfect cleavage and different optical properties serve to distinguish these minerals from those of the scapolite group.

Scapolite is usually white but, again, colour can be variable. Tetragonal prisms capped with pyramids are typical forms. Major property changes are associated with the structural-compositional change from marialite to meionite. Specific gravity varies from 2.5–2.6 in marialite to 2.6–2.8 in meionite. The optical properties of scapolite, marialite, and meionite vary with the sodium/calcium ratio and thus provide a good estimate of composition. In addition to their optical properties, the scapolite minerals are distinguished from feldspar minerals by their cleavage angle and absence of twinned crystals and from cancrinite by their lesser solubility in hydrochloric acid.

#### SYNTHESIS AND NATURAL OCCURRENCE

The natural occurrence of minerals can be treated from a geographic viewpoint, but knowledge of the reasons for such occurrences or the interpretation of the conditions of formation stems largely from experimental data on mineral synthesis. In this sense, the synthesis and natural occurrence of the feldspathoids are best considered jointly, particularly because they commonly grow and develop under metastable conditions; that is, conditions that may permit further change before final stability.

**Nepheline and kalsilite.** At low temperatures, the stability fields (as a function of temperature for varying compositions between  $\text{NaAlSi}_3\text{O}_8$  and  $\text{KAlSi}_3\text{O}_8$ ) of nepheline and kalsilite are separated by an area in which the two phases do not mix and thus coexist. At temperatures of less than 400° C (750° F) the boundary (solvus) of this area approaches the compositions  $\text{KAlSi}_3\text{O}_8$  and  $\text{KNa}_3\text{Al}_3\text{Si}_3\text{O}_{16}$ . Nepheline inverts to carnegieite at 1,250° C (2,280° F), and kalsilite inverts to an orthorhombic form (one referable to three mutually perpendicular but unequal crystallographic axes) at 900° C (1,650° F).

Kalsilite occurs in volcanic rocks rich in potassium from Uganda, Zaire, and Italy as phenocrysts (isolated crystals) and in the groundmass (fine-grained matrix). Some phenocrysts consist of an intergrowth of kalsilite with nepheline resulting from breakup of a high-temperature, potassium-rich nepheline. Kalsilite also occurs in the linings of blast furnaces.

Kaliophilite occurs only in ejected blocks from Italian volcanoes, where it probably grew metastably at a temperature of about 1,000° C (1,800° F).

**Nepheline-leucite-analcime.** The occurrence of these minerals is intimately related to that of feldspar in the three-component system  $\text{SiO}_2\text{--NaAlSi}_3\text{O}_8\text{--KAlSi}_3\text{O}_8$ . To delineate the stability fields of these minerals it is necessary to consider temperature, hydrostatic pressure, and the pressure of water vapour. In laboratory synthesis, pressure commonly is applied in the form of water vapour. When the crystal products are anhydrous (*i.e.*, waterless), the addition of water acts merely as a catalyst promoting the growth rate. When analcime or melt is involved, however, the water actually enters the silicate material.

Figure 4 shows the composition ranges for the crystallization of the first mineral from a silicate melt containing excess water at a pressure of 1,000 atmospheres (one atmosphere is the barometric pressure at sea level—1.03 kilograms per square centimetre, or 14.7 pounds per square inch). The contours show the temperatures for the beginning of crystallization: these are generally 200°–400° C (350°–700° F) lower than for the dry system. In agreement with these data, kalsilite, leucite, nepheline, and alkali feldspar occur as phenocrysts in volcanic rocks of appropriate chemical composition.

Mineral stability fields

Figure 4: Composition regions at which nepheline (ne), kalsilite (ks), leucite (le), and sanidine feldspar (f) are the first to crystallize from the melt at 1,000 atmospheres  $H_2O$  pressure. Temperatures in  $^{\circ}C$  (some estimated) are shown by contours. The boundary between the nepheline kalsilite fields is probably near the 1,200 $^{\circ}C$  contour.

When the liquid has been consumed by crystallizing minerals, the minerals that coexist over temperatures ranging down to 700 $^{\circ}C$  (1,300 $^{\circ}F$ ) are as shown in Figure 5. Nepheline coexists with either sanidine feldspar,

Figure 5: Composition regions in which feldspathoids coexist at temperatures from 700 $^{\circ}C$  to the beginning of melting. In the triangles, three minerals coexist. In the shaded areas one mineral exists. In the striped area two minerals coexist with compositions represented by the ends of the line.

feldspar + leucite, or leucite + kalsilite. At temperatures below 500 $^{\circ}C$  (930 $^{\circ}F$ ), leucite is no longer stable, and sanidine feldspar is replaced by microcline and albite.

The natural occurrence of leucite is compatible with the laboratory syntheses because leucite occurs only in potassium-rich volcanic rocks. Important localities are Leucite Hills, Wyoming; central Montana; Rome; Uganda; and Zaire. Pseudo-leucite is the name for trapezohedral crystals of a mixture of nepheline and feldspar plus alteration products. Their origin is controversial, but the most probable explanation is that phenocrysts of leucite, containing considerable sodium, are reconstituted as nepheline and feldspar.

Nepheline is the most abundant mineral of the alkaline rocks, such as nepheline-syenites and gneisses, in which it is typically associated with feldspars. Whether these rocks form by igneous processes or by the chemical alteration of sediments by sodium-rich fluids is controversial. Famous localities are the Haliburton-Bancroft area of Ontario; Oslo, Norway; and Alnö, Sweden; Norra Kärr, Finland; and Kola Peninsula, Russian Soviet Federated Socialist Republic. Local reaction of silica-poor magma with carbonate-rich sediments produces other nepheline-bearing rocks in the British Isles at Camas Mor, Muck, and Scawt Hill. Nepheline commonly is accompanied by sodalite, cancrinite, or scapolite. Nepheline in volcanic rocks is glassy, but in deep-seated rocks it has a greasy lustre that is caused by alteration to cancrinite and other minerals. Nepheline occurs in walls of furnaces. In the chemical industry, the  $NaAlSi_3O_8$  composition at temperatures near 100 $^{\circ}C$  (212 $^{\circ}F$ ) in aqueous solution yields an important zeolite known as Type A.

Analime has a tremendous range of environmental occurrences. Under high water pressure, analime replaces nepheline and feldspar as the mineral first crystallizing from a melt of potassium-poor material. This explains its occurrence as phenocrysts in extrusive rocks, such as phonolites and trachybasalts. At lower pressures, analime is not stable with a liquid, but it occurs at lower temperatures for a composition range overlapping that of  $NaAlSi_3O_8$ . The occurrence of analime in vesicles of

basalts and in wide areas of very low-grade (slightly altered) metamorphosed sediments, such as volcanic ash in New Zealand, is consistent with laboratory syntheses up to 200 $^{\circ}C$  (400 $^{\circ}F$ ). Volcanic ash commonly alters in the presence of solutions (or in lake beds or on the ocean floor) to a variety of zeolites or clay minerals. Analime is increasingly common in the older rocks, thus indicating that it is more stable than erionite, mordenite, and other zeolites. Silica-rich analime transforms slowly to albite.

Analime also precipitates from lakes that are fed by alkaline waters. Huge beds of analime-rich rocks, tens of feet thick and covering thousands of square miles in Wyoming, Utah, the Sahara, and Zaire, show no evidence of residual volcanic ash and are believed to have originated by direct precipitation.

**Sodalite and cancrinite groups.** The stability conditions of the sodalite and cancrinite groups are poorly known, partly because of the metastable growth of these minerals and partly because of extensive chemical substitutions that may occur. Because of the special relation between their framework geometry, sodalite and cancrinite minerals can be polymorphous. Cancrinite contains more water and therefore is the low-temperature phase.

Cancrinite grows from 200 $^{\circ}$  to 1,250 $^{\circ}C$  (400 $^{\circ}$  to 2,300 $^{\circ}F$ ), at which temperature it melts to nepheline plus liquid. Hydroxycancrinite grows up to 800 $^{\circ}C$  (1,500 $^{\circ}F$ ). Natrodavine breaks down above 600 $^{\circ}C$  (1,100 $^{\circ}F$ ) to a sodium carbonate form of noselite. Continuous chemical substitution exists between noselite and haiyūnite but not with sodalite. Hydroxysodalite has been synthesized extensively during growth of zeolite molecular sieves. Noselite and haiyūnite typically occur in volcanic rocks, which is consistent with the data for breakdown of natrodavine. Noselite occurs in phonolites of the Cape Verde Islands and Wolf Rock, Cornwall, and in ejected blocks of Laacher See, Rhine district. Haiyūnite occurs in Italian and Laacher See volcanoes and in alnöite rocks at Oka, Quebec, and Winnett, Montana.

Chlorine-rich sodalites occur in both volcanic and plutonic rocks and in metasomatic rocks, indicating a very wide temperature range of formation. Famous localities include the nepheline-syenites of Litchfield, Maine; Rhodesia; Korea; nepheline-syenite pegmatites of Burma, the Republic of Guinea, and Bearpaw Mountains, Montana; phonolites of Scotland and the Sahara; trachytes of Naples and Laacher See. In Angola, sky-blue crystals as long as 20 centimetres occur. The hackmanite variety, characterized by a pink colour that fades on exposure to light, occurs in Bancroft, Ontario; Magnet Cove, Arkansas; Kola Peninsula; and Korea.

Cancrinite minerals typically occur as alteration products of nepheline and feldspar or by contact metamorphism of a limestone by an igneous intrusion. Famous localities are at Alnö, Sweden; Fen district, Norway; Iivara, Finland; and Iron Hill, Colorado.

**The scapolite group.** Very little is known about the stability of scapolite minerals: indeed, the first proven syntheses were accomplished only in 1962. Scapolite does not occur as phenocrysts in volcanic rocks and, typically, is a metamorphic and metasomatic (completely replaced by chemical substitution) mineral requiring the availability of carbonate and sulfate. The principal occurrences are in regionally metamorphosed rocks of all metamorphic grades in Quebec and Ontario; hydrothermally altered igneous rocks associated with iron ores at Kiruna, Sweden, and Bucks County, Pennsylvania; contact skarns between limestone and igneous rocks in Queensland, Australia; and metamorphosed volcanic blocks of Laacher See.

## Fellini, Federico

With films such as *La strada*, *La dolce vita*, and *8½*, the Italian director Federico Fellini assured for himself a place of prime importance in the history of film making. His best films, all of which were in part written by him, are freely structured tales in which dream and reality, autobiography and fantasy, mingle in a world of symbols. Breaking with traditional techniques of motion-picture production, he succeeded in making the film such a personal medium that his own creative and personal problems became a legend. At the same time he revitalized the medium by emphasizing the dramatic solitude of man in the modern world.

Paris Match—Pictorial Parade

Fellini, 1965.

Family  
and  
childhood  
influences

Federico Fellini was born on January 20, 1920, in Rimini, Italy, a summer-resort area on the Adriatic. Throughout his films there are allusions to persons, scenes, and incidents associated with his childhood and youth in Rimini. Fellini's father, a simple, middle-class food-products salesman who died in 1956, was recalled nostalgically both in *La dolce vita* and in *8½*. His mother, his grandmother, and his aunts also play important roles in the world of childhood that his films evoke. The Catholic boarding school that he attended in Fano is recreated imaginatively as a combination of meanness and liturgical pomp in *8½*. Other salient childhood influences were the theatre and especially the circus, the dazzling impact of which may be seen in his 1970 film for television, *Clowns*. And Fellini's adolescence, during which he often was the ringleader in the escapades of his schoolmates, is reproduced in his film *I vitelloni*.

Bored with his aimless existence in Rimini, Fellini, who was gifted with a talent for drawing, went in 1938 to Florence, where he worked on a humorous weekly and on science fiction serials. In 1939 he went to Rome in the hope of becoming a journalist, and sold caricatures in restaurants. At this time he met the actor Aldo Fabrizi, whose tales of the rough life of the small-time comic actor were to be used by Fellini in some of his films. In 1940, during World War II, Fellini became an editor of *Marc'Aurelio*, a popular satirical weekly magazine. In 1943 he wrote a radio serial in which the actress Giulietta Masina appeared; she became Fellini's wife in that year. When Allied forces took Rome in 1944, Fellini opened a "funny face shop," in which he drew caricatures and made voice recordings of soldiers passing through.

Associa-  
tions with  
Rossellini  
and  
Lattuada

Fellini became a friend and associate of the director Roberto Rossellini, who was then making *Roma città aperta* (1945; *Open City*), in which Fabrizi played the lead. The film became the best known example of Italian neorealism. Fellini made an even more significant contribution to Rossellini's next film, *Paisà* (1946; *Paisan*). By then, Fellini had fallen in love with cinema, and he went on to contribute to the writing of some of the most important neorealist films, including *Il miracolo* (1948; *The Miracle*), the highly controversial second part of

Rossellini's *Amore*; the U.S. Supreme Court ruled that it could not be banned for being "sacrilegious."

A decisive step in Fellini's career came in 1950, when he codirected and coproduced *Luci del varietà* with Alberto Lattuada, a prominent Italian director for whom Fellini had worked as a writer. Fellini's wife appeared in it and played a very small part in the next film he directed, this time on his own, *Lo Sceicco bianco*, the story of a bride on her honeymoon who is infatuated with the hero of a photographic comic strip. Though neither film was successful financially, he went on the following year to make *I vitelloni*, which struck deep and with bitter sarcasm at the idle mamma's boys of the provinces. It won an award at the Venice Film Festival, and some critics still consider it to be Fellini's masterpiece.

In 1954 Fellini resumed work on an old project, the story of two wandering, scruffy mountebanks, *La strada*. Starring Giulietta Masina, the film was shot on location in the desolate countryside between Viterbo and Abruzzo; the great empty spaces reflect the virtual inhumanity of the relationship between the principal characters. Although it was criticized by the left-wing press in Italy, the film was highly praised abroad, winning the Academy Award and the New York Film Critics award as the best foreign-language film of 1956.

Fellini's next film, *Il bidone* (Roman slang for "gyp"), dealt with petty swindlers. More successful was *Le notti di Cabiria*, again starring Giulietta Masina, this time as a simple Roman prostitute whose confidence in the future never flags. It again won an Academy Award for Fellini. He had a difficult time in getting his next film underway, however, because of its allegedly chaotic script and nearly unknown star (Marcello Mastroianni), but he found an understanding producer in the publisher Angelo Rizzoli, with whom he worked for the next seven years. In the course of making the film, *La dolce vita*, Fellini had Rome's main thoroughfare, the Via Veneto, rebuilt as a set. When the film was finished, it proved to be a panorama of the times, a compelling indictment of the ruthless journalists and *paparazzi* (unscrupulous yellow-press photographers), of television, of the movie-star craze, of decadent intellectuals and aristocrats. Immediately hailed as one of the most important films ever made, it won first prize at the Cannes Film Festival.

The  
making of  
*La dolce  
vita*

Like *La dolce vita*, Fellini's next film has no conclusion but is a tale freed from conventional limitations. Entitled *8½*, after the number of films Fellini had made to that time, it shows the plight of a famous director who is in a creative paralysis, unable to make a film. It achieves a perfect balance between symbolism and realism. It met with violent controversy but also with widespread applause.

A world of fantasy was again explored in *Giulietta degli spiriti*, his first full-length colour film, again starring Giulietta Masina. Its scant success and a series of misunderstandings led to an end to the relationship between Rizzoli and Fellini, who spent the next few years looking for new ideas, and a new financial patron. His next major venture was the *Fellini Satyricon*, inspired by the ancient Roman writer Petronius but also drawing on the works of another ancient Roman author, Apuleius, and others. The film tells of the wanderings of a group of aimless young men in the world of antiquity. Without concern for historical accuracy, Fellini attempted to explore the human condition in an age before men knew Christianity and the concept of original sin. Fascinating in its flamboyant, colourful images, *Fellini Satyricon* is often bizarre. Perhaps as a reaction, Fellini's next film, *Clowns*, sponsored by Italian, French, and German television, returned to autobiography. A moving tribute to the world of the circus, it recalls, because of its simplicity and coherence, the poetic spell of *La strada*.

### MAJOR WORKS

*Luci del varietà* (1950; *Variety Lights*); *Lo Sceicco bianco* (1952; *The White Sheikh*); *I vitelloni* (1953; "Spivs"); *La strada* (1954; "The Street"); *Il bidone* (1955; *The Swindle*); *Le notti di Cabiria* (1956; *The Nights of Cabiria*); *La dolce vita* (1960; "The Sweet Life"); *Otto e mezzo* (1963; *8½*); *Giulietta degli spiriti* (1965; *Juliet of the Spirits*); *Fellini Satyricon* (1969); *The Clowns* (1970).

**BIBLIOGRAPHY.** ANGELO SOLMI, *Storia di Federico Fellini* (1962; Eng. trans., *Fellini*, 1967), contains critical analyses of the production and contents of Fellini's films and includes biographical notes.

(A.So.)

## Fencing

Fencing (French *escrime*; Italian *scherma*) is a sport involving the skillful use of swords for attack or defense according to set rules and movements. It has a long and fascinating history, and its roots can be traced to the traditions of chivalry. The sport has been included in the program of every Olympic Games since their revival in Athens in 1896, and today it is increasingly practiced throughout the world. The sport is divided into three major branches, depending on the weapons employed: foils, sabres, and épées.

This article covers the origins and early history of swords and swordsmanship and the development and organization of fencing as a sport of national and world competition and championships. Fencing weapons and equipment, the conduct of matches, and principles and techniques are described in the context of understanding the action and strategy of the sport.

### HISTORY

**Origins and early history.** Swords in many different forms have been used by man since before the dawn of recorded history. There are many examples of well-made swords dating from the Bronze Age. Swordsmanship was practiced widely by all the ancient civilizations—Persian, Babylonian, Egyptian, Greek, and Roman—both as a pastime and in single combat and war.

The earliest record of a fencing match is to be found in a relief carving in the temple of Madinat Habu near Luxor in Upper Egypt built by Rameses III about 1190 bc. This certainly depicts a practice bout or a tournament and not a battle or duel, because the points of the swords are covered, and the fencers, who are parrying with narrow shields strapped to the left arm, are wearing masks, tied to their wigs and fitted with large bibs and padded over the ears. The relief includes a group of spectators from Syria, the Sudan, and Egypt, and the judges and other officials can be recognized by their feathered wands. A hieroglyphic inscription records one fencer as saying "On guard and admire what my valiant hand shall do."

In the Middle Ages swords were heavy and clumsy, and an astonishing amount of strength was required to wield the long two-handed swords, the battle axes, and the maces and other lethal weapons that have survived. The general use of armour made it impossible to apply skill and finesse in the use of the weapons required to bludgeon the well-protected adversary into submission.

The introduction of gunpowder in the 14th century led gradually to the disuse of complete armour in war, and this caused a transformation of weapons to lighter and more manageable forms. Without the protection afforded by armour, skillful swordplay became of paramount importance. By the 15th century, guilds of fencing masters were formed throughout Europe to develop the art of swordsmanship. One of the first, and perhaps the most famous, of these guilds was the Marxbrüder or the Association of St. Marcus of Löwenberg, with headquarters at Frankfurt and branches in many other towns. The Marxbrüder were granted letters patent by the Emperor Frederick at Nürnberg in 1480.

The guilds, or fencing schools, became very powerful and jealously guarded their monopoly of teaching fencing. The early fencing methods were somewhat rough and ready and included almost as many wrestling tricks as fencing strokes. Various strokes were "discovered" by different guilds and were sold for large sums to their pupils as being guaranteed to bring success in combat. These "secret" strokes were, of course, more or less orthodox fencing movements, some of which are still in use. But when they were first devised and assiduously practiced in great secrecy, they no doubt proved most effective when suddenly produced in combat.

An example of this occurred during a duel which took

place at Saint-Germain-en-Laye on July 10, 1547, between Guy Chabot, baron de Jarnac, and François de Vivonne, seigneur de La Châtaigneraie, the finest swordsman and wrestler in France, in the presence of King Henry II and his court. La Châtaigneraie was so certain of success that he had had a banquet prepared to celebrate his victory. But suddenly Jarnac produced a hitherto unknown stroke, a drawing cut inside the knee that severed the hamstrings of his opponent, who was so mortified that he refused all aid and died from loss of blood. This stroke is known as the *coup de Jarnac*. Another secret stroke called *botte de Nevers*, reportedly invented by a Parisian fencing master and first used in a duel by the Duc de Nevers was in fact a stop hit between the eyes.

**Emergence of swordsmanship.** The Italians are said to have been the first to discover the effectiveness of the dextrous use of the point rather than the edge of the sword. By the end of the 16th century, their lighter weapons and simple, nimble, and controlled fencing style had spread throughout Europe as rapier fencing. The Italians may therefore be credited with being the originators of true swordsmanship that emphasizes skill and speed rather than force. Most of the wrestling tricks were abandoned, the lunge was discovered, and fencing may be said to have been established as an art.

The long rapier then used was a beautifully balanced sword, excellent in attack and for keeping the opponent at a distance but too heavy to carry out all the offensive and defensive movements required in combat. Defense was effected by parrying with the left hand, which was armed with a dagger or protected by a gauntlet or cloak. The opponent's thrusts were often avoided by ducking (*passata sotto*) or by the side step (*in quartata*). Rapier fencing was thus a two-handed contest in which the fencers stood almost square to each other as they circled around seeking advantage of light or terrain.

In the early 17th century, the Spaniards developed a specialized school of rapier fencing based on a complex series of movements related to various lines drawn within a circle on the ground about which the fencers moved with mathematical precision. This method was never adopted as widely as the Italian school.

In the last half of the 17th century, the evolution of swords and swordsmanship changed dramatically with a general change of style in dress. At the court of Louis XIV in France, fashion decreed the wearing of silks and satins—panniered dresses and elaborate coiffures for the ladies, silk stockings, breeches, and brocaded coats for the men. The long trailing rapier had been appropriate for the doublet and hose, the top boots, and cloaks of an earlier age but was no longer suitable for the elegance of the court of the Sun King. Every gentleman had, however, always to carry a sword, ready to defend his honour, so fashion decreed the wearing of a light, short court sword. The French court set the tone in Europe as surely as the Italians had done in earlier times. Proficiency with the small sword soon became an indispensable accomplishment for every gentleman.

**Development as a sport.** Although at first regarded with derision as mere "toys," it was soon recognized that the short court sword was an ideal light weapon with which all attacking and defensive movements could be performed using one weapon wielded with one hand. The use of the left hand or of the dagger was no longer required. Hits were made with the point only, and defense was effected mostly by the blade alone. Swift and subtle swordplay became a reality, and true fencing, as it is understood today, emerged as the light sword of the French school rapidly displaced rapier fencing. The speed with which light swords could be used at close quarters, even when practicing with blunted weapons, involved the risk of injury to the eyes: indeed it was said that no good fencing master could hope to end his days with two eyes. It is a curious fact that although the mask was used by the ancient Egyptians, it was quite unknown in Europe until the second half of the 18th century.

To minimize the risk of injury to the participants, it became necessary to impose rules and conventions to regulate fencing with the court sword or its practice counter-

# Introduction of rules and conventions: foils

part, the foil. Thus, valid hits were restricted to those that arrived on the right breast, and the fencer who initiated an attack had the "right of way"—i.e., the right to complete his movement, unless it was effectively parried, before his opponent could in turn attack or riposte (offensive action after a successful parry). The "invention" of the mask by the celebrated French master La Boëssière about 1750 made it possible to engage in more complex swordplay. Once the mask was established in general use, longer phrases (sequences of movements), including the remise or redoublement (renewed attacks after the original attack is parried), the counter-riposte (riposte following the parry of the opponent's riposte), and compound movements (attack or riposte involving one or more feints), became possible without undue risk of injury.

The rules and traditional conventions already mentioned had to be maintained and indeed amplified because otherwise swift and complex blade movements made at close quarters, instead of building up a fencing phrase, or conversation with the foils, would have degenerated into a brawl of simultaneous actions that would have been inconclusive and of little interest. These rules and conventions have endured as the basis of the modern rules that govern foil and sabre fencing.

Fencing with the foil became increasingly stylized, but meanwhile duelling continued. The complexities of foil fencing as practiced under the ideal conditions of the schools, with reverence for the set rules and conventions, produced a game that became an art of absorbing interest. But this orthodox, controlled swordplay was of little account on a cold gray morning on greensward or gravel path, when facing a determined opponent with a sharp and heavier weapon who disregarded all conventions. The *épée de combat* was therefore evolved in the mid-19th century. The *épée* was a regulation, though blunted, duelling sword, and it was used without limitation of target or other conventions. Indeed, when training for a duel, it was customary for those concerned to fence without mask or jacket and with sharp triple points attached to their weapons.

The *épée* became an established competition weapon fenced without limitation of target or conventions under rules approximating as closely to the conditions of a duel as the use of protective clothing allowed. At first, competitions usually took place out of doors with bouts for a single hit. With the introduction of an electrical judging apparatus, *épée* competitions were fenced indoors, and the number of hits in a bout were increased to five.

The heavy cutting weapons of the Middle Ages continued as the backsword (single-edged) or the broadsword (double-edged) until the 18th century. Indeed, backswording with "wasters," or wooden swords, or with basket hilted cudgels or singlesticks (one-handed wooden swords or sticks) continued far longer as popular amusements, especially in the English countryside.

In the late 18th century the Hungarians introduced a curved sabre adapted from the Eastern scimitar for the use of their cavalry, and this was soon adopted by other European armies. The heavy military sabre (and its counterpart, the naval cutlass) with its hanging guard and wide circular cuts was used in the fencing schools until the end of the 19th century. During the last quarter of that century, the Italians introduced a light sabre that was soon adopted universally both as a fencing and as a duelling weapon.

The technique of fencing with light sabres was developed by the famous Milanese master Giuseppe Radaelli. This method was later considerably modified by the Hungarian school, which was developed by Italo Santelli (1866–1944) and proved far superior in competitions. Sabre fencing in schools and competitions has become a formal sport with a limited target and is governed by conventions and rules similar to those in *forcé* at foil.

**Organization and governing bodies.** The earliest organizations were the European guilds of fencing masters, mentioned above. In Britain, swordsmanship was practiced from the earliest times. But a statute of Edward I enacted in 1285 forbade the teaching of fencing or the holding of tournaments within the precincts of the city of

London because the city fathers regarded fencing schools as places that encouraged duelling, brawling, and all manner of ruffianism. Indeed, swordsmen continued to be regarded with disfavour until Henry VIII, a great lover of all manly sports, granted letters patent to a Corporation of Masters of Defence some years before 1540, thus banding together the more reputable British and foreign masters in the first governing body for fencing in Great Britain. The Corporation was given a coat of arms and privileges that included the lucrative monopoly of teaching the art of fencing in the King's realms.

The first governing bodies for fencing in European countries were corporations of fencing masters generally called academies that regulated the training of young masters attached to schools and held regular tests of skill before granting diplomas.

Although fencing had been practiced in schools and clubs for centuries, both as an academic pursuit and as a preparation for duelling, it was only toward the last quarter of the 19th century that it became a competitive sport. The necessity of establishing rules for competitions led to the formation of amateur governing bodies. In Great Britain, a fencing branch of the Amateur Gymnastic Association was formed in 1895, and the Amateur Fencing Association was founded as a separate governing body in 1902. The *Fédération des Salles d'Armes et Sociétés d'Escrime* was formed in France in 1906.

After the Olympic Games of 1912 at Stockholm, when France refused to take part and Italy withdrew from the *épée* events because they disagreed with the rules, it was decided to form an international federation to codify the rules for all three weapons. On Nov. 29, 1913, the *Fédération Internationale d'Escrime* was founded at a meeting in Paris attended by the representatives of nine countries. It has become the amateur governing body for world fencing to which all national governing bodies recognized by their national Olympic committees are affiliated.

Professional fencers have their own governing bodies, or academies, in many countries, and there is a professional world governing body, the *Académie d'Armes Internationale*.

**Competition.** Europe has always been the centre of world fencing; but, especially since World War II, the sport has spread to all five continents; and in the 1970s there were over 70 nations affiliated to the International Federation. Besides the Olympic Games, a World Championship and a World Youth (under 20) Championship are organized annually for fencing with all weapons, and these have been staged in such distant places as Moscow, Montreal, Cuba, Ankara, Chicago, and Teheran. Fencing is also included in many regional games such as the British Commonwealth Games; the Pan-American Games; the Caribbean Games; the Oceanic Games; and the Universiade, or World University Games.

The earliest forms of competitive fencing were matches fought for stakes, or prizes, popularly known as prize fights, which consisted of displays and trials of swordsmanship and, from the 16th century, were exceedingly popular with all ranks of the population and were frequently patronized by royalty. In Great Britain these prize fights were held on a stage erected in a hall or a public garden, and the champions would challenge each other to bouts with a variety of weapons. These bouts were often fought with "sharps" (as opposed to blunted blades) and were most sanguinary encounters.

During the early 18th century, James Figg, known as the Atlas of the Sword and the first British boxing champion, introduced fisticuff fights into prize fights. Eventually these bare-knuckle fights became so popular that they ousted the bouts with swords so that prize fights came to be associated with boxing rather than with fencing.

From the end of the 19th century, the major international competitions at foil and *épée* were dominated by France and Italy and at sabre by Hungary and Italy, although, of course, individual champions emerged from time to time from other countries such as Cuba, Denmark, Sweden, Belgium, The Netherlands, and Poland. In the mid-1950s, however, what has come to be known as the eastern European school was established. This was

Fédération  
Internationale  
d'Escrime

based on a simplified technique with emphasis on speed, mobility, and physical attributes and the virtual abandoning of the concept of fencing as a complex and highly technical art.

This development was enhanced, especially at foil, by the introduction of the electrical judging apparatus in 1955 that removed much of the uncertainty of human judgement and led to the objective of scoring hits by the simplest methods, secure in the knowledge that the apparatus would record them. This reinforced the emphasis on youth and speed in international fencing, and many world and Olympic champions now may be in their teens or early 20s, a situation that would have been unthinkable only two decades earlier. During that period especially, interest in fencing spread throughout the world. The Japanese, for example, for centuries devoted to their highly stylized sport of fencing with staves (*kendō*), have taken up modern fencing and developed impressive proficiency, especially at foil. The long domination of international fencing by France and Italy has virtually been replaced at all weapons by the U.S.S.R., Poland, Romania, Hungary, and other eastern European countries, and the U.S.S.R. now produces the dominant teams and individual champions at all weapons.

#### THE SPORT OF FENCING

**Challenges and attractions.** Fencing provides concentrated physical exercise in a short space of time, independent of the weather, without excessive cost, without the need for a large number of players (any multiple of two persons can fence), or without expensive venues or apparatus. It develops coordination of mind and body. Indeed, it is so concentrated, swift, and absorbing that it is impossible to fence and to think of anything else at the same time. The hard physical exercise combined with total concentration of the mind makes an evening in the *salle d'armes* a complete relaxation from other cares that brings a sense of freshness and well-being.

Those concerned with sport, especially for young people, have long recognized the value of fencing for developing quick thinking, poise, balance, and muscular control and for strengthening the limbs and back. As an individual combat sport, it suits many young people who have no aptitude for ball or other games. It can be started at an early age, say 9 to 12 years old, and can be continued into maturity. Despite the recent emphasis on youth in international competition, there are many fencers who have still been in championship class at the age of 50 or more, and fencers well beyond that age can often hold their own in the *salle* with far younger and faster opponents who lack their experience and technique.

Fencing is a game of skill, speed, and finesse in which there is little advantage in mere brute strength. Control of movement and quick thinking can overcome to a great extent lack of height, reach, or strength that would be a severe handicap in many other sports.

Foil fencing is as suitable for women as for men, and, for the reasons given in the preceding paragraph, members of both sexes can fence together on far more equal terms than is possible at most active sports.

Fencing is a complex and difficult art to master. The stance, lunge, and footwork do not come naturally to most people, and much practice is needed before the necessary discipline of mind and muscles can be acquired to enable a beginner to use light weapons accurately at close quarters and with considerable speed.

Much of the interest in fencing derives from the need of the fencer not only to induce the opponent to misjudge his real intentions, but to correctly anticipate the opponent's reactions so that he can avoid them. When a thrust is made, for example, the opponent's natural reaction is to deflect the threatening blade by moving his own blade laterally to meet it; this is a simple parry. When making such a parry the sword hand has to move only a few inches across the defender's body whereas the attacker's point must travel several feet to reach the target. Obviously, to land an attack successfully this handicap of time and distance must be overcome.

The simplest way to make an opening for an attack is to

straighten the sword arm and make a direct thrust with the point threatening some unprotected part of the opponent's target; this is called a feint. When the opponent moves his hand across to parry the feint, this parry is deceived, or avoided, by moving the attacker's point to the part of the defender's target that is perforce left exposed by the parry.

If the parry is made as described above by moving the sword hand laterally from one side of the body to the other, it can be deceived by passing the attacker's blade under the defender's blade to the opposite and now exposed side of the target, a manoeuvre called a disengagement.

But a parry may also be made by keeping the sword hand in the original on guard position while making a circular movement with the blade to gather the attacker's blade and bring it back to the original position. If the opponent performs this circular form of parry, it obviously cannot be deceived by a disengagement because the circular movement of the defender's blade will collect the attacker's blade. In this case the correct stroke after making a feint is to perform a circle with the point just ahead of the defender's circular parry so that the attacker's blade ends up on the "open" side of the target toward which the original feint was made; this is called a *doublé*.

Therefore it is obvious that when launching this simple form of attack—a feint followed by a deception of the parry—it is necessary for the attacker correctly to anticipate the defender's reaction to the feint; that is, which form of parry he will favour if the attack is to have any chance of being concluded successfully.

When facing a new opponent, the fencer tries by various feints and movements to ascertain the opponent's likely reaction in order to choose the stroke likely to outwit him. But fencing is a game of subtlety, bluff, and counter-bluff, and an astute opponent may realize what is happening and may appear to favour some form of reaction to induce a certain stroke or strategy from which he, in turn, can profit.

The quicker and more complex the actions that experienced fencers attempt during a bout, the greater the speed of anticipation and execution of the counter movements that will be required. As a result, fencing has been likened to a game of chess played at lightning speed.

**Equipment and weapons.** Fencing equipment is relatively inexpensive. It consists of a fencing jacket, a mask, a glove, a foil, or other weapon, with trousers or fencing breeches, white stockings and rubber-soled gym shoes or flat-soled fencing shoes.

There is no danger in fencing—even when a blade breaks—provided regulation equipment and a mask in good condition are used at all times. In particular, the material from which fencing clothing is made must be of adequate strength for the weapon used. Thus a stronger canvas is required to resist the stiffer *épée* blade than is necessary at foil or sabre, and the sleeve, armpit, and breast on the swordarm side must be double lined and an undergarment, or *plastron*, must be worn. Ladies' jackets must include rigid breast protectors.

**Weapons.** The fencer's weapon consists of a blade and mounting. The stronger half of the blade, which is nearer to the guard, is called the *forte* and the remainder is called the *foible* (see Figure 1). The mounting consists of

Anticipating the defense

the guard, the form of which varies according to the weapon and within which there is often a small cushion to protect the fingers. There is a handle or grip with

Comparison of foil, épée, and sabre

which the weapon is held and manipulated and through which passes the shank, or tang, of the blade, to the end of which a pommel or locking nut is screwed. The pommel not only serves to hold the whole sword together but also balances the weapon.

Modern fencing is practiced with three weapons: the foil, the épée, and the sabre. The foil is just over one metre long (1.1 metre or 43.3 inches) and it weighs up to 500 grams (about 17.5 ounces). The blade is rectangular, tapering, flexible, and has a blunt point called the button. The épée is the same length as the foil but is heavier, up to 770 grams (about 27 ounces), and the blade is triangular in section and is rigid. When electrical apparatus is not used, the épée is tipped with three small prongs. When the electrical apparatus is used at foil or épée, a flattened, spring-loaded point is attached to the blade from which wires running down the blade connect to the apparatus. To score a hit by depressing the point requires a force of 500 grams (17½ ounces) at foil and 750 grams (26¾ ounces) at épée. The sabre is the same weight as the foil but is a little shorter (1.05 metres or 41.3 inches); the blade is V-shaped and narrow, rigid on the cutting edges but flexible on the flat. The sabre guard sweeps around the back of the hand to the pommel to protect the knuckles against cuts. Because of the emphasis on speed, weapons used are often lighter than the maximum weights stated above.

**The piste.** The fencing mat, or piste, on which bouts are held consists of a linoleum, cork, rubber, or composition mat or strip about 2 metres (6 feet 6¾ inches) wide and 14 metres (46 feet) long, with an extension or run back at either end of 2 metres (6 feet 6¾ inches). It is marked with a centre line, on-guard lines, warning lines, and rear-limit lines. If a retreating fencer crosses the rear-limit line after having been warned at the warning line he is penalized one hit; if he steps off the side of the strip, he incurs penalties which vary according to the weapon used. When an electric judging apparatus is used at foil or épée the whole of the piste and its extensions are covered with an insulated mat of metal mesh.

**Foil fencing.** The foil is the basic weapon with which the technique of fencing is learned, even though later on the fencer may prefer the épée or sabre. This is because the foil is the most easily manipulated of the three, and all fencing movements can be carried out with it. Also, the rules and conventions enforced at foil teach appreciation of fencing time, distance, and phrasing. A sound basic technique acquired at foil is easily adapted to the requirements of épée and sabre.

There have long been two main methods of fencing both at foil and at épée, the French and the Italian schools, and practically all variations of technique approximate to one or the other. The fundamental difference between them is the form of the mounting, which determines the method of manipulating the weapon. The French foil or épée has a bell-shaped guard and a plain, slightly curved handle. The sword is held lightly in the hand and is manipulated by the fingers. The first finger and thumb, called the manipulators, direct the sword and impart movements to the blade either by "pulling" or "pushing" with these fingers or by rolling the handle between them. The remaining fingers are wrapped round the handle and are known as the aids. The Italian foil or épée has a crossbar fixed to the inner edge of the guard and sometimes has two metal rings within. The first fingers of the sword hand are slipped through the crossbar, while the pommel of the shorter handle is bound to the wrist by a strap or a long leash. This gives great strength when holding the weapon, but there is a corresponding limitation of finger play. Neither school is superior to the other, but one or the other may prove best suited to the individual fencer's temperament and physique.

Besides these two types, a variety of specialized handles, known as orthopaedic handles, are designed to fit the hand and give greater strength of grip. They often have a flattened extension strapped to the wrist and their use approximates to the Italian style, although they are usually fitted to a French type of guard. Many fencers favour them for the heavier electrical weapons.

**The on-guard position.** The basic position adopted by a fencer is known as the on-guard position. It is designed to be the position of perfect balance from which the fencer can perform all fencing movements swiftly and smoothly. The distance maintained between two fencers when facing each other on guard is called the fencing measure, normally one at which a fencer cannot hit the nearest part of his opponent's target merely by extending his sword arm but must make a full lunge to do so.

Obviously, the fencing measure will vary according to the height and reach of the fencers, but it also varies at the different weapons. Thus at foil, the nearest part of the opponent's target is the body, and so the fencing measure is shorter than at épée or sabre where the nearest part of the target is the opponent's wrist or forearm.

A fencer adjusts the fencing measure by advancing or retiring on the piste, which is known as gaining or breaking ground. Normally this is done by taking short steps in rapid succession by advancing the leading foot a short pace and immediately bringing up the rear foot the same distance. This enables the fencer to move up and down the piste swiftly and smoothly while preserving the position of perfect balance. Other methods of adjusting the fencing measure are by a short jump forward, known as a *balestra*, usually followed by a lunge or by a running attack at great speed, known as a *flèche*.

The most effective way of landing a hit on the opponent's target from the on-guard position is by a swift extension of the sword arm, body, and legs, known as the lunge. The lunge and the recovery to the on-guard position are called the development and the return to guard.

**The target.** The target area on which a hit is valid varies with the weapon. At foil it is restricted to the opponent's trunk, back, and front and excluding the head, arms, and legs. The collar of the jacket is included in the target, but the bib of the mask, which covers part of the collar, is not. Hits must be made with the point of the foil only and are valid only if they land on the target.

For convenience, the target is divided by imaginary lines into parts that are related to the positions in which a fencer places his sword hand when on guard. When a fencer comes on guard, the parts of his target that his opponent can see above the swordhand are called the high lines and those below, the low lines. The target is divided also by a vertical line; the parts farthest from the

Figure 2: (A) Foil target. (B) Parts of the target.

sword arm are known as the inside lines, and those on the same side as the sword arm are the outside lines.

There are, in theory, eight lines that are named after the parries that are designed to protect them. Two cover each quarter of the target area. When a fencer is on guard, his sword hand will be so placed that his blade is "covering," or protecting, one of the lines of his target. This is called his fencing position, and he is said to be "on guard in quarte" or some other line.

The French and Italian schools

**Basic guard and parry positions.** The four positions that are most commonly used are quarte and sixte, septime and octave. The first two protect the high lines on either side of the target, while the last two similarly protect the low lines. In these positions the sword hand is either in supination—that is, with the fingernails upward—or in half supination, with the fingernails to the side. The four remaining positions, prime and tierce (high lines) and seconde and quinte (low lines), are less usually used at French foil. In all four the sword hand is in pronation; that is, with the fingernails downward.

When a fencer threatens with his blade some part of the opponent's target, the latter will move his sword across his body to deflect the attacking blade, which is known as the parry. The parry is named according to the line it is covering. Thus a fencer may "parry quarte" or "parry sixte" and so on.

When two fencers are on guard and cross swords, this is known as the engagement. In this position one fencer is said to be covered when he protects a line with his opponent's blade outside his own so that a direct thrust cannot reach his target. Obviously this covered position is one of

Engage-  
ment and  
disen-  
gagement

advantage and security because, in order to attack successfully, the opponent must move his blade into another line either by passing his blade under his opponent's blade by a disengagement or over it by a cutover, or coupé. Fencers frequently endeavour to gain a covered position when on guard by a change of engagement; that is, by moving the blade swiftly by finger play to another line with the opponent's blade outside. This movement can be circumvented by a counterdisengagement.

If two fencers come on guard without crossing blades, they are said to be fencing with absence of blade.

**Attacks and parries.** The object of fencing with any weapon is to land a hit on the opponent's target. There are two main types of attack. A simple attack is made by a thrust either in the line of engagement (direct) or in an opposite line by a disengagement, cutover, or counterdisengagement (indirect). A compound or composed attack is one in which the final thrust is preceded by one or more false attacks or feints designed to draw the opponent's premature parry, thus leaving some part of his target open for a hit to land.

In defense, a parry is not made by striking the threatening blade aside, which would lead to wide, easily deceived movements, but seeks to place the defender's blade in such a position that it covers the line into which the attack is launched in such a way that if the attack is pressed home it will be deflected clear of the target.

There are three basic types of parries. The simple, or direct, parry is made by the natural reaction that moves the sword laterally across the body to cover the line that is being attacked. The semicircular, or indirect, parry is made from an engagement in the high line to meet an attack directed into a low line, or vice versa. In a semicircular parry, the defender's blade describes a half circle while the sword hand is maintained in its original position. The circular or counterparry is made by a circular movement of the blade without altering the position of the sword arm, so that the threatening blade is gathered and brought back to the original line of engagement.

**The riposte.** After a fencer has successfully parried an attack, he can, in his turn, take up the offensive by making a reply, or riposte. Ripostes are similar to attacks in that they may be simple, either direct or indirect, or compound.

If an attack is parried and the riposte is parried, the next offensive movement made by the original attacker is called the counterriposte. Counterripostes may be simple or compound, and there may be a whole series of counterripostes in a fencing phrase before a hit is scored.

**Counterattacks.** In certain circumstances, when an attack is launched, the defender may be able to seize the initiative and score with a counterattack either by making a direct thrust or stop hit or by making a stop hit with opposition that deflects the attacker's blade at the same time. If an opponent can be induced to attempt a stop hit, either by an invitation or a false attack, this can be turned to advantage by parrying the stop hit and scoring with a riposte. This is called countertime, or second intention, and is used especially at épée and sabre.

**Preparations of attack.** Against an experienced opponent, it is often necessary to create an opening for an attack. This may consist merely of a change of distance by a step forward or backward or some movement designed to deflect the opponent's blade or obtain a reaction from it. Preparations of attack may consist of attacks on the blade such as a beat, pressure, or graze along the opponent's blade or of *prises de fer* (taking the blade) by an envelopment, bind, or *croisé*. These various forms of preparation may be used singly or combined in various ways. They may be used strongly—for example, a strong beat that strikes the defender's blade aside—or with subtlety—for example, a slight pressure that induces the opponent to respond in the same line. These preparations may precede a simple or compound attack and they can be used equally well to make an opening for a riposte.

Competition foil fencing is subject to rather complex rules designed to encourage a sequence of movements that will build up a fencing phrase and discourage a mere series of simultaneous jabs. The judging of a bout at foil

is based on the convention referred to above; namely, that an attack, which may be defined as an offensive movement that continuously threatens some part of the opponent's target, has the right-of-way until it is deflected or parried, after which the right-of-way passes to the defender for his riposte. If the riposte is parried, the right-of-way reverts to the original attacker for his counterriposte, and so on until a hit is scored.

An exception to the foregoing is the stop hit, which is a counterattack made on the opponent's offensive movement. It is usually attempted if the attack is made slowly or with a bent arm or with too many feints or while the attacker is advancing. Under the rules, a stop hit is only valid if it arrives at least one period of "fencing time" before the attack. Fencing time is defined as the time taken to perform one single fencing movement, which may be a blade movement, an arm movement, or a foot movement such as a step forward. As different fencers will perform such movements at different speeds, the period of fencing time will vary according to the fencer.

**Épée fencing.** The épée is held and manipulated with the fingers in the same way as the foil. The on-guard position, however, is somewhat different because the forearm, being part of the target, has to be protected at all times by the guard of the weapon. Moreover, as already mentioned, the fencing measure is taken from the opponent's wrist. Mobility and lightness of footwork are essential for the épéeist to overcome this wider measure or prevent the opponent from doing so, and for the same reason the *flèche* attack is much used. Accuracy in placing the point on the small and usually moving target provided by the wrist or forearm, at speed and from any angle, is an essential attribute for an épéeist. The stop hit, countertime, and renewals of attack are much used in bouts with this weapon. Indeed, the everpresent threat of a stop hit brings a special caution to épée fencing. To minimize this risk, preparations of attack, especially *prises de fer*, are much used, and the épéeist tries to ensure that his movements are made covered.

The rules governing épée fencing are designed to make this weapon conform as closely as possible to the conditions of a duel. Hits made with the point are valid wherever they arrive on the opponent or his equipment. There are no conventions about rights of attack and so on. If both fencers are hit, priority between the hits is established entirely according to the relative time of the arrival of the hits. If no practical difference of time between the hit exists, a hit is scored against each competitor, called a double hit. Similarly, if a bout ends with an even score of hits against each, a double defeat is recorded.

**Sabre fencing.** The sabre is the cut and thrust weapon. Hits at sabre may be made with the whole of the front edge or the third of the back edge nearest the point (cuts) as well as with the point. The valid target includes the arms, head, and trunk down to a line just below the waist.

The sabre is held somewhat differently than the other two weapons, but it is similarly manipulated by finger play. The blade is directed by the thumb and first finger, but these movements are assisted by the little finger. To make a cut, the sword arm is extended and the edge of the sabre is presented at the target.

Great mobility of footwork and exact judgement of distance are essential to deal with the wide fencing measure usually maintained, and the *balestra* and *flèche* are much used. The wide target necessitates constant vigilance against a stop hit on the forearm, and attacks on the blade and countertime are much used.

The use of cuts as well as thrusts introduces a special variety into sabre play and gives an advantage at this weapon to the attack over defense. Parries often have to withstand cuts made with considerable force. It is therefore essential that parries be taken firmly by opposing the edge of the sabre to the attacker's blade and ensuring that the principle of defence—namely, opposing the forte of the defender's blade to the foible of the attacker's (which indeed applies at all weapons)—is strictly observed.

There are six parries at sabre covering every part of the target and corresponding, of course, to the lines of en-

Right of  
way and  
fencing  
time

A modern  
duel

Parries and  
ripostes

gement. While sixte is rarely used, the normal third position with the hand breast high is differentiated from the low third with the hand held level with the hip and the blade almost vertical.

Sabre fencing, which is conducted according to rules and conventions similar to those that govern foil fencing, combines the conventional orthodoxy of the foil with the tactics and opportunism of the épée. It requires more athletic qualities than either of the other weapons. The use of the edge as well as the point, combined with the comparatively wide target, increases the variety of

strokes available. Variations of cadence and rhythm are much used.

**Judging of bouts.** A bout between men at foil, épée, or sabre is fenced for five hits (best of nine hits). At ladies' foil a bout is four hits. The time limit for a bout is six minutes of actual fencing time for men and five minutes for ladies.

Judging a fencing competition requires great experience because of the complexity and speed of movements and the constant mobility of the competitors. A good judge must be able to "read the phrase"; that is, to follow and

Figure 4: The sabre parries.

Electrical  
judging  
apparatus

be able to reconstruct all the fencing movements exchanged that led up to the scoring of a hit.

Foil and épée competitions are judged with an electrical judging apparatus that registers the arrival of hits. The weapon is fitted with a spring-loaded point connected by fine wires that run down a groove in the blade to a plug inside the guard; this is connected through wires running inside the sleeve of the fencer's jacket to a spring-loaded spool at the end of the piste that takes up the slack as the fencers move up and down, which in turn is connected to the central judging apparatus that registers hits on either fencer by light and sound signals.

At foil it is necessary for the apparatus to differentiate between hits made on the target (the trunk) and hits that arrive off the target. The fencers, therefore, wear metallic overjackets that entirely cover the valid target. A hit on the target is registered by a coloured light, while a hit off the target is registered by a white light. A white and a coloured light on the same side of the apparatus shows that a hit off the target has preceded a valid hit. Otherwise the foil apparatus does not indicate any priority between the arrival of hits on either fencer. It is therefore necessary to have a president (also called a referee or director) to "read the phrase" and award hits according to rules and conventions applicable to foil fencing.

At épée, the apparatus judges completely and automatically because it can time exactly the arrival of hits. If a hit on one fencer arrives more than  $\frac{1}{25}$  of a second before he makes a hit on his opponent, only the first hit will be recorded. If both fencers are hit within  $\frac{1}{25}$  of a second the apparatus registers a double hit. At épée, therefore, the president directs the bouts and sees that the rules are observed, but the arrival and judgement of hits is completely registered by the apparatus without his intervention.

No electrical apparatus is used for judging sabre. It is necessary, therefore, to have two pairs of judges, one pair at either end of the piste, to observe the arrival of hits and decide whether such hits are on or off the target. The president controls the bout and awards hits according to the rules and conventions applicable to sabre fencing.

(C.-L.de B.)

## Ferdinand II, Emperor

Ferdinand II, Holy Roman emperor, archduke of Austria, king of Bohemia and Hungary, is known principally as the emperor of the Counter-Reformation—the reassertion and reform of Catholicism—and for his attempted eradication of Protestantism in his lands, which led to the Thirty Years' War. He was born in Graz on July 9, 1578, the eldest son of the archduke Charles, the ruler of Inner Austria (Styria, Carinthia, and Carniola),

and Maria, a daughter of Albrecht V, duke of Bavaria. From 1590 to 1595 Ferdinand was educated by Jesuits at the University of Ingolstadt whose aim was to make him a strict, rigidly Catholic ruler. In 1596 he took over his hereditary lands and, after a pilgrimage to Loreto and Rome, set about suppressing Protestantism by forcing the great majority of his subjects to adopt the Catholic faith. In 1600 he married Maria Anna of Bavaria, who bore him four children. He avoided committing himself in a quarrel between his cousins, the emperor Rudolf II and his brother Matthias, who eventually succeeded Rudolf as emperor. Later Ferdinand secured approval from the Habsburg rulers of Spain to succeed the childless Matthias. In return he promised in a secret treaty (1617), to cede to them the Alsace and the imperial fiefs in Italy. In the same year Ferdinand was recognized by the Bohemian Diet as king of Bohemia and in 1618 was elected king of Hungary. In 1619, however, the largely Protestant diet of Bohemia deposed him, electing Frederick V, elector of the Palatinate, as their king. This was, in effect, the beginning of the Thirty Years' War. Though elected emperor on August 28, 1619, Ferdinand was able to maintain himself only with support from Spain, Poland, and various German princes. Aided by Maximilian I, duke of Bavaria, his troops annihilated the rebel army on the White Mountain, near Prague, on November 8, 1620. He confiscated the estates of the rebel magnates, reduced the diet to impotence by a new constituent ordinance (1627), and forcibly catholicized Bohemia. Protestants of Upper and Lower Austria were subjected to compulsory conversion.

Ferdinand II, engraving by an unknown artist.

During the first decade of the Thirty Years' War, Ferdinand strengthened his position by transferring the Palatinate's electoral office to Maximilian of Bavaria and, with the help of Spain and the league of Catholic princes of Germany, but chiefly through the victories of his generalissimo Albrecht von Wallenstein, gained important successes over his opponents in Germany and the King of Denmark. Until then the war largely had been confined to Germany, but Swedish and, later on, French intervention turned it into a European conflict. Ferdinand's Edict of Restitution (1629), which forced Protestants to return to the Roman Catholic Church all property seized since 1552, revealed to the German princes the threat of imperial absolutism. Their opposition forced Ferdinand in 1630 to dismiss Wallenstein, the mainstay of his power. The victorious advance of the Swedish army, however, made the Emperor recall Wallenstein. Eventually, for reasons of state, Ferdinand reluctantly gave his consent to a second dismissal and the assassination of Wallenstein, who had treacherously entered into

Ferdinand  
and Wal-  
enstein

negotiations with the enemy (1634). After his victory over the Swedes (September 1634) at Nördlingen, Ferdinand reached a compromise with the Protestant princes in the Peace of Prague (1635) and, in 1636, succeeded in having his son Ferdinand elected king of the Romans (successor-designate to the emperor). Ferdinand II, who had been married to his second wife, Eleonora Gonzaga of Mantua, since 1622, died in Vienna on February 15, 1637.

In the prime of his life Ferdinand was described as a blue-eyed, somewhat corpulent, middle-sized man who wore Spanish court dress. A good-natured, benevolent, affable monarch, he was imbued with the belief in the splendour of the imperial crown and the greatness of his dynasty. Besides German he spoke Italian, French, and Spanish, was fond of music, and liked reading religious books, but his passion was hunting. Although he kept a frugal court, he was a bad financier who too generously gave away the greatest part of confiscated estates to his faithful followers. A very pious Catholic, he especially favoured the Jesuits. Yet, basing his policies chiefly on religious principles, he suffered from discrepancies between his religious goals and the maxims of a modern *raison d'état*. An indecisive man, he depended much on the influence of his councillors and his Jesuit confessors. Yet in the face of the shifting fortunes of war he showed much steadfastness, although he often lacked political agility. A person of moderate talents and willpower, he nevertheless exerted a strong influence on the events of his time by his strict and uncompromising religious policy.

By promoting the Counter-Reformation, Ferdinand II set the course of Austrian Habsburg policy for the next century. By creating an independent Austrian court chancellery and by establishing in his will the principles of Austria's indivisibility and of primogeniture in his family, he made an essential contribution to the country's national integration. Yet by maintaining the country's historical provinces and estates, after their subjugation, he preserved the principle of federalism in Austria. Ferdinand's Catholic contemporaries considered him a saint-like monarch; his Protestant opponents feared him as a tyrant. Catholic historiography of the 19th century assigned him too high a place, while liberal historians were likely to underestimate his importance. Modern historians tend to view Ferdinand's religious policy as determined by his time, to acknowledge his importance in molding Austria's provinces into an integral whole, and to see in his imperial policy an attempt at creating a Catholic German state, however, inconsistently carried out.

**BIBLIOGRAPHY.** F. HURTER, *Geschichte Kaiser Ferdinands II. und seiner Eltern*, 11 vol. (1850-64), still has to be referred to above all, in spite of its biased glorification of Ferdinand. F. STIEVE, "Kaiser Ferdinand II.," in *Allgemeine Deutsche Biographie*, vol. 6 (1877), is the first critical biographical valuation of the Emperor, with a strong liberal colouring. H. HANTSCH, "Kaiser Ferdinand II.," in *Gestalten der Geschichte Oesterreichs* (1962), evaluates the deeds of Ferdinand very positively from a strictly Catholic point of view; H. VON SRBIK, *Wallensteins Ende* (1952), is very critical of Ferdinand. An English-language account is C.V. WEDGWOOD, *The Thirty Years War* (1944).

## Ferdinand II, the Catholic, of Aragon

Known by different names in Sicily, Aragon, Castile, Naples, Navarre, and other kingdoms under his unified government, Ferdinand II of Aragon (Ferdinand V of Castile), called the Catholic, was a monarch who formed a bridge between the Middle Ages and the modern period. He established important bases for national unity in Spain, created the framework for the modern sovereign state, and initiated an international policy of imperial expansion. He has been controversial because of some of his personal qualities and methods of government, but historians have regarded him as a political king, a master of statecraft.

Ferdinand was born in Sos on March 10, 1452, the son of John II of Aragon and Juana Enríquez, both of Cas-

tilian origin. In 1461, in the midst of a bitterly contested succession, John II named him heir apparent and governor of all his kingdoms and lands. Ferdinand's future was assured when he came of age, in 1466, and when he was named king of Sicily, in 1468, in order to impress the court of Castile, where his father ultimately wished to place him. In addition to participating in court life, the young prince saw battle during the Catalan wars. In the summer of 1468, beginning to sow his wild oats, he went courting; the first fruits of these adventures were Alfonso of Aragon, future archbishop of Saragossa and his father's favourite, and Juana of Aragon.

John II was careful about Ferdinand's education and took personal charge of it, making sure that Ferdinand learned as much as possible from experience. He also provided him with teachers who taught him humanistic attitudes and wrote him treatises on the art of government. Ferdinand had no apparent bent for formal studies, but he was a patron of the arts and a devotee of vocal and instrumental music.

Ferdinand had an imposing personality but was never very genial. From his father he acquired sagacity, integrity, courage, and a calculated reserve; from his mother, an impulsive emotionality, which he generally repressed. Under the responsibility of kingship he had to conceal his stronger passions and adopt a cold, impenetrable mask.

He married the princess Isabella of Castile in Valladolid in October 1469. This was a marriage of political opportunism not romance. The court of Aragon dreamed of a return to Castile, and Isabella needed help to gain succession to the throne. The marriage initiated a dark and troubled life, in which Ferdinand fought on the Castilian and Aragonese fronts in order to impose his authority over the noble oligarchies, shifting his basis of support from one kingdom to the other according to the intensity of the danger. Despite the political nature of the union, he loved Isabella sincerely. She quickly bore him children: the infanta Isabella was born in 1470; the heir apparent, John, in 1478; and the infantas Juana (later Joan the Mad), Catalina (later Catharine of Aragon), and María followed. The marriage began, however, with almost continual separation. Ferdinand, often away in the Castilian towns or on journeys to Aragon, reproached his wife for the comfort of her life. At the

Assessment

Early life

## Early reign

same time, the restlessness of his 20 years drove him into other women's arms, by whom he sired at least two female children, whose birth dates are not recorded.

Between the ages of 20 and 30, Ferdinand performed a series of heroic deeds. These began when Henry IV of Castile died on December 11, 1474, leaving his succession in dispute. Ferdinand rushed from Saragossa to Segovia, where Isabella had herself proclaimed queen of Castile on December 13. Ferdinand remained there as king consort, an uneasy, marginal figure, until Isabella's war of succession against Afonso V of Portugal gained his acceptance in 1479 as king in every sense of the word. That same year John II died, and Ferdinand succeeded to the Aragonese throne. This initiated a confederation of kingdoms, which was the institutional basis for modern Spain.

The events of this period bring out the young king's character more clearly. In portraits he appears with soft, well-proportioned features, a small, sensual mouth, and pensive eyes. His literary descriptions are more complicated, although they agree in presenting him as good-looking, of medium height, and a good rider, devoted to games and to the hunt. He had a clear, strong voice. He was something of a ladies' man, which caused Isabella jealously for several years.

From 1475 to 1479 Ferdinand struggled to take a firm seat in Castile with his young wife and to transform the kingdom politically, using new institutional molds partly inspired by those of Aragon. This policy of modernization included a ban against all religions other than Catholicism. The establishment of the Spanish Inquisition (1478) to enforce religious uniformity and the expulsion of the Jews (1492) were both part of a deliberate policy designed to strengthen the church, which would in turn support the crown.

## Conquest of Granada

The years 1482–92 were frantic for Ferdinand. In the spring months he directed the campaign against the Kingdom of Granada, showing his military talent to good effect, and he conquered the kingdom inch by inch, winning its final capitulation on January 2, 1492. During the months of rest from war he visited his kingdoms, learning their geography and problems firsthand.

The conquest of Granada made it possible to support Christopher Columbus' voyages of exploration across the Atlantic. It is not known what Ferdinand thought of Columbus or how he judged his plans, nor can it be stated that the first trip was financed from Aragon; the sum of 1,157,000 maravedis came from the funds of the Santa Hermandad (Holy Brotherhood). Nevertheless, Ferdinand was present in the development of plans for the enterprise, in the negotiations to obtain the pope's backing for it, and in the organization of the resulting American colonies.

At the age of 50 Ferdinand was an incarnation of royalty, and fortune smiled on him. For various reasons, particularly for his intervention in Italy, Pope Alexander VI gave him the honorary title of "the Catholic" on December 2, 1496. But he also suffered a succession of tragedies: the heir apparent and his eldest daughter both died, and the first symptoms of insanity appeared in his daughter Joan. He was wounded in Barcelona in 1493, but this was unimportant compared with the family injuries he suffered, which culminated in the death of Isabella in 1504, "the best and most excellent wife king ever had."

To secure his position in Castile, Ferdinand married Germaine de Foix, niece of the King of France, on October 19, 1505; this was a political marriage, although he always showed her the highest regard. A stay in Italy (1506–07) demonstrated how badly he was needed by the peninsular kingdoms. Once more in Castile, he managed his European policy so as to obtain a hegemony that would serve his expansionary ends in the Mediterranean and in Africa. In 1512, immediately after the schism in the church in which the kings of Navarre participated, he occupied their kingdom and incorporated it into Castile—one of the most controversial acts of his reign.

In 1513 his health began to decay, though he was still

able to direct his international policy and to prepare the succession of his grandson Charles. In early 1516 he began a trip to Granada; he stopped in Madrigalejo, the little site of the sanctuary of Guadalupe, where he died on January 23, 1516. The previous day he had signed his last will and testament, an excellent picture of the monarch and of the political situation at his death.

Many considered Ferdinand the saviour of his kingdoms, a bringer of unity. Others despised him for having oppressed them. Machiavelli attributed to him the objectionable qualities of the Renaissance prince. The German traveller Thomas Müntzer and the Italian diplomat Francesco Guicciardini, who knew him personally, compared him with Charlemagne. His will indicates that he died with a clear conscience, ordering that his body should be moved to Granada and buried next to that of his wife Isabella, so that they might be reunited for eternity. He died convinced that the crown of Spain had not been so powerful for 700 years, "and all, after God, because of my work and my labour."

## Assessments of Ferdinand

**BIBLIOGRAPHY.** *V Congreso de Historia de la Corona de Aragón*, 5 vol. (1956–62), the most important study of Ferdinand's life and work, with a full critical bibliography; J. VINCENS VIVES, *Fernando el Católico, príncipe de Aragón, rey de Sicilia (1452–78)* (1951), a well-documented account of the period to 1479; R. DEL ARCO, *Fernando el Católico, artífice de la España imperial* (1939), a fairly recent and complete biography; W.H. PRESCOTT, *History of the Reign of Ferdinand and Isabella, the Catholic of Spain*, 4th ed., 3 vol. (1846), an outstanding seminal work, now somewhat dated; H. KAMEN, *The Spanish Inquisition* (1965), an important contribution to the understanding of this institution; B. NETANYAHU, *Don Isaac Abravanel, Statesman and Philosopher* (1953), an indispensable study for understanding Ferdinand's role in the expulsion of the Jews; T. DE AZCONA, *Isabel la Católica: estudio crítico de su vida y su reinado* (1964), a study of many aspects of Ferdinand's life and work, particularly his religious and ecclesiastical policy.

## Ferdowsī

The Persians regard Ferdowsī (Firdawsī, Firdusi, Firdousi) as the greatest of their poets. For nearly a thousand years they have continued to read and to listen to recitations from his masterwork, the *Shāh-nāmeḥ* ("Book of Kings"), in which the Persian national epic found its final and enduring form. Though written before the Norman conquest, it is as intelligible to the average, modern Persian as is the Authorized (King James) Version of the Bible to a modern Englishman. The language, based as the poem is on a Pahlavi original, is pure Persian with only the slightest admixture of Arabic. European scholars have criticized what they have regarded as the monotonous metre, the constant repetitions, and the stereotyped similes of this enormous poem; but to the Persian it is the history of his country's glorious past, preserved for all time in sonorous and majestic verse.

**Legends of his life.** The real name of the creator of the *Shāh-nāmeḥ* was Abū ol-Qāsem Mānšūr (or Ḥasan or Ahmad), Ferdowsī being a nom de plume. He was born c. 935 in a village on the outskirts of the ancient city of Tūs (near the city of Meshed in northeast Iran). In the course of the centuries many legends have been woven around the poet's name but very little is known about the real facts of his life. Something can be gathered from the personal references scattered here and there throughout his poem, but otherwise the only reliable source is the account given by Neẓāmī-ye 'Arūzī, a 12th-century poet who visited Ferdowsī's tomb in 1116 or 1117 and collected the traditions that were current in his birthplace less than a century after his death. According to Neẓāmī, Ferdowsī was a *dehqān* or landowner, deriving a comfortable income from his estates. He had only one child, a daughter, and it was to provide her with a dowry that he set his hand to the task that was to occupy him for 35 years. The *Shāh-nāmeḥ* of Ferdowsī, a poem of nearly 60,000 couplets, is based mainly on a prose work of the same name compiled in the poet's early manhood in his native Tūs. This prose *Shāh-nāmeḥ* was for the most part the translation of a Pahlavi (Middle Persian) work, the

*Khvatāy-nāmak*, a history of the kings of Persia from mythical times down to the reign of Khosrow II (590–628), but it also contained additional material continuing the story to the overthrow of the Sāsānians by the Arabs in the middle of the 7th century. The first to undertake the versification of this chronicle of pre-Islāmic and legendary Persia was Daqīqī, a poet at the court of the Sāmānids, who came to a violent end after completing only 1,000 verses. These verses, which deal with the rise of the prophet Zoroaster, were afterward incorporated by Ferdowsī, with due acknowledgements, in his own poem.

The *Shāh-nāmah*, finally completed in 1010, was presented to the celebrated sultan Maḥmūd of Ghazna, who by that time had made himself master of Ferdowsī's homeland, Khūrasān. Information on the relations between poet and patron is largely legendary. According to Nezāmī-ye 'Arūzī, Ferdowsī came to Ghazna in person, and through the good offices of the minister Aḥmad ebn Hasan Meymandī was able to secure the sultan's acceptance of the poem. Unfortunately, Maḥmūd then consulted certain enemies of the minister as to the poet's reward. They suggested that Ferdowsī should be given 50,000 dirhams, and even this, they said, was too much, in view of his heretical Shī'ite tenets. Maḥmūd, a bigoted Sunni, was influenced by their words, and in the end Ferdowsī received only 20,000 dirhams. Bitterly disappointed, he went to the bath and, on coming out, bought a draft of *foqā'* (a kind of beer) and divided the whole of the money between the bath attendant and the seller of *foqā'*.

Fearing the sultan's wrath, he fled first to Herāt, where he remained in hiding for six months, and then, by way of his native Tūs, to Mazanderan, where he found refuge at the court of the Sepahbād Shahreyār, whose family claimed descent from the last of the Sāsānians. There Ferdowsī composed a satire of 100 verses on Sultan Maḥmūd that he inserted in the preface of the *Shāh-nāmah* and read out to Shahreyār, at the same time offering to dedicate the poem to him, as a descendant of the ancient kings of Persia, instead of to Maḥmūd. Shahreyār, however, persuaded him to leave the dedication to Maḥmūd's name, bought the satire from him for 1,000 dirhams a verse and caused it to be expunged from the

poem. Nezāmī adds that Ferdowsī also destroyed his rough copy of the satire and that in his day only six verses remained extant. This is, of course, inconsistent with the fact that the whole text, bearing every mark of authenticity, has survived to the present day.

**Last days.** It was long supposed that in his old age the poet had spent some time in western Persia or even in Baghdad under the protection of the Būyids, but this assumption was based upon his presumed authorship of *Yūsuf o-Zalikhā*, an epic poem on the subject of Joseph and Potiphar's wife, which, it later became known, was composed more than 100 years after Ferdowsī's death. For an account of his last days it is necessary to fall back upon the narrative of Nezāmī-ye 'Arūzī. Sultan Maḥmūd was returning from one of his campaigns in India when the minister Aḥmad ebn Hasan Meymandī, by means of an apposite quotation from the *Shāh-nāmah*, reminded him of his shabby treatment of Ferdowsī. The sultan determined to make amends and, upon returning to Ghazna, gave orders that 60,000 dinars' worth of indigo should be given to Ferdowsī and that it should be transported to Tūs on the royal camels. The indigo reached Tūs in safety; but as the camels were entering the town by one gate, Ferdowsī's bier was being carried out through another. A fanatical preacher had denied the poet burial in the Muslim cemetery, and his body was being taken to its final resting place in a garden that belonged to the poet outside the walls of the town. Ferdowsī was survived by his daughter, who proudly refused the sultan's gift; in the end the money was spent on repairing a rest-house on the boundaries of Tūs. Nezāmī does not mention the date of Ferdowsī's death. The earliest date given by later authorities is 1020 and the latest 1026; it is certain that he lived to be more than 80.

**BIBLIOGRAPHY.** The only complete translation of the *Shāh-nāmah* ("The Book of Kings") is still the French version by J. MOHL, facing the text of his edition of the original (1838–78) and also published separately (1876–78). The best and most recent English translation is *The Epic of the Kings* by REUBEN LEVY (1967), which embraces the whole work but summarizes many of the linking passages. T. NOELDEKE's splendid monograph, *Das iranische Nationalepos*, 2nd ed. (1920), remains unsurpassed; and E.G. BROWNE, *A Literary History of Persia*, 2 vol. (1902–06), may still be consulted with profit; but for a digest of research of the past 50 years, see J. RYPKA et al., *History of Iranian Literature* (1968), which also contains a very full bibliography.

(J.A.Bo.)

## Fermat, Pierre de

Together with René Descartes, Pierre de Fermat was one of the two leading mathematicians of the first half of the 17th century. In the modern theory of numbers he was without a peer until the time of Leonhard Euler, a century later. Independently of Descartes, Fermat discovered the fundamental principle of analytic geometry. For his methods for finding tangents to curves and their maximum and minimum points, he has been regarded as the inventor of the differential calculus. Through his correspondence with Blaise Pascal he was a co-founder of the theory of probability. For Fermat, a punctilious counselor of the parliament of Toulouse and a lover of classical learning, mathematics was only an avocation. Since he made his living as a jurist, he became known as the "Prince of Amateurs."

Fermat is reported to have been born on August 17, 1601, at Beaumont-de-Lomagne (on his tombstone his age at death is given as 57). Little is known of his early life and education; of Basque origin, he received his primary education in a local Franciscan school. He studied law, probably at Toulouse and perhaps also at Bordeaux. Having developed tastes for foreign languages, classical literature, and ancient science and mathematics, Fermat followed the custom of his day in composing conjectural "restorations" of lost works of antiquity. By 1629 he had begun a reconstruction of the long-lost *Plane Loci* of Apollonius, the Greek geometer of the 3rd century B.C. He soon found that the study of loci, or sets of points with certain characteristics, could be facilitated by the application of algebra to geometry through a coordinate

Early work in geometry

Flight from the sultan

system. Meanwhile, Descartes had observed the same basic principle of analytic geometry, that equations in two variable quantities define plane curves. Because Fermat's *Introduction to Loci* was published posthumously in 1679, the exploitation of their discovery, initiated in Descartes' *Géométrie* of 1637, has since been known as Cartesian geometry.

By courtesy of the Musées de la Ville de Narbonne, France

Fermat, portrait by Roland Lefèvre (1608–77). In the Musées de la Ville de Narbonne, France.

In 1631 Fermat received the baccalaureate in law from the University of Orléans. He served in the local parliament at Toulouse, becoming councillor in 1634. Sometime before 1638 he became known as Pierre de Fermat; there is uncertainty as to the authority for this designation. In 1638 he was named to the Criminal Court.

Fermat's study of curves and equations prompted him to generalize the equation for the ordinary parabola  $ay = x^2$ , and that for the rectangular hyperbola  $xy = a^2$ , to the form  $a^{n-1}y = x^n$ . The curves determined by this equation are known as the parabolas and hyperbolas of Fermat according as  $n$  is positive or negative. He similarly generalized the Archimedean spiral  $r = a\theta$ . These curves in turn directed him in the middle 1630s to an algorithm, or rule of mathematical procedure, that was equivalent to differentiation. This procedure enabled him to find equations of tangents to curves and to locate maximum, minimum, and inflection points of polynomial curves, which are graphs of linear combinations of powers of the independent variable. During the same years he found formulas for areas bounded by these curves through a summation process that is equivalent to the formula now used for the same purpose in the integral calculus. Such a formula is:

$$A = \int_0^a x^n dx = a^{n+1}/(n+1).$$

It is not known whether or not Fermat noticed that differentiation of  $x^n$ , leading to  $na^{n-1}$ , is the inverse of integrating  $x^n$ . Through ingenious transformations he handled problems involving more general algebraic curves, and he applied his analysis of infinitesimal quantities to a variety of other problems, including the calculation of centres of gravity and finding the lengths of curves. Descartes in the *Géométrie* had reiterated the widely held view, stemming from Aristotle, that the precise rectification or determination of the length of algebraic curves was impossible; but Fermat was one of several mathematicians who, in the years 1657–59, disproved the dogma. In a paper entitled "De Linearum Curvarum cum Lineis Rectis Comparatione" ("Concerning the Comparison of Curved Lines with Straight Lines") he showed that the semicubical parabola and certain other algebraic curves were strictly rectifiable. He solved also the related problem of finding the surface area of a segment of a paraboloid of revolution. This paper appeared in a supplement to the *Veterum Geometria Pro-*

*mota*, issued by the mathematician Antoine de La Loubère in 1660. It was Fermat's only mathematical work published in his lifetime.

Fermat differed also with Cartesian views concerning the law of refraction (the sines of the angles of incidence and refraction of light passing through media of different densities are in a constant ratio), published by Descartes in 1637 in *La Dioptrique*; like *La Géométrie*, it was an appendix to his celebrated *Discours de la méthode*. Descartes had sought to justify the sine law through a premise that light travels more rapidly in the denser of the two media involved in the refraction. Twenty years later Fermat noted that this appeared to be in conflict with the view espoused by Aristotelians that nature always chooses the shortest path. Applying his method of maxima and minima and making the assumption that light travels less rapidly in the denser medium, Fermat showed that the law of refraction is consonant with his "principle of least time." His argument concerning the speed of light was found later to be in agreement with the wave theory of the 17th-century Dutch scientist Christiaan Huygens, and in 1849 it was verified experimentally by a French physicist, A.-H.-L. Fizeau.

Through the mathematician and theologian Marin Mersenne, who, as a friend of Descartes, often acted as an intermediary with other scholars, Fermat in 1638 maintained a controversy with Descartes on the validity of their respective methods for tangents to curves. Fermat's views were fully justified some 30 years later in the calculus of Sir Isaac Newton. Recognition of the significance of Fermat's work in analysis was tardy, in part because he adhered to the system of mathematical symbols devised by François Viète, notations that Descartes' *Géométrie* had rendered largely obsolete. The handicap imposed by the awkward notations operated less severely in Fermat's favourite field of study, the theory of numbers; but here, unfortunately, he found no correspondent to share his enthusiasm. In 1654 he had enjoyed an exchange of letters with his fellow mathematician Blaise Pascal on problems in probability concerning games of chance, the results of which were extended and published by Huygens in his *De Ratiociniis in Ludo Aleae* (1657). Fermat vainly sought to persuade Pascal to join him in research in number theory. Inspired by an edition in 1621 of the *Arithmetic* of Diophantus, the Greek mathematician of the 3rd century AD, Fermat had discovered new results in the so-called higher arithmetic, many of which concerned properties of prime numbers (those positive integers that have no factors other than 1 and themselves). One of the most elegant of these had been the theorem that every prime of the form  $4n + 1$  is uniquely expressible as the sum of two squares. A more important result, now known as Fermat's lesser theorem, asserts that if  $p$  is a prime number and if  $a$  is any positive integer, then  $a^p - a$  is divisible by  $p$ . Fermat seldom gave demonstrations of his results, and in this case proofs were provided by Gottfried Leibniz, the 17th-century German mathematician and philosopher, and Leonhard Euler, the 18th-century Swiss mathematician. For occasional demonstrations of his theorems Fermat used a device that he called his method of "infinite descent," an inverted form of reasoning by recurrence or mathematical induction. One unproved conjecture by Fermat turned out to be false. In 1640, in letters to mathematicians and to other knowledgeable thinkers of the day, including Blaise Pascal, the French writer and scientist, he announced his belief that numbers of the form  $2^{2^n} + 1$ , known since as "numbers of Fermat," are necessarily prime; but a century later Euler showed that  $2^{2^5} + 1$  has 641 as a factor. It is not known if there are any primes among the Fermat numbers for  $n > 5$ . Carl Friedrich Gauss in 1796 in Germany found an unexpected application for Fermat numbers when he showed that a regular polygon of  $N$  sides is constructible in a Euclidean sense if  $N$  is a prime Fermat number or a product of distinct Fermat primes. By far the best known of Fermat's many theorems is an unsolved problem known as his "great," or "last," theorem. This appeared in the margin of his copy of Diophantus' *Arithmetic* and states that the equation

Fermat numbers

Analyses of curves

$x^n + y^n = z^n$ , where  $x, y, z$ , and  $n$  are positive integers, has no solution if  $n$  is greater than 2.

Fermat was the most productive mathematician of his day. But his influence was circumscribed by his reluctance to publish. During the three centuries following his death at Castres on January 12, 1665, no substantial biography appeared.

**BIBLIOGRAPHY.** Much of Fermat's work, edited by his son, was published in *Opera mathematica*, 2 vol. (1679). The definitive edition, in Latin and French, is the *Oeuvres de Fermat*, ed. by PAUL TANNERY and CHARLES HENRY, 5 pt. (1891–1922). A substantial and authoritative summary of Fermat's achievements is provided in J.E. HOFMANN, "Pierre Fermat—ein Pionier der neuen Mathematik," *Praxis der Mathematik*, 7:113–119, 171–180, 197–203 (1965); and MICHAEL S. MAHONEY, *The Mathematical Career of Pierre de Fermat, 1601–1665* (1973). For more specialized aspects of Fermat's work see L.E. DICKSON, *History of the Theory of Numbers*, 3 vol. (1919–27); C.B. BOYER, *History of Analytic Geometry* (1956) and *History of the Calculus and Its Conceptual Development* (1959); ISAAC TODHUNTER, *A History of the Mathematical Theory of Probability from the Time of Pascal to That of Laplace* (1865, reprinted 1949); and PER STROMHOLM, "Fermat's Methods of Maxima and Minima and of Tangents: A Reconstruction," *Arch. Hist. Exact Sci.*, 5:47–69 (1968).

## Fermi, Enrico

Enrico Fermi, Italian–U.S. theoretical physicist, was one of the chief architects of the nuclear age. He discovered the effectiveness of the "slow" neutron in producing artificial disintegration of the atom and was also the first to achieve a controlled nuclear chain reaction. In theoretical physics he is well-known for the so-called Fermi–Dirac statistics, a mathematical method for predicting atomic structure and behaviour.

Fermi.

Fermi was born in Rome on September 29, 1901, the youngest of the three children of Alberto Fermi, a railroad employee, and Ida de Gattis. Enrico, an energetic and imaginative student prodigy in high school, decided to become a physicist. At the age of 17 he entered the Reale Scuola Normale Superior, which is associated with the University of Pisa. There he earned his doctorate at the age of 21 with a thesis on research with X-rays.

After a short visit in Rome, Fermi left for Germany with a fellowship from the Italian Ministry of Public Instruction to study at the University of Göttingen under the physicist Max Born, whose contributions to quantum mechanics were part of the knowledge prerequisite to Fermi's later work. He then returned to teach mathematics at the University of Florence.

In 1926 his paper on the behaviour of a perfect, hypothetical gas impressed the physics department of the University of Rome, which invited him to become a full professor of theoretical physics. Within a short time, Fermi brought together a new group of physicists, all of them

in their early 20s. In 1926 he developed a statistical method for predicting the characteristics of electrons according to Pauli's exclusion principle, which suggests that there cannot be more than one subatomic particle that can be described in the same way. In 1928 he married Laura Capon, by whom he had two children, Nella in 1931 and Giulio in 1936. The Royal Academy of Italy recognized his work in 1929 by electing him to membership, as the youngest member in its distinguished ranks.

This theoretical work at the University of Rome was of first-rate importance, but new discoveries soon prompted Fermi to turn his attention to experimental physics. In 1932 the existence of an electrically neutral particle, called the neutron, was discovered by Sir James Chadwick at Cambridge University. In 1934 Frédéric and Irène Joliot-Curie in France were the first to produce artificial radioactivity by bombarding elements with alpha particles, which are emitted as positively charged helium nuclei from polonium. Impressed by this work, Fermi conceived the idea of inducing artificial radioactivity by another method: using neutrons obtained from radioactive beryllium but reducing their speed by passing them through paraffin, he found the slow neutrons were especially effective in producing emission of radioactive particles. He successfully used this method on a series of elements. When he used uranium of atomic weight 92 as the target of slow-neutron bombardment, however, he obtained puzzling radioactive substances that could not be identified.

Fermi's colleagues were inclined to believe that he had actually made a new, "transuranic" element of atomic number 93; that is, during bombardment, the nucleus of uranium had captured a neutron, thus increasing its atomic weight. Fermi did not make this claim, for he was not certain what had occurred; indeed, he was unaware that he was on the edge of a world-shaking discovery. As he modestly observed years later, "We did not have enough imagination to think that a different process of disintegration might occur in uranium than in any other element. Moreover, we did not know enough chemistry to separate the products from one another." One of his assistants commented that "God, for His own inscrutable ends, made everyone blind to the phenomenon of atomic fission."

Late in 1938 Fermi was named a Nobel laureate in physics "for his identification of new radioactive elements produced by neutron bombardment and for his discovery of nuclear reaction effected by slow neutrons." He was given permission by the Fascist government of Mussolini to travel to Sweden to receive the award. As they had already secretly planned, Fermi and his wife and family left Italy, never to return, for they had no respect for Fascism.

Meanwhile, in 1938, three German scientists had repeated some of Fermi's early experiments. After bombarding uranium with slow neutrons, Otto Hahn, Lise Meitner, and Fritz Strassmann made a careful chemical analysis of the products formed. On January 6, 1939, they reported that the uranium atom had been split into several parts. Meitner, a mathematical physicist, slipped secretly out of Germany to Stockholm, where, together with her nephew, Otto Frisch, she explained this new phenomenon as a splitting of the nucleus of the uranium atom into barium, krypton, and smaller amounts of other disintegration products. They sent a letter to the science journal *Nature*, which printed their report on January 16, 1939.

Meitner realized that this nuclear fission was accompanied by the release of stupendous amounts of energy by the conversion of some of the mass of uranium into energy in accordance with Einstein's mass–energy equation, that energy ( $E$ ) is equal to the product of mass ( $m$ ) times the speed of light squared ( $c^2$ ), commonly written  $E = mc^2$ .

Fermi, apprised of this development soon after arriving in New York, saw its implications and rushed to greet Niels Bohr on his arrival in New York City. The Hahn–Meitner–Strassmann experiment was repeated at Columbia University, where, with further reflection, Bohr

The  
Manhattan  
Project

suggested the possibility of a nuclear chain reaction. It was agreed that the uranium-235 isotope, differing in atomic weight from other forms of uranium, would be the most effective atom for such a chain reaction.

Fermi, Leo Szilard, and Eugene Wigner saw the perils to world peace if Hitler's scientists should apply the principle of the nuclear chain reaction to the production of an atom bomb. They composed a letter, which was signed by Einstein, who, on October 11, 1939, delivered it to Pres. Franklin D. Roosevelt, alerting him to this danger. Roosevelt acted at once, and ultimately the Manhattan Project for the production of the first atom bomb was organized in 1942. Fermi was assigned the task of producing a controlled, self-sustaining nuclear chain reaction. He designed the necessary apparatus, which he called an atomic pile, and on December 2, 1942, led the team of scientists who, in a laboratory established in the squash court in the basement of Stagg Field at the University of Chicago, achieved the first self-sustaining chain reaction. The testing of the first nuclear device, at Alamogordo Air Base in New Mexico on July 16, 1945, was followed by the dropping of atom bombs on Hiroshima and Nagasaki a few weeks later.

Having satisfied the residence requirements, the Fermis had become American citizens in 1944. In 1946 he became Distinguished-Service Professor for Nuclear Studies at the University of Chicago and also received the congressional Medal of Merit. At the Metallurgical Laboratory of the University of Chicago, Fermi continued his studies of the basic properties of nuclear particles, with particular emphasis on mesons, which are the quantized form of the force that holds the nucleus together. He also was a consultant in the construction of the synchrocyclotron, a large particle accelerator at the University of Chicago. In 1950 he was elected a foreign member of the Royal Society of London.

Fermi made highly original contributions to theoretical physics, particularly to the mathematics of subatomic particles. Moreover, his experimental work in neutron-induced radioactivity led to the first successful demonstration of atomic fission, which is the basic principle of both nuclear power and the atom bomb. The atomic pile in 1942 at the University of Chicago released for the first time a controlled flow of energy from a source other than the sun; it was the forerunner of the modern nuclear reactor, which releases the basic binding energy of matter for peaceful purposes. Element number 100 was named fermium in his honour, and the Fermi Award was established by the U.S. Atomic Energy Commission. He was named the first recipient of this award of \$25,000 in 1954. Fermi died of cancer on November 28, 1954, in Chicago.

**BIBLIOGRAPHY.** LAURA FERMI, *Atoms in the Family* (1954), a biography written by Enrico's wife; BERNARD JAFFE, *Men of Science in America*, ch. 20 (1958), covers the life and work of Enrico Fermi; EMILIO SEGRE, *Enrico Fermi: Physicist* (1970), written by his earliest and closest collaborator; HENRY D. SMYTH, *Atomic Energy for Military Purposes* (1945), a detailed description of Fermi's work on the first atomic pile, released immediately after the dropping of the first atomic bomb.

(Be.J.)

## Fern

Ferns are plants belonging to the vascular plant class Polypodiopsida (Filicopsida of some classifications). Estimates of the number of fern species range from as low as 9,000 to as high as 15,000, the numbers varying because certain groups are still poorly studied and new species are still found in unexplored tropical areas. The ferns are extremely diverse in habitat, form, and reproductive methods. In size alone they range from minute filmy ferns only two to three millimetres (0.08 to 0.12 inch) tall to huge tree ferns ten to 15 metres (30 to 50 feet) in height. Some ferns are twining vines; others float on the surface of ponds. The majority of ferns grow in warm, damp areas of the Earth, their numbers diminishing with increasing latitude and decreasing moisture. Dry, cold areas have few or no ferns.

Some ferns play a role in ecological succession, grow-

ing from the crevices of bare rock exposures and in open bogs and marshes prior to the advent of forest vegetation. The best known fern genus over much of the world, *Pteridium*, the bracken, is characteristically found in old fields, where in most places it is ultimately succeeded by woody vegetation. The finest display of fern diversity is seen in the tropical rain forests, where in only a few acres over 100 species may be encountered, some of which may comprise a prominent element of the vegetation. Also, many of the species grow as epiphytes (upon the trunks and branches of trees).

As a class of plants, ferns are not of much use to man. A few, however, are used for decoration, some are popular in horticulture, and edible fern crosiers (young leaves with rolled, hook-shaped tips) are popular in some parts of the world. The major significance of ferns is probably in biological research, for they have retained a primitive life cycle, involving two separate and more or less independent generations or growth phases, the plants of which are wholly different in many respects. The familiar plant is the sporophyte generation, a moderately large leafy plant that produces spores in special structures usually located on the lower surfaces of the leaves. Much less conspicuous and usually overlooked is the gametophyte generation, a tiny plant resembling in some respects a tiny moss and often living only for a short time. The ferns constitute an ancient class of vascular plants, some of them as old as the Coal Age (Carboniferous Period, beginning about 345,000,000 years ago) and perhaps older. Their type of life cycle, dependent upon spores for dispersal, long preceded the seed-plant life cycle.

### NATURAL HISTORY

**Life cycle.** The typical fern, a sporophyte, consists of stem, leaf, and root; it produces spores, and its cells each have two sets of chromosomes, one set from the egg and one from the sperm. The sporophyte of most ferns is perennial—it lives for several years—and reproduces by vegetative propagation from offshoots of the underground stem, or rhizome, often forming large, genetically uniform colonies or clones. A few ferns propagate by root proliferations, and some reproduce by leaf proliferations. The fern sporophyte, in contrast to that of mosses and liverworts, is obviously the dominant generation. In the ferns, however, unlike seed plants, which also have dominant sporophytes, reproduction is accomplished by production of spores—minute single cells covered by a protective wall and readily carried by wind—rather than by seeds. In this respect, the ferns are similar to club mosses (*Lycopodium*), spike mosses (*Selaginella*), quillworts (*Isoetes*), and the scouring rushes and horsetails (*Equisetum*). The life cycles of all of these plants are referred to as pteridophytic, or fernlike, in contrast to spermatophytic (seed plant-like).

The spores are haploid—i.e., they have one set of chromosomes—and are produced in specialized organs, the spore cases, or sporangia. Once released, the spores are carried by wind currents, and a small percentage of them fall in appropriate germination sites to form the sexual plants, or gametophytes. In ferns the gametophytes are commonly referred to as prothallia, and they are best known to biologists as laboratory objects in artificial culture. They are rarely observed in nature without arduous searching, and the gametophyte stage of the majority of fern species has never been seen in the wild.

The prothallia are tiny—usually less than five millimetres (0.2 inch) long—and kidney-shaped in the majority of species. They grow only until the new sporophyte is formed by fertilization; then they dry up and die. The process of fertilization is accomplished by sperms and eggs produced upon the same or different gametophytes, and both the fertilized egg (zygote) and the resultant embryo are held within the tissues of the prothallium until the embryo grows out as an independent plant.

**Ecology.** Ecologically, the ferns are mostly plants of shaded, damp forests of both temperate and tropical zones. Some fern species grow equally well on soil and upon rocks; others are confined strictly to rocky habitats,

Economic  
and  
botanical  
importance

Spore  
dispersal

Figure 1: Fern life cycle.  
Drawing by M. Pahl

where they occur in fissures and crevices of cliff faces, boulders, and talus. Acidic rocks such as granites, sandstones, and quartzites have characteristic associations of species in contrast to those of alkaline rocks such as calcites and dolomites. A few appear to be confined to serpentine and related rocks. In the tropics as many as one-third of the ferns of an area may grow as epiphytes, or air plants, on the shaded lower trunks or in the crowns of trees, often on exposed boughs. A number of so-called epiphytic ferns are actually climbers that originate upon the ground and grow up tree trunks. In these, the lower fronds (bathyphylls) are usually sterile and often differ in form from those at the higher levels (acrophylls), which are entirely or partly fertile in that they bear sporangia over their surfaces.

Both epipetric (upon rocks) and epiphytic ferns may show structural adaptations to dry habitats similar to those of desert plants. These adaptive features include such specializations as hard tissues and thick texture; in addition, the surface cells, or epidermis, may be provided with a very thick cuticle (a waxy layer), and abundant hairs or scales may be found on the leaf and stem surfaces. Terrestrial ferns growing on the ground may also possess such modifications, especially those that grow in salt marshes (e.g., leather ferns, *Acrostichum*) and open, fully exposed prairies and savannas (e.g., bracken, *Pteridium*; lip ferns, *Cheilanthes*; brakes, *Pteris*).

Ferns that grow in the open are often referred to as sun ferns and do not (at least as mature plants) require shade, as do most ferns. Water ferns—waterclovers (*Marsilea*), water spangles (*Salvinia*), and mosquito ferns (*Azolla*)—surprisingly, are very commonly inhabitants of dry regions. They appear only after rains, however, and their growth and life cycles are accomplished very rapidly, probably as an adaptation to the need for quick utilization of water. These ferns have two types of spores that essentially lack the vegetative phase of other ferns; they simply produce sex organs and sperms and eggs rapidly, utilizing food in the spores. Many inhabitants of dry rock cliffs, especially in the maidenhair family, Adiantaceae, have developed a modified type of life cycle, known as “apogamous,” in which fertilization is bypassed. This type of life cycle is also believed to foster quick reproduction in connection with brief damp periods; the gametophytes grow fast, and the sperms do not require free water for fertilization.

Apogamous reproduction

Parasites and animal grazers upon ferns do not seem to be numerous, although the information available is not very complete. Fungi infect ferns, some of them producing sorus-like (i.e., resembling the sorus, or sporangium cluster of ferns) dark bodies, or sclerotia. Snails commonly attack young, uncurling fronds of some species, and various beetles have been observed to graze upon ferns. Damaged fronds are not commonly observed in most fern species, however, which suggests that they may possibly contain repulsive substances that ward off grazers.

The sporophytes of certain ferns (e.g., wood ferns, *Dryopteris*; holly ferns, *Polystichum*) evidently require a resting or dormant period, especially in the temperate zones; others, however, are capable of growing continuously, whenever conditions are suitable, even in warm winter periods (e.g., spleenworts, *Asplenium*). Although the sporophyte is long-lived, the fern gametophyte is usually ephemeral. It develops in a microenvironment characterized by: little competition from other plants (including even mosses and algae); exposed humus, rotten plant materials, or fresh mineral surfaces; deep to moderate shade; and a humid atmosphere. Even ferns whose sporophytes tolerate sun and drought tend to have these requirements for their gametophytes. On rocks, for example, the gametophytes form in protected crevices in which light is minimal and moisture maximal. Because of their requirements for exposed soil, development of fern gametophytes is promoted by damage to mature vegetation, such as wind blowdowns in the forest, flooding, and deep erosion. Prothallia are observed in nature most commonly upon shaded soil banks in forests and along streams and upon rotting, mossy logs. As the bulk of reproduction of ferns is probably vegetative in the sporophytic stage, the presence of a large “stand” of a particular kind of fern results not necessarily from sexual reproduction by gametophytes but rather from clone formation by rhizomes (horizontal, rootlike stems) and in some cases by root or leaf proliferations.

**Distribution and abundance.** Geographically, most ferns are confined to the tropics. Arctic and Antarctic regions have few species. On the other hand, a small, tropical country such as Costa Rica in Central America may have more than 900 species of ferns—approximately three times as many as are found in all of North America north of Mexico. Ferns are conspicuous in the moist tropics not only for their diversity but for sheer numbers as well, and indeed certain forest communities may be dominated by them. A number of families and subfamilies are almost exclusively tropical—e.g., Marattiaceae, Gleicheniaceae, Grammitidoideae, Schizaeaceae, Vittariaceae, Cyatheoideae, and Davalliaceae. Most of the other families and subfamilies occur in both the tropics and the temperate zones. Only certain genera are primarily temperate and Arctic, and they tend to extend

Tropical ferns

Figure 2: Generalized fern sporophyte.  
Drawing by M. Pahl

into the tropics at high altitudes on the peaks of mountain ranges and volcanoes.

Ferns as weeds are uncommon, although a few occur in greenhouses, conservatories, and in tropical gardens. Fern species have been introduced into tropical or subtropical areas (e.g., southern Florida and Hawaii); in some cases the species have become naturalized and have spread into the native forest. Examples include some of the most familiar ferns in the world: the giant polypody (*Phymatodes scolopendrium*), Japanese climbing fern (*Lygodium japonicum*), green cliff brake (*Pellaea viridis*), silver fern (*Pityrogramma calomelanos*), Japanese holly fern (*Cyrtomium falcatum*), "garden" maidenhair (*Adiantum hispidulum*), Cretan brake (*Pteris cretica*), and ladder brake (*P. vittata*).

Because of their ability to disperse by spores and their capacity to produce both sex organs on the same gametophyte and to self-fertilize, it would seem logical to assume that the ferns possess higher powers of long-distance dispersal and establishment than do seed plants. This conclusion tends to be supported by facts that indicate that remote disjunctions—separated growing regions—in range are frequent among ferns. Some of the patterns of distribution include interisland and intercontinental disjunctions east and west, as well as wide north-south disjunctions; included are examples of species found in the Northern and Southern hemispheres that skip the tropics. Some disjunctions seem to follow the pattern of prevailing winds; the main centre of distribution of a species often may have downwind groups consisting of one or a few small populations sometimes hundreds or thousands of miles away. Examples of west-to-east transcontinental North American disjunctions are Wright's cliff brake (*Pellaea × wrightiana*), mountain holly fern (*Polystichum × scopulinum*), and forked spleenwort (*Asplenium septentrionale*)—all of these ferns are well known in the Western United States, and they exist as tiny populations in the mountains of the East as well.

#### FORM AND FUNCTION

**The spore.** The fern spore—a single living cell, usually protected by a thick wall—is the main source of population dispersal, being readily carried by wind. Ferns display a wide diversity of spore types in terms of shape, wall structure, and sexuality, and these types have proved to have great value in determining taxonomic relationships. The full functional significance of the different types, except on the grossest scale, is not yet fully understood; for example, the minute differences in sculpturing of the outer wall surface do not, in the present state of knowledge, appear to have functional significance.

The  
tetrahedral  
spore

**Spore shape.** The basic spore shape among ferns is tetrahedral; the proximal face (the one facing inward during the tetrad, or four-cell, stage following reduction division, or meiosis) is made up of three sloping planes, and the distal, or outer, face consists of a single, rounded surface. The tetrahedral structure is commonly obscured in so-called globose spores, the walls of which are thin and soft. Typically, the wall is composed of exospore (outer spore layer) only, there being no additional jacket, or perispore. The wall may be either unsculptured and smooth or provided with a variety of sculpture patterns. The tetrahedral spore is formed by simultaneous division of the products of the spore mother cell.

In contrast, the bilateral spore type of many fern species is formed by successive cell divisions of the spore mother cell. Where the tetrahedral spore possesses a triradiate scar on the proximal face—corresponding to the contact with three other spores in the tetrad—the bilateral spore has only a narrow, linear scar running parallel to the long axis. Most bilateral spores in ferns are bean shaped and jacketed by a perispore layer, a distinctive covering of the outer wall.

**Spore size.** A few fern families have dimorphic spores, small ones (the microspores) and large ones (the megaspores). The gametophytes of ferns with dimorphic spores are endosporous; that is, they do not emerge in germina-

tion and fail to grow beyond the confines of the spore walls. Photosynthesis is essentially lacking, the food being stored in the spore. The microspores produce sperms in antheridia, and the megaspores produce eggs in archegonia. The vegetative phase of the gametophyte in these forms has been practically eliminated, and the developing embryo in the megaspore lives on stored food materials. The differentiation between male and female gametophytes ensures cross-fertilization. This set of conditions, known only in the families Marsileaceae, Azollaceae, and Salviniaceae, is called "heterospory." All other living ferns are homosporous (i.e., they produce uniformly sized spores), although some do show slight spore differentiation, suggesting incipient heterospory.

Thick-walled spores are capable of survival for a number of years, in some cases up to several decades. Some spores have walls so thick that they fail to germinate at all under normal culture conditions in the laboratory, and some have never been germinated. Most natural germination of fern spores (except for water ferns) occurs on exposed damp surfaces of rock, soil, or dead plant materials.

A number of fern genera (e.g., *Osmunda*, *Grammitis*, and *Hymenophyllum*) possess thin-walled spores. In practically all known examples, such thin-walled spores are also green pigmented, being provided with chloroplasts. Such spores are common among rain forest genera; they are short-lived and require a very short time for germination.

**The gametophyte.** When the spore wall cracks under appropriate moist conditions, the fern gametophyte is formed. Emerging from the spore at the time of germination are a nongreen rhizoid (rootlike organ), which attaches the plant to the growing surface, and a green, single cell—the mother cell that gives rise to the rest of the gametophyte. At first, in most homosporous ferns, growth is in the form of a single filament, which may continue in this fashion if lighting conditions are weak. If lighting is optimum, however, the gametophyte becomes a two-dimensional sheet of cells and later a layered, three-dimensional structure. The apical cell soon is replaced by an embryonic zone, or meristem, which, as a result of the directions of cell division and enlargement, comes to lie in an apical notch in the gametophyte, surrounded on either side by the prothallial wings—flat, platelike protrusions one cell thick. The average size of the gametophyte at the time of fertilization is approximately one to four millimetres (0.04 to 0.16 inch) long and up to three millimetres wide.

**Specialized gametophyte forms.** From a basic type of gametophyte, probably somewhat like that just described, a number of highly specialized forms have evolved that are characteristic of certain genera. Ribbonlike gametophytes are known especially among tropical rain forest ferns, such as the subfamilies Vittarioideae, Grammitidoideae, and Hymenophylloideae, and are characterized by attenuate, flat thalli that are usually irregularly and extensively branched, forming large masses of intertwining ribbons. Some of these are actually more abundant than their corresponding sporophytes in certain localities (e.g., the Appalachian Mountains, where "pure cultures" of gametophytes totally lacking sporophytes have commonly been found). Filamentous gametophytes are known in the genera *Trichomanes* (Hymenophylloideae) and *Schizaea* (Schizaeoideae).

Tuber-like gametophytes occur in several groups—the family Ophioglossaceae (all members), subfamily Schizaeoideae (*Actinostachys*), and the family Gleicheniaceae (*Stromatopteris*). All are nongreen, underground plants that have close associations with fungi and are therefore assumed to be saprophytic; i.e., dependent for nutrition upon rotting organic material in the soil. They commonly occur five to ten centimetres deep.

In heterosporous ferns, the endosporous gametophytes are much reduced. The male gametophyte in the microspore is made up of the equivalent of one antheridium and its complement of sperms. The female gametophyte, although considerably larger in size, is equally reduced in a morphological sense, the greater space within the

Growth  
of the  
gameto-  
phyte

megaspore being filled by stored nutritive materials and tissues formed around the base of the female sex organs.

**Vegetative reproduction.** Vegetative propagation of some photosynthetic fern gametophytes is accomplished by continued growth and fragmentation, but this does not spread the gametophyte very far. Some subfamilies (Vittarioideae, Grammitidoideae, Hymenophylloideae) produce specialized filaments, or gemmae, that break off and are carried away by water droplets or wind to initiate new colonies. Some gemmae are formed upon specialized cells (sterigmata) and are spindle shaped or more or less ovoid. Others occur as chains of cells.

**Sexual reproduction.** The sex organs of ferns are differentiated. The sperm-producing organs, antheridia, are composed of a sterile jacket of cells and sperm-producing cells within. The antheridia may be sunken (as in the families Ophioglossaceae and Marattiaceae) or protruding. Antheridia vary in size from those with hundreds of sperms to those with only 12 or so. The egg-producing organ, the archegonium, contains one gamete (sex cell), which is always located in the lower, more or less dilated portion of the archegonium, the venter. The upper part of the archegonium, the neck, consists of four rows of cells containing central neck cells. The uppermost of the neck cells are the neck canal cells; the lowest cell is the ventral canal cell, which is situated just above the egg.

Fertilization is attained by the ejection of sperms from antheridia; the sperm swim through free water toward simple organic acids released at the opening of the archegonium, the neck of which spreads apart at the apex, permitting the neck cells to be extruded and the sperm to swim in and penetrate the egg. The sperms are made up almost entirely of nuclear material, but their surface is provided with spiral bands of cilia, hairlike organs of locomotion. When the egg is fertilized, the base of the

neck closes, and the embryo develops in the expanding venter.

**The embryo.** Within the archegonial venter the zygote undergoes characteristic cell divisions to form the embryo, which remains encapsulated in the gametophyte until it breaks out and becomes an independent plant. The pattern of development in most ferns is a distinctive one, and indeed only in the orders Ophioglossales and Marattiales are found conditions of embryonic development resembling those of seed plants. In *Botrychium* subgenus *Sceptridium* and in all species of the family Marattiaceae thus far studied, the first division of the zygote is transverse, and the inner cell grows inward, producing the stem and first leaf. The outer cell divides to form a foot, a mass of tissue that exists as part of the embryo and disappears when its function, presumably absorption, is over. The root appears later within the stem and grows outward. In all other known ferns, the zygote divides neatly into four quadrants, the first division approximately parallel to the long axis of the archegonium and the following division at right angles. This results in initial cells that give rise to four organs: the outer forward cell (*i.e.*, toward the growing apex of the gametophyte and the neck of the archegonium) becomes the first leaf, the inner forward cell the stem apex, the outer back cell the first root, and the inner back cell the foot. Thus, the majority of ferns tend to have a precise arrangement of the organs and the divisions that produce them in the embryo.

The young sporophytes of ferns remain attached to the gametophytes for varying lengths of time, absorbing nutrients from the gametophyte through the foot. The gametophyte soon shrivels away, once the sporophyte has developed independent existence and the root has penetrated the soil. The first few leaves are generally sharply different from the mature leaves, not only in their size but in their architecture as well. A common, overall pattern is a falsely dichotomous condition, in which the central part of the leaf blade is aborted (undeveloped) and midribless, and the main veins are forked. Certain ferns, however (*e.g.*, grape ferns, *Botrychium*; and sword ferns, *Nephrolepis*), have first leaves that are organized ternately (three parted) or pinnately (with a central axis from both sides of which veins or leaflets branch).

**The stem.** Fern stems vary from the tall, narrow trunks of certain tree ferns that reach over 20 metres (70 feet) tall down to creeping rootstocks, or rhizomes. Rhizomes are the most common stem form; the majority of them grow horizontally upon or just beneath the surface of the soil. Some fern stems are so narrow as to be threadlike, as in many tropical epiphytic ferns. A few ferns in different parts of the world have evolved radically specialized stems containing ant-filled chambers. The role of the ants in the lives of these ferns is unknown. Vinelike ferns are common, but shrubby ferns are extremely rare. The nearest to shrubby ferns are members of the genus *Oleandra*, which have stiffly branched, woody-textured stems.

Stem growth is initiated by one to several large apical cells. These are usually well protected by various types of hairs or scales and by the over-arching embryonic leaves. Leaves and leaf bases play a major role in protection of fern stems, and many stems are said to have a leaf armour. Such stems are densely covered with old, sclerified (hardened) leaf bases, which increase the apparent size of the stem many times. In most species the stems are indeterminate in growth, and thus can theoretically continue to grow indefinitely. Annuals—short-lived species that complete development, shed spores, and die in a single growing season—are exceptional; only one or two examples are known.

Whether covered with leaf armour or not, the surface of the fern stem is protected by an epidermis, or "skin," a single layer of epidermal cells, which are more or less flat cells with thick outer walls. There are usually also protective epidermal hairs or scales in most ferns; these are so distinctive that they are valuable in identification and classification. The trichomes (*i.e.*, epidermal emergences, or "plant hairs") embrace such diverse types as

Ant  
chambers  
in fern  
stems

simple glands (unbranched, one- to several-celled hairs with a headlike cluster of secretory terminal cells); simple (unbranched), nonglandular hairs; dendroid hairs (branching filaments); and scales (flat cell plates) of many patterns. Scales (known as paleae, or ramenta) are defined as trichomes with a cell plate of two or more cell rows, at least at the base. Most scales are attached broadly at the base and become narrowed toward the usually pointed apex; but a number of species, especially among epiphytes, possess peltate (shieldlike) scales, the attachment of which is central with the scale cells radiating out in all directions. Scales are generally brownish or tannish in colour; the walls are evenly pigmented except when they are very young, when they are white or hyaline (clear or transparent). In some scales, however, the top and bottom walls are transparent and unpigmented, but the lateral walls are thickly coated with dark-maroon or black secondary walls. Such scales are called clathrate (*i.e.*, latticework) scales and when present are valuable for recognizing certain genera.

Drawing by M. Pahl

Figure 4: Stem structures in ferns.

The cortex—the region outside the vascular cylinder but below the surface of the stem—is composed of ground tissue consisting of storage parenchyma cells (a relatively generalized cell type) with more or less thick walls. Rooting animals, such as pigs, occasionally dig up fern rhizomes for the starchy materials contained in them. There is a strong tendency for the outermost cortical cells to become darkly pigmented and thick walled.

**Vascular tissues.** The patterns of vascular tissue, or steles—cylinders of vascular tissues in stem centres—in ferns are so various that a brief description is not possible. Basically, most common ferns possess “dictyosteles,” steles consisting of interconnected vascular strands so that, in any given cross section of a fern stem, several distinct bundles can be observed. These are separated by

regions filled with parenchyma cells known as leaf gaps. There are, however, solenostelic ferns, in which the gaps do not overlap and a given section shows only one gap; and numerous protostelic ferns, in which there are no gaps formed at all. Very complex stelar patterns are known in some species, as in the common bracken fern (*Pteridium*), which has a dorsiventral, polycyclic dictyostele, one in which one stele occurs within another stele. Strands of fibre-like cells running between them form mechanically specialized hard tissue, or sclerenchyma. In certain genera and subgenera of the order Ophioglossales are found steles that somewhat resemble those of seed plants in a number of ways. That is, they exhibit secondary growth (growth rings), radial alignment of cells, development of endodermis (a special layer of cells surrounding the stele), and the same relative position of xylem and phloem tissues (water- and food-conducting vascular tissue).

Usually fern stems can be distinguished from those of seed plants because the former lack secondary growth. No rhizomes of ferns have yet been discovered that show stelar patterns, such as those of monocotyledonous flowering plants (*i.e.*, grasses, palms, orchids, lilies, and others) with scattered vascular bundles. Like monocots, however, fern bundles are usually closed and incapable of undergoing secondary thickening.

**Cells of the vascular system.** The cells of the vascular strands in ferns are mainly tracheids, sieve cells, parenchyma, and endodermal cells. The tracheids, which comprise the xylem, or water-conducting tissue, are normally long, very narrow, and attenuated at the tips. Their secondary walls display ladder-like (scalariform) pitting. The largest fern tracheids are several centimetres long, but most are much smaller. Vessel cells, which have evolved in several lines of fern evolution, are modified tracheids in which the end walls have lost their primary membranes, thus enabling direct, unimpeded connections for water transport between the cells. Vessels, the longitudinal channels composed of linear series of such perforated cells, have been reported from such diverse ferns as waterclover (*Marsilea*) and bracken (*Pteridium*). The phloem cells of ferns are composed mainly of sieve cells—narrow, elongated units that differ from the tracheids in having persistent protoplasts and nuclei (*i.e.*, they are still alive at functional maturity) and in lacking secondary walls with elaborate pitting. Sieve cells usually display more or less distinguishable sievelike areas, through which, presumably, organic foods pass in their travels through the stem and other plant organs. There are various arrangements of xylem and phloem, but usually a single strand composed of both is surrounded by parenchyma cells, the pericycle (a thin zone of living cells just within the endodermis), and by an outer layer of cells with specialized walls, the endodermis. Endodermal cells in young stems are provided with special strips of secondary wall material known as Casparian strips on their radial walls (*i.e.*, on all the cell walls except the two that face toward the stem axis and the stem surface). As the stems age, however, there is a tendency for the endodermal cells to become thick walled all around.

**Other cell types.** The pith is made up of parenchyma cells as a rule, but in many fern genera scattered tracheid-like cells are found as well. True stone cells, such as the brachysclereids or astrosclereids (“bone-shaped” or dumbbell-shaped, and “star-shaped,” thick-walled structural cells, respectively), so common in many seed plants, are absent. Likewise, the cells of fern stems differ from those of many seed plants in lacking collenchyma, modified parenchyma cells with expanded primary walls. Latex-producing cells are rare in ferns.

Most common ferns produce leaves alternately along the rhizome, and the leaf traces (strands of vascular tissue) run from either side of each leaf gap in the stele out through the cortex into the leaf base, or petiole. The basic leaf trace departure from the stele is therefore double, two strands arising from the stele for each leaf. There are, however, many variations on this theme. The vascular strands that arise from the stele to serve the

Types of  
vascular  
cylinders

construction  
of  
ferns  
contrasted  
to other  
plants

roots also arise in the leaf gap, usually at its base. Thus, each leaf as a rule has its own associated root system.

**The root.** Taproots are unknown in ferns. All fern roots are referred to as adventitious, in the sense that they arise at points along the stem. Observed superficially, their association with leaves is more or less obvious, depending on the genus and species. In internal structure, fern roots are generally regarded as being much less diverse than stems. They are protostelic, lacking pith and gaps, and they grow from one or more apical initials (cells that divide to produce all the cells and tissues of an organ), producing a root cap outwardly and the permanent tissues of the root inwardly. They lack secondary growth—continued growth in thickness—entirely. The surface cells of the epidermis produce root hairs near the root apex. These are generally thin walled, in contrast to the cells of the inner cortex, which ultimately may become very thick walled. The root hairs have fundamental importance in absorption of water and nutrients and in attachment to the soil or other growing surface. The endodermis of the root is well marked, and Casparian strips are present, as in the stem. There is also a tendency for the endodermis in older parts of the roots to become thick walled and sclerified. The production and development of xylem tissue in the steles of most fern roots is diarch or triarch; *i.e.*, the first matured xylem is along two or three lines at the outer periphery of the xylem strand. The xylem is surrounded by phloem, and the branch roots arise from the endodermis, unlike the main roots produced by the stem, which arise from the pericycle.

The appearance of roots in relation to the stems is a valuable identification tool. For example, in certain tree ferns (*e.g.*, *Cibotium*), the entire surface is covered by masses of roots, as it is also in the royal ferns (*Osmunda*). Pieces of such root masses have proved to be useful in horticulture for purposes of cultivating orchids and bromeliads; if large enough, the dead tangles of roots can be cut with a saw into various shapes suitable for attaching epiphytic greenhouse plants. Certain tropical ferns have elaborately hairy roots; their surfaces are covered with locks of silky golden or brown trichomes.

**The leaf.** *Leaf shapes.* The basic plan of leaf construction is pinnate (*i.e.*, “feather-like”—with a central axis and smaller side branches) in practically all ferns, and this is considered to be the primitive condition because of its widespread occurrence. Although the ultimate ancestors of the ferns may well have had repeatedly forking, or dichotomous, leaves, the immediate ancestor, at least of ferns living today, is thought to have had pinnately constructed leaves. From this basic type there has evolved a very broad diversity of forms. Some ferns have palmate leaves (with veins or leaflets radiating from one point), and some have secondarily evolved falsely dichotomous leaves.

Whether a given leaf is divided into segments (compound) or not (simple) is of considerable value in identification. The difference between divided and undivided leaves is not a profound one, however, and closely related species will commonly differ from one another in whether their leaves are divided or not. In some situations, in fact, simple-leaved species are known to cross with compound-leaved species to form viable hybrids.

The extent of division in fern leaves ranges from the conditions in which the leaf margins are merely so deeply lobed as to have narrow-based segments to the ultimate condition of having obviously stalked leaflets or pinnae. The pinnae themselves may also be lobed or truly divided with stalked segments as well, and the resulting segments, the pinnules, may also be lobed or divided. Depending on the degree of cutting, fronds are described as simple, once divided, twice divided, thrice divided, and so on. Some ferns are known in which the blades are exceedingly divided and delicate, with blades five times compound that result in segments so small as to be almost hairlike.

**Leaf venation.** Basically, the vein patterns (which can be seen readily by holding the specimen up to a strong light) are pinnate and the veins are free, in the sense

Figure 5: Fern leaves, showing leaf types, leaf venation, and internal petiole vascularization. Drawing by M. Pahl

that they all diverge and never coalesce, either along their sides or distally (at the ends). Nevertheless, there are numerous fern groups in which netted or reticulate venation is found. The patterns are for the most part like other ferns, except that various systems of networks and areoles (areas enclosed within loops of veins) develop between the major, pinnately arranged veins. There are several reticulate patterns known, plus many minor variations. One of the more striking patterns is that in which each loop or areole contains one or more free included veinlets, as shown by various members of the family Polypodiaceae. Another is the herringbone pattern, believed to result from evolutionary concrescence of pinnae, as shown by certain tree ferns (*Cyathea*), lady ferns (*Athyrium*), and marsh ferns (*Thelypteris*).

**Features of the fern leaf stalk.** The petiole-blade relationships of fern leaves vary from the condition, commonly noticed in strap-shaped leaves, in which there is essentially no petiole or stalk (described as sessile) to the condition, commonly observed in broadly oval or triangular leaves, in which there is a pronounced leaf stalk, or stipe (the petiolate, or stipitate condition). Narrowly elongated leaves in ferns are usually erect, spreading, or, in certain epiphytes, pendent. Leaves that are broadly ovate or triangular tend to be borne at right angles to the incident light. Broad-leaved ferns thus become more or less bent at the blade base, an arch occurring at the top of the petiole.

Anatomically, the petioles or stipes of pteridophylls (fern leaves) show nearly as much diversity in cross-sectional pattern as do the stems. The simplest vascular strands of fern petioles are round or (more commonly) crescent shaped, single bundles. In more and more elaborate petiolar patterns, the crescent takes on the form of the Greek letter *omega*, opening adaxially (*i.e.*, up-

Leaf position

The primitive fern leaf plan

ward or toward the central axis of the plant). The latter shape, with many variations, occurs very widely among ferns, especially those considered on other grounds to be primitive. Double-stranded ferns (the *omega* now divided into two parts and unconnected below) are usually associated with more specialized genera. Any of the generalized patterns may exist as broken-up strands; the separation is commonly associated with size—small leaves have only one or two strands; large leaves have many. Just as in stems, this size factor plays a role in the number of strands observed. Petiolar vascular bundle shapes have been found to be so definitive as to have a certain value in separating fern genera and families.

**Tissues of the fern leaf.** At the tissue level, the leaf blades have certain differences from those of other plants, but the same general picture prevails: there is an upper epidermis without stomates (microscopic pores) or with only a few and a mesophyll, or inner layer of spongy cells, with more or less large, intercellular spaces except for the adaxial side, which is composed of palisade cells, elongate cells arranged parallel and oriented with the long axis vertical to the leaf surface. The veins range from the massive trunks of the major midribs, or rachises, which have well-defined xylem, phloem, pericycle, and endodermis, to the delicate capillaries (fine veinlets) represented by little more than a single file of tracheids and that sometimes end in a cluster of terminal, somewhat modified tracheids. Underneath a sporangium, or sorus, the veins may become dilated and multilayered (the so-called fertile veins). In some ferns the palisade layer of the mesophyll is substituted for by parallel, inward projections of the epidermal cells that contain chloroplasts (small bodies that contain the photosynthetic pigment, chlorophyll) and presumably function as do the typical palisade cells. In many ferns all or nearly all of photosynthesis is accomplished by the epidermis, either one layer or two, the mesophyll having been eliminated in evolution. An example is the common maidenhair fern (*Adiantum pedatum*), the blade of which, between veins, is made up of mainly two layers, the upper and lower epidermis, in which most of photosynthesis occurs.

Plant hairs  
on fern  
leaves

The trichomes—hairs and scales—of fern leaves are like those of the stem but usually fewer, more widely separated, and smaller in dimensions. Many ferns are described as having glabrous leaf blades (*i.e.*, bald), but in many instances this is misleading because there are actually at least a few microscopic hairs, which are usually glandular and appressed to the blade surface.

**Comparisons with leaves of other plant groups.** The fern leaf or pteridophyll is most similar to that of the cycads when compared to other living vascular plant groups. The pteridophyll differs from the leaf (euphyll, or “true leaf”) of the flowering plants in its vernation, or manner of expanding from the bud, which is circinate—it unrolls from the tip and has the appearance of a fiddle-

head rather than expanding from a conduplicate, or folded, condition. It also differs in its venation, which is usually free or simply reticulate, rather than being highly complex and made up of areoles containing numerous branched free-ending veinlets. Fern leaves differ from the leaves (sphenophylls) of conifers and articulates or horse-tails (*Equisetum* species) in their usually well-developed central midrib with lateral vein branches rather than a dichotomous, midribless pattern or a mere simple vein in a narrow needlelike or straplike leaf. Although a few ferns that have narrow leaves also have only a single central vascular strand (*e.g.*, certain species of *Schizaea*), these may usually be distinguished readily from the merely scalelike or awllike leaves (microphylls) of lycopside (club mosses) on the basis of other characteristics, such as the position of the sporangia and the mode of leaf development. A few genera of ferns (*e.g.*, sword ferns, *Nephrolepis*; *Jamesonia*; *Blechnum* subgenus *Salpichlana*; climbing ferns, *Lygodium*; and staghorn ferns, *Dicranopteris*) have members with more or less indeterminate—continuous—leaf growth accomplished by periodically quiescent buds, but fern leaves are mostly determinate; *i.e.*, they stop growing at a certain stage of development. They grow from apical cells in most ferns, and these delicate embryonic cells are protected by the curled over spiral of the crozier (unrolling tip of a young fern leaf) and by trichomes. When the blade formation is complete, there is no longer an embryonic tip.

In overall length, mature leaves vary from one or two millimetres (0.04 or 0.08 inch) in certain filmy ferns (subfamily Hymenophylloideae) to 30 or more metres (100 feet; family Gleicheniaceae). The term frond, which presumably derives from the concept of a large, compound leaf, such as that of a wood fern, cycad, or palm, has been traditionally applied to the leaves of ferns, even when they are only small, simple leaves resembling superficially the euphylls—true leaves—of flowering plants. Approximately one-third of all living ferns have simple, nonfrondose leaf blades.

**The sporangium and sorus.** The sporangia, or spore-producing structures, in ferns range from globose, sessile (nonstalked) organs over one millimetre in diameter down to microscopic stalked structures, the capsules of which are only 0.3 millimetre (0.01 inch) in diameter. The former are known as eusporangia, the latter as leptosporangia. Eusporangia occur in the orders Ophioglossales and Marattiales, and leptosporangia occur in the majority of the species in the order Polypodiales, as well as in the Marsileales and Salviniaceae. There are, however, many intermediate forms between the two types of sporangia, and these are known in various primitive species of the Polypodiales, such as members of the family Osmundaceae.

The capsule wall in eusporangia tends to be relatively massive and made up of two layers or more. In leptosporangia, in contrast, the wall is thin and, at least at maturity, composed of one layer of cells. Opening of the capsule in eusporangia, such as those of the genus *Botrychium* and intermediate types such as *Osmunda*, is accomplished by separation along a well-differentiated line of dehiscence (opening); but in most typical leptosporangia, except for a few stomial—“mouth”—cells that separate along one side, the process of dehiscence tears the cells apart more or less irregularly. The opening process in eusporangia is the result of a generalized stress on drying walls, the cells of which are differentially thickened. There is no mechanism to throw the spores, and they are simply carried away by the wind. In contrast, leptosporangia display more or less specialized bows, or annuli, consisting of usually a single row of differentially thickened cells. The mechanical force for opening and for throwing the spores derives, apparently, entirely from these bow cells—all the other capsule cells are thin walled and unmodified. The drying of the bow cells imposes stresses that result in the collapse of the outer sides of the cells, thus straightening out the bow and ripping the soft lateral cells of the capsule apart. As the bow cells continue to be deformed by the cohesive forces of the increasingly tense water molecules within, the spore case

Types of  
spore-  
producing  
structures

Figure 6: Representative surface structures. (A) Types of hairs. (B) Scale types. (C) Uncurling leaf, or crozier, showing circinate vernation and surface scales.

becomes completely open. Finally, the cohesive capacity of the water molecules is exceeded, the water film between the outer walls of the bow cells breaks, and the entire bow snaps back to its original position, tossing the spores into the air.

Most primitive sporangial types are stalkless, or sessile. If a stalk is present at all, it is merely a slightly raised multicellular area at the base of the sporangial capsule. In typical leptosporangia, however, there are commonly well-developed stalks, and these are often extremely long and narrow (e.g., as in *Davallia* and *Loxoscaphe*), made up of only one or two rows of cells and up to 1.7 to two millimetres (0.07 to 0.08 inch) in length.

The trend in sporangial evolution is evidently from solitary large capsules to more and more elaborate groupings of smaller sporangia. These changes are accompanied by the appearance of such refinements as paraphyses and indusia. Paraphyses are sterile structures that grow among the sporangia. Indusia are papery tentlike structures that cover clusters of sporangia.

Drawing by M. Pahl from (top) F.C. Steward, *About Plants: Topics in Plant Biology* (1966); Addison-Wesley, Reading, Mass. and (bottom right) P. Martens & N. Pirard, "The Glandular Organs of *Polypodium virginianum*," *La Cellule*, 49(3): 393-406 (1943)

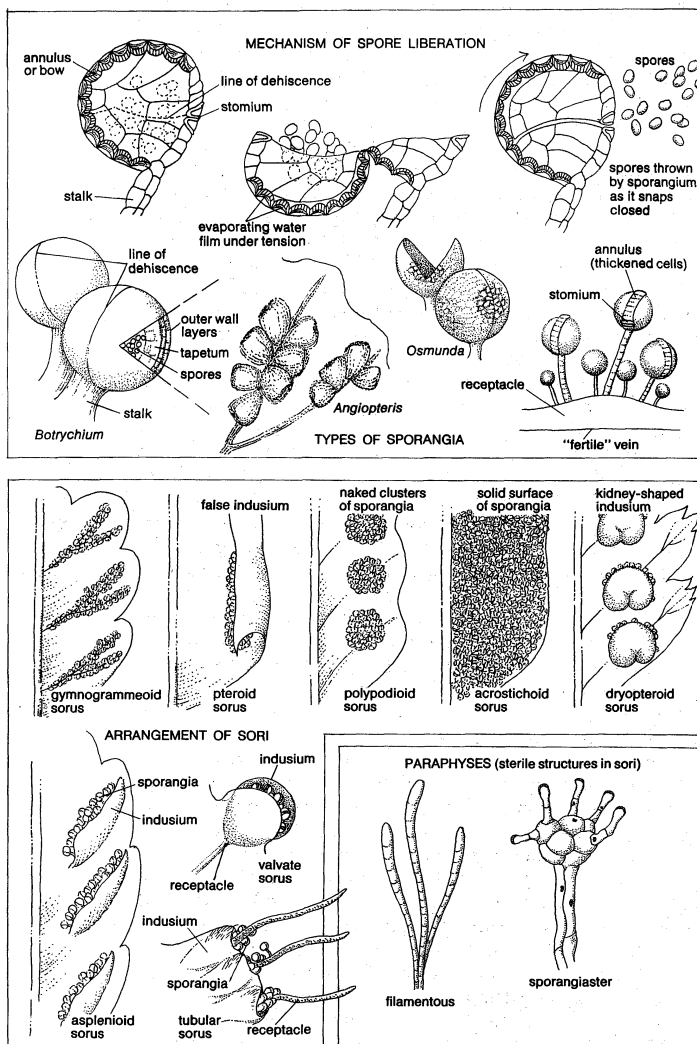

Figure 7: Fern sporangia, their arrangement into sori, and other structures found in the sorus.

**The sorus.** Hand in hand with the reduction in size of single sporangia are seen more and more complex aggregations of sporangia known as sori. The meristematic area—the region of new cell growth—that produces them may continue its activities over a number of weeks, producing sporangia of all ages, the older ones becoming pushed aside as the new ones mature in their turn. Persons seeing sori developing upon the leaves of their house

ferns for the first time have often interpreted the young stages as tiny insects or older stages as fungus diseases, not realizing that such organs are necessary for the normal reproduction of the plant.

The stages in progressive evolution of sori can be visualized as follows: (1) simple clusters of sporangia, these more or less coalesced (family Marattiaceae) or separate (Gleicheniaceae), all of them maturing at the same time; (2) gradate clusters of sporangia, the outermost ones maturing first, the innermost last; and (3) mixed clusters of sporangia, all ages present, the younger ones arising from the same meristematic zones as the older ones. The adaptive significance of this change is probably related to the duration of spore production, the mixed condition of specialized sori extending the period beyond that of solitary sporangia or of simple, simultaneously maturing sori.

**Sorus types.** Sporangia and especially sori have traditionally been the most important characters for fern classification. Indeed, many unrelated ferns were once classified together because of what are now believed to have been coincidental convergences in soral structure. Adjectives derived from the classical generic names of ferns, which were based upon superficial resemblances, are still used to describe the prominent types. Between one-half and two-thirds of the species of ferns have one or another of the following six soral types: (1) The gymnomermeoid type (from the genus *Gymnomerme*, meaning "naked line") is a linear arrangement of sporangia along veins, avoiding the leaf area between the veins. It is found in many fern genera, especially in the family Adiantaceae. (2) The pteroid sorus (from *Pteris*, a classical fern genus) is a line of sporangia along the leaf edge, protected usually by a rolled-over and modified laminar margin. (3) Polypodioid sori (from *Polypodium*) are round and naked. (4) Acrostichoid sori (from *Acrostichum*) are so large that they are usually expanded over the entire undersurface of the blade or pinna. Acrostichoid sori probably arose by fusion or smaller clusters. Of the many types of indusiate sori (i.e., sori that are protected by indusia, special scalelike structures), two of the most widespread types are (5) the asplenoid (from *Asplenium*), a linear or oblong sorus covered from one side by a narrow indusium, and (6) the aspidioid (from *Aspidium*), in which the sorus is round but covered with a kidney-shaped or shieldlike indusium.

**The indusium.** The protection of the sporangial cluster from exposure, drying, and other factors is accomplished in various ways—by the formation of the sori in grooves or pockets or by the production of various forms of covers. The false indusium is the rolled-over leaf margin, under which the sporangia form and mature. The indusium is a separate and unique structure, the structural origins of which are not clear, which develops a more or less papery covering over the sorus. A widespread type of indusium among members of the family Cyatheaceae is one shaped like a bell or cup, which arises around the base of the sorus (e.g., *Cyathea*, *Trichomanes*). A variation is the two-lipped or valvate indusium (*Dicksonia*, *Hymenophyllum*). When sori fuse laterally to form continuous lines or coenosori, any indusia also tend to fuse, resulting in continuous linear cell plates.

**Paraphyses.** Other sterile structures in the sorus are the paraphyses. These are sterile organs intermixed with the elements of a sporangial cluster, and they are, like indusia, believed to perform protective functions. Approximately one-third of fern species have paraphyses of one type or another. These structures, which are usually hairs or modifications of hairs, arise variously in the sorus—in some cases upon the receptacle, on the sporangium (stalk or capsule or both), and within the indusium. They have many forms, including simple, glandular, dendroid (branched in the manner of a tree), or stellate (branched in "star-shaped" patterns) hairs; scales; or obviously much modified sterile sporangia—so-called sporangiasters. In various genera of ferns, the paraphyses have proved to be valuable sources of taxonomic data.

**Cytogenetics in fern biology.** The study of chromosomes, hybrids, and breeding systems has revealed much of value in understanding ferns. The chromosomes of

Stages in the evolution of the sorus

Sterile structures in the fern sorus

ferns tend to have high base or  $x$  numbers, ranging from approximately 20 to 70, with the majority between 25 and 45. The familiar genus *Osmunda*, for example, has  $x = 22$ ; *Pteris* has 29, *Asplenium* 36, *Dryopteris* 41, *Botrychium* 45, and *Pteridium* 52. Among homosporous ferns, exceptions to the rule of high chromosome numbers are rare; in one species of filmy fern (*Hymenophyllum petatum*)  $x = 11$ , the lowest number reported. Among heterosporous ferns, however, the situation is conspicuously different, and all have low base numbers (Marsileaceae,  $x = 10, 13$ , or  $19$ ; Salviniaceae,  $x = 9$ ; *Azolla*,  $x = 22$ ). The explanation traditionally adopted by cytologists is that the high numbers in homosporous ferns arose from polyploidy, the repeated reduplication of whole sets of chromosomes. Indeed, some workers regard homosporous ferns as nearly 100 percent polyploid. An alternative hypothesis should also be considered, however, namely that homosporous ferns were primitively high numbered and that heterosporous ferns derived their low numbers through reduction.

The base chromosome numbers (indicated by the symbol  $x$ ) have been used for systematic (classification) purposes. Commonly, the base number is uniform for a genus or family, or it fluctuates around a given number. More rarely, the number varies drastically, as in the genus *Thelypteris*, which has  $x$  numbers ranging from 27 to 36, or *Lindsaea*, with  $x$  numbers from 34 to about 50. In groups in which the chromosome base number does vary so much, it suggests that the "genus" concerned may be unnatural. Simple polyploid series—multiples of the base number—are very common among ferns, and a few species have been reported to have diploid (with two times the base number of chromosomes), tetraploid (four times), and hexaploid (six times) races or forms (e.g., the fragile fern, *Cystopteris fragilis*, has races with the number of chromosomes per nucleus in the sporophyte generation—represented by  $2n$ —equal to two, four, and six times the base number of  $x = 42$ , or  $2n = 84, 168$ , and  $252$ ). Species with both diploid and tetraploid forms are common, especially among widespread, abundant ferns. In most cases the cytological races are differentiated on quantitative characters, especially the sizes of such cells as spores, epidermis guard cells (cells next to stomates), and hair cells. The genetics of polyploidy in ferns is not understood, but good hypotheses exist that eventually are expected to provide an explanation.

Genetically, homosporous ferns differ from heterosporous pteridophytes and from seed plants in their ability for intragametophytic selfing—fertilization of an egg by a sperm produced in the same gametophyte. One gametophyte may have both antheridia (sperm-producing structures) and archegonia (egg producers) present on the thallus simultaneously, enabling the formation of an embryo and sporophyte that is homozygous for all alleles (i.e., the homologous—matching—chromosomes contributed by the egg and sperm are identical). This not only bears upon the evolutionary potential of invading (into new areas) fern individuals derived from single spores but also may have significance in interpreting the high chromosome numbers. This may also explain why a number of ferns have wide ranges with large disjunctions (interruptions in distribution).

In certain temperate fern genera, such as spleenworts (*Asplenium*), wood ferns (*Dryopteris*), and holly ferns (*Polystichum*), hybridization between species may be so frequent as to cause serious taxonomic problems. Hybridization between genera is rare but has been reported. Fern hybrids are conspicuously intermediate in their characteristics between their parents, and simple dominance of single characters is unusual. Occasionally, when the interspecific crosses involve strongly different characteristics, the hybrid displays an irregularity in expression of these characteristics, often involving marked asymmetry. The majority of hybrids are sterile and reproduce, if at all, only by vegetative propagation.

Reproduction in sterile fern hybrids is also accomplished by the process of apogamy, in which spores possessing the same chromosome complement as the sporophyte are produced—normal spores have only half the

chromosome number as the parent plant cells. These unreduced spores (diplospores, which have the  $2n$  number of chromosomes) are viable and germinate into normal-appearing gametophytes, which may or may not form sex organs. The hybrid gametophytes do not, however, undergo normal sexual fusion. Instead, the meristematic (cell-producing) region of the prothallium simply buds off a new sporophyte, and there is a direct conversion in growth from gametophyte to sporophyte generations. In the ameiotic form of apogamy the spore mother cells simply undergo mitosis (simple cell division) to form unreduced diplospores. In another and much more common form, meiotic apogamy, the spore mother cells are unable to form bivalents (chromosome pairs) at meiosis, and reduction division merely results in irregular, deformed, and inviable spores. In some or most of the sporangia, however, automatic doubling of chromosomes occurs by endomitosis (duplication of chromosomes without formation of two nuclei), and each of the spore mother cells has a restitution nucleus—one with doubled chromosomes. In these doubled sporangia there are, therefore, only eight spore mother cells rather than the usual 16, and they undergo meiosis, producing viable diploid spores. The rest of the process of sporogenesis is like that in ameiotic apogamy. Apogamous ferns are known in a number of genera of higher ferns in various families, including *Adiantum*, *Asplenium*, *Cheilanthes*, *Dryopteris*, *Pellaea*, *Polypodium*, and *Pteris*.

Besides apogamous hybrids, there are numerous demonstrated or suspected "allopolyploid hybrids" that are believed to have originated by doubling of the chromosomes of sterile crosses through faulty mitotic or meiotic divisions. Although intermediate in their characteristics between well-known parental species, these crosses tend to behave like normal, divergent species, alternating sporophytes with gametophytes and undergoing normal meiosis and fertilization. Both apogamous and allopolyploid hybrids may enjoy wide geographical ranges and occur in as great abundance as do normal species. Both types of hybrids are also capable of creating additional hybrids by backcrossing (to the parent species) or by crossing with other species. In apogamous ferns it is assumed that the sperms are generally viable and capable of fusing with eggs of other, normal species. In total, hybrids—sterile, apogamous, and allopolyploid—may make up as many as 20 percent of the "kinds" of ferns in a given flora.

#### ORIGIN AND EVOLUTION OF FERNS

**Fossil record.** Fernlike characteristics are known to be combined in numerous fossils coming from geological strata as old as the Devonian (beginning about 395,000,000 years ago). Modern ferns, however, are relatively uniform in basic structure, and they share a large number of characteristics, combined in a very distinctive way. All of the living families, with the exception of the heterosporous ones, possess a ground plan of correlated characteristics that seems clearly to bind them together as being a monophyletic (i.e., one evolutionary line) assemblage. In spite of this, as shown in the enumeration of character trends given below, there is still wide variation present. The norm of modern ferns is so distinctive that the vast majority of them can be immediately recognized as members of this class of plants. Nevertheless, various workers, especially among paleobotanists, have singled out fossil fragments and speculated that they represent fern ancestors, sometimes giving them such names as *Archaeopteris* (primitive fern) or *Protopteridium* (first fern). No convincing fern ancestors are known, however, and the first relatives of modern ferns in the fossil record are usually classifiable into living groups.

The earliest true ferns arose during Carboniferous times (about 280,000,000 to 345,000,000 years ago) and have been classified in four families—Marattiaceae, Osmundaceae, Gleicheniaceae, and Schizaeaceae. So-called Coenopteridales (members of an extinct order of fernlike plants) may represent related lines of evolution, but, since so many Carboniferous plants showed fernlike properties, they are no better candidates for fern ancestors than certain other groups. The immediate ancestors of the seed

Fern  
hybrids

Age of  
fossil  
fernlike  
vegetation

ferns (pteridosperms) may also have been the immediate ancestors of modern ferns, judging from numerous data on sporangial arrangements and shapes and on leaf anatomy. What used to be considered impressions of fern leaves from the Coal Age (Carboniferous Period) have been shown in many cases to have borne seeds or to have been associated with seed-bearing plants. By the time of the Mesozoic Era (beginning about 225,000,000 years ago), the modern fern families were well established, and there are fossil records of the families Osmundaceae, Marattiaceae, Schizaeaceae, Matoniaceae, Dipteridaceae, Adiantaceae, Cyatheaceae, Aspleniaceae, Marsileaceae, Azollaceae, and Salviniaceae.

**Evolutionary development.** Despite a relatively large number of theories, the actual origins of the vegetative organs of the ferns are still unknown. It is usually suggested that the original fern stem was protostelic, but this is not necessarily true of the immediate ancestor of modern ferns. In fact, it is conceivable that eustelar stems with secondary growth (*i.e.*, in thickness like those of modern conifers and woody flowering plants) gave rise to modern fern stems through reduction and disappearance of cambial—secondary—growth and replacement of the cauline (stem) stele by its elimination and by the substitution of overlapping leaf traces. The leaf is equally—if not more—problematical from the standpoint of its ultimate origin. Various hypotheses have been made to account for its origin, of which the telome theory (*viz.*, that the leaf arose from fusions and rearrangements of branching stem systems) and the “enation theory” (that the leaf arose from the elaboration of original, simple enations, or outgrowths, such as modern leaf primordia) are the two most popular. The true story seems to be lost in antiquity and perhaps will never be known. Modern fern leaves or pteridophylls, with their characteristic fiddleheads, acropetal growth (*i.e.*, “seeking the apex”—the leaf tissues mature from the base toward the tip, where the youngest tissues are produced), and pinnate structure, are, nevertheless, very distinctive and differ in various respects from sphenophylls such as those of coniferophytes, and from euphylls such as those of flowering plants. It is possible that these leaf types had different origins and even that different examples of each had different origins.

Theories of  
fern-leaf  
evolution

#### CLASSIFICATION

**Annotated classification.** The classification presented here is derived mainly from Copeland (1947), Alston (1956), Holttum and Sen (1961), and Pichi-Sermolli (1958). It attempts to harmonize differences among these systems by utilizing, in addition to family, the category of subfamily. Numbers given for the species are only rough approximations of living groups.

#### CLASS POLYPODIOPSIDA (true ferns)

Spore-dispersed vascular plants with free-living sporophyte and gametophyte generations, the sporophyte dominant. Leaves frondose, circinate (expanding by unrolling), possessing petiole (stalk), midrib, and blade, the latter or its subdivisions with free or netted venation patterns. Sporangia solitary or variously soriate (in clusters) and borne upon the leaf blades or their modified parts, marginally or abaxially (on the under surface, or surface facing away from the central axis of the plant). Stems upright or creeping, mostly lacking secondary thickening, and bearing roots associated with leaf bases. Meristems (growing points) protected by hairs or scales. Gametophytes monomorphic (all with similar structure) and developing outside of the spores (exosporic), hermaphroditic, surficial (growing on the surface) and photosynthetic, or subterranean and saprophytic and symbiotic with fungi; or gametophytes dimorphic (with two forms), endosporic, antheridial (male) or archegonial (female).

#### Order Ophioglossales

Leaf divided into sterile and fertile segments, leaf base more or less clasping; eusporangiate (with unstalked, globose sporangia); ferns mostly small and fleshy, occurring in early ecological succession. Not known as fossils. Three living genera with about 55 species.

**Family Ophioglossaceae.** Characters of the order.

**Subfamily Botrychioideae** (grape ferns, moonworts). Leaf blade pinnately lobed or divided; veins free; sporangia not sunken, borne upon branches of many-branched fertile struc-

ture. Two genera (*Botrychium*, *Helminthostachys*) and 25 species.

**Subfamily Ophioglossoidae** (adder's-tongue ferns). Leaf blade simple or furcately (forked) lobed, midrib obscure or absent; veins reticulate; sporangia sunken in unbranched silique-like (elongate capsule-like) “spike.” One genus (*Ophioglossum*) with 30 species.

#### Order Marattiales (giant ferns)

Leaves pinnately divided, pulvinate (enlarged or swollen at leaf base or stem region just below attachment point of leaf stalk) in living genera, and with well-developed fleshy stipules (appendages at leaf base); sporangia eusporangiate, in sori, or more or less coalescent in “synangia” (clusters). Mostly massive, fleshy ferns of tropical forest. About 100 species.

**Family Marattiaceae.** Characters of the order. Six genera, including *Angiopteris*, *Marattia*, *Danaea*. (The extinct Carboniferous and Permian *Psaronius* may belong here or in separate family.)

#### Order Polypodiales

Leaves nonpulvinate and mostly nonstipulate; sporangia intermediate or leptosporangiate (stalked), solitary or in sori; if soriate, then with or without indusia (protective coverings) and paraphyses (sterile structures). Mostly medium-sized sclerenchymatous (with hardened tissues) plants with cosmopolitan distribution; the order includes most common ferns.

#### Suborder Osmundineae (royal ferns)

Sporangia on axes of much-reduced segments or along veins on unmodified blade, maturing nearly simultaneously, intermediate between eusporangia and leptosporangia, lacking a definite annulus; petioles with distinct stipule-like dilations. About 20 species.

**Family Osmundaceae.** Characters of the suborder. Three genera (*Osmunda*, *Todea*, *Leptopteris*) and 20 species, plus 5 to 10 extinct genera from the Carboniferous and Permian periods.

#### Suborder Polypodiineae

Sporangia with clearly differentiated annuli or bows; petioles lacking distinct stipular organs or at most dilated at base. Genera number 170 to 250 with about 7,000 to 9,000 species, many tropical ones still undescribed.

**Family Plagiogyriaceae.** Leaves 1-pinnate, dimorphic (two forms), with trophophylls (sterile fronds) and sporophylls (fertile fronds), the latter contracted and containing scattered sporangia with strongly oblique annuli (rings of special cells); petiole bases swollen; stem apex and young leaves covered with mucilage from secretive hairs. One genus (*Plagiogyria*) and about 30 species distributed in tropical regions.

**Family Gleicheniaceae** (staghorn ferns). Leaves mostly sprawling over other vegetation, falsely dichotomous, the segments mostly narrowly lobed; sporangia with oblique annuli and organized in simple sori; stems creeping, protostelic. *Gleichenia*, *Hicriopteris*, and 3 other genera with about 150 species distributed in the tropics.

**Family Matoniaceae.** Leaves either fanlike, with lobed, narrow segments, or climbing with long midribs; sporangia with oblique annuli, the simple sori covered by a thick peltate indusium-like structure. Two genera (*Matonia* and *Phanerosorus*) and about 4 species distributed in the Old World tropics.

**Family Dipteridaceae** (umbrella ferns). Leaves fan-shaped, venation free or finely reticulate with free, included veinlets; sporangia with oblique annuli; sori small, with paraphyses; stem with solenostele, covered with narrow bristle-like trichomes. One genus (*Dipteris*) with about 8 species.

**Family Cheileporeiaceae.** Leaves dimorphic, with complex reticulate veins, the sterile leaves midribless, once or twice forked; sporangia with oblique annuli and 4-rowed stalks; sorus acrostichoid and with paraphyses; stem protostelic or solenostelic. One genus and species (*Cheileporeia bicuspis*) distributed in the Old World tropics.

**Family Polypodiaceae.** Plants mostly epiphytic; leaves usually lobed or simple; sporangia with typical erect bows, numerous, borne in round sori. Genera 42 to 64, with about 1,050 species, mainly tropical in distribution.

**Subfamily Polypodioideae** (true polypodies). Exposed epiphytes, often in fairly dry habitats; leaves with articulate petioles and reticulate veins; stem creeping, dictyostelic; scales commonly clathrate (lattice); spores bilateral nongreen; gametophyte cordate (heart-shaped), nongemmiferous (not producing gemmae, tiny clusters of cells that break off and grow new gametophytes). Genera include *Polypodium*, *Pyrrosia*, *Platynerium*, and 30 to 50 others depending upon the authority consulted, with 550 species.

**Subfamily Grammitidoideae** (dwarf polypodies). Shaded rain forest epiphytes; leaves nonarticulate, veins free; stem

upright, solenostelic or dictyostelic; stem scales with uniform walls; spores tetrahedral-globose, green; gametophyte narrowly cordate to ribbon shaped, gemmiferous. *Grammitis* and 8 to 10 additional genera and 500 species. This subfamily has long been confused with true polypodies.

**Family Schizaeaceae.** Vegetative organs various; sporangium with its annulus composed of a subapical uniseriate or multiseriate ring of thickened cells. Six genera and about 160 species, mostly tropical.

**Subfamily Anemioidae.** Leaves typically frond-like; sporangia with apical plate within annulus composed of several cells, borne upon margins of unmodified pinnae or upon erect, strongly dimorphic pinnae; spores tetrahedral. Two genera (*Anemia*, *Mohria*) and 90 species.

**Subfamily Lygodioidae** (climbing ferns). Leaves climbing by their twisting rachises (central axes); sporangial apical plate of a single cell ordinarily; sporangia attached laterally in two rows, produced on specialized lobes of the blade; spores tetrahedral. One genera (*Lygodium*) with 40 species.

**Subfamily Schizaeoideae.** Leaves long-petioled, often rather grasslike, simple or forked; sporangial apical plate of a single cell; sporangia borne within extremely contracted and folded blades; spores bilateral; gametophytes filamentous or tuber-like and subterranean. Three genera: *Schizaea*, *Lophidium*, *Actinostachys* (these genera are commonly merged into one as subgenera) and 30 species.

**Family Adiantaceae.** Sporangia in lines along the veins or on or at the vein tips, either unprotected, in grooves, or covered by more or less rolled leaf margin—the “false indusium”—or rarely acrostichoid; sporangia with typical erect bows; spores mainly tetrahedral, nonperisporial. About 16 to 23 genera and 850 species, cosmopolitan in distribution.

**Subfamily Adiantoidae** (cliff brakes, maidenhair ferns, lip ferns). Mainly small, xerophytic (with adaptations to dry habitats) ferns, the plants epipetric (growing upon rocks) or terrestrial and rigid; leaves 1- to multipinnate; veins mostly free. *Adiantum*, *Cheilanthes*, *Notholaena*, *Pellaea*, *Pteris*, and 5 to 10 other genera with a total of 750 species.

**Subfamily Ceratopteridoideae** (aquarium ferns). Plants soft, rooted in mud or floating; leaves 2- to 3-divided, upright or spreading; veins anastomosing. One genus (*Ceratopteris*) and 3 species.

**Subfamily Vittarioideae** (shoestring ferns). Plants leathery, epiphytic; leaves simple, pendent; veins anastomosing. *Vittaria*, *Antrophyum*, and 3 to 5 other genera with 100 species.

**Family Cyatheaceae.** Habit extremely diverse, ranging from mosslike plants to tree ferns; trichomes mainly simple hairs or very narrow scales (except in certain members of the subfamily Cyatheoideae); sori indusiate, the indusia basically tubular or 2 lipped; spores mostly tetrahedral, nonperisporial. Genera number 24 to 57 with about 1,500 species, mainly tropical in distribution.

**Subfamily Cyatheoideae** (tree ferns, bracken). Terrestrial, medium to very large ferns, the rhizomes ranging from ropelike and creeping to trunklike and upright. Genera number 22 including *Thyrsopteris*, *Loxosoma*, *Dicksonia*, *Cibotium*, *Lophosoria*, *Cyathea*, *Dennstaedtia*, *Microlepia*, *Pteridium*, with 850 species.

**Subfamily Hymenophylloideae** (filmy ferns). Rain forest epiphytes; mostly tiny ferns with lamina of only 2 or 1 cell thickness between veins; spores globose, green, commonly with triradiate germination; gametophyte ribbon shaped or filamentous, gemmiferous. Principal genera are *Hymenophyllum* and *Trichomanes*. Numerous subgenera or segregate genera are maintained by some authorities resulting in number of genera from 2 to 35; there are 500 species.

**Subfamily Lindsaeoideae.** Mainly terrestrial, medium-sized ferns with protostelic or solenostelic creeping stems covered with hairs or narrow scales; leaves appearing for the most part to be glabrous (smooth), the divisions or segments having cuneate (wedge-shaped) bases; sori marginal, either terminal on single veins or fused on a submarginal connecting vein. Genera include *Lindsaea*, *Sphenomeris*, *Odontosoria*, and 8 others, with a total of 250 species.

**Family Aspleniaceae.** Rhizomes mainly scaly; sori abaxial with peltate (shieldlike), reniform (kidney-shaped), oblong, or linear indusia; sporangia with typical leptosporangiate bows; spores mostly bilateral, provided with perispore (an outer coat). The most common and largest family of ferns, cosmopolitan in distribution, and containing 67 to 82 genera and approximately 3,000 species.

**Subfamily Dryopteridoideae** (wood ferns, lady ferns, halberd ferns, and others). Rhizome scales nonclathrate; sori various, but basically round—connected by intermedial lines to a wide variety of derived forms, including asplenoid and acrostichoid. Fifty to 60 genera and 1,900 species.

**Subfamily Blechnoideae** (chain ferns). Rhizome scales non-clathrate; sori in “loops” along the major veins, following the costal areoles, the indusia opening inward; young foliage commonly red, turning to green. Genera 5 to 10 including *Blechnum* and *Woodwardia*, with 250 species.

**Subfamily Asplenoideae** (spleenworts). Rhizome clathrate; petiole strand x-shaped; sori lunate (crescent-shaped) to linear, indusiate; sporangia with single-rowed stalks. Genera 12 including *Asplenium* and *Phyllitis*, with 800 species.

#### Order Marsileales

Aquatics with long, usually rooted rhizomes; leaves long-petioled with 2 or 4 terminal leaflets or none; sporangia contained in sporocarps along petiole; heterosporous. Three genera and about 70 species.

**Family Marsileaceae.** Characters of the order. *Marsilea* (waterclover), *Pilularia*, *Regnellidium*.

#### Order Salviniaceae

Floating aquatics with small, rounded sporangia contained in saclike indusia; leaves sessile; heterosporous. Two genera and 15 species.

**Family Salviniaceae** (water spangles). Leaves in whorls of 3, 2 oval in outline and floating, with complex hairs on the top surface, the third finely divided and hanging rootlike in the water; true roots absent. One genus (*Salvinia*) with 10 species.

**Family Azollaceae** (mosquito fern). Leaves alternate, overlapping, vertically divided into two lobes, the upper floating, the lower submersed; true roots present. One genus (*Azolla*) with 5 species.

**Critical appraisal.** The classification of ferns has been in a state of flux over the past several decades, but there is increasing agreement over relationships between genera. The differences in classification have more and more to do with the level of categories deemed appropriate, and the system that is presented above is a compromise between extremes. It has the advantage of serving the purposes of workers dealing with small fern floras, who would want to use the families only, and those dealing with large, complex fern floras, who would find the subfamilies of value as well.

Many fern groups show their relationships more by connecting links rather than by single character clusters shared by all members. In this sense, then, the ferns are polythetic, and many of the groups, such as the family Cyatheaceae of the present classification, are difficult to define with a single description.

Some authorities still regard the ferns as being related to club mosses (class Lycopodiopsida), horsetails (Equisetopsida), and whiskferns (Psilotopsida) and refer to all of the latter as “fern allies.” In many respects, pertaining especially to the life cycle, the ferns do indeed resemble the so-called fern allies, but in other respects, especially those having to do with the vegetative body of the plant, the ferns are quite distinct.

Sci.*, 36:349–482 (1962), not only illustrative of modern approaches to the comparative study of ferns, but contains much useful information on the relationships of Schizaeaceae; B.K. NAYAR and S. KAUR, "Gametophytes of Homosporous Ferns," *Bot. Rev.*, 37:295–396 (1971), a thorough summation of the knowledge of the haploid generation of ferns, including extensive bibliography; Y. OGURA, "Anatomie der Vegetationsorgane der Pteridophyten," in K. LINSBAUER (ed.), *Handbuch der Pflanzenanatomie*, sect. 2, pt. 2, vol. 7 (1938), brings together data on fern anatomy up to the 1930s, but is written in German and needs much updating; R.E.G. PICHI-SERMOLLI, "The Higher Taxa of the Pteridophyta and Their Classification," in OLOV HEDBERG (ed.), *Systematics of Today*, pp. 70–90 (1958), an essay on classification, of special interest for its viewpoint on the relationships of ferns with other pteridophytes; K.R. SPORNE, *The Morphology of Pteridophytes: The Structure of Ferns and Allied Plants*, 2nd ed. (1966), a brief book summarizing ideas of fern structure; FRANS VERDOORN (ed.), *Manual of Pteridology* (1938); EDGAR T. WHERRY, *The Fern Guide: Northeastern and Midland United States and Canada* (1961), an excellent example of a useful field guide, scientifically accurate but useful to amateurs.

(W.H.Wa.)

## Ferrites

Ferrites are hard, brittle, ceramic-like materials with magnetic properties that make them useful in portable radios, television receivers, computers, and other types of electronic equipment. They are polycrystalline (made up of a large number of small crystals) and are generally gray or black in appearance. They can be formed into permanent magnets and can be used as core material for electrical transformers, used to change voltages, and coils, used to produce electromagnetic effects; they have a very high electrical resistance and can be operated at high frequencies without excessive losses.

A ferrite material is basically an iron oxide (iron is represented by the symbol Fe and oxygen by O) with which another metal has been chemically combined. Many variations of its chemical composition and crystal structure are possible, leading to an almost infinite variety of characteristics and permitting ferrites to be tailor-made for specific applications.

**History.** Although the classical ferrite, the ferric oxide called magnetite ( $\text{Fe}_3\text{O}_4$ ), was known to man long before biblical times, the peculiar properties of natural and man-made ferrites were not recognized until late in the 19th century, and synthetic ferrites were first prepared in 1909. Important theoretical studies, leading to microwave applications of ferrites, were formulated by two Soviet scientists in 1935, and the new materials and their properties were studied by a number of researchers, culminating in the work of the Dutch physicist Jacob Louis Snoek and his co-workers, whose experiments created a solid foundation for ferrite physics and technology. The announcement of their results in 1946 marked the beginning of industrial use and of intense research effort by hundreds of scientists and engineers in Europe, the United States, and Japan. A French physicist, Louis Néel, formulated an extensive theory of ferrites on the atomic scale, coining the term ferrimagnetism

to distinguish ferrite properties from those of ferromagnetic metals.

**Properties.** The crystal structure, chemical composition, and heat treatment of ferrites determine their magnetic and electric losses. In general, the ferrite material behaves in most respects like a ferromagnet, exhibiting domains (regions in which all elementary north-south magnetic poles [dipoles] are aligned in a common direction), a hysteresis loop (a curve showing how the material reacts to magnetizing and demagnetizing forces), and saturation of the magnetization  $M$  at relatively low applied magnetic fields (see the Table). Practical values for Curie temperature (the temperature at which the magnetic properties disappear) range from 100° to 600° C (200° to 1,100° F). Resistivity, or opposition to the flow of electrical current, comparable to that of good insulators has been obtained.

Each type of crystal structure (spinel, garnet, and hexagonal) permits adjustment of ferrite properties over a wide range as needed for particular applications. A typical spinel ferrite is nickel (Ni) ferrite,  $\text{NiFe}_2\text{O}_4$ . Other ferrites may be obtained by substituting magnetic ions (cobalt, nickel, manganese) or nonmagnetic ions (aluminum, zinc, copper) for some of the nickel or iron ions, to produce the desired characteristics. Yttrium-iron garnet (YIG),  $\text{Y}_3\text{Fe}_5\text{O}_{12}$ , a classical ferrimagnetic garnet, combines very low magnetic loss with high resistivity at very high radio (microwave) frequencies. Substitution of magnetic rare-earth ions (gadolinium, ytterbium, holmium, europium) for yttrium and of nonmagnetic ions (gallium, aluminum) for some of the iron ions leads to many different ferrite compositions with a wide range of properties, including exceptional temperature stability.

**Manufacture.** Ferrite manufacture is similar to that of other ceramic materials in its use of the sintering process (heating a powdered mixture to a high temperature) for the formation of crystallites (small crystals) of prescribed chemical composition. The need for simultaneous control of mechanical, electrical, and magnetic properties, however, imposes stringent requirements on a complex series of operations, starting with the precise weighing of raw materials. Normally, extremely pure powdered metal oxides are mixed to a high level of uniformity and presintered at about 1,000° C (1,800° F). The material is then broken up into granules of uniform size and mixed with a binder or lubricant to prepare it for the formation of the desired piece parts by pressing or extrusion. The final step is a sintering process in a controlled atmosphere within an electric furnace. Preformed piece parts are heated to a temperature between 1,200° and 1,500° C for several hours and then cooled at a controlled rate to room temperature.

Any shaping of the ferrite pieces after sintering can be done by normal ceramic machining techniques such as grinding, diamond-saw cutting, and ultrasonic drilling.

**Applications.** Many types of ferrite materials formed into hundreds of shapes are being used to perform a multitude of tasks. To distinguish among major fields of applications, it is convenient to separate ferrites into five groups: soft, square-loop, hard, microwave, and single-crystal (see the Table).

**Soft ferrites.** These have a slender, S-shaped hysteresis loop and tend to lose their magnetism very easily after the magnetizing field is removed. Manganese-zinc and nickel-zinc ferrites with spinel structure exhibit these properties and permit their adjustment over a wide range of values through variations in composition. These ferrites are uniquely suited as cores for radio, television, and carrier telephony coils and transformers and permit miniaturization of such components. Movable ferrite cores can be used for easy adjustment of inductance (opposition to the flow of alternating current) in coils. Small and effective antennas for portable radios can be built by taking advantage of electromagnetic-field concentration in a ferrite core.

**Square-loop ferrites.** These materials exhibit an almost rectangular hysteresis loop and return to one of two distinct states of magnetization when the magnetizing field is removed. All practical square-loop ferrites

Ferrimagnetic structures

Summary of Ferrite Applications					
type	crystal structure	typical composition	typical properties	typical frequency	applications
Soft	spinel	$\text{Ni}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$ $\text{Mn}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$	high permeability $\mu_i = 15$ to $10,000$ , low loss, remanence, and coercive force, temperature stability	15 kHz to 100 MHz	carrier telephony inductors, television inductors and transformers; radio antennas
Square-loop	spinel	Mg-Mn-Zn ferrites, Li-Ni ferrites	rectangular hysteresis loop, low coercive force, temperature stability	pulsed operation 1 MHz	large two- and three-dimensional computer memory systems, logic devices for computers
Hard	hexagonal	$\text{BaFe}_{12}\text{O}_{19}$ $\text{SrFe}_{12}\text{O}_{19}$	high coercive force 2,000 to 10,000 oersteds	...	permanent magnets in loudspeakers, small motors and generators, measuring instruments, novelties, toys
Microwave	garnet	$\text{Y}_3\text{Fe}_5\text{O}_{12}$ (YIG) Gd, Yb, Ho and Ga, Al substitutions	$M = 200$ to $800\text{Gs}$ , low dielectric and magnetic losses	1-5 GHz	reciprocal and nonreciprocal phase shifters, on-off and transfer switches, isolators, 3-port and 4-port circulators, tunable devices, latching devices
	spinel	$\text{MeFe}_2\text{O}_4$ Me = Ni, Co, Mn, Al, Cu, Zn	$M = 1,000$ to $5,000$ gauss, low dielectric and magnetic losses	2-30 GHz	
	hexagonal	$\text{BaFe}_{12}\text{O}_{19}$ Sr, Ni, Co, Al substitutions	high anisotropy fields which act as biasing fields	30-100 GHz	
Single-crystal	spinel, garnet	$\text{Y}_3\text{Fe}_5\text{O}_{12}$ with rare-earth substitutions	optically transparent (garnets), extremely narrow line width, high anisotropy, nonlinear response to signal strength	...	recording heads for high-fidelity tape recorders, magnetic bubble devices for computer memory and logic functions, microwave filters, microwave power limiters, magneto- optical devices

have a spinel structure. The magnesium-manganese-zinc system has retained its pre-eminent position in computer-memory applications for more than two decades since its discovery in 1951. Recently, lithium-nickel ferrites and more complex systems containing lithium, manganese, and aluminum have become competitive in applications requiring stability and fast switching over a wide range of temperatures.

Ferrite  
toroids for  
computer  
memories

Billions of tiny ferrite toroids (doughnut-shaped cores) are manufactured annually for use in the core memories of large electronic computers. Because such a core retains its magnetization in either one of two directions, it permits storage of bits of information; typically, magnetization in one direction would indicate a 0 and in the other direction a 1 in a binary system. A change in the state of magnetization resulting from a current pulse through a wire threading the core produces a signal on a second threaded wire for recovering the stored information. Only current pulses above a threshold value will permit a signal to be stored or recovered. Pulses below threshold will leave the ferrite core unchanged.

This feature of the ferrite core has been exploited in the design of circuitry for selectively recovering information from large computer memories with thousands, even millions of individual cores. Typically, each core is threaded by three wires, two crossed wires (x and y, Figure 1) for write-in, and one for read-out. Two equal

and simultaneous (coincident) current pulses on one of the x- and y-wires produce a combined magnetic-field strength sufficient to change the state of the core threaded by both wires. All other cores on the same x- and y-wires receive only half of the required pulse and thus remain unchanged. A reversal of magnetization on any one core produces a signal on the read-out wire. This coincidence method permits individual addressing of, for example, 10,000 cores with 100 x- and 100 y- circuits whereas 10,000 circuits would be needed otherwise.

**Hard ferrites.** These are characterized by a hysteresis loop enclosing a large area and by the ability to function as a permanent magnet.

Typical hard ferrites have a hexagonal crystal structure with barium (Ba) serving as the metal combining with the iron oxide, leading to the chemical formula  $\text{BaFe}_{12}\text{O}_{19}$ . The barium may also be replaced by strontium. Many hard ferrites are highly anisotropic; *i.e.*, their magnetization occurs along a specific direction. This anisotropy is built-in during manufacture by orienting the tiny individual crystals with a strong magnetic field. An important application of hard ferrites is as permanent magnet cores in high-fidelity loudspeakers. Permanent ferrite magnets are also found in small motors, generators, measuring instruments, novelties, toys, and many other products for home and industry.

**Microwave ferrites.** These have garnet, spinel, and hexagonal crystal structure, with low electric- and magnetic-loss factors. Substituted and pure garnets, magnesium-manganese-aluminum ferrites, and magnesium-manganese ferrites are used at the lower part of the microwave spectrum. In the millimetre-wave region at frequencies of 30 to 100 gigahertz (one gigahertz equals 1,000,000,000 hertz, or cycles per second), nickel-zinc ferrites and hexagonal ferrites of various compositions are employed.
