Pongid dentition is clearly established in the fossil record of the Miocene Epoch and probably originated earlier. There appears to be progressive increase in the size of the incisors and widening of the symphysial region of the mandible with eventual formation of the simian shelf (a distinctive bony part of the anthropoid ape mandible). Strong, conical, sexually dimorphic canines that interlock in diastemata are found throughout the pongids (except for gibbons). The cutting function of the first lower premolar is accentuated with the development of a strong anterior root. Postcanine teeth preserve parallel or slightly divergent alignment in relatively straight rows, as opposed to the rounded hominid dental arcade. First deciduous molars remain predominantly unicuspid, and there is no apparent acceleration in the eruption of permanent canines. Pongid dentition belongs to an animal that feeds on large stalks of vegetation (tearing and rending them with large molar teeth), using enormous canines to lever, chisel, and support.

Skeletal (especially cranial) comparison of living and fossil Hominidae and Pongidae once led to widely varying conclusions. Relatively few cranial characteristics provide evidence for obviously different evolutionary directions for the two families. For example, the cranial capacity of *Australopithecus* is relatively small, ranging from 450 cubic centimetres to more than 600 cubic centimetres. There are strongly built supraorbital tori, and among larger individuals a low sagittal crest occurs at the vertex of the skull (frontoparietal). When hominid adaptation was better understood, these features no longer were held to indicate pongid affinities. Yet it is understandable that early in the 20th-century authorities were reluctant to classify australopithecines as Hominidae. As long as notions of what constitutes an early hominid prompt a search for a tiny version of *Homo sapiens*, most fossil hominids will be rejected. Nevertheless, hominid adaptations are manifest in *Australopithecus*. Dental characteristics that are hominid as opposed to pongid also occur in *Ramapithecus*. Clearly, elements of the adaptive complex that is called hominid were present in the late Miocene, and perhaps earlier.

Cranial distinctions

ECOLOGICAL ASPECTS OF HOMINID ORIGINS

Based on sparse evidence, discussions of the ecology of hominid origins are fraught with controversy and confusion. Clearly different from all living pongids, the only modern hominid is terrestrial. No living primate seems to provide an obvious model for reconstructing the ecological situation of the immediate ancestor of the hominids. One popular view is that a hominoid arboreal bra-

chiator (from which it is believed modern pongids also developed) was a transitional stage between prehominids and hominids. Another view is that hominid progenitors were terrestrial, with a highly social way of life resembling that of modern baboons. Others believe that the prehominid hominoid was arboreal, clinging to and feeding from small branches at the ends of limbs of tall trees in the forests. It also has been suggested that a semiterrestrial, semibrachiator preceded hominids. This typological view, despite temporary popularity, is based on dubious assumptions.

How is a decision to be made among alternatives of this sort? Each assumes a specific environment, a distinctive ecological system. Anatomic data (the best evidence available) suggest to some investigators that muscle and bone arrangements in the shoulder of *Homo* are a recent derivation from a lineage that brachiated. Other equally respected authorities interpret most of the anatomy as derived from the basic structure of the orthograde trunk of all primates, rather than from an anatomy specifically adapted for brachiating. Man's hand resembles that of terrestrial Primates, and some take this as supporting the view that the immediate ancestor of the Hominidae must have been terrestrial. Others point to startling resemblances between the hands of gibbons (true brachiators) and those of men. The notion that progenitors of the Hominidae occupied the small branches of trees is based on analysis of rather specialized modern primates. The few available postcranial bones of early Miocene Hominoidea once were believed to belong to brachiating primates. This view, however, is untenable, since all known Miocene hominoids are quadrupedal and are not brachiators in the sense that gibbons are. An arboreal brachiator probably should not be postulated as either the structural or the ecological progenitor of the hominids.

The inert fossil record can show no direct evidence for determining most of the structural and behavioral adaptations of the prehominids and earliest hominids. But it is possible to speculate about the sort of animal implied by early Miocene fossil fragments attributed to the Hominoidea.

The Miocene hominid *Ramapithecus* unfortunately is known only through maxillae and mandibles. Although the dentition in many ways is more like that of *Homo* than that of *Australopithecus*, firm statements about the mode of locomotion and general ecological situation of this beast are not yet supportable. Nonetheless, the small anterior dentition is probably good evidence that hominid dietary adaptation had already been achieved. If this is so, then it is not unreasonable to suggest that *Ramapithecus* was structurally adapted for hominid locomotion and for the hominid segment of the habitat. The hypothetical population from which *Ramapithecus* diverged was probably not specifically adapted to a brachiator's environment, but equally at home in trees or on the ground. Besides having a dentition approximating that of *Ramapithecus*, it must have had hands that were relatively free of locomotor tasks, and its pelvic girdle must have been less specialized than that of any pongid.

To speculate further: suppose that an early Miocene or late Oligocene hominoid (medium sized, smaller and slighter than modern chimpanzees, with smaller front teeth and defter hands than most other anthropoids) is faced with major environmental change. There is some evidence that (in Africa, at least) the distribution of great forests grew restricted and savanna grasslands expanded. The first of the prehominid hominoids might well have been able to respond to a changing environment by changing posture and locomotion. It seems reasonable that ecological conditions provided the selective advantage for the shift from orthograde quadrupedalism to erect bipedalism. In such a new adaptive zone, hunting and the gathering of small, hard food objects (seeds for instance) would become essential. It would include a change in ecology from thick forest cover to open woodlands, bush, and savanna. Clearly, a change in primate social organization is indicated: from random food gathering, like that of modern pongids, to a pattern of organized hunting and gathering. Indeed, almost all contemporary human groups that live by hunting are basically organized to subsist on vegetable material gathered by specifically assigned members.

The development of such cooperative groups that could exploit the savanna and grasslands very likely provided the selective pressure that emphasized erect posture, bipedal gait, skillful use of the hands, symbolic behaviour, and humanoid social structure. Erect bipeds with small anterior dentitions and talented hands would not have been able to create cooperative hunting and gathering groups without modifying their social organization. The rather loose social groupings of chimpanzees or the somewhat more organized baboon troops suggest what early prehominid hominoids may have been like socially and that a change in social organization was required. Organized foraging as a characteristic of a species imposes some differentiation in the social roles of those who care for infants and those who hunt. Cooperation among hunters develops, and family groups tend to become permanent and well integrated. Awareness must develop that allows for planning and discussion; the prey to be hunted, the tools needed for future hunting, and the probable harvest of wild grains and fruits. (Baboons and chimpanzees are justly characterized by the phrase, "out of sight, out of mind.") A lineage of primates in which these capacities emerged would be under strong pressure to continue to develop along such lines in an environment that presumably was changing rapidly from forest to bush and savanna. The transition from hominoid to early hominid to human involved reorganization of hand, pelvis, and foot, as well as brain. The unique social life of *Homo sapiens* seems to have its roots in a shift made by a prehominid hominoid from random food gathering to organized hunting and gathering on the African and Asian plains.

The probable origins and evolution of the Hominidae are better known than they once were. The number and variety of fossils available for study have increased; more importantly, preconceptions that hindered earlier investigations are dissipating. Major problems that remain include the need for finding more fossils and for refining the analyses of the anatomical, ecological, and, even, behavioral complexes these fossils imply.

ROBINSON, "The Australopithecines and Their Bearing on the Origin of Man and of Stone Tool-Making," *S. Afr. J. Sci.*, 57:3–13 (1961); and in P.V. TOBIAS, *Olduvai Gorge* (1967).

(J.B.-J.)

Homo Erectus

One of the extinct species belonging to the human family (see HOMINIDAE) is *Homo erectus* (formerly called *Pithecanthropus*). Members of this species differ in a number of respects from modern man, who is classified as a distinct primate species called *Homo sapiens*. The history of *Homo sapiens* may go back for 100,000 years, or perhaps even 200,000 or 300,000 years. Earlier than that, the fossil record tells of the existence of another kind of man, classified as *Homo erectus*. His remains have been found over large parts of the Old World—Africa, Asia, Europe—and he may well have inhabited these parts of the globe for as long as 500,000 to 1,000,000 years. His "moment" in geological time lies in the Pleistocene Epoch (2,500,000–10,000 years ago) and more particularly, in a rather vaguely defined subdivision, the middle Pleistocene.

Both in space and time, *Homo erectus* is well placed to have been the direct ancestor of *Homo sapiens*. Herein lies his special importance in the general theory of human evolution, for he seems undoubtedly the strongest claimant to fulfill the position of modern man's immediate predecessor. This reading of the evidence is widely accepted today; nevertheless, there are differences of opinion on such details as where and how *Homo erectus* evolved into *Homo sapiens*. That a development from the earlier *erectus* species into the later *sapiens* species did take place, however, is the consensus among most students of human evolution. Some of the possible pathways by which the evolutionary transition from *H. erectus* to *H. sapiens* may have occurred will be examined here.

Homo erectus is not, by any means, the earliest representative of the hominids (*i.e.*, the family of man). More archaic hominids are known from the early part of the middle Pleistocene, from the preceding lower Pleistocene, and even from the Pliocene Epoch (perhaps 4,000,000 years ago), which is the second last epoch of the Cenozoic Era, last of the great divisions of time in the earth's geologic record. This earlier phase of emergent humanity consists of a diverse array of upright-walking (though small-brained) creatures ranging from very large toothed, heavy-muscled, robust-boned forms to lighter, smaller toothed, more petite hominids. The most important of this group of fossil progenitors is called *Australopithecus*; and in body structure and function, as well as in their occurrence in time and space, some populations of *Australopithecus* (*q.v.*) fulfill the requirements for the ancestry of later forms of man.

In other words, the fossil evidence available today strongly suggests that one or another branch of *Australopithecus* evolved further, eventually giving rise to *Homo erectus*. Again, there is no absolute unanimity; a few dissident voices have placed a somewhat different interpretation on the sequence of events to be inferred from the fossils. These alternative interpretations are also reviewed, and the most probable reconstruction of events is considered.

If one accepts the majority view for the moment, *Homo erectus* may be interpreted as a transitional form of mankind, poised briefly (as geological eons go) between apeman, on the one hand, and modern man on the other. According to this view, in *Homo erectus* was wrought the revolution that converted an intelligent animal into a thinking, forward-looking, planning, imagining, and speaking man.

Ever since the time of the great Swedish naturalist Carolus Linnaeus (or Carl von Linné), it has been the practice to consider the world of living things as divided into species; several closely related species, in turn, are grouped into a genus (plural genera). To name a species, Linnaeus (1759) proposed that the genus and species be designated—like a surname and forename—in that order. The domestic dog, for instance, is called *Canis familiaris;* this refers to the *familiaris* species of the genus *Canis*. There are other related species in this genus, like *Canis lupus*, the wolf, and *Canis aureus*, the jackal. Modern man is called *Homo sapiens;* he belongs to the *sapiens* species of the genus *Homo*. The fossil hominid species that is of concern here is *Homo erectus*, another species of the genus *Homo*.

For more than three-quarters of a century, fossils have been coming to light showing more or less of the anatomical features of *Homo erectus*. Traditional in this field of study is the tendency for investigators to endow newly discovered fossils with newly invented names. In this way, the discoverers of newly found fossil specimens often have given the impression that their finds are completely different from any other specimens previously known. Not only have species names for hominids multiplied apace but even the proposed genera, within which the species are grouped, have presented a bewildering array—to confound the unfortunate student and to obscure the broader evolutionary trends. Thus, fossils that today are recognized by many workers as belonging to *Homo erectus*, at one time or another have been given such generic (genus) names as *Pithecanthropus, Sinanthropus, Atlanthropus*, and *Telanthropus*.

With the passage of time, paleoanthropologists (people who study the fossil history of man) have learned increasingly about the variability of living and fossil species. Minor anatomical differences—which once were taken as the definitive criteria for a new species or even a new genus—have come to be appreciated as individual or, at most, regional variants within the same species. Gradually, as the number of available samples of hominid fossils has grown with new discoveries, emphasis has been transferred from minor aspects of anatomical dissimilarity to the major points the ancient bones have in common. It has come to be realized that a whole group of hominid fossils has more in common with one another than any of them has with *Homo sapiens* or with *Australopithecus*. If these early fossil men were even nearly as variable as are modern species, then it seems to most authorities that they must all have belonged to a single species (now called *Homo erectus*).

It may be tempting to be snobbish and cynical about the name-making and species-inventing propensities of earlier workers; but it should not be forgotten that it was only the growth of understanding about variability in modern species, as well as the accumulation of additional fossils, that led to the more recent tendency to lump many different fossils into a single species bearing a single name. The changeover in approach was a consequence of history, rather than the exclusive result of any heightened understanding of biology among today's anthropologists.

HISTORY OF DISCOVERIES OF HOMO ERECTUS

Of the many names earlier given to representatives of *Homo erectus*, one is of more than passing interest: *Pithecanthropus*. Indeed, this name had already been coined before the discovery of the fossil to which it came to be applied. The name was invented by the German zoologist, Ernst Heinrich Haeckel, in the 19th century. He was one of those biologists who enthusiastically adopted Charles Darwin's theory of natural selection as the cardinal mechanism of evolutionary change. Haeckel postulated the former existence of a yet-to-be-discovered ancestral hominid, a kind of missing link that would be found to bridge the gap in the evolutionary chain between man and ape; and he called this creature of his scientific imagination *Pithecanthropus*.

The missing link

Years later, in 1891, Dutch army surgeon Eugène Dubois discovered the vault (braincase) of a skull and a few other fossilized bones at a place called Trinil in central Java. Considering its low-set braincase, retreating forehead, prominent eyebrow ridges, and a marked constriction of the skull behind the eye sockets, Dubois concluded that this cranium showed anatomical characteristics intermediate between those of men, as then understood, and those of apes; he revived Haeckel's old term and named his discovery *Pithecanthropus* (literally, apeman). Near the cranium he found a distinctly hominid thighbone (femur). Since this long, straight bone was so much like a modern human femur, Dubois decided that its owner must have walked erect. He assumed that the femur had belonged to the same individual, or at least the

same kind of hominid as did the skull—and so he named the species represented by the little cache of remains *Pithecanthropus erectus*.

The scholarly world's cynical reaction to the first claims about *Pithecanthropus erectus* eventually changed; and so did Dubois's own thinking—for at the time he died, many years later, he was much more inclined to stress the apelike features and to play down the hominid affinities of his discovery.

Distribution of Homo erectus. Subsequent discoveries gradually established the case for a new and separate species of fossil man. At first, these discoveries were centred largely in Asia. At several different places in Java (now part of Indonesia), essentially similar fossils were found: the sites are Trinil, Kedung Brubus, Modjokerto, and Sangiran. Another series of finds was made in China, especially in a famous cave called Chou K'ou-Tien near Peking (Peiping), although virtually all the remains from there were subsequently lost during the Sino-Japanese War, about 1939–40. Newer discoveries have since been made in this cave, while two new Chinese sites, in the Lan-T'ien district of Shensi Province, have yielded remains attributable to *H. erectus*.

Other finds in Asia and Africa

By the end of World War II, the freakish pattern of early discovery had given rise to an idea that *H. erectus* was a peculiarly Asian expression of early mankind. Then new discoveries in Africa served to change this view, and it came to be realized that Europe, too, may have harboured *H. erectus*.

In Africa, excavations at a place called Ternifine, east of Mascara, Algeria, in 1954–55, yielded remains whose nearest affinities seemed to be with the Chinese form of *H. erectus*. Other hominid fragments from northwest Africa—parts of a skull found in 1933 near Rabat in Morocco and jaws and teeth from Sīdī ʿAbd ar-Raḥmān (1954) in Morocco—show features reminiscent of *H. erectus*, though they are rather more advanced in structure than are those of Ternifine and of Asia. Another fossil probably related to *H. erectus* is a cranium found in 1960 at Koro Toro, Chad. Unfortunately, this cranium is fractured, distorted, and very worn. The most complete and convincing evidence for the existence of *H. erectus* in Africa came with the discovery in 1961 of a characteristic *H. erectus* braincase in Olduvai Gorge in Tanzania (so-called Olduvai hominid 9).

A further African claimant to membership in the species *H. erectus* is represented by skull fragments from a limestone cave deposit at Swartkrans in the Transvaal, South Africa. These fragments, found alongside remains of a robust *Australopithecus* population, were at first called *Telanthropus* but have since been assigned by many authorities to *Homo erectus*. Their incompleteness makes positive identification difficult, however.

The realization that Africa as well as Asia was apparently peopled by a form of mankind classifiable as *H. erectus* led to a re-examination of some of the earliest hominid fossils from Europe. An isolated lower jawbone had been found in a sandpit at Mauer, close to Heidelberg, Germany, in 1907. Although it had been given a variety of names over the years, its exact affinities to other fossils remained uncertain, since no associated cranium was found. In recent years, a number of investigators have come to regard the Mauer jaw as representing a member of the species *Homo erectus*. Although its geological age would appear to be slightly greater than that of Trinil in Java, Chou K'ou-Tien in China, and Ternifine in Algeria, this skeletal fragment from Europe shows more modern structural features than do the Asian and African jaws of *H. erectus*. The exact significance of these features in the Mauer jaw is still being debated; they could be the mark of an individual variant, highlighting the fact that it is not yet known how variable in bony structure *H. erectus* was. Alternatively, the Mauer specimen could represent a subspecies or race of *H. erectus* that is slightly more advanced in anatomic structure than are the African and Asian populations; or the Mauer man could have been a member of a very early population of *Homo sapiens*. Evidence for the latter has been provided by a newer discovery made in Hungary.

Possible European specimens

In 1965, remains of two individuals—a child and an adult—were found in a travertine quarry at Vértesszőllős, about 50 kilometres (roughly 30 miles) west of Budapest in Hungary. The remains of the child are milk teeth, and enough of them is preserved to show affinities with the Chinese *H. erectus* of Chou K'ou-Tien. The adult is represented by a large part of an occipital bone (at the back of the head) from a large-brained skull. While showing some features reminiscent of *H. erectus*, the general form and the capacity of the Hungarian cranium also suggest an affinity with an early branch of *H. sapiens*. In fact, it appears to be related to somewhat later middle Pleistocene skulls (perhaps 200,000 years old) from Europe, such as those of Swanscombe and Steinheim, which are accepted as early members of *H. sapiens*. Since such twofold affinities are exhibited by the Vértesszőllős group of remains, authorities differ as to whether to call the population they represent *H. erectus* or *H. sapiens*. The same uncertainty applies to some of the fossils found in North Africa; the Sīdī ʿAbd ar-Raḥmān and Rabat remains are regarded by some experts as late surviving members of *H. erectus* and by others as forms transitional between *H. erectus* and *H. sapiens*.

The European fossils that are of comparable age to those of Ternifine, Chou K'ou-Tien, and Trinil (namely the jaw from Mauer and the isolated milk teeth and occipital bone from Vértesszőllős) appear to have more structural features in common with early *H. sapiens* than do their Asian or African contemporaries. Some investigators would say that these anatomical differences are negligible compared to inferences they make that the remains from Mauer and Vértesszőllős are contemporary with *H. erectus* elsewhere, and that they represent a man whose way of life or cultural status was equivalent to that of *H. erectus* elsewhere. Even if these two inferences were accepted as facts, however, the approach taken by these investigators would represent a departure from the way in which paleontologists usually decide whether two groups of specimens belong to the same or to separate species.

Uncertainties

At this stage in the understanding of the early middle Pleistocene populations of Europe, it would probably be safest to conclude that the case is not yet convincingly established for the existence in Europe of *H. erectus*—as known from Asia and Africa.

The antiquity of Homo erectus. To reconstruct the position of *H. erectus* in hominid evolution, it is essential to define his place in time as precisely as possible. Modern developments in such disciplines as physics have placed at the disposal of the paleoanthropologist a variety of techniques that permit increasingly accurate assessments of the absolute age of fossils. Many of these methods are based upon the effectively constant (or absolute) rate at which radioactive isotopes of such elements as potassium and argon decay (see DATING, RELATIVE AND ABSOLUTE). When the newer methods cannot be applied, investigators may still ascribe a relative age to a fossil. This can be done by noting the contents of the layer of rock or the deposit in which the fossil was found; a layer containing, for instance, evidence of the remains primarily of extinct animals is probably older than one containing signs of predominantly recent or still living forms.

Such lines of evidence have led to the tentative conclusion that the species *Homo erectus* is essentially of early middle Pleistocene age. The oldest appearing fossil examples unfortunately all lack absolute dates; but, by relative dating from associated remains of other animals, it would seem probable that the hominid remains from Lan-T'ien in China, Sangiran and Modjokerto in Java (more especially, fossils from older deposits called the Djetis beds), and those from Swartkrans in South Africa (if, indeed, these are correctly to be designated *H. erectus*) are the oldest representatives of *H. erectus* thus far discovered.

On the other hand, the youngest accepted hard-core representatives of *H. erectus* in the fossil record would seem to be the group from Peking in China, Trinil in Java, Ternifine in Algeria, and the braincase of Olduvai

hominid 9 from Tanzania. Repeated potassium-argon datings of the Trinil beds has yielded an estimate of their age in years as 550,000 BP (before present).

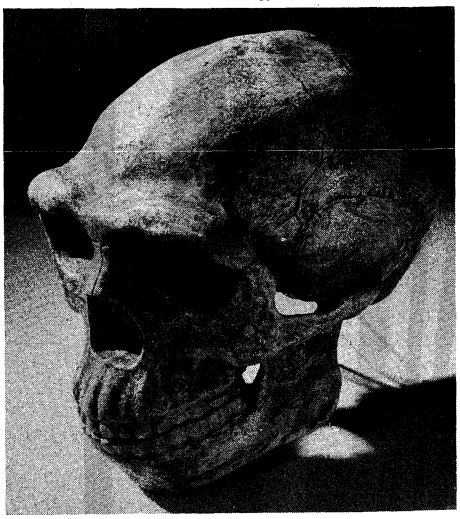
Until more complete evidence is available it would seem reasonable to suggest 1,500,000 to 500,000 BP as a time range for *Homo erectus*. Beyond this time range are a group of earlier fossils that some scientists have called *Homo habilis*, a few members of which are regarded by other investigators as representing an early expression of *H. erectus*. These fossils are best known from the Olduvai Gorge in Africa, and the oldest specimen from there seems to be about 1,800,000 years old. On the other hand, there is a group of later specimens that show some features of *H. erectus* but that are commonly regarded as transitional forms or as members of *H. sapiens;* these include later middle Pleistocene specimens from Europe (discovered at sites at Swanscombe, Steinheim, and Montmaurin) and from Africa (Sīdī ʿAbd ar-Raḥmān and Rabat). Still later forms suggest *H. erectus* biological ancestry, such as certain upper Pleistocene fossils from Asia (Solo man from Ngandong in Java) and from Africa (sites called Tēmara, Tangier, Lake Eyasi, Broken Hill [Kabwe], Cave of Hearths, and Hopefield). Thus, backward and forward in time from the dating of the hard-core *H. erectus* specimens, the problem of recognizing fossils as belonging to *H. erectus* becomes more difficult; the "lower" and "upper" boundaries of the species become blurred. These are the transitional zones in which a predecessor species seems to have been grading imperceptibly into its evolutionary product, *Homo erectus*, and in which *H. erectus* apparently was undergoing further evolutionary change into its descendant species, *H. sapiens*, to which modern man belongs.

Homo habilis

THE BODILY STRUCTURE OF HOMO ERECTUS

It is striking that the anatomical differences observed between *H. erectus* and *H. sapiens* have been confined to the skull and teeth. The limb bones thus far discovered have been indistinguishable from those of *H. sapiens;* on this evidence it has been inferred that *H. erectus* was an upright-walking man of medium stature.

By courtesy of the University Museum of Archaeology and Ethnology, Cambridge



Reconstructed skull of Peking man (*Homo erectus pekinensis*).

An estimate of the size of his brain may be obtained from the capacity of the interior of the fossil braincase (cranium). Such endocranial (interior) capacity measurements show that *H. erectus* was smaller brained than is modern man. The average capacity for 14 crania of *H. erectus* from Java, China, and Africa is 941 cubic centimetres (cc; 57 cubic inches); the smallest and largest capacities determined for this group of fossils are 750 and 1,225 cc. The average capacity in modern *H. sapiens* is 1,350 cc (82 cubic inches), but the range for modern man is appreciable, perhaps 1,000 to 2,000 cc (61 to 122 cubic inches). Manifestly, the upper part of the range for *H. erectus* overlaps the lower part for *H. sapiens.*

Some difference in estimated brain size is apparent between the Javanese and the Chou K'ou-Tien (Peking Chinese) populations of *H. erectus.* Thus, for seven Javanese crania, the average is 883 cc (54 cubic inches), with a range from 750 to 1,030 cc (46 to 63 cubic inches); while for five Chou K'ou-Tien crania, the capacity ranges from 915 to 1,225 cc (55 to 75 cubic inches) and averages about 1,045 cc (64 cubic inches). That is, the mean capacity in the Peking fossils of *H. erectus* exceeds that of the Javanese by about 160 cc (10 cubic inches). Investigators note with interest that the Lan-T'ien cranium (also Chinese), which comes from an earlier period than do those of Chou K'ou-Tien, and is an approximate contemporary of the earlier fossils from Java, shares with the Javanese group a smaller cranial capacity (780 cc). Theoretically, the difference in brain size between the two groups of Asian fossils of *H. erectus* may be the consequence of further evolutionary increase in brain size in later populations of *H. erectus.* Alternatively, it may simply be interpreted to represent differences in average features between two different "races" or subspecies of *H. erectus.* The solitary African value available is that of Olduvai hominid 9, which has a capacity of 1,000 cc (61 cubic inches).

Differences in brain size

While the cranial capacity of *H. erectus* falls short of that of *H. sapiens* by about 470 cc (29 cubic inches) on the average for the Javanese group, and about 300 cc (18 cubic inches) for the Peking group, *H. erectus,* in turn, exceeds the australopithecine capacities (see AUSTRALOPITHECUS) by an average of about 430 cc (or 26 cubic inches) in the case of the Javanese fossils and about 600 cc (or 37 cubic inches) for Peking man. Thus, the cerebral gap between *Australopithecus* and *H. erectus* is slightly greater than that between *H. erectus* and *H. sapiens.* Into the former gap fit the cranial capacities of that rather mysterious and controversial little group of fossils known in the literature as *H. habilis.* Clearly, the last word has not been written on their affinities. The possible evolutionary place of the cranial capacity of *H. erectus* seems to emerge clearly in the following list (progressing from some of the most ancient fossils to today's man).

Average capacity of braincase	
Smaller *Australopithecus* (6 fossil examples)	450 cc
Robuster *Australopithecus* (2)	515 cc
Homo habilis (3)	656 cc
Javanese *H. erectus* (7)	883 cc
Chinese (Peking) *H. erectus* (5)	1,043 cc
H. sapiens (many modern men)	1,350 cc

Apart from their characteristically small capacity, the skulls of *H. erectus* show a series of distinctive features. The braincase is low, with sides that taper upwards, and the bones of the cranial vault are thick. Over the eye sockets is a strongly jutting ledge of bone, called a supraorbital torus, while a markedly thickened shelf of bone (occipital torus) adorns the hind end of the skull. There is a receding forehead—a wit has called these men the original lowbrows—and the front part of the cranium immediately behind the supraorbital torus is appreciably constricted from side to side.

The nose of *H. erectus* is wide, the jaws and palate being broad and somewhat prominent. The teeth are on the whole larger than those of *H. sapiens,* though smaller than those of *Australopithecus.* The front teeth (incisors and canines) are especially large for a hominid, some even exceeding in size those of *Australopithecus.* A few *H. erectus* specimens from Java have so well-developed an eyetooth (or canine) that the tip protrudes beyond the crowns of the adjacent teeth. In terms of evolutionary theory, this is considered an archaic trait, since it occurs in apes, but in no other hominids, extinct or living. Several other primitive characteristics are preserved in the teeth, such as the presence of three roots on a few of the upper first premolars and an increasing length of the lower molars from first to third. Considered as a totality, however, almost all authorities agree that the dentition of *H. erectus* is hominid in character, rather than pongid (of the ape family).

The total pattern of the bodily structure of *H. erectus*, as preserved in his bones, shows a provocative blend of advanced features—such as his lower limbs or locomotor apparatus, which suggest that he stood upright and walked on two legs, as is typical of *H. sapiens*—and of primitive features—such as his archaic dental traits (testifying to his probable genetic inheritance from more ape-like forebears) and his brain size, which is smaller than that of modern man, though not so small as that of *Australopithecus*. In addition, in his thick skull bones and extraordinarily developed eyebrow ridges and occipital torus, some investigators say they see unique, specialized features, not characteristic either of his presumed ancestors or of apes and not pointing to *H. sapiens* as the direction of subsequent evolution.

Some scientists even infer that these last traits show *H. erectus* to have specialized so far off the modern human line that it could not have been ancestral to *H. sapiens*. Certainly it is notable that the more ancient *Australopithecus* had thin skull bones and only modest protuberances on his cranium; while the later *H. sapiens* also tends to have thin skull bones with a marked diminution in the size of crests and ridges sculpted on the surface of the cranium. It is often said that only two choices are open in interpreting this situation: either *H. erectus*, with his thick cranium and monstrous adornments on the skull, could not have been on any direct evolutionary line from *Australopithecus* to *H. sapiens;* or else, it must be postulated that *H. erectus* evolved his specialized features from *Australopithecus* and then lost them again (or underwent a kind of evolutionary reversal) to produce the thin, smooth cranium of modern *H. sapiens*.

Yet, the two choices offered for solving the problem are judged by some authorities to be over simplified. It has been observed that the exponents of this view probably fail to take into account that there is very little evidence about the variability of these features—cranial thickness and external embellishments of the skull—among members of even one population of *H. erectus*, let alone among different populations of *H. erectus* dispersed through two or three large continents. Then, too, practically nothing is known about the climatic or ecological conditions under which cranial thickening occurred, or of the effect on skull growth of the brain enlargement that was so striking a feature of the evolutionary advance of early middle Pleistocene Man to the men of the late middle and of the upper Pleistocene. These and many other questions need answers before *H. erectus* can be written off as an ancestor of *H. sapiens*. In the meantime, another hypothesis that meets most of the available evidence is that the anatomical structure of *H. erectus* was a blend of ancient and modern features, precisely because he belonged to a people in transition. It is suggested that he was in the process of evolving from pre-*Homo erectus*, probably *Australopithecus* and *Homo habilis*, to post-*Homo erectus;* that is, to *H. sapiens*. In most details, his bodily structure fulfills what might have been predicted for an intermediate between *Australopithecus* and *H. sapiens*.

Unanswered questions

INFERRED BEHAVIOUR OF HOMO ERECTUS

To understand this species of fossil man more completely requires looking past his bones and beyond his dispersal in time and space. What evidence exists that bears upon the behavioral or cultural pattern of his daily existence?

First, the discovery sites themselves may throw light on this question. At Chou K'ou-Tien, the remains of *H. erectus* were found in a cave deposit; this in itself does not prove that these men were consistent cave dwellers. But the additional evidence of associated remains of stone and bone that seem to have been accumulated by these creatures—charred animal bones, collections of seeds, and what could be ancient hearths and charcoal—all point to *H. erectus* as having spent appreciable periods of time as a troglodyte (cave dweller) at Chou K'ou-Tien. The remains of Lan-T'ien, Trinil, Sangiran, Modjokerto, as well as Ternifine and Olduvai, were all found in open sites, sometimes in stream gravels and clays, sometimes in river sandstones, in conglomerate and volcanic rocks, or in lake beds. These suggest that *H. erectus* also lived in open encampments along the banks of streams or on the shores of lakes; proximity to water was crucial to the survival of man. The remains of Vértesszőllős Man showed that he occupied mud flats deposited along with minerals around springs in a tributary of the Danube River. These open presumed campsites revealed by excavation contain abundant stone implements and stone chips that seem to have resulted from their manufacture, fractured and partly burnt bones of animals that could have been hunted for food, and traces of what appears to have been a hearth.

Thus, both Chou K'ou-Tien and Vértesszőllős have shown signs that early middle Pleistocene Man had a controlled mastery of fire. Indeed, outside the cave at Chou K'ou-Tien, charcoal was found along with traces of a stone toolmaking industry in an open gully deposit that seems to be slightly older than the cave deposit itself (containing the bones of *H. erectus*). In this region of China, therefore, it has been observed that the earliest convincing indication of the use of fire by men immediately precedes the earliest example of a cave being occupied by them. This supports the notion that successful cave dwelling by human creatures depended on their first having mastered fire.

Mastery of fire

It was not only cave dwelling that mastery of fire seems to have made possible. Able to keep warm, man was now apparently able to move into colder climes; indeed, this factor may have speeded the migrations of ancient men into the chilly, often glaciated regions of prehistoric Europe. Sooner or later, too, man started cooking his food, thus reducing the work demanded of his teeth. This, in turn, may have played an important part in minimizing the evolutionary advantage of big teeth—cooked food needs far less cutting, tearing, and grinding than does raw food. This relaxation of the evolutionary selective pressure that favoured the survival of people with strong, big teeth may, in turn, have led directly to a diminution in the size of the teeth—one of the features, it will be recalled, that distinguish *H. sapiens* from *H. erectus*.

Other signs of the culture of *H. erectus* are the implements found in the same deposits as his bones. Chopping tools made from split pebbles characterize both the Chou K'ou-Tien and Vértesszőllős deposits; both are members of a so-called chopper–chopping-tool family of industries described for prehistoric Southeast Asia in the scientific literature. At both sites, stone flakes and bone artifacts showing human workmanship occur too. This evidence has been thought by some to support efforts to classify Vértesszőllős Man as belonging to *H. erectus*. The uncertainty entailed in trying to infer from cultural evidence to biological classification is shown by the cultural associations of the Ternifine man. This northwest African *H. erectus* was found in association with totally different kinds of stone implements; these comprise bi-faced hand axes and scrapers that have been characterized as representing what archaeologists call an early Acheulean industry (Acheulean II). This is part of a great Acheulean hand ax complex of human industry, remnants of which are found widely spread over large parts of Europe, Africa, and Asia (except Southeast Asia). An Acheulean industry is known also from Olduvai Gorge, as is a local ancient form of stone-chopper manufacture known as the Oldowan culture; but the exact cultural associations of these stone tools with the African *H. erectus* (as exemplified by Olduvai hominid 9) are uncertain.

Hence, *H. erectus* has been found associated in some parts of the world with a chopper–chopping-tool tradition and in other places with an Acheulean bifaced hand ax industrial complex. This serves as a timely reminder that hereditary aspects of race or bodily structure are not inextricably interlinked with such cultural manifestations as toolmaking traditions. It is most reckless, and indeed fallacious, to infer from stone implements the physical type of the man who might have made them. Apparently *H. erectus* had considerable versatility in manufacturing implements. Even during this early phase

Reckless inferences

of stone toolmaking activities, a well-diversified suite of tool types is recognizable, within both the east Asian chopper-tool industries and the African Acheulean complex.

Numerous nonhominid animal bones have been found with *H. erectus* remains; sometimes they seem to have been cooked, deliberately broken, and even fashioned. From this evidence, it seems that *H. erectus* was a hunter. His bodily (including cerebral) endowment and his manufactured equipment were so much superior to those of *Australopithecus* that it is highly probable his food-collecting techniques, including hunting, were better, too. Many scientists hold that *Australopithecus* was more of a scavenger than a hunter, perhaps at best an opportunistic hunter who seized his chance when a weak, young, sick, or aged animal crossed his path; indeed, many of the animal bones found in australopithecine deposits are of juvenile and aged creatures. *H. erectus*, on the other hand, seems to have been a confirmed hunter, a habitual eater of fresh meat; and his prey included animals of all age groups.

It can credibly be supposed that, as with present-day hunters (such as the Kalahari Bushmen and the Australian Aborigines), meat from the hunt formed only a part of the diet of *H. erectus*. Other juicy morsels may have been furnished by snakes, birds and their eggs, locusts, scorpions, centipedes, tortoises, mice and other rodents, hedgehogs, fish, crustaceans, and a myriad other edible forms of life. Many of these even children could have caught—as they do in the Kalahari today, before they are allowed to accompany the older men on the hunt. Vegetable food also must have played a big part in the diet of *H. erectus*, in the form of fleshy leaves, fruits, nuts, and roots. Accumulations of hackberry seeds, for example, were found in the Chou K'ou-Tien cave deposit.

There seems little doubt that *H. erectus* must have been omnivorous (as *H. sapiens* is today), for such a diet is the most opportunistic of all, and modern man is the most opportunistic of all living primates. Emancipated from too narrow an environmental dependence, from too restricted a dietary regimen, man has come to live off many diets, in many surroundings. He is *par excellence* the creature that lives with an eye for the main chance. *H. erectus* was probably one of the earliest of the great opportunists; and it is likely that his very opportunism endowed him with evolutionary flexibility, with adaptability, with a very plastic survival kit.

Another question one may ask about his culture is whether there is any evidence of ritual among these extinct people. There is no sign yet that *H. erectus* buried his dead; no complete burials have been found, no graves, no grave goods, no red ochre (a mineral used as a paint by later forms of man) on or around the bones. That cannibalism was practiced seems most probable; it has been pointed out that the human bones of Chou K'ou-Tien are in the same broken and splintered state (perhaps for eating the marrow) as are those of other animals. The preponderance of human skulls in the Chou K'ou-Tien deposit has been interpreted as evidence that *H. erectus* went in for headhunting. The site has yielded thousands of pieces of nonhominid animal remains pertaining to every part of the skeleton; but, although the bones of *H. erectus* are those of more than 40 individuals, the overwhelming majority are represented by parts of skulls, there being only a very few fragments of human limb bones. Human heads would seem to have been selected, much as one finds them in the lairs of later headhunters.

Signs of cannibalism and headhunting

Evidence of collecting skulls is not the only sign of ritual observances. In no single *H. erectus* cranium known (whether from China, Java, or Africa), is the base of the cranium intact. Every one shows damage to the region around the foramen magnum (the hole in the base of the skull through which the stem of the brain passes on its way to become the spinal cord). This damage appears to have been deliberately inflicted; that this is one of the thinnest parts of the cranium is an unconvincing argument for accidental damage; indeed, even in the much thinner walled crania of *Australopithecus* this region is typically found intact. On the other hand, very similar signs of intentional mutilation are found on the skulls of early and later Neanderthal men, as well as on those of the Bronze Age of Germany. Present-day headhunters of Borneo and New Guinea inflict very similar cranial mutilations on special ritual occasions; they extract the brain through the aperture they have made and eat it ceremonially, holding that this permits the name of the deceased victim to be handed on to the son of the ritual cannibal. At any rate, some authorities consider that the damage to the base of the crania of *H. erectus* was not only deliberate but that it is an indication of ritual mutilation with ritual (rather than nutritional) cannibalism. If this interpretation is correct, perhaps headhunting, ritual mutilation of the skullbase, and, possibly, ritual cannibalism were the earliest semblance of ritual in the life of *H. erectus*.

RECENT CONTROVERSIES CONCERNING THE RELATIONSHIP BETWEEN HOMO ERECTUS AND HOMO SAPIENS

Erectus as a direct ancestor of sapiens. One leading worker in recent times has energetically opposed the view that *Homo erectus* was the direct ancestor of *Homo sapiens;* paleontologist L.S.B. Leakey (1903–72) held that the anatomical features of *H. erectus* are too specialized for the species to have evolved into *H. sapiens*. In his view, the lightly constructed and unspecialized *Homo habilis* was the direct forebear of *H. sapiens*. Those of the lower Pleistocene hominids that evolved into *H. erectus* had, according to Leakey, gone out on an evolutionary limb, doomed to extinction and destined to make no contribution to *H. sapiens*.

Most other workers do not accept this view and recognize *H. erectus* as ancestral. Anthropologist P.V. Tobias has proposed a compromise view; he acknowledges that there is a small but significant body of evidence for the existence of middle Pleistocene hominids that did *not* show the classical features of *H. erectus*—such as thick cranial-vault bones, large brow ridges and occipital ridges, and big teeth. Examples are provided by the Kanjera crania from Kenya, the remains of Vértesszőllős, Swanscombe, Steinheim, Mauer, and the little group of East African fossils known as *H. habilis*.

The existence of what appear to be two forms of man in the middle Pleistocene is susceptible of several interpretations other than that proposed by Leakey. The remains may all belong to *H. erectus*, but the species may have been very much more variable than was suggested in earlier definitions (like that of Sir Wilfrid Le Gros Clark)—so variable, in fact, as to make the old anatomical definition of *H. erectus* virtually meaningless. Or, a dichotomy into a "specialized" line—the classical *H. erectus*—and a slender, unspecialized, thin-skulled line may have occurred. In this view, neither line would be excluded from contributing to the genetic heritage of *H. sapiens*. Some populations, it is suggested, could have reached *sapiens* status via the *H. erectus* pathway, others by way of the non-*erectus*, *habilis*, and pre-*sapiens* route.

More likely, the two lines did not remain distinct everywhere; crossing may have occurred to mingle the genes of the two forms. In that event, it is unlikely that one would be justified in calling each of the two lines a separate species; this comes back to the idea that the two supposed lines may represent nothing more than two subspecies, or "races," of the same species (that is, of *H. erectus*). According to this view, *H. erectus*—like *H. sapiens* today—was a polytypic species; that is, one divided into two or more different forms, each known as a subspecies. Indeed, it has been observed that a number of subspecies of *H. erectus* are recognized (*e.g., H. erectus erectus, H. erectus pekinensis, H. erectus mauritanicus*).

Supporting the compromise view (rather than Leakey's) is the appreciable number of *H. erectus* features to be found in some early members of *H. sapiens* of the late middle Pleistocene and the upper Pleistocene, and even in some modern men. It is argued that at the very least these features prevent the exclusion of *H. erectus* from having contributed to the ancestry of modern man.

The erectus–sapiens threshold. The U.S. anthropologist C.S. Coon, in his book *The Origin of Races,* has suggested that the passing over from *H. erectus* to *H. sapiens* represented the crossing of a kind of evolutionary Rubicon; that is, a clearcut boundary, or threshold, marked by not only bodily changes but striking cultural changes. This supposed interrelation of cultural achievement and the shape and size of teeth, jaws, and brain is a theorized state of affairs with which many students of fossil man strongly disagree. Throughout the human fossil record, there are examples of dissociation between skull shape and size, on the one hand, and cultural achievement on the other.

A smaller brained fossil *H. erectus* from China seems to have been among the first men to tame fire, while much bigger brained people in other regions of the world, and living later in time, have yielded no evidence that they knew how to handle fire. (Differences in inferred cultural activities between African and Asian members of *H. erectus* have already been emphasized above.)

In fact, evolutionary theory recognizes continuity between one species and a succeeding species in the same lineage. Such successive species in the evolutionary sequence are called chronospecies. The "boundaries" between chronospecies seem almost impossible to determine by any objective anatomical or functional criteria; one is reduced to the guesswork of "ruling off" at a moment in time to draw the boundary. Thus, competent authorities have seriously suggested that, in the last analysis, such a chronological boundary may have to be drawn arbitrarily between the last survivors of *H. erectus* and the earliest members of *H. sapiens.* The problem of defining the limits of chronospecies is not peculiar to *H. erectus;* it is one of the most vexing questions in paleontology today.

This kind of vague boundary, drawn for convenience at a moment in time, with the earlier hominids grading imperceptibly across this line into the later, is a different conception from Coon's theory that there is a firm, specific, biologically and culturally definable threshold, or boundary, between *H. erectus* and *H. sapiens.* It is with the latter assertion that many workers have expressed disagreement since the appearance of Coon's book; the concept he proposed has not so far gained wide acceptance.

Multiple erectus–sapiens evolutions. Here again, Coon has advanced a theory with which most workers concerned with human evolution have found themselves in serious disagreement. Assuming the validity of his notion of an *erectus–sapiens* threshold, Coon has claimed that *H. erectus* evolved into *H. sapiens* not once but five times, as each subspecies of *H. erectus,* living in its own territory, passed the postulated critical threshold. Since this part of Coon's theory depends on accepting his supposed *erectus–sapiens* threshold as correct, those who find this threshold concept at variance with the modern genetic theory of evolutionary change cannot accept this idea of Coon's either.

A corollary of this concept is Coon's suggestion that different subspecies (or "races") of man evolved at different rates and, hence, crossed the *erectus–sapiens* threshold at different times. In particular, Coon has suggested that "the step from the ancestral *Homo erectus* to the modern *Homo sapiens* was taken by Caucasoid man in Europe no less than 200,000 years before the same step was taken by Negro man in Africa." This part of Coon's reasoning is not only based on a concept that is at odds with modern evolutionary theory, but some of the assumed "facts" on which it is based are highly problematical. He has claimed that the races of today had already appeared before the *erectus–sapiens* transition. Apparently by allocating two very early fossil human skulls from Europe (Swanscombe from England and Steinheim from Germany) to the European, or Caucasoid, "race," although they lived 250,000 years ago, he has concluded that the supposed *erectus–sapiens* transition had occurred *among Europeans, or Caucasoids,* as long ago as 250,000 BP. Few if any paleoanthropologists would agree with Coon that these early skulls are to be recognized as those of members of the Caucasoid, or European, "racial" group, as generally understood.

Coon's belief that Europeans evolved before Africans

Turning to Africa, Coon has claimed that Broken Hill man (represented by parts of two skeletons found in Zambia in 1921) belonged to *H. erectus.* Since it is probable, on archaeological evidence, that Broken Hill man lived perhaps 30,000 or 40,000 years ago, Coon (by attributing these Zambian bones to *H. erectus*) has claimed that *H. erectus* was still present in Africa long after he had disappeared from the European scene. The crux of this argument hinges on controversial judgments of the species to which Broken Hill man is to be assigned. In contrast to Coon, most paleoanthropologists regard Broken Hill man as a member of a Neanderthal-like African subspecies of *H. sapiens,* commonly dubbed *H. sapiens rhodesiensis.* If that one set of Zambian bones has been misdiagnosed by Coon as *erectus,* one major prop of his argument—that the *erectus–sapiens* threshold was crossed in Africa much later than elsewhere—falls away.

The evidence for the late survival of *H. erectus* in Africa is questionable at best. No less suspect is the evidence on which Coon has based his claim that the first *H. sapiens* appeared in Africa very late. In the 1930s, Leakey discovered the heavily fossilized remains of a group of human skulls at a place called Kanjera on the shores of Lake Victoria in Kenya. The remains have relatively smooth brows and suggest affinity with *H. sapiens.* At least two possible interpretations have been advanced. The Kanjera cranias may represent a relatively smooth-browed variant of the polytypic species, *H. erectus,* since the Kanjera deposits in which they belong are of middle Pleistocene age; or they may represent an early African branch of *H. sapiens.* One is confronted here with the same twofold possible interpretation as was faced (above) in discussing the Hungarian fossils from Vértesszőllős. Coon has classified the Kanjera fossils as *H. sapiens* but has allocated them a date of 40,000 years, a dating for which there seems to be no evidence. As mentioned, the Kanjera deposit is known on the basis of associated remains of nonhuman animals to be of middle Pleistocene age. If the fossilized human skulls found there indeed do belong to the same time period as do the other animal bones, then Kanjera Man would be of the same age as are the earliest *sapiens* skulls found in Europe. Chemical tests so far performed support the view that the human and animal bones of Kanjera were contemporaneous. If this is correct, the age of the Kanjera crania would be far greater than Coon's figure of 40,000 years. Yet it is precisely the latter, dubious date that supports Coon's claim that the earliest known African representative of *H. sapiens* dates from this relatively recent, upper Pleistocene date.

Since considerable doubts surround Coon's statements about both the Broken Hill (Kabwe) and Kanjera skulls, his claim (based on this "evidence") that the supposed *erectus–sapiens* threshold was crossed in Africa very recently, and perhaps 200,000 years later than in Europe, has not been sustained.

This controversy about *H. erectus,* in which Coon's concepts have understandably gained no serious support, rests both on evolutionary theory and on the fossil facts. There seems to be no valid evidence for saying that African man has been *H. sapiens* for only 30,000 or 40,000 years and that Europeans of that species have been present for 250,000 years. One should be obliged on present evidence to conclude that Africa's earliest claimant to *sapiens* status (Kanjera) is of about the same age as the earliest *sapiens* men in Europe.

The controversy underlines the continuing need for more fossils (to establish the range of physical variation of *H. erectus*) and for more discoveries in good archaeological contexts that permit increasingly precise dating. Hopefully, additions to these two bodies of data will settle the remaining controversies and bring the unsolved problems of phylogeny and classification of *H. erectus* nearer to resolution.

Homoptera

The members of this large group of sucking insects, considered a suborder of the Hemiptera by many entomologists but a separate order by others, exhibit considerable diversity in body size and number more than 32,000 species. All of the Homoptera are plant feeders, with mouthparts adapted for sucking plant sap from a wide assortment of trees and wild and cultivated plants. Many homopterans cause injuries or destruction to plants, including fruit trees and grain crops; others are vectors of plant diseases; and a few provide secretions or other products that are beneficial and have commercial value to man. Most members of the Homoptera fall into one of two large groups; the Auchenorrhyncha contain the cicadas, treehoppers, froghoppers or spittlebugs, leafhoppers, and planthoppers or fulgorids; the Sternorrhyncha include aphids or plant lice, phylloxerans, coccids, scales, whiteflies, and mealybugs.

From Richard A. Pimentel, *Invertebrate Identification Manual* (1967); Reinhold Publishing Corporation

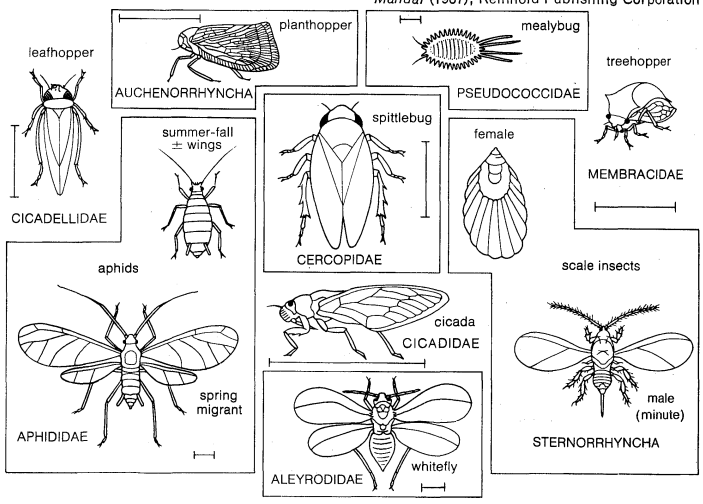

Figure 1: Representative homopterans. Line scales indicate approximate sizes of insects.

GENERAL FEATURES

Size range. The majority of homopterans range from 4 to 12 millimetres in length. There are cicadas in Borneo and Java, however, that are eight centimetres long with wingspreads of 20 cm. The large fulgorid or lanternfly can attain this size also. On the other hand, some scale insects are only ½ mm in length.

Distribution and abundance. Although Homoptera are distributed throughout the world, the relative numbers of individual species vary in a given locale. Only one cicadid species is known in Great Britain, fewer than 12 in all Europe; however, more than 200 cicadid species are known in North America, and about 180 in Australia.

The abundance of any species in a given environment depends upon the biotic potential of the insect, the abundance of the food plant, and other factors favourable for development of large populations. Certain species never reproduce in excessive numbers, while others, considered pests, produce millions of offspring. Insect species that feed on available crops or other plants present in quantities sufficient to support them normally develop large populations; for example, the oyster shell scale (*Lepidosaphes ulmi*) on fruit trees and ornamentals; the greenbug (*Toxoptera graminum*) on wheat; the potato leafhopper (*Empoasca fabae*) on potatoes, beans, and alfalfa; and grape leafhoppers (*Erythroneura*) frequently develop large populations that result in heavy plant losses.

IMPORTANCE

Homopterans, because they feed on sap sucked from plants, often cause injuries or destruction to the plants that nourish them. When such plants happen to be cultivated crops (*e.g.*, grains or fruit trees) or ornamentals valued by man, the economic loss resulting from infestations is severe. In addition, some homopteran species act as vectors of virus- and bacteria-caused diseases of their plant hosts (see DISEASES OF PLANTS). The check exerted upon insect pests by other insects is an important mechanism of natural control of populations. Predacious insects feed on small, weak species; parasitic insects live on or in a host and feed at its expense. Aphids, for example, are parasitized principally by members of the Hymenoptera; two important aphid predators are ladybird beetles and lacewings. Pests also may be controlled by chemical and biological methods (*e.g.*, development of resistant plants, as with European grapevines; see PEST CONTROL).

Plant injury

The homopterans are responsible for injuring numerous plants of economic importance to man. Cicadas or dog-day harvestflies are well-known pests frequently misnamed locusts. Characterized by their large size and the strident song of the male, periodical cicadas emerge every 13 or 17 years in large numbers, swarm in trees, mate, and lay eggs in green twigs. Of economic importance is the permanent damage to fruit twigs caused by egg deposition slits; when the weakened twigs mature into fruit-bearing limbs, they break under the weight of the fruit, and the crop is lost. Failures of this sort can be avoided by not planting young fruit trees in years of cicada emergence.

Leafhoppers alone cause various types of plant injury by interfering with the normal physiology of the plant. The salivary secretion of the potato leafhopper, for example, causes leaf cell hypertrophy that impairs transport of sugars; the resulting sugar accumulation in the leaves destroys chlorophyll and causes the leaves to turn brown and die. This injury, termed "hopper burn," can result in complete loss of a potato crop if not controlled. Another type of injury is caused by leafhoppers that feed upon plant mesophyll tissue. In addition to removing excessive amounts of sap, these insects also destroy the plant's chlorophyll, resulting in yellow spots on the leaves that eventually turn yellow or brown. *Erythroneura, Typhlocyba,* and *Empoasca* species cause this injury to apple trees and grapevines. Grape leafhoppers check growth and foliage function and cause formation of grapes that are inferior in size, colour, flavour, and sugar content. Plants are injured also when insects lay eggs in green twigs; for example, the egg punctures of several leafhoppers and treehoppers reduce the flexibility of plant limbs. Plant stunting and severe curling of leaves occur when the leafhopper *Empoasca fabae* punctures the undersurfaces of leaves and veins of bush beans and inhibits growth; the same leafhopper attacks alfalfa and causes leaves to turn yellow and drop off. In the same way, aphids and mealybugs cause leaf curling on potatoes and many types of ornamental plants, and the potato psyllid feeds on potato leaves and causes curling and yellowing known as "potato yellows."

The froghoppers, often called spittlebugs because immature stages live in spittlelike masses, feed upon a vari-

ety of plants. One important species, *Philaenus leucophthalmus*, a meadow insect that feeds extensively upon clover and alfalfa, causes severe stunting that can result in loss of up to 50 percent of a crop. Scale insects, unless parasitized, produce enormous populations on green twigs, young limbs, leaves, and fruit; when tree bark or shrubs become encrusted with one or more layers of scales, the entire plant often dies. Damage is caused to apples by the rosy apple aphid. Females of the third seasonal generation remain on the apple leaves until after small apples have formed. Many aphids crawl onto these tiny apples and puncture them causing dimpling of the fruit and normal incision of tiny apples. The cluster of apples, known as aphid apples are small and gnarled.

More than 100 species of leafhoppers are known organisms causing plant diseases. Some important plant disease viruses transmitted by leafhoppers are aster yellows (transmitted by *Macrosteles fascifrons*); potato yellow dwarf (several species of *Aceratagallia* and *Agallopsis*); and phony peach disease and Pierce's disease of grape (species of *Cuerna*, *Homalodisca*, and *Oncometopia*). Corn stunt is transmitted by species of *Dalbulus;* curly top of sugar beet by *Circulifer tenellus;* eastern and western x-disease by species of *Colladonus;* and elm phloem necrosis by *Scaphoideus luteolus*. One species of spittlebug is a vector for a yellow virus of peaches. Aphids are vectors for several virus mosaic disease organisms. A membracid species transmits the virus that causes pseudocurly top of tomato and tobacco, and two species of fulgorids are vectors of virus disease organisms of rice. The whitefly *Bemisia tabaci* transmits the virus that causes tobacco leaf curl, and species of mealybugs are vectors of the virus that causes pineapple wilt. The bacteria that cause fire blight disease on pear, apple, and quince trees are transmitted by several types of insects including leafhoppers. The bacterial pathogen, *Neofabraea perennans*, that causes perennial canker of apple is transmitted by the woolly apple aphid.

Because homopterans suck more sap from plants than they need, the surplus is excreted from the tip of the abdomen as sweet droplets known as honeydew. If the insect is feeding on apple foliage and honeydew falls on apples, a sooty fungus grows in each droplet; and the apples become black spotted and are no longer marketable.

Beneficial aspects

Of great economic importance are insects that secrete lac on twigs in tropical and subtropical regions. The lac is refined and used in preparing shellac and varnishes. More than 4,000,000 pounds of lac are refined annually. Other waxes secreted by aphids and scale insects are used in candlemaking and in medicines.

Although few homopterans produce food for man, the tamarisk manna scale, *Trabutina mannipara*, is thought to have produced the biblical manna for the children of Israel. The females produce large quantities of honeydew that solidify in thick layers on plant leaves in arid regions. This sugarlike material, still collected by natives of Arabia and Iraq, is considered a great delicacy. The term manna often refers to plant products also. Certain species of scale insects produce a gum that was used as chewing gum by tribes of North American Indians. Female root-inhabiting scale insects, species of *Margarodes*, enclose their bodies in gold and bronze coloured wax cysts that are used in strings of beads. Certain colour patterns and designs of the forewings of tropical species of leafhoppers and planthoppers have been used in artwork by various peoples. For many generations the Mexican Indians have used a black, white, and red colour design in their art. The design is that of the forewings of a brilliantly coloured *Agrosoma* leafhopper, found on bushes along streams.

NATURAL HISTORY

Life cycle. Generally, homopterans are bisexual, have periods of mating, and produce eggs; however, individual life cycles vary in length and complexity. Metamorphosis is simple or gradual; immature stages resemble adults except that the latter usually have wings. The life cycles of most homopterans are short. A typical example is the common meadow spittlebug, *Philaenus leucophthalmus;* it has one generation a year. Eggs, laid in late summer on stems or sheaths of host plants, hatch the following spring. Adults appear and mate during the summer.

Periodical cicada. The life cycle of three species of periodical cicadas is the longest known; it lasts 17 years. In the temperate zone enormous numbers of orange-winged adults emerge in spring and mate within a week; the females lay eggs a few days later. Using her strong ovipositor, the female cuts deeply into green twigs and through the harder wood of deciduous trees; she inserts 12 to 14 eggs through drilled slots into each of two chambers separated by a thin partition of wood. The female drills slots until she has deposited a total of 400 to 600 eggs. Injury to oaks, hickories, and young fruit trees is severe; and branches usually die beyond the point of egg insertion. Although eggs may be deposited in some 75 different kinds of trees or shrubs, the females prefer hickory, oak, apple, peach, pear, and grape.

Tree damage

The eggs hatch after two to six weeks; the young drop or crawl to the ground, enter the soil using their large digging claws, and begin a subterranean life, feeding on suitable tree and shrub roots for 16 years (periodical cicada). In apple orchards the young feed at depths of 2 to 18 inches; in wooded areas, at depths of 18 to 24 inches. "Harvestflies," common black and green species, appear in summer and feed on tree roots from two to five years. The periodical cicadas that live in central areas of the United States have a 17-year cycle, but three southern species complete their development in 13 years, and there are species that complete the cycle in one year. Since enormous numbers of nymphs feed on tree roots, many trees would die if the metabolic rate of the insect were not low; however, sap is taken from roots very slowly over a period of several years, and most trees survive. Although nymphs are almost full grown in eight years, they continue to feed and develop until the 13th or 17th year when mature nymphs emerge from the soil, climb any convenient tree or post, and attach themselves firmly. The dorsal line of the integument splits, and the adults emerge slowly through this opening. Adults live only a few weeks. Broods of both the 17- and 13-year cicadas have been studied. The largest and most widespread brood of the 17-year form occurs in abundance over much of the northeastern quarter of the United States.

Leafhopper. Many leafhoppers (*e.g., Empoasca maligna, Gyponana mali*) have cycles that involve passing the winter as eggs inserted in apple twigs. Other leafhoppers, however, such as *Empoasca recurvata* and *Erythroneura*, hibernate as adults during the winter. The sugar-beet leafhopper, *Circulifer tenellus*, winters as an adult in desert areas and produces an early spring generation on desert plants. As desert plants become unfavourable for feeding, the leafhoppers migrate to available cultivated plants where from one to four summer generations are produced. When the crop is harvested or the plants become unfavourable for feeding, the leafhoppers return to desert plants. Although definite alternation of desert and cultivated host plants occurs in this life cycle, no specific plant serves as a primary or secondary host. Plant selection by migrating leafhoppers is determined largely by the amount of rainfall and succulence of plants, both wild and cultivated. While most species have one generation a year, a few have two or three. The life cycle of planthoppers or fulgorids is similar to that of leafhoppers, while the pear psylla, *Psylla pyricola*, hibernates as an adult and can produce four generations of nymphs.

Alternation of host plants

Whiteflies. The whiteflies, common on citrus trees and in greenhouse plants, do not survive winter out of doors in the North but produce several generations a year in the South. The metamorphosis of whiteflies varies from the typical gradual form. In the first instar (interval between molts) the young, active, wingless forms are usually called larvae; during three subsequent instars, the sessile and scalelike nymphs undergo internal wing development. The molt from last larval instar to pupa occurs inside the last larval skin, which forms a puparium. Metamorphosis is essentially complete.

Aphids. The aphids or plant lice, soft-bodied insects that develop large populations, have several types of complex life cycles. Generally aphids overwinter in the egg stage on twigs or plant buds, usually designated a primary host. In the spring the eggs hatch into females that reproduce parthenogenetically, giving birth to living young. Several generations may be produced during the season in this way. Early generations are usually wingless, but by the third generation winged individuals appear. In many species these winged forms migrate to a secondary host plant, usually an annual, and the same type of reproductive process continues. In the latter part of the season, winged aphids of both sexes appear and migrate back to the primary host where mating occurs, and the females lay the overwintering eggs. There are two distinctive characteristics in the aphid life cycle: first, seasonal alternation of food plants involving a primary host (typically a perennial) during the winter and a secondary host (an annual) during the summer; second, there is alternation between sexual and asexual cycles, with eggs resulting from sexual mating and living young, usually females, being produced asexually.

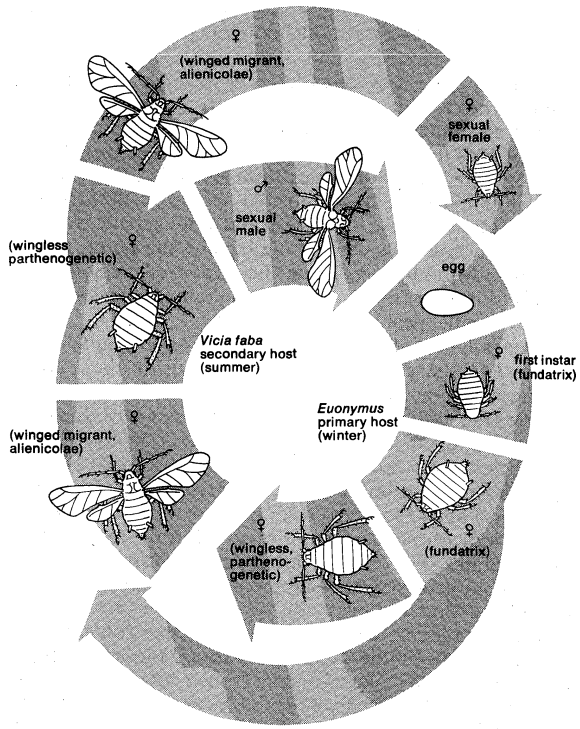

Figure 2: Life cycle of *Aphis fabae* (see text).

Scale insects. The scale insects have modified life cycles also; for example, the oyster shell scale, *Lepidosaphes ulmi*, typically passes the winter as an egg beneath a secreted scale covering; however, the San José scale *Aspidiotus perniciosus* produces living young. In either case newborn young, active crawlers, leave the scale covering to search for food. After a few days they molt, losing their legs, antennae, and anal spines, and retaining poorly developed eyes. They secrete a hard scale about their soft bodies, insert their mouthparts into a plant, and remain sessile. As the females mature, they increase in size, enlarging the scale covering periodically, but do not change form or develop wings.

Young males also have a crawler stage but become sessile and inactive after the second molt, passing through a more complete metamorphosis beneath the scale covering. The last preadult instar has two external wings and is called the pupa. Adult males have two wings and two small knobs or halteres where the second pair of wings would normally develop. Some males have three pairs of eyes. Adult males seek out wingless females, concealed beneath the scale covering, and mate with them; eggs form in the female. As many as three males may mate simultaneously with one female.

Reproduction and growth. Reproduction is bisexual among the homopterans; but asexual reproduction occurs in the aphids, in a few primitive leafhoppers, and possibly in species whose life cycles are not known in detail. An unusual situation occurs in the normally hermaphroditic cottony cushion scale *Icerya purchasi;* both sexes are present in one individual, and the eggs of any individual may be fertilized by its own sperm.

Egg laying

In the Auchenorrhyncha eggs are laid by the female, who uses an egg-laying structure, the ovipositor, to insert eggs into plant tissue. In the Sternorrhyncha (*e.g.*, aphids) the female places her eggs on the surface of the plant. The eggs of scale insects are retained in the body of the female or remain under the scale covering if separated from the female. In mealybugs and certain "cottony" scales, eggs are extruded from the body and remain in a mass enclosed by waxy plates or shreds. In most homopterans, each female produces a few hundred eggs. Exceptions occur in some scale insects (*e.g.*, cottony maple scale) where a female may lay 5,000 eggs.

Growth is gradual and is accompanied by periodic molting. The nymphal stages, or instars, between egg and adult usually number five in leafhoppers and related species. Wings, if present, develop when the fifth instar molts and the adult emerges.

Sexual dimorphism. Sexual dimorphism occurs in most groups of Homoptera. Males and females often are coloured differently; for example, the male leafhopper *Arundanus nacreosus*, a species common on cane, is orange, the female, milk white. Size and form vary between males and females also; the male marsh leafhopper *Hecalus lineatus* is not only a different colour than the female but also only half as long. In treehoppers the pronotum (the dorsal sclerite of the prothorax) often is so different in shape and size between the two sexes that they appear to be two species; examples of this are *Umbonia crassicornis* and *Philya inflata.* Among scale insects most females lack wings, legs, and antennae, while males have all three; males and females are so diverse in appearance that previous knowledge is necessary to associate two sexes of the same species. Most homopterans lack defense mechanisms; however, one scale insect, *Phenacoccus echeveria,* extrudes a honeydew-like material from the posterior ostioles as a defense mechanism.

Ecology. *Habitats.* Every insect lives in a habitat defined by specific physical, chemical, and biological conditions. If these conditions are changed sufficiently, the insect cannot survive and will either migrate to available acceptable conditions or perish. Temperature and humidity are important climatic factors in determining geographical regions and local habitats of specific homopterans. The distribution of homopterans is influenced also by conditions that favour distribution of host plants.

Influence of plant distribution

Plant distribution is determined largely by rainfall-evaporation ratios; insects with specific host relationships occur in the same regions where the plants are found. Other climatic factors may limit the insect to a smaller range within the host plant range; for example, selection of food plants by the desert species of sugar beet leafhopper depends on the abundance of rainfall during one season. Host plants of a given species may be closely related, as legumes on which eggs are deposited and adults live; or the life cycle may be divided between alternate unrelated host plants. The fact that most species are specific in their plant relationships determines habitats such as swamp, marsh, bog, meadow, prairie, desert, deciduous or coniferous forest. Certain species occur only on sagebrush or rabbit brush in the desert, on blueberry bushes in a bog, on white oak in a deciduous forest, or on white pine in a coniferous forest.

Moisture or humidity relationships also affect the habitats of homopterans. The eggs of most auchenorrhynchans are deposited in tender plant stems or in the undersides of leaf ribs or veins. Thus, the incubation period is passed in saturated humidity. After hatching, the nymphs feed on the under surface of the leaf and remain in high

relative humidity since most of the stomata, through which transpiration occurs, are on the under surface. A reduction in relative humidity due to reduced transpiration can destroy large field populations. Certain leafhopper and fulgorid species, although they are not adapted for aquatic life, can live on plants and produce normal populations under conditions of periodic tidal submergence, even in cold waters.

Formation of galls. Insect galls, abnormal growths of plant tissue, are caused usually by the mechanical or chemical stimulus of egg laying in plant tissue and by subsequent activities of the hatching young. The young usually live and feed inside the gall and complete their development before emerging. Some 60 species of homopterans, including aphids, psyllids, and coccids, cause plant galls, although aphids are responsible for a majority of them. Galls frequently seen on foliage include aphid leaf galls, caused by the grape phylloxera *Phylloxera vitifoliae;* the leaf petiole gall of poplar, caused by the aphid *Pemphigus populitransversus;* and the elm cockscomb gall on elm leaves, caused by the aphid *Colopha ulmicola.* Different species cause the formation of different types of plant galls.

Associations with other insects. There are insects that attack homopterans as predators or parasites or use them to provision their nests. Colonies of aphids and scale insects are prey for several kinds of ladybird beetles. Female beetles lay their eggs on leaves or twigs where aphids are feeding; when the beetle eggs hatch, the larvae feed upon the homopterans in the colony. One larva of *Hippodamia convergens* can consume 300 aphids in a two week developmental period, while the adult female devours several thousand aphids in three months. Certain species of flower flies or syrphids commonly lay their eggs on leaves or twigs where colonies of aphids are feeding. The hatching larvae thrust their piercing mouth structures into the bodies of the aphids and devour them by extracting visceral and body fluids. Another predator is the aphidlion larva, a chrysopid with mandibles like the ladybird larva; however, instead of chewing the aphids, the aphidlion larva inserts its mandibles into the body of the aphid and sucks fluids through a channel or groove on the inside of its mandible. Green winged adult aphidlions lay eggs in aphid colonies, placing them on stalks, so that when the young larvae hatch, there is an adequate food supply nearby. Most larvae of the chamaemyiids (*i.e.*, aphidflies) feed on aphids, scale insects, and mealybugs; the larvae of Drosophila known as pomace flies, are predacious on mealybugs and other small Homoptera; and the larvae of a few gall midges (*i.e.*, cecidomyiids) prey on aphids and scale insects. Certain Diptera have parasitic larvae that feed on the internal tissues of homopterans including certain scale insects, leafhoppers, and planthoppers. Some moth larvae are parasites of fulgorids, while other larvae are internal parasites of female gall-like coccids of the genus *Kermes.*

Homopteran predators

Among the Hymenoptera, certain wasps are parasites of planthoppers, leafhoppers, and treehoppers. The larvae of dryinid wasps develop internally in the host although part of the body of the larva protrudes from the body of the host, forming a saclike structure between the abdominal and thoracic segments. Most encyrtid wasps are parasites of aphids, scale insects, and whiteflies. The female eulophid wasp develops as a parasite of scale insects, while the male, developing as a hyperparasite, attacks parasites of the scale insects (often females of its own species). The thamid wasps have habits similar to those of the eulophids in that both parasitize scale insects and whiteflies or are hyperparasites of chalcid wasps that parasitize homopterans.

Another interesting insect association concerns the sand wasps. They paralyze homopterans by stinging them, then store them in burrows, lay eggs, and rear young using the homopterans as food. Best known of these is the large cicada-killer wasp (*Sphecius speciosus*); the female digs a burrow in well drained soil, stings a cicada until it ceases to struggle, places it in the bottom of the burrow, lays her eggs on the cicada, covers the burrow, and dies. The larvae develop on the cicada, remain in the burrow until the following spring or summer, and emerge as adult wasps. Other wasps also burrow in the soil and provision their burrows with one or more kinds of Homoptera, particularly leafhoppers, planthoppers, or treehoppers. Aphid wasps use the same method of provisioning their nests, while squareheaded wasps usually use leafhoppers of one species to provision burrows in decomposed wood.

Subterranean life. Many species of adult and young aphids are subterranean and feed on the roots of plants. In some species the alternate food plant is no longer used, and the aphids no longer develop wings. Some entire colonies spend years below the surface of the soil; other species spend most of each year underground; and a few species appear above ground, locate a new host plant, and immediately seek roots. The woolly aphid can live indefinitely on the roots of apple trees but can exist only part of the year on elm, the alternate host. The strawberry root louse has a sexual cycle in which eggs are laid, but these aphids are dependent upon ants for survival; not only do the ants care for the eggs in their nests but they also carry the young aphids from plant to plant. In some subterranean aphids the sexual cycle, and with it the egg-laying stage, has disappeared entirely. Subterranean aphids have no predators and few parasites. Other root feeders are young cicadas, certain young cercopids, some cixiid nymphs of the fulgorids, and immature stages of a few leafhoppers.

FORM AND FUNCTION

External features. *Polymorphism.* Polymorphism is marked in several groups of Homoptera. The Cicadidae are similar in form but vary in size and coloration. The Cercopidae include different types. The small *Clastoptera* are short, ovate, and froglike in appearance and are called froghoppers; the more elongated *Philaenus* are often called spittlebugs. The Membracidae, or treehoppers, have an enlarged prothorax that often covers the head, thorax, and abdomen; it may protrude forward resembling a coarse spine, project anteriorly at the sides so that the insect appears to possess a pair of pointed horns, or produce a large keeled hump above the abdomen. The most bizarre and curiously shaped treehoppers are found in tropical American countries; here the prothorax develops into chitinous adornments and processes.

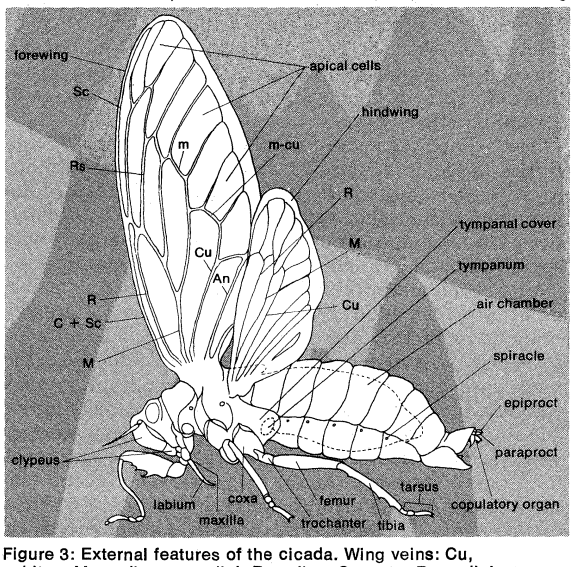

Figure 3: External features of the cicada. Wing veins: Cu, cubitus; M, media; m, medial; R, radius; C, costa; Rs, radial sector; An, anal; m-cu, mediocubital; Sc, subcosta.

The bodies of the Cicadellidae, or leafhoppers, are dorso-ventrally flattened or cylindrical; and the head varies in shape and size from short, broad, and rounded to long, thin, and bladelike. The head size and structure of ful-

gorid genera vary. Species of *Scolops* have a long, slender, anterior projection of the head that resembles a beak or snout; however, the true mouth structures are beneath the head. In the genus *Apache* the head is flattened laterally and projects as a vertical thin leaflike structure, while in *Cyrpoptus* the head, flattened dorso-ventrally, is horizontal. Dimorphism in the Aleyrodidae or whiteflies occurs only when inactive and sessile immature stages succeeding the first instar pass through a quiescent stage (a pupa) that has no resemblance to the winged adult.

Typically aphids have both winged and wingless adults. Some species ("woolly" plant lice) have waxy plates or fibres over their bodies. Most aphids, however, do not secrete waxy materials. Some aphids are root feeders, some are gall formers, but most are leaf and stem feeders. Polymorphism can result from host-induced variation; for example, progeny of a European fruit *Lecanium* female develop into morphologically different insects depending on the host plant. Generally, homopteran body form is similar to that of other insects. It consists of head, thorax, and abdomen, all covered with a chitinous exoskeleton (see INSECTA).

Head. The head is usually fitted with a pair of large compound eyes, but in certain male scale insects three pairs of eyes are present. Simple eyes or ocelli usually occur on the head and probably function as organs of light perception. Cicadas normally have three, while other homopterans have two or none. Vision is variable among the homopterans. Reactions to visual stimuli are greatest in leafhoppers, spittlebugs, planthoppers, treehoppers, and jumping plant lice; reaction is slower in cicadas, much slower in aphids, and practically nonexistent in scale insects and mealybugs. Leafhoppers as well as some spittlebugs, planthoppers, and tropical cicadas are attracted to lights at night. Members of other groups seldom respond to light.

A pair of antennae, arising below and between the eyes, are usually short and bristlelike, varying in length throughout the group. They are probably the most important sensory structures and are of taxonomic significance in species identification of aphids. Mouth structures of homopterans arise at the back of the head. The beak (or proboscis), elongate and segmented, is composed of a sheathlike labium that encloses four piercing stylets, two mandibles, and two maxillae. The stylets alone enter the plant tissue; the mandibles do the piercing; and the two inner stylets, the maxillae, fit together to form a sucking tube composed of two channels, one for conducting food, the other for saliva. In the Auchenorrhyncha the beak arises at the back of the head, while in the Sternorrhyncha it appears to arise between the front coxae; this difference in point of origin of the beak also is of taxonomic significance.

Legs. Each segment of the thorax bears a pair of legs. In the cicadellids, fulgorids, cercopids, membracids, and psyllids, the hindfemurs are enlarged and adapted for jumping; in the other groups the femurs are normal in size. The type and arrangement of spines on the femur are of taxonomic importance in separating certain families. The mesothorax and metathorax both bear a pair of wings in the adult stage; the wings are usually membranous or of the same texture. Adult female scale insects and most female aphids lack wings. Male scale insects have one pair of wings on the mesothorax; wing rudiments, called halteres, are found on the metathorax. The first pair of wings are hyaline, opaque, pigmented with various colours, or covered with waxy secretions in the form of powder, shreds, or plates. The second pair of wings are always membranous.

Abdomen. The abdomen, typically 11-segmented, appears to have only 7 or 8 segments because the last few segments are modified as specialized genital structures. Genital segments 8 and 9 bear structures associated with external openings of genital ducts. In the male these structures are modified for copulation and transfer of sperm to the female; in the female they are modified for oviposition. Although external genital structures, these are usually enclosed in a genital chamber. The female genitalia in the Auchenorrhyncha consists of an ovipositor, formed by the appendages (gonopods) of segments 8 and 9. The ovipositor, a pair of basal plates and three pairs of elongate bladelike structures, generally is used to pierce or drill slots in plant tissue for oviposition. The variable external genitalia of the male, often complex, are frequently of considerable taxonomic value. In the Auchenorrhyncha they are contained in a genital chamber consisting of portions of the ninth segment. The genitalia consist of the styles and the aedeagus, equipped with a gonopore through which sperm are discharged during mating. When the male mates, the aedeagus and styles are exposed directly to the base of the female ovipositor, where the sperm are transferred.

Internal features. In general the internal organs and systems are similar to those of other insects. Although the respiratory systems of homopterans and heteropterans

From R.E. Snodgrass, *Principles of Insect Morphology* (1935); McGraw-Hill Book Co.

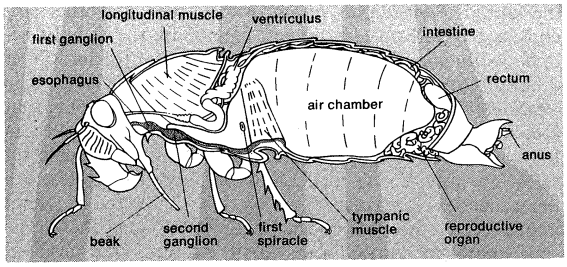

Figure 4: Internal features of the cicada.

are adapted for terrestrial life, certain species of both groups can live on submerged plants. The circulatory system is open, and blood circulates freely in the body cavity. The nervous system is composed of a ventral nerve cord with ganglionic masses for almost every segment.

The alimentary system is composed of three major parts, the foregut or stomodaeum, the midgut or mesenteron, and the hindgut or proctodaeum. The structure and function of the alimentary canal differ from other insects because homopterans feed entirely upon plant sap and ingest large amounts of it. Little absorption of food can take place in the foregut. The midgut, where digestion and absorption occur, is lined with epithelial cells that produce enzymes and absorb food after digestion. The residue passes into the ileum (small intestine) where, together with the waste products from the malpighian tubules, it passes to the colon for excretion.

Physiology and biochemistry. *Honeydew.* Plant sap contains a large quantity of water. In order to extract sufficient nutrients to survive, a large quantity of sap must be ingested. The filter chamber is a modification of the alimentary tract that allows nutrients to be concentrated in the midgut and small intestine as excess water (containing some sugar and waste materials) bypasses the midgut and small intestine to be exuded from the rectum as honeydew. It attracts ants and other hymenopteran and dipteran insects that feed on sweet nutrients.

Aphids are often called ant's cows. One well-known association is the corn root aphid and the corn field ant. The ants collect eggs in autumn, carry them to their nests, maintain the eggs through the winter, and place the young aphids on the roots of small weeds and grasses in the spring. As soon as newly planted corn seeds germinate, the ants place the aphids on corn roots and obtain honeydew by stroking the aphids with their antennae. The aphids are almost totally dependent upon the ants and are almost helpless in finding their preferred host, the roots of corn plants, without assistance. In a similar manner virgin female *Acropyga* ants carry in their mandibles on their nuptial flight a fertilized female mealybug as a source of honeydew for the new nest.

Spittle. Exuded from the alimentary tract by nymphs of the Cercopidae (*i.e.*, spittlebugs) are spittle masses commonly found on stems of meadow plants. The spittle fluid is voided from the anus after it has been mixed with a mucilaginous substance excreted by epidermal glands

of the seventh and eighth abdominal segments. Air bubbles are introduced into the spittle by means of the caudal appendages of the nymph. Immature spittlebugs rest head downward on the plant; as spittle is voided, it covers the nymph and is not easily dislodged, even by heavy rains. Adults do not produce spittle.

Wax and lac

Glandular secretions. Wax, produced by numerous wax glands and secreted by cornicles, is secreted by many aphids and scale insects. Mealybugs, whiteflies, woolly aphids, and cottony scales are named for white wax on their bodies or wings. Probably the best known wax producers are males of the Chinese wax scale *Ericerus pe-la;* they secrete large amounts of pure white wax useful in making candles. The Indian wax scale *Ceroplastes ceriferus* secretes a wax that is used for medicinal purposes.

There are several lac insects; some secrete highly pigmented wax. The Indian lac insect *Laccifer lacca* is important commercially. It is found in tropical or subtropical regions on banyan and other plants. The females, globular in form, live on twigs in cells of resin; their bodies are covered with exudations of lac, sometimes so heavy that the twigs become coated to a thickness of ½ to 1⅓ inch. The twigs are cut; lac is melted off, refined, and used in shellac and varnishes.

A group of small scale insects that typically live on desert cacti and resemble mealybugs are known as cochineal insects. *Dactylopius coccus* is the source of a natural crimson or scarlet dye called cochineal dye, originally used by the Indians of Mexico. Mature females are brushed from the cacti and dried; the pigments are extracted from the dried bodies. The Spanish used these dyes as early as 1518, and they were exported to Europe until replaced by the aniline dyes about 1870. The crimson colour of cochineal dye is attributed to cochinealin or carminic acid.

Sound production. At one time it was thought that the familiar call of male cicadas was the only sound produced by homopterans. It is now known, however, that sound production is common among other Auchenorrhyncha (leafhoppers, treehoppers, planthoppers, and spittlebugs) although their songs cannot be detected by the human ear unless amplified. Sound has been observed also in a few aphids and in one psyllid (both Sternorrhyncha).

The auchenorrhynchan Homoptera have evolved the most complex insect sound-producing mechanism known, the timbal organ. A pair of timbals, circular membranes supported by heavy chitinous rings, occur on the dorsolateral surface of the first abdominal segment. Contraction of a large timbal muscle attached to the membrane causes distortion of the timbal, producing a sharp click or pulse. The timbal springs back by its own elasticity when the muscle is relaxed. If the rates of muscle contraction and relaxation are rapid, the sound seems continuous to the human ear. The frequency contractions of the timbal muscles range from 120 to 480 per second. Associated with timbal organs in cicadas are large tracheal air sacs that open to the exterior and have resonant frequencies comparable to timbal vibration frequencies.

Although the timbal organ is similar in all species studied, the songs produced are variable; apparently this variation is caused by actions of tensor muscles and air sacs. The tensor muscles control pulse repetition frequency and sound intensity; abdominal movements control expansion and contraction of the air sacs and the consequent resonance frequency. The timbal is the only sound-producing mechanism evolved in the Homoptera except for a scraping of tibial stout hairs over reticulations of the abdomen of aphid colonies (*Toxoptera coffeae*); the sound produced is a rhythmic and synchronous scraping.

Cicada songs

Each cicada species has a characteristic song, often useful in identification. The analysis of periodical cicada songs has been the basis for morphological separation and determination of geographical range for several 13- and 17-year species. Thirteen-year species sometimes occupy parts of the same geographical areas as 17-year species. The primary song in cicadas, produced by the male, is a mating or pair-forming (aggregating) call. Female cicadas have no sound-producing organs. Males, attracted to calls of other males, stimulate each other to sing in chorus. Most mating takes place under these conditions. Male cicadas are stimulated to sing in the presence of tape recordings of songs of their species. Courtship songs or signals occur after pair formation or aggregating calls. Courtship interruption calls occur also for pair reforming. Calls produced when the insect is attacked, trapped, or in "distress" have been observed and are known as "dying yells."

Sound-producing organs occur in males of some cercopids, membracids, fulgorids, and cicadellids and in females of certain cicadellids. In *Doratura* both sexes have well developed sound-producing organs. The female of *Paropia* has a striated timbal that is poorly developed in the male. The sound-producing organ in the female is probably a primitive condition. Unlike cicadas, several leafhopper males produce calls in darkness and commonly produce mating calls when females are near. Rivalry calls between males also have been observed, usually accompanied by leg movements (kicks) that are attempts to strike and drive away a rival male.

EVOLUTION AND PALEONTOLOGY

Paleontologists do not agree on the exact or relative ages of either the Homoptera or Heteroptera (see HETEROPTERA). While some entomologists consider each group a separate insect order, others feel they have a common origin and classify them as suborders of the order Hemiptera. Although characteristics of the earliest Homoptera are not known, it is probable that the Protohomoptera had three tarsal segments, three ocelli, two pairs of wings about equal in size and shape with complete venation, an alimentary tract lacking a filter chamber, and male genitalia fitted with harpogones and subgenital plates.

Proto-homoptera

Based on the primitive nature of the ovipositor, the primitive sucking pump, and simple alimentary canal, the fulgorids are considered to be different from other Auchenorrhyncha and probably evolved earliest. The ovipositor of *Scolops pungens* is more primitive than that found in many of the Orthoptera. Thus the Fulgoridae are a combination of specialized sucking mouthparts and a primitive ovipositor.

The similarity of the thoracic sterna combined with jumping hind legs places the cicadellids, membracids, and cercopids together and differentiates them from the cicadas, which have different thoracic characters, lack the enlarged hindfemurs, and have a third (median) ocellus on the head. The Cercopidae show some relationship to the Cicadidae by having a complete tentorium in which the anterior tentorial arms are connected with the posterior arms; but in this respect they differ from the Cicadellidae and Membracidae, in which the tentorial structure is reduced. The hind legs of both Cicadellidae and Membracidae bear rows of spines that are absent on the hind legs of Cercopidae. Therefore, although the cicadellids, membracids, and cercopids are related and differ from other Auchenorryncha, the Cicadellidae and Membracidae are more closely related to each other than are the Cercopidae to either group. Furthermore, the cicadas and cicadellids, both of which retain different combinations of primitive characteristics, cannot be related through the cercopids, which lack these characteristics entirely. The cicadellids, in their structural and biological diversity, differ from other Homoptera and show a greater array of evolutionary stages in various combinations. Unlike other groups, cicadellids contain groups that stabilized at different evolutionary levels.

The Sternorrhyncha were probably separated from the Auchenorrhyncha as early as the Lower Permian (about 270,000,000 years ago). Although small in size, many fossil psyllids are found in the Upper Permian (about 230,000,000 years ago) strata and onward. If fossil remains have been identified properly, the aleurodids date from the Upper Permian also. They are highly specialized, both biologically and structurally. The aphids exhibit various degrees of polymorphism. The female geni-

talia are usually reduced; however, two groups, Adeligidae (part of the family Chermidae) and the family Phylloxeridae, have retained a true basic ovipositor. A fossil wing of *Permaphidopis sojaneusis* from the Permian resembles the wing of recent aphids.

Female coccids, wingless and sessile, are unlike the tiny winged males. Although the structural characters that have not been lost provide little information on phylogeny, they do show varying degrees of specialization. Most coccids, for example, have a single tarsal segment, but all species of *Xylococinae* have two; the male genitalia is a simple tubular, heavily sclerotized organ similar to the genitalia of aleurodids. The Peloridoidea represents a primitive form, probably a Paleozoic relic (about 225,000,000 to 570,000,000 years old). Highly specialized in some respects, it still has some primitive characteristics.

The Fulgoridae were the earliest group differentiated from the base of the Auchenorrhyncha stem; the cicadellids probably were next, apparently in Late Permian or early Triassic (about 220,000,000 years ago). The cercopids probably were derived from this stock; certainly the membracids were, later. The cicadas probably arose from the early cicadellid stem but are not found in fossils until the Cretaceous (about 65,000,000 to 136,000,000 years ago). If fossil forms have been properly placed, cicadellids and cicadas differentiated no later than the Permian; and cercopids and fulgorids must have had an even earlier origin. In the Sternorrhyncha group the psyllids, probably the earliest group to be differentiated, are known from abundant fossils in the Late Permian. The aleurodids also apparently arose in the Late Permian; the aphids date back to the Late Triassic (about 200,000,000 years ago); and the precretaceous fossil, *Mesoccus asiatica* Bekker-Migdisova, from the Permian seems to place the coccids in this geologic age.

CLASSIFICATION

Distinguishing taxonomic features. The beak and the wings are the most distinctive features of homopterans. The beak (or proboscis), fastened rigidly to the head, appears to arise from the ventral margin and consists of two pairs of stylets (mandibles and maxillae) adapted for piercing and sucking. In most homopterans, both pairs of wings are transparent or slightly thickened; the front pair have a uniform structure throughout. When at rest, the forewings are held rooflike over the dorsum with a slight overlapping on the inner margin near the tip. The digestive tract is complex, forming a filter chamber in most groups.

The suborders are distinguished by point of origin of beak, length and appearance of antennae, and number of tarsal segments. Separation of families of the Auchenorrhyncha is based on characters of the ocelli, position of antennae, form of pronotum, and spination of legs. Families of Sternorrhyncha are separated on the basis of number of tarsal segments, structure and venation of wings, and presence or absence of cornicles.

Annotated classification.

ORDER HOMOPTERA

Mostly small (4–12 mm); wings, when present, number two or four; sucking mouthparts; plant feeders; more than 32,000 species; worldwide distribution.

Suborder Coleorrhyncha

Origin of beak at antero-ventral extremity of face; propleura form a sheath for base of beak; hind wings absent; forewings held flat over abdomen when at rest; no flight function; prothorax with paranota; digestive tract lacks filter chamber.

Family Peloridiidae

Most primitive Homoptera; Tasmania, New Zealand, South America.

Suborder Auchenorrhyncha

Beak arises at antero-ventral extremity of the face, not sheathed by propleura; antennae with one to three basal segments, with a terminal seta; forewings rooflike when at rest; filter chamber present; all males apparently produce sound.

Family Cicadidae (cicadas)

Also called dog-day harvest-flies; usually large; three ocelli on face; front wings membranous; male with audible sound-producing organs on ventral base of abdomen, non jumping.

Family Membracidae (treehoppers)

Usually less than 12 mm in length; two ocelli; enlarged pronotum extends over head, thorax and all or part of abdomen; jumping hindtibia; wings largely concealed by pronotum.

Family Cercopidae (froghoppers or spittlebugs)

Less than 15 mm in length; two ocelli; jumping hindtibia with one or two stout spines, and circlet of stout spines at apex; hindcoxae short, conical.

Family Cicadellidae (leafhoppers)

Two ocelli or none; variable in size, 2 to 25 mm; jumping hindtibia with two or more rows of spines; hindcoxae transverse.

Family Delphacidae (planthoppers)

Hindtibia with broad movable apical spur; sexes often dimorphic, very different.

Family Derbidae (planthoppers)

Anal area of wing not reticulate; without cross veins; terminal segment of beak not more than 1½ times as long as wide.

Family Cixiidae (planthoppers)

Head not prolonged in front; carina of head median or absent; tegulae present; claval suture distinct, abdominal terga 6–8, rectangular.

Family Kinnaridae (planthoppers)

Terminal segment of beak at least twice as long as broad; front wings usually not overlapping as apex of clavus; head not prolonged in front; tegulae present; median ocellus usually present; abdominal terga 6–8, chevron shaped.

Family Dictyopharidae (planthoppers)

Head prolonged in front; or frons with two or three carinae or the tegulae absent; claval suture obscure.

Family Fulgoridae (planthoppers)

Second segment of hind tarsus large, apex with row of small spines; anal area of hind wing reticulate with cross veins.

Family Achilidae (planthoppers)

Terminal segment of beak at least twice as long as wide; claval vein extending to apex of clavus; body somewhat flattened; forewings overlapping at apex.

Family Tropiduchidae (planthoppers)

Second segment of hind tarsi with two apical spines, one on each side; apex reduced or conical; front wings longer than abdomen; cross veins between costal margin and apex of clavus.

Family Flatidae (planthoppers)

Costal and/or apical border of wing with numerous cross veins; wings longer than body, in repose held almost vertically at sides of body; clavus with numerous small pustule-like tubercles.

Family Acanaloniidae (planthoppers)

Also called Amphiscepidae; hindtibia without spines except at apex; front wings very broad, costal margin broadly rounded, venation reticulate; wings longer than body, at repose held almost vertically at sides of body.

Family Issidae (planthoppers)

Wings usually shorter than body, if longer than abdomen, usually oval; clavus without numerous small pustule-like tubercles; costal border of wings usually without numerous cross veins.

Suborder Sternorrhyncha

Beak appears to arise either between fore coxae or behind them; antennae usually long, filamentous, without a well differentiated terminal seta.

Family Psyllidae (jumping plant lice)

Beak long; mouthparts well developed in both sexes; tarsi two-segmented with two claws; antennae 5 to 10 (usually 10), segmented; front wings often thicker than hindwings, not exceeding 7 mm in length.

Family Aleyrodidae (whiteflies)

Very small; covered with a white powdery, waxy material; wings opaque; not jumping insects.

Family Aphididae (aphids or plantlice)

Wings membranous, Rs vein present in forewing; cornicles usually present; sexual females oviparous, parthenogenetic females viviparous; females and usually males with functional mouthparts; without abundant wax glands.

Family Eriosomatidae (woolly and gall-making aphids)

Aphididae in part; Rs vein present in forewing; cornicles indistinct or lacking; M vein in forewing not branched; wax glands usually abundant; sexual forms with the mouthparts atrophied and not functional.

Family Chermidae (pine and spruce aphids)
Adelgidae and Phylloxeridae in part; feed on needles, twigs, and leaves of conifers; Rs vein in forewing absent; cornicles absent; all females viviparous; Cu_1 and Cu_2 in forewing separated at base; apterous parthenogenetic females covered with wax.

Family Phylloxeridae (phylloxerans)
Chermidae in part. Rs in forewing absent; cornicles absent; all females oviparous; Cu_1 and Cu_2 in forewing stalked at base; apterous parthenogenetic females not covered with wax.

Family Margarodidae (giant coccids, ground pearls, cottony cushion scales)
Males with compound eyes and ocelli; anal ring reduced, without pores or setae; females wingless and legless.

Family Ortheziidae (ensign coccids)
Male with ocelli only; abdominal spiracles absent; anal ring distinct and flat, bearing many pores and 6 long setae; females wingless.

Family Diaspididae (armoured scales)
Apical segments of female fused, forming a pygidium; female with scale covering separate from body; legs absent; beak 1-segmented; antennae rudimentary.

Family Coccidae (soft scales, wax scales, tortoise scales)
Females flattened, elongate oval; exoskeleton hard, smooth, or wax covered; legs present or absent; antennae absent or much reduced. Females often tortoise-shaped; males winged or wingless; anus covered by two dorsal plates.

Family Aclerdidae (aclerdid scales)
Scales attacking grasses; openings of wax glands rarely 8-shaped; pygidium absent; male with ocelli only; anus covered by a single dorsal plate.

Family Lacciferidae (lac scales)
Females globular in form, legless; antennae 3- or 4-segmented, minute; body enclosed in cells of resin; tropical or subtropical.

Family Asterolecaniidae (pit scales)
Females without pygidium; beak with more than 1 segment; posterior end of body not cleft; abdomen not narrowed posteriorly or produced into an anal tube; wax gland openings 8-shaped, usually in rows; legs vestigial or absent.

Family Pseudococcidae (mealybugs)
Covered with a white powdery secretion; wax gland openings on dorsum, not 8-shaped; anal ring with four or more setae; dorsal ostioles and usually 1 to 4 circuli present.

Family Eriococcidae (scales)
Pseudococcidae in part; anal ring with 4 or more setae; dorsal ostioles and ventral circuli absent; body not covered with powdery secretion.

Family Dactylopiidae (cochineal insects)
Occur on cacti; abdomen not narrowed posteriorly; wax gland openings on dorsum; anal ring absent; wax gland ducts minute, arising from centre of cluster of sessile pores; setae stout and cut off at end.

Family Kermidae (gall-like coccids)
Females spherical, hemispherical or oval; legs absent in adult; antennae 6-segmented; anal ring absent; wax gland ducts not minute, openings not 8-shaped.

Critical appraisal. The Homoptera, along with the Heteroptera, are considered by many entomologists as suborders of the order Hemiptera, mainly on the bases of similar types of piercing–sucking mouthparts and on the general type of gradual metamorphosis. This system, however, places only minor importance on the distinct differences in structure and in details of metamorphosis that have led some workers to propose separate ordinal rank for Homoptera and Hemiptera and abandonment of the term Heteroptera. The mouthparts vary considerably in detail; in the Heteroptera the beak arises from the front of the head and is movable, while in the Homoptera the beak is fastened rigidly to the head, cannot be moved, and appears to arise from the dorsoventral portion. Little considered is the fact that certain Homoptera (*e.g.*, scale insects and whiteflies) pass through a stage in their development resembling complete metamorphosis. The names Heteroptera and Homoptera are derived from their different wings. In the Heteroptera only the apical portion of the wing is membranous and has visible veins; the basal portion of the wing is thickened and leathery. When these wings are at repose, they are held flat upon the dorsal portion of the abdomen; and the apical portions of the wings completely overlap. On the other hand, the forewings of the Homoptera are either membranous or of the same texture and contain visible veins throughout. At repose these wings are held at an angle rooflike over the abdomen, overlapping only slightly on the inner apical margin. Those who classify these two groups as suborders of the Hemiptera place only minor emphasis upon these distinct differences.

Homo Sapiens

In the past it has often been the task of philosophers, theologians, politicians, and ideologists to define true man, to describe the human condition, and to set the boundaries of humanity. On the whole, such writers have been undeterred by their frequent lack of scientific information about man, with the result that their conclusions were often biassed or based upon false premises. But since the 1920s, with the rapid progress made in the field of human evolution, the problem of defining true man—*Homo sapiens*—has attracted the attention not only of anthropologists and anatomists but also of geneticists, biochemists, biostatisticians, taxonomists, and a number of other biological specialists. This concentration of scientific effort and expertise has resulted in a critical reappraisal of the typological concept of evolution, which depends on the classification of individuals according to a narrow definition of the species type. This concept has largely been replaced by the idea that a population, not an individual, is the evolving unit. When this distinction was made clear, differences between the fossil remains of individual prehistoric human beings fell into perspective, aided by modern knowledge of the range of normal variability in human populations. Still the realization that populations, themselves, vary widely and cannot be narrowly typed brings us face-to-face with the problem of classification, a problem foreseen by Charles Darwin, who wrote in his *Descent of Man:*

> In a series of forms graduating insensibly from some ape-like creature to man as he now exists, it would be impossible to fix on any definite point when the term man ought to be used.

Nonetheless, several attempts have been made to establish a point in his evolution at which man's prehistoric

ancestors are to be considered human beings (*Homo sapiens*) by making use of a so-called human attribute as an absolute criterion.

Scottish anatomist and physical anthropologist Sir Arthur Keith regarded the relatively large size of the human brain as of paramount importance, arguing that mental activities of a higher order would result and that these activities, in turn, would lead to more successful sexual, maternal, and social behavioral patterns. Thus, an arbitrary line was drawn: ". . . any group of the great primates which has attained a mean brain volume of 750 cc. and over should no longer be regarded as anthropoid, but as human." This was Keith's "Rubicon 'twixt ape and man." Such a view could not last, however, because man cannot be defined by any single anatomical criterion.

A more plausible approach was suggested by the British paleontologist Kenneth P. Oakley, who made use of a primarily behavioral criterion to define man: the ability to make tools. The systematic making of tools for future as well as present use implies a capacity beyond that of modern apes, who will freely improvise tools from sticks or branches but will nearly always use them to solve by perceptive means an immediate and visible problem. Clearly "man the toolmaker" as a definition involves not only a hand structure capable of toolmaking and tool use but also a brain with a capacity for conceptual thought. Here again, functional anatomy and behaviour are inseparable and highly correlated.

Taxonomic definition of *Homo sapiens*

The problem here, however, is not to define humanity but *Homo sapiens*, the human species, and it was the British anatomist W.E. Le Gros Clark who emphasized the importance of making a clear distinction between colloquial terms and Latin names of definable zoological meaning, which follow the rules of the International Code of Zoological Nomenclature. Le Gros Clark offered a definition of *Homo sapiens* that makes particular use of specific anatomical criteria that relate to the skeleton, because the principal use of such a definition is in the evaluation of fossil bones. Thus, *Homo sapiens* was provisionally defined by him in precise anatomical terms:

> A species of the genus *Homo* characterized by a mean cranial capacity of about 1,350 cc.; muscular ridges on the cranium not strongly marked; a rounded and approximately vertical forehead; supra-orbital ridges usually moderately developed and in any case not forming a continuous and uninterrupted torus; rounded occipital region with a nuchal area of relatively small extent; foramen magnum facing directly downward; the consistent presence of a prominent mastoid process of pyramidal shape (in juveniles as well as adults), associated with a well-marked digastric fossa and occipital groove; maximum width of the calvaria usually in the parietal region and the axis of glabello-maximal length well above the level of the external occipital protuberance; marked flexion of the sphenoidal angle, with a mean value of about 110°; jaws and teeth of relatively small size, with retrogressive features in the last molars; maxilla having a concave facial surface, including a canine fossa; distinct mental eminence; eruption of permanent canine commonly preceding that of the second molar; spines of cervical vertebrae (with the exception of the seventh) usually rudimentary; appendicular skeleton adapted for a fully upright posture and gait; limb bones relatively slender and straight (from W.E. Le Gros Clark, *The Fossil Evidence for Human Evolution;* The University of Chicago Press, © 1955, © 1964).

A definition of this kind attempts to take account of the total morphological (structural) pattern of the species and pinpoints anatomical features of supposed taxonomic relevance or groups of features that form a functionally significant complex; *e.g.*, a prehensile hand or a bipedal foot. Functional affinity may be deducible from structural similarity, and degrees of functional affinity are quantifiable. Such estimates have been shown to be of particular value when calculated from numbers of measurements that are subjected to multivariate statistical analysis. It must be added, however, that, although the aim of such studies is to try to provide an objective measure of taxonomic (classificatory) affinity, the choice of measurements for analysis is subjective; but with that proviso the choice of functionally significant dimensions will lead to a functional discrimination that, in turn, may be taxonomically significant. Nevertheless, the mere demonstration of significant "morphological distance" between populations need not mean that they must inevitably belong to different species.

The term *Homo sapiens* is a proper Linnean biological term the use of which is governed by rules of priority as set forth by the International Code of Zoological Nomenclature. Attribution of a new fossil find to the group must take account of the definition of both the genus and the species. But the weakness of typological taxonomy of this kind (where a narrow definition of human characteristics is given) is obvious when samples of fossils are small and specimens are incomplete; furthermore, the problem is compounded when closely related or transitional forms are being considered. Characteristics may be found that are typical of less evolved specimens; yet, at the same time, more advanced features may be present in the same specimen. This situation is the result of mosaic evolution—the idea that not only do different populations evolve at different rates but also that different individual parts may evolve differentially. It follows that mosaic evolution will cloud the issues of classical Linnean taxonomy, because the Linnean system depends upon the identification of a set of clearly defined characters of taxonomic relevance occurring together according to an agreed definition.

Mosaic evolution

It is becoming increasingly clear that early *Homo sapiens*, evolving relatively rapidly during the late middle Pleistocene Epoch (about 250,000–100,000 years ago), was subject to this mosaic process.

FOSSIL REMAINS OF HOMO SAPIENS

The sapient skeletal system. Fossil remains of early *Homo sapiens* are known from sites in both Europe and Africa, but later examples come from a wide range of sites in the Old World as a whole. It is of particular interest to look at the skulls of some of the early specimens, for it is in their functional morphology that the combination of features that results in attribution to *Homo sapiens* is often found.

Evolution of the human skull. The human skull is composed of both cranial and facial portions. The cranium consists of the skull vault and base, while the facial skeleton consists of the region of the eye sockets, nose, cheekbones, upper jaw (orbital and maxillary region), and the region of the lower jaw (mandibular region). During the evolution of the hominid skull from its apelike precursors, there are a number of general trends that can readily be discerned. The principal trends are the gradual increase in brain size (as measured by cranial capacity), the rounding of the cranial vault, and the gradual reduction of the size of the whole masticatory complex, including both the upper and lower jaws and the teeth. These trends lead to an overall change in skull shape and proportions, so that, while the vault expands, the "muzzle" tends to retract from a protruding (prognathic) form to a straighter-faced (orthognathic) appearance. At the same time, the whole skull tends to become lighter and more delicate in its structures. If this process is examined a little more closely, it can be at least partly explained in mechanical terms. A comparison of the skull of *Homo erectus* (the species of man immediately preceding *Homo sapiens* in the course of human evolution) and a modern *Homo sapiens* skull illustrates the point (Figure 1).

The skull of *Homo erectus* (the species lived from approximately 1,000,000 years ago until about 200,000 years ago) has a low skull vault, a sharply receding forehead, a low cranial capacity (800–1,100 cubic centimetres [cc]), a large face with big teeth and jaws, and a jutting occipital region (the back of the head). Muscles in the occipital region relate principally to the balance of the head on the vertebral column (spine); those of the temporal region (at the sides of the head) relate to the working of the jaw apparatus. In a skull with a large face and a heavy jaw, the muscles of the occipital region, which balance the head on the neck (nuchal musculature), must be strong in order to counterbalance the heavy face and jaw. This results in marked occipital

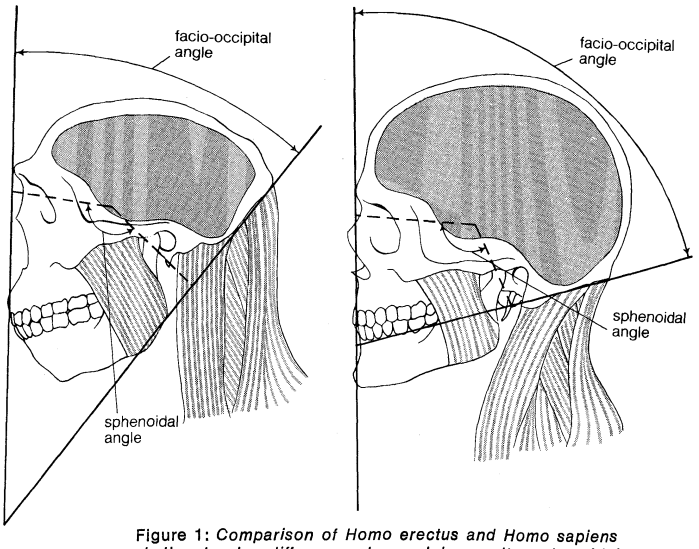

Figure 1: *Comparison of Homo erectus and Homo sapiens skulls, showing differences in cranial capacity, sphenoidal angle, and facio-occipital angle.*
(Left) Small brain, large muscles, and flattened skull vault of *Homo erectus* skull. (Right) Large brain, small muscles, and rounded skull vault of *Homo sapiens* skull.

ridges in *Homo erectus*. Similarly, large jaws and teeth demand well-developed muscles of mastication with strong attachments to the cranium. In order to dissipate the considerable forces produced by these muscles when the teeth meet during chewing, there is in *Homo erectus* a stout maxilla (upper jaw) and a heavy supraorbital ridge, or torus (brow ridge), extending the whole width of the cranium, a ridge rendered even more necessary because *Homo erectus* had a skull of low cranial capacity and therefore lacked a well-developed forehead. Such skulls are found in the examples of *Homo erectus* known from both Peking and Java (see HOMO ERECTUS).

The skull of *Homo sapiens*

By comparison, the skulls of *Homo sapiens* show an expanded cranial vault with a high maximum breadth and a well-developed vertical forehead, resulting from expansion of the frontal region of the brain, so that the supraorbital ridge is, as it were, "overgrown" and buried. At the same time, the face is shortened by a reduction in size of the jaws, which also bear smaller teeth. The masticatory muscles, therefore, need not be so large; and the forces that they produce are less, so that the need to neutralize them through the face is reduced. Thus, the facial structure can be more delicate, and the need for a heavy supraorbital ridge is removed. Finally, the lighter face does not require such powerful muscles behind the point of balance of the skull; as a result, the neck muscles can be reduced in size and their areas of attachment to the skull brought more underneath the back of the head.

The decrease in the size of the teeth of *Homo sapiens* tends to leave the nose and point of the jaw as prominent features of the face. Thus, the presence of a mental protuberance (chin) is an obvious character of the jaw of *Homo sapiens* and provides external support for the symphysial region (the point at which the two sides of the jaw have grown together).

Dental characteristics. The dental characteristics of *Homo sapiens* revolve around the basic fact of reduction of the masticatory apparatus. Thus, the dentition as a whole shows tooth crowding (dento-alveolar disproportion), accompanied by smallness of the individual teeth and marked reduction in size of the third molar. In modern populations the third molar tends to be genetically unstable; *i.e.*, it is frequently absent or malpositioned (impacted wisdom teeth). Similarly, but less frequently, the lateral incisors (the cutting teeth on either side of the "front teeth") may be absent. In other respects the dentition of *Homo sapiens* is best contrasted with that of *Homo erectus* in that it lacks some of the special features known from this species. For example, the teeth of *Homo sapiens* are less likely to show secondary enamel wrinkling of the occlusal (chewing) surface of the teeth, and less taurodontism (pulp space enlargement), although this is still well-known from Neanderthal man. The eruption sequence of teeth seems to be an unreliable criterion because variability is common in modern populations and may well have been so in the past. The teeth of *Homo sapiens* are small, unspecialized, crowded, and liable to be genetically unstable, particularly the wisdom tooth.

Postcranial skeleton. The form of the skeleton of the trunk and limbs of *Homo sapiens* (postcranial skeleton) is characterized by its adaptation for a fully upright posture and a striding bipedal gait. This remarkable locomotor capability is the final expression of an evolutionary process that has taken at least 2,000,000 years to achieve, and so some aspects of the process are well-known from earlier members of the genus *Homo* and also from the genus *Australopithecus* (which may have been ancestral to the genus *Homo*).

Bipedal posture and gait

In terms of posture, the bipedal vertebral column is held upright and shows two secondarily developed curves when viewed from the side, one in the lumbar region of the back (small of the back) and the other in the neck region. From the front the column should appear straight. These curves allow the weight to be evenly disposed about the line of gravity, which passes vertically through the second sacral vertebra (at the base of the spine) and behind the rotation centres of the two hip joints. This permits the pelvis to tip backward just beyond the vertical and rest upon a straplike ligament across the front of the hip joint, a sophisticated effort-saving mechanism that allows most of the muscles around the hip to relax so that the upright stance is an economical posture. Associated with this is the ability to lock the knees back, which also relaxes some surrounding muscles. To rise from the squatting or seated position requires considerable power of extension of the hip joints, and this is provided by the large buttock muscle (gluteus maximus) and a backward extension (posterior superior iliac spine) of the bony pelvic flange (blade of the ilium) for its attachment.

An alternating bipedal gait, to be fully efficient, must allow each leg to swing clear of the ground during walking; this is provided for by a pelvic-tilt mechanism that raises the side of the swinging leg. In addition, such a gait must avoid wild side-to-side movements of the centre of gravity, and this is achieved by inclining the thigh bones toward the midline and thus bringing the feet closer together. Finally the bipedal adaptations of the modern human foot are such that both weight and force are transmitted to the ground through a propulsive system of short levers that permits a heel–toe stride.

The upper limb adaptations to bipedalism are fewer and are concerned with the dynamic balance of the body while moving. Arm swinging is a normal part of bipedalism and compensates for the twist of the body toward the side opposite to the advancing foot. The selective advantages of bipedalism, in terms of the upper limb, are immense in that they free the hands for the carriage of infants, food, tools, or weapons, as well as permitting the development of the hands for a manipulative role such as toolmaking. Although hominids below the human level of evolutionary advance could make tools, the refinement and exploitation of tools demanded hands capable of both power and precision grips. The power grip involves primarily the inner, or ulnar, side of the hand and permits a firm grip on a branch, a rock, or hammer handle. The precision grip involves the outer, or radial, fingers and thumb, as in using a small stone for engraving, a small brush for painting, or a pen for writing (Figure 2). This requires the bringing together of the tips of the opposed thumb and the next two fingers in order to grip a small object, a grip that demands that the lengths of the index finger and thumb be proportionate and that the joint at the base of the thumb be of a special saddle-shaped variety. It seems likely that the precision grip evolved later than the power grip and that its perfection may even have been a specialization in *Homo sapiens*. Only when human hands had evolved to this level, concomitantly with brain expansion, could manipulative

Freeing the hands for tool use

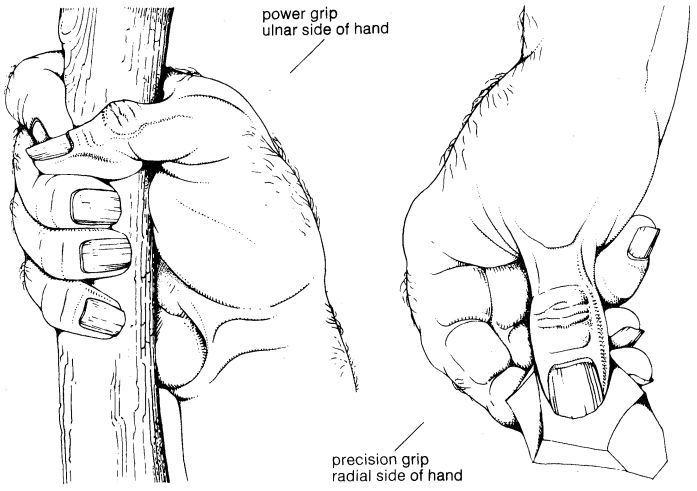

Figure 2: Hand grips.

skills give expression to the artistic impulse in terms of cave painting, bas-relief, and sculpture in the round, all of which are sophisticated behavioral correlates of a highly evolved individual, in terms of both locomotor and intellectual skills.

Having looked at the problems of the identification of human characteristics and also at the difficulties of interpreting the significance of these characteristics singly or in groups, it is appropriate to consider the early fossil materials that might provide reasonable candidates for attribution to *Homo sapiens*. These are likely to be found during the late middle Pleistocene to upper Pleistocene (about 200,000 to about 15,000 years ago)—in archaeological terms, the Paleolithic, or Old Stone Age. Naturally the quantity of fossil material recoverable tends to increase markedly as more recent periods are dealt with, so that the total number of human specimens amounts to some hundreds. On the other hand, toward the earlier end of this time range, the fossils available for study are far fewer in number. Advances in dating methods in recent years have eliminated a number of specimens formerly given an antiquity that they do not deserve, so that the picture has been somewhat clarified. A number of specimens remain that have often in the past been divided into the Neanderthals and the sapients (*i.e.*, members of *Homo sapiens sapiens*, the same subspecies as modern man).

The problem of Neanderthal man. This group was originally recognized by a combination of cranial, dental, and postcranial features that were generally considered distinct enough to classify Neanderthal man as a separate species. Thus *Homo neanderthalensis* was described on morphological grounds and regarded as a specialized group of the genus *Homo* that lived during the last glaciation (Würm Glacial Period) in Eurasia. The sites from which examples of the Neanderthalers were recovered have commonly produced tools of the Mousterian culture, a stone-tool industry dating from about 90,000 to about 40,000 years ago. Quite suddenly these people disappeared from the fossil record, and various theories have been put forward to account for their disappearance. In addition to these "classic" Neanderthalers, exemplified by remains from Neanderthal (Germany); La Chapelle-aux-Saints, Le Moustier, La Ferrassie, La Quina (France); Gibraltar; Monte Circeo (Italy); Shanidar (Iraq); Kiik-Koba (Russia), and many other sites, there is a second group sometimes known as the generalized Neanderthalers. These have included remains from Krapina (Yugoslavia), Saccopastore (Italy), Ehringsdorf (Germany), and Skhūl (Mt. Carmel, Israel). Some of these preceded or at least were contemporaneous with the classic Neanderthalers, whereas others of this second group appear to have existed rather later, since reappraisals of the dates first given to some of the sites have questioned their antiquity; *e.g.*, Krapina, Mt. Carmel.

Many have considered that the classic Neanderthalers were a cold-adapted, specialized side branch from the human line that became isolated in Europe and then became extinct as the climate improved. The generalized Neanderthal group is considered to have avoided this specialization and continued to give rise to the later modern sapient populations. This involves invoking the so-called catastrophic demise of classic Neanderthal man. An alternative view placed classic Neanderthal man in the modern human evolutionary line, his disappearance both anatomically and culturally being due to an absorption process involving some contribution of Neanderthal genes to the succeeding populations. Most modern systematists tend to include Neanderthal man within the species *Homo sapiens* and only accord subspecific status to the combination of morphological characters that make up the anatomy of the classic Neanderthalers of the last (Würm) glaciation; they are thus named *Homo sapiens neanderthalensis* rather than *Homo neanderthalensis*.

Neanderthal man's place in human evolution

In addition to the European and Near Eastern evidence of Neanderthal man, a number of specimens from Africa and Asia must be considered. These have been termed "Neanderthaloid" in the sense that, although they show some cranial characters that parallel the better known European type of classic Neanderthal structure, they also show a number of other (sometimes more advanced) features of the skeleton. Examples of this group would include Rhodesian man (Zambia, formerly Northern Rhodesia), Solo man (Java), and Saldanha man (South Africa), all from upper Pleistocene deposits (100,000 to 10,000 years ago). Their very presence shows that the whole problem of defining *Homo sapiens* must be considered in a wider context and cannot be reasonably considered in European terms alone. Clearly, the problem of the origin of *Homo sapiens* from his middle Pleistocene forebears is complex; hence, it is valuable to examine in detail those specimens that come from the earliest well-dated sites, in order to try to discern the centre of sapient evolution (if such a centre exists) and to discover which are the earliest specimens that show incipient sapient characters. Bearing in mind the principle of mosaic evolution, which has been demonstrated as an important part of the evolutionary process, it is not reasonable to suppose that all of the features that have been mentioned as characteristic of *Homo sapiens* will appear together in these early specimens. Thus, a mixture of advanced and less advanced features may be expected in early forms, some perhaps relating to *Homo erectus* (the species from which *Homo sapiens* descended), to Neanderthal man, or to modern man as he is today.

Vértesszőllős man. In 1965 some fossil remains were recovered from a site in Hungary at the foot of the Gerecse Mountains. In a quarry cut into the fourth terrace of the Danube River system, a number of occupation layers were recognized. The third of these layers contained some human remains as well as a tool culture and some fossil mammalian bones. The site is known as Vértesszőllős, and the first finds were some fragments of milk teeth from the lower dentition of a child (Vértesszőllős I). Rather more important was the second find (Vértesszőllős II), a fine adult occipital bone (the bone at the back of the skull) that was broken into two fragments. The bone is stoutly constructed, having thick walls in the ear region, whereas the floor of the depression for each cerebellar hemisphere (at the base of the skull) is relatively thin. In profile, the bone can be divided into two parts, an upper, curved occipital portion and a lower, flattened neck portion. The flattened area is incomplete and does not include the margin of the foramen magnum (the opening at the base of the skull through which the medulla passes), the borders of which are broken away. The attachments of the neck muscles are well marked on the outer surface of the flattened area, which also has signs of an occipitomastoid crest (a crest of the occipital bone near the mastoid process, which is a projection of bone behind the ear), a primitive feature. The occipital ridge, or torus, that divides the upper, curved portion from the lower, flattened area is prominent and continuous across the bone; indeed, it is so prominent that

Features of cranial remains

in its central portion it is even undercut. Internally, the cerebellar fossae (depressions in the skull where the lobes of the cerebellum lay) are rather small by comparison with the impressions above for the occipital lobes of the brain. The internal occipital protuberance lies well below the external occipital protuberance (inion), and the impressions for the venous sinuses (marks where blood vessels lay against the skull) are distinct. The cranial volume of this individual has been estimated at 1,400 cubic centimetres.

The remains have been attributed to a male under 30 years of age. The thickness and the breadth of the bone, as well as the undivided occipital ridge, are relatively primitive features, whereas the height and curvatures of the upper segment are modern features. Similarly, the configuration of the brain is primitive despite its large size. The morphological comparisons and the statistical analysis of this specimen suggest that, although this population took its origin with *Homo erectus*, it had differentiated from this group and perhaps ought to be classified as at the beginning of a progressive evolutionary line.

Perhaps the principal significance of this specimen, apart from its structure, is that it is dated to a warm phase within the second (Mindel) glaciation, 500,000 to 400,000 years ago. The specimen has been assigned to an unusual new category *Homo (erectus seu sapiens) palaeohungaricus;* whatever the precise taxonomic meaning of this name, it is clear that it is regarded as an intermediate form, the mixed *Homo sapiens* and *Homo erectus* features of which are the result of evolutionary mosaicism.

Swanscombe man. A more widely known example of early *Homo sapiens* is derived from the Thames Middle Gravels at Swanscombe in North Kent, England, which are gravels attributed to the Mindel-Riss Interglacial Stage, 400,000 to 200,000 years ago. Here, at a site well-known for its Paleolithic tools, two parts of a human skull were recovered in 1935 and 1936. About 20 years later, a third piece was recovered that fits with the other two pieces to form the back half of a cranial vault. All three bones are virtually complete, and it is believed that they belonged to a young adult. Generally speaking, the bones are modern; however, the bones of the skull vault are rather thick, and the skull is broad at the back. The occipital bone shows no sign of the heavy occipital torus, or "chignon," characteristic of Neanderthal man, and the occipital ridge is modest, although a little more prominent at its ends than in the middle. This bone is rounded both above and below the ridge, in contrast with the Vértesszőllős occipital. The position of the foramen magnum and the joints for the vertebral column are modern, so that the posture of the head does not appear to differ significantly from that of modern man. In the original report on these bones, it was stated that by measurements the Swanscombe skull could not be distinguished from that of *Homo sapiens*. Despite this, several authorities have been less convinced by the sapient features of Swanscombe man and have emphasized the Neanderthal features of the bones. In a recent reappraisal of the Swanscombe material, making use of multivariate statistics, it has been suggested that it is necessary to emphasize the inter-relatedness of all the early forms of *Homo* and that it is no longer possible to maintain specific status for each form. It is preferred, rather, to regard them all as a spectrum of varieties within one species. It was suggested further that Swanscombe should be regarded as belonging to a "Neanderthaloid Intermediate" group that contains the Ehringsdorf, Skhūl V, Krapina, and Steinheim specimens.

Classifying Swanscombe man

Once again, as with Vértesszőllős, there is a mixture of features that, at this somewhat later date in Europe, combine sapient and Neanderthal characteristics in keeping with the concept of mosaic evolution.

Steinheim man. Another skull of approximately the same age as the Swanscombe skull is known from Steinheim, near Stuttgart, West Germany. This skull was recovered in 1933 from a gravel pit cut into Pleistocene deposits that have been dated to the Mindel-Riss Interglacial Stage. This skull is more complete than either of those mentioned above but suffers from some distortion, perhaps due to the pressure of the deposits. It consists of the cranium and the right side of the face of a young adult; much of the base of the skull is missing, but there is a good deal of the palate and also some teeth present, including a premolar and all the molars of both sides. The face is straight, with little projection of the upper jaw, while the vault of the skull appears to be long and narrow but fairly well rounded in profile, and there is only moderate frontal flattening. The occipital region is marked by a very low occipital ridge, and it does not have a Neanderthal "bun." The frontal region has a pronounced but divided brow ridge. The cranial volume has been estimated variously between 1,070–1,175 cubic centimetres, but the distortion precludes accurate measurement.

The teeth are of particular importance because they are perhaps the earliest sapient teeth known. The premolar crown is symmetrical in shape but has a large outer and a smaller inner cusp. The molars decrease in size order from front to back, but the third molar is markedly smaller than the other two. All of the teeth have some degree of taurodontism (enlarged pulp cavities).

Again, there is a mixture of primitive and advanced features in this skull, the principal resemblances of which are, with the Swanscombe skull, described above. The contour of the occipital region and the rounded vault are advanced sapient features, whereas the broad nasal opening and the brow ridge recall the Neanderthal shape. The teeth are small and sapient both in form and molar size order, while the marked reduction of the size of the third molars is a distinctly modern feature. The enlarged pulp cavities are sometimes regarded as primitive since they are widely known from both *Homo erectus* and Neanderthal teeth. However, this trait is still frequently observed in the teeth of modern populations.

Taxonomic affiliations of Steinheim man

Earlier opinions have suggested that Steinheim man represented an intermediate stage between *Homo erectus* and the later forms of *Homo*, thus being ancestral to both Neanderthal and modern man. Another view does not accept the Steinheim fossil as being ancestral to the classic Neanderthal and modern man, suggesting, instead, that it represents a stage on a separate but parallel line leading to modern man. Both views now appear to be too simplistic and not in harmony with the findings of modern population genetics; the pattern of mixed characters that is becoming apparent follows the general trend of cranial enlargement and rounding, accompanied both by facial and dental reduction.

Fontéchevade man. The fourth early sapient skull known from Europe is less well preserved than the preceding specimens. It consists of some vault fragments that are known from Fontéchevade, Charente, France. The material was recovered during the excavation of a cave site that had produced tools from higher levels. The fossil layer has been attributed to the last (Riss-Würm) interglacial period because of the fauna and the tool culture that it contains. The first specimen (Fontéchevade I) is a small fragment of rather thin frontal bone, but the second specimen is large and includes both parietal bones and part of the frontal bone. French anthropologist H.V. Vallois, who has studied the remains, denies any difference between these remains and those of *Homo sapiens;* he makes it clear that there was no supraorbital ridge and that the cranial volume was over 1,400 cubic centimetres. It is only fair to say that the Fontéchevade remains are fragmentary, and it would be a mistake to place too much reliance on their evidence alone; nonetheless, Vallois has taken the view that Swanscombe and Fontéchevade are related types at the base of a progressive line leading toward modern man, whereas Steinheim would have led to the more specialized Neanderthal group.

Thus, in Europe there is one specimen from the Mindel Glacial Period (500,000–400,000 years ago), with early sapient features; two examples of early *Homo sapiens* from the Mindel-Riss Interglacial Stage (400,000–200,000 years ago); and at least one from the Riss-Würm Interglacial (100,000–70,000 years ago). If this is re-

garded as scanty evidence, then that from Africa has been even more sparse until the most recent finds.

Omo man. In 1967 the Kenyan group of the International Omo Expedition to southern Ethiopia, led by Kenyan paleoanthropologist Richard Leakey, recovered large parts of two skulls and a large number of limb bones from two sites that have been dated to the East African upper middle Pleistocene or early upper Pleistocene Epoch (about 200,000 to 70,000 years ago). The most complete skull (Omo II) is long and narrow with a receding forehead, a rounded cranial vault, and a prominent occipital ridge, below which lies a flattened neck region. The bones of the skull vault are thick, and the maximum breadth of the skull is low in the temporal region, which is marked by the presence of large mastoid processes (bony projections below and behind the ear). The completeness of this skull has allowed accurate estimations of the cranial volume at 1,430 cubic centimetres. Preliminary assessment of the taxonomic affinities of this skull has suggested that, while it shows a number of specialized features, some of which are reminiscent of the earlier *Homo erectus* skulls, it also has some advanced features, such as the rounding of the vault, the large mastoid processes, and the high cranial capacity. In view of this, it has been regarded as an early example of the African segment of evolving *Homo sapiens.*

Features of the Omo skulls

The other skull (Omo I) recovered from the same general area and attributed to the same geological layer was accompanied by a large number of limb bones and is in many ways quite different from Omo II. Although the forehead still slopes from a prominent supraorbital (brow) ridge, the vault is very well rounded down to the occipital region. There is a prominent downturned mastoid process. The vault of this skull is robust by modern standards, but it is less so than that of Omo II.

Viewed from the rear, the two skulls show striking differences—the Omo I skull is far more modern in outline. The limb bones of Omo I are rugged and well marked by muscle impressions, but in general they have few, if any, features that would distinguish them from the limb bones of *Homo sapiens.* A preliminary assessment of Omo I therefore suggests that, although it has some specialized features, they are far fewer than those of the Omo II skull; at the same time, its advanced features are perhaps more marked.

Perhaps the most striking feature of the whole Omo assemblage is once again the mixed character of each of the two principal specimens that are said to be of the same geological age. The Omo II skull undeniably has features that can be paralleled in earlier forms of *Homo,* and at the same time the Omo I specimen seems to foreshadow the later morphology of modern *Homo sapiens,* particularly in the occipital region of the skull and in the limb bones. It is possible that the mosaic evolutionary process is seen here in microcosm. Not only is differential evolution occurring within individual representatives of contemporary populations but also between populations in one area of East Africa.

Obviously, the specimens considered here do not comprise all of the available material that has been or could be attributed to fossil *Homo sapiens;* much of the remainder is of a rather later date, however, such as the Rhodesian remains, the Solo skulls, the Wadjak skulls, the Upper Cave remains from Peking, and materials from a number of other sites. Only a few taxonomists would still say that these remains merit species status on their own (*e.g., Homo rhodesiensis, Homo soloensis, Homo wadjakensis*); the majority accept that they all belong to the same species as modern man, *Homo sapiens.* Some would permit classification according to subspecies or variety, mostly on a combined geographic, temporal, and morphological basis. This implies that *Homo sapiens soloensis* or *Homo sapiens steinheimensis* are representatives of a local population from a given time period in a given area, similar to modern racial groups. The aggregate of the populations represented by fossil remains and all modern populations is a polytypic species (one that cannot be represented by a single typical individual because of physical variation such as skin colour and size of brow ridges within the species), valid both "horizontally and vertically"; *i.e.,* both geographically and through time. Classification by subspecies is no doubt useful in hominid taxonomy, at least for the purposes of communication and description, but whether or not one or two specimens, distinguished by a few morphological characteristics of the bones alone, truly form a valid basis for attribution to a separate subspecies in zoological terms is less certain.

Classifying the later human remains

In examining the earliest specimens that have been attributed to the species *Homo sapiens,* it is apparent that they comprise a very small sample of the populations that must have existed. Their diversity may perhaps be seen in perspective by considering the wide differences that exist in mankind today, differences that are certainly all accommodated within one species.

It seems that the evolution of man must be considered in terms of successive evolving populations, each showing a range of structural and geographic diversity at any given time, a diversity due to groups that have evolved similar but not identical characteristics in different places. Not all of these evolutionary lines necessarily developed into forms that exist today, but neither was the modern line necessarily genetically isolated from the past populations represented in the fossil record.

CULTURAL ASSOCIATIONS OF FOSSIL HOMO SAPIENS

While bones and teeth provide the most direct evidence of the form and locomotor capabilities of fossil man, there are other sources of information from which to obtain some concept of both his surroundings and his activities. This information comes from the careful excavation of the geological deposits from which the fossil remains are taken. Modern methods in archaeology make use of an increasing number of scientific techniques, and through these studies it is sometimes possible to reconstruct both the environmental situation and the behavioral activities of fossil man at a given site and time period.

Cultural remains preserved in the fossil record. In considering early *Homo sapiens* from a cultural standpoint, there are a few general considerations to be taken into account. The evidence that can be found must be inherently capable of preservation; thus, the types of materials that are most likely to be found are stone tools or stone structures and often fossilized animal bones and teeth. On the other hand, wood and plant remains are much rarer because such materials are more subject to decay. It must not be assumed, therefore, that the absence of wooden materials in the fossil record implies that they were not used by early man. Materials not normally preserved may be present in some situations and provide valuable clues; hence, fossil pollens, dealt with by the science of palynology, can give enormous insight into the vegetational structure and thus the climate of the time. Other general considerations relating to a fossil site include the likelihood of its location being close to a source of water, both for man and the animals that he may have hunted. Similarly, it is likely that sources of stone for the manufacture of tools will be found near living sites. Given these basic requirements, the living sites of early man can clearly be either in temporary structures in the open, in caves, or in rock shelters. In many circumstances it is likely early man had little choice about where to shelter, but under glacial conditions the ability to find, acquire, and defend a cave or shelter could have been crucial and might have overridden other considerations. During interglacial periods, when warmer conditions prevailed in summer in Europe and possibly all the year round nearer the Equator, a temporary open-air site with a makeshift windbreak or skin tent may have sufficed.

Homo sapiens' early distribution

The known occupation sites of early *Homo sapiens* are so few that it is unlikely that any valid distribution pattern can be described at this stage. The principal early sites are from Europe, but they vary in age to such an extent that it would be unwise to draw conclusions as to possible migrations or to population density at any given time period. Little more can be said than that early *Homo*

sapiens was possibly present in southeastern Europe 350,000 years ago, in western Europe 200,000–250,000 years ago, and in East Africa 130,000 years ago. After those times, evidence of *Homo sapiens* becomes widespread and can be found in the rest of Europe, the Mediterranean, southern Africa, China, and the Far East. Finally, America was occupied from north to south via the Bering Strait at least 20,000 years ago, and Australia was occupied from the Southeast Asian peninsula a little earlier.

The Vértesszőllős site. The deposits that produced the fossils from this site show four layers of dried mud that may have come from thermal springs. The lowest of these layers was five centimetres thick and contained the fossils. A number of fossil mammalian bones were recovered from the site including those of a beaver (*Trogontherium schmerlingi*), Etruscan rhinoceros (*Didermocerus etruscus*), wild dog (*Canis etruscus*), a large sabre-toothed carnivore (*Epimachairodus*), and a large number of the bones of smaller mammals. The lower two of the four occupation layers correspond with a period of mild climate, and the upper two layers correspond to a period of colder conditions. The imprint of beech leaves in the lower two layers suggests that the remains should most probably be dated to an interval of temperate climate within the Mindel Glacial Period, roughly 350,000 years ago.

In addition to the fossil bones a large number of stone tools of small size were found. They consist of pebble tools, chopper tools, and numerous stone flakes. The stone-tool industry has been termed the Buda industry, and it contains no hand axes, significant because early pebble-tool industries usually also contained hand axes, which later ceased to be used in parts of Europe. Traces of fire were confirmed at this living site; thus, Vértesszőllős man must rival Peking man (*Homo erectus*) as the first known fire user, and he is without doubt the first sapient fire user, if the attribution of the Vértesszőllős remains to early *Homo sapiens* is fully confirmed.

Although from such scanty environmental and cultural evidence it is possible to build only an incomplete picture of the situation of Vértesszőllős man at this site, some of the general considerations seem to apply. The site is in the fourth terrace of the Danube River system, which supplied water; the tools are made of flint and quartz from nearby sources; and the mammalian fauna suggests the availability of quarry for hunters. If the climate was temperate, it may not have been necessary to seek shelter all the year round, so that an open site such as this could have been acceptable. The evidence of fire could suggest the cooking of food, but perhaps it is more likely to have been a necessity in the occupation of an open site as a means of warding off predators, such as the sabre-toothed carnivore, at night. Finally, the concentration on the site of the bones of large mammals could indicate the need for cooperative hunting or trapping.

The Swanscombe site. The environmental and cultural information concerning Swanscombe man has been obtained from the river gravels in which the skull was found and from the layers immediately below. These gravels form part of the 100-foot terrace of the Thames River; the skull was found in the Upper Middle Gravels. Twenty-six species of fossil mammals are known from this layer, and the character of the assemblage suggests that the climatic conditions were relatively warm. Among the species recorded are Merck's rhinoceros (*Didermocerus kirchbergensis-mercki*), straight-tusked elephant (*Palaeoloxodon antiquus*), cave lion (*Panthera spelaea*), wolf (*Canis lupus*), horse (*Equus caballus*), fallow deer (*Dama clactoniana*), giant ox (*Bos primigenius*), red deer (*Cervus elaphus*), and hare (species of *Lepus*). A number of these species would have provided suitable food for Swanscombe man. Although there is no direct evidence that the animals were hunted, it can be inferred that this was the case.

Swanscombe fauna

During the Mindel-Riss Interglacial Stage, the river was very wide and at times slow flowing, with marshy ponded areas along its banks. It is likely that herds would have gathered to drink and browse near the waterside and in this situation would have been very vulnerable to hunting by early sapient man. Some recent evidence from the boundary between the lower loam and lower gravel deposits that precede the layer in which Swanscombe man occurs suggests that kills were butchered at the river edge. It is not unlikely that temporary encampments would have been made after a successful hunt, but so far no true living floor has been found at this site.

Many nonmarine mollusks found at the site have contributed information concerning the environment. These include land snails of species known from European Mindel-Riss Interglacial Stage sites and aquatic snails that had probably spread to the Thames from the Rhine, which by this stage had become connected with the Thames. The types of land snails found suggest a temperate climate with summers that were warmer than those of today and indicate the nearness of dry grassland, marshy riverbank, and scrub and woodland. The bird remains from Swanscombe are mainly those of aquatic birds such as geese (species of *Anser* and *Branta*), ducks (*Anatidae*), and cormorants (species of *Phalacrocorax*), while the scanty fish remains are confined to a large bone from the lower jaw of a common pike (*Esox lucius*) from the lower gravel.

The Swanscombe Middle Gravels are rich in stone tools, many of which are in fine condition, suggesting that they have not been moved very far by the action of water. This tends to confirm that the stream was relatively sluggish and that early *Homo sapiens* discarded these tools nearby. The implements recovered include numerous hand axes of the Middle Acheulean stone-tool culture (*c.* 200,000 years ago) and a number of flake tools (made by chipping stone flakes from a prepared core of stone). Recent studies of new cultural material from the earlier lower loam deposits has shown that some of these implements were made on the spot. A number of flakes have been found, in a circumscribed area of the deposit, that fit together neatly to reconstruct the original nodule of flint, which must have been brought to the site from some nearby source. A rubber mold of the cavity within the reconstructed nodule has shown the shape of the core that was produced by the flaking process. To find a group of flakes that fit in this way is convincing evidence of activity at this site and also shows that there was previously a land surface at this point. This was confirmed not far away by the presence of a preserved deer slot, or footprint.

The Swanscombe site is a good example of how specialists in a variety of fields can each contribute information that in conjunction enormously enhances the value of the whole. Fauna, flora, and climate are always closely linked, and with cooperative scientific efforts it is sometimes possible to build a convincing reconstruction of the ecological situation, as in this case.

The Steinheim site. The Steinheim site is on the Murr River, near Stuttgart, in West Germany, and is situated in a gravel pit excavated into the Pleistocene deposits washed down by this river. There are present a number of layers of sands and gravels that are overlain by a layer of loess—windborne deposits laid down during a subsequent cold phase. Four layers of gravels have been characterized, the third of which contained the Steinheim skull and numerous mammalian bones but no implements. The third-layer mammals include straight-tusked elephant (*Palaeoloxodon antiquus*), giant ox (*Bos primigenius*), bear (*Ursus arctos*), and lion (species of *Felis*). It is generally agreed that this constitutes an interglacial woodland fauna and should be attributed to the Mindel-Riss Interglacial Stage. Further speculations about the environmental situation of Steinheim man lack substance, as no evidence of a land surface or a living floor, in the shape of tools or evidence of fire, has been discovered. It can only be presumed that Steinheim man lived and hunted near a water source, but knowledge of his cultural attainments is entirely lacking.

The Fontéchevade site. The Fontéchevade cave is cut into the side of the valley of the Tardoire River near Montbron, Charente, France. When the cave floor was

Cave dwellers

excavated for the second time, a thick layer of stalagmite was exposed, beneath which was found the layer that contained the human remains. The thickness of the layer of stalagmite has separated the deposits into two principal layers and suggests a considerable time difference between them. The first excavation had removed a lot of later cultural material—including Magdalenian, Aurignacian, and Mousterian implements—but no human remains. The layer beneath the stalagmite contained a number of fossil mammalian bones and stone tools. The fossil fauna includes rhinoceros (species of *Didermocerus*), fallow deer (*Dama*), tortoise (*Testudo graeca*), and bear (*Ursus*), fauna that suggest warm or temperate interglacial conditions. The tools recovered belong to two aspects of the flake industry that existed contemporaneously but distinct from a hand-ax culture during the Paleolithic, or the Old Stone Age, a term covering the time period from the oldest stone tools—*c.* 2,000,000 years ago—up to the use of polished stone tools—*c.* 10,000 years ago. The earlier flake tools at this site are termed Clactonian tools (type site Clacton, England), while the later are known as Tayacian tools (type site Tayac, Dordogne, France). On the grounds of the fauna and the tools, the fossil layer has been attributed to the Riss-Würm Interglacial (100,000 to 70,000 years ago).

In many ways the Fontéchevade site fits the general picture of early sapient sites: once again it is near to water; there is an apparent availability of game; there is possibly some evidence of fire use; and early stone tools were used in the cave. Although the flake cultures are relatively unsophisticated in their workmanship and finish, the tools need not be much less effective for general purposes on that account. Fontéchevade may be the earliest European site from which early sapient man is known to have led a relatively settled existence.

The Omo site. This site is situated to the north of Lake Rudolf in the valley of the Omo River in southern Ethiopia. The early sapient remains were found in member I of the Kibish Formation (Site KHS), a group of middle to upper Pleistocene layers (*c.* 100,000 years old) that overlie the older Nkalabong Beds. The Omo River drains southward into Lake Rudolf and is subject to considerable seasonal variation in level; this appears to have been the case over a long period of time. Frequent dry-land emergence characterizes the deposits and indicates the local appearance of brackish pools and marshy reeded areas in a deltaic region.

The Omo I skull and postcranial remains (remains of the skeleton other than the head) were found *in situ* near a minor unconformity, and they were associated with a few worked stone flakes, although not enough to characterize a stone-tool industry. In addition to the stone flakes some fossil mammalian bones and teeth were found from an early example of the modern African elephant (*Loxodonta africana*), from an advanced "archaic" elephant (*Elephas recki*), and from both the white and black rhinoceros (*Ceratotherium simum, Diceros bicornis*). The complete skeleton of a buffalo (*Syncerus caffer*) was collected *in situ* from the deposit in which the skeleton of Omo I was found.

Omo II discovery and dating

The Omo II skull was recovered from the other side of the valley from a site (Site PHS) spread over the side of a small clay deposit next to a hill representing the upper half of Member I and the lower third of Member II of the Kibish Formation strata. While the stratigraphic position (position in the layered geological deposits) of Omo II is not certain, the sedimentary sequence of PHS is analogous to that at KHS, and thus there seems little reason to question the assignment of both sites to the same geological level. No faunal or cultural remains were recovered with the Omo II skull. The dating of these remains was at first given as late middle Pleistocene or early upper Pleistocene (200,000–80,000 years old) on the grounds of geological inference, but later radiometric dating has indicated an age of 100,000–130,000 years.

To build an environmental and behavioral picture from this evidence is again difficult, but the association of early sapient sites with free water, the presence of suitable stone for flaking, and large mammals for hunting is confirmed once more. It can be assumed that the climate was not harsh at this latitude, so that an open-air riverside occupation site would have been possible. The presence of a group of waste flakes or flake tools could indicate local activity on a temporary land surface, much as has been found at Swanscombe, but there is no evidence of the remains of a stone structure or of fire at the places where Omo I or Omo II were found.

Stone tools associated with Homo sapiens. Having considered the fossil remains of early *Homo sapiens* and the environmental and cultural situation of the group by means of the analysis of remains associated with the fossils, it is possible to look further by considering other sites that have provided tools but no human remains. Sites of this kind are very numerous and it is easy, but unwise, to speculate as to the kind of man that occupied them on the theory that human types and tool types will invariably go hand in hand. Experience has shown that such a correspondence cannot be safely inferred in most cases because overlap both of differing human populations and differing tool cultures is known to exist.

Stone tool cultures

In general terms, the earliest known stone-tool culture from the lower Pleistocene (*c.* 1,000,000 years ago) seems to have split into two basically parallel cultural systems, the hand-ax cultures and the flake-tool cultures (Figure 3). Within each of these types there is evidence of late diversification, so that the variety of tools increases; each presumably was used for more specific purposes.

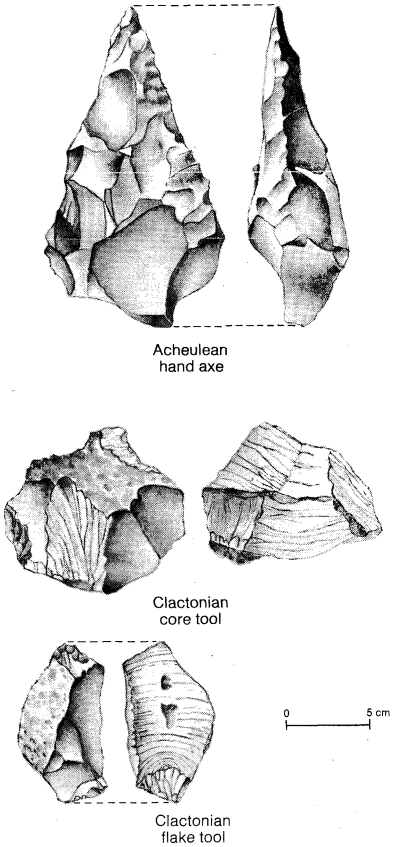

Figure 3: Early stone tools.

The distribution of tool sites shows some general features, such as the restriction of hand-ax cultures to Africa, western Europe, Arabia, and India, whereas the flake cultures overlap with the hand-ax cultures in western Europe but extend through the Balkans and into Southeast Asia. It seems clear that in Africa hand axes were developed from chopping tools, such as those found at Olduvai Gorge in Kenya, by the gradual extension of the flaking process around the edges until the flaked areas

met on the other side of the stone. The earlier stages of this process have been shown at Olduvai, but it is uncertain whether all hand-ax cultures are derived from a single African dispersal centre. The early Oldowan chopper tools lead eventually to the principal group of hand axes known as the Acheulean culture, and it seems very likely that early Acheulean hand axes were made by *Homo erectus*. This does not mean, however, that the later products of this industry must also be attributed to *Homo erectus*, as has been shown by the fine Acheulean tools recovered from Swanscombe and many other sites of much later date.

Flake-tool cultures

The parallel, but not mutually exclusive, flake cultures seem to have originated in the large chopper-tool industries, such as those made by *Homo erectus* at Peking (Choukoutienian tool industry). Similar early flake cultures are known from Burma (Anyathian), Malaysia (Tampanian), and from the North Punjab (Soan). The early "Buda" industry of Vértesszőllős has no hand axes but has many choppers and flake tools made from pebbles, perhaps the most primitive tools yet associated with *Homo sapiens*. The principal early development of the flake industry is the Clactonian culture, which is known from a number of European sites between the Mindel and Riss glacial periods (400,000 to 200,000 years ago). In this industry the choppers and chopping tools were made from large flint nodules by striking off coarse but useful flakes. In its later and more evolved form, this tool industry has been termed Tayacian (it dates from *c.* 200,000 BC) and is known from sites in the Dordogne, in France. Beyond this, the flake and the hand-ax cultures seem to merge into the Mousterian phase, while the more advanced Levallois technique leads on the Solutrean culture. (These are all stone-tool industries of the Upper Paleolithic in Europe—80,000–15,000 years ago.) All of the latter industries are well associated with *Homo sapiens* of the upper Pleistocene (after *c.* 100,000 years ago).

Cultural Correlations in the Paleolithic Era

geological periods	years before present (000)	hand-axe cultures	flake cultures	sapient sites
Würm III Glaciation		Magdalenian		Neanderthal and later sapient sites
Paudorf Interstadial		Solutrean		
Würm II Glaciation		Aurignacian		
Gottweiger Interstadial		Perigordian		
Würm I Glaciation		Mousterian		
Third Interglacial (Riss-Würm)	100–130		Tayacian	Fontéchevade Omo
Riss II Glaciation

	250	Acheulean		
Second Interglacial (Mindel-Riss)			Clactonian	
Mindel II Glaciation				
Inter-Mindel Interstadial	350 (?)		Buda	Vértesszőllős
Mindel I Glaciation				
First Interglacial (Günz-Mindel)		Abdevillian		

DATING HOMO SAPIENS SITES

One of the most important aspects of the investigation of a fossil is the determination of its age. Not only does accurate dating set the remains in a proper stratigraphic context but it also has a strong bearing on the phylogenetic (natural evolutionary ordering) interpretation of fossil populations, since their order of succession cannot be safely determined on morphological grounds alone.

Methods of dating fossils. The methods of determining the antiquity of buried objects have improved immensely in recent years with the development of both chemical and radiometric techniques; nonetheless, the traditional means of dating deposits are still valid. At any fossil site it is of the utmost importance that the geology of the area be well understood in terms of both geomorphology and stratigraphy, for herein lies the basis of geochronology, the science of dating. Sequences of deposits usually conform to the superposition principle—that younger layers overlie older layers and, a priori, that objects contained in a layer will be of the same age as that layer. The problem is complicated, however, by the possibility of younger objects finding their way into older layers by burial or older objects finding their way into younger layers by erosion and redeposition.

Relative and absolute dating

In dating fossils it is first necessary to identify the geological layer in which they are found and then to establish that they are of the same age as that layer. This gives the so-called relative dating of the object, and once this is established it is reasonable to attempt to fix the absolute, or chronometric, date of the object in years before the present (BP). In practice it is rarely possible to use all of the many dating methods available, since the materials upon which they depend are not present at every site; thus some sites and some fossils are better dated than others (see the Table). For a discussion of the methods of geological and archaeological dating, see DATING, RELATIVE AND ABSOLUTE.

Dating the remains of Homo sapiens. *The dating of Vértesszőllős.* The geology and stratigraphy of the Vértesszőllős site has been investigated and the fossil layer confirmed as being in the fourth terrace of the Danube system. Its contemporaneity with that layer has been established by the estimation of the amount of fluorine in the fossils and associated remains. This test depends on the principle that buried bone gradually accumulates fluorine from the groundwaters of the deposit. The total quantity of fluorine in the fossil will depend finally upon the concentration of fluorine in the groundwaters, the time spent by the bone in the ground, the nature of the deposit, and the permeability of the bone. Since these are all variable factors, the method is of little value as a means of chronometric dating but is of very great value in determining the contemporaneity of a group of fossil bones. For example, it may show that a human skull is of the same age as the bones of an extinct animal with which it is associated, or it may reveal that the human remains were introduced into the layer at a later date by showing their fluorine level to be much lower than that of the associated remains. The contemporaneity of the remains at Vértesszőllős having been established, the faunal and archaeological evidence from the site can be considered by allowing comparisons with other sites. This comparative evidence has established the relative dating of the site to the Inter-Mindel Interstadial Period. Direct chronometric dating by the uranium–thorium method has given the site an age of 350,000 years BP.

The dating of Swanscombe. The recovery of the Swanscombe remains *in situ* from the 100-foot terrace of the Thames has strongly suggested that these remains became buried during the Mindel-Riss Interglacial Stage. The contemporaneity of the human bones with other mammalian remains has been confirmed by the fluorine method, by the determination of the organic nitrogen content of the bones, and by radiometric assay of their uranium content. The satisfactory results of these relative dating techniques also confirm the contemporaneity of the Swanscombe skull with the tool culture found in the Upper Middle Gravels of the site; this, in turn, correlates well with other Acheulean sites. No direct chronometric date has been given for Swanscombe, either on the specimens or the source deposit, but its age—about 250,000 years BP—can be inferred by correlation of this bed with others that have been determined.

The dating of Steinheim. In the past there has been some difference of opinion regarding the dating of the Steinheim find. The gravels have been assigned by some to the Mindel-Riss Interglacial and by others to the Riss-Würm Interglacial. The contemporaneity of the find with the associated remains has been established by the fluorine method, and recent paleontological opinion is united in attributing the layer to the earlier of these two interglacial periods—*i.e.*, the Mindel-Riss Interglacial. No direct chronometric date has been determined either on the

specimen or the source deposit, but its age in years can be inferred at about 200,000 years BP by correlation of this bed with others that have been determined to be of that age.

The dating of Fontéchevade. The Fontéchevade site is a cave deposit stratified by archaeological layers and a stalagmite layer. The fossil layer has been attributed to the Riss-Würm Interglacial, in view of the fauna and the tool culture that it contains. Confirmation of the contemporaneity of the specimen with the other remains in the layer has been obtained by the fluorine test. No direct absolute date has been determined on either the specimen or the source deposit, but its age in years can be inferred by correlation with other sites at somewhere between 70,000–150,000 years BP.

The dating of Omo. The Omo I human remains were partly *in situ* in Member I of the Kibish Formation, a layer of undeformed Pleistocene lake and river sediments to the north of Lake Rudolf. The Kibish Formation consists of four members (major strata), the lowest of which (Member I) is over 40 metres thick and has seven stratigraphic sub-units. It was from Member I that the Omo I skull was recovered, while the Omo II skull has been referred to the same level in an analogous stratigraphic sequence.

The relative dating of the site has been established by means of the fluorine, nitrogen, and uranium tests, and the fauna recovered is not inconsistent with the upper middle Pleistocene date (*c.* 100,000–200,000 BP), but it cannot be positively dated to this time level. The stone flakes are also undiagnostic in terms of relative archaeological dating. Direct chronometric dating has been attempted on material from the deposit, making use of both the carbon-14 and the uranium–thorium radiometric methods. The carbon-14 test has shown that the upper part of Member III, Member II, and Member I are all too old to be dated by this method and, therefore, older than 35,000–40,000 years BP. The uranium–thorium method depends upon the decay of uranium with the formation of thorium. Since the rate of decay of uranium is known, a chronometric date can be calculated from the proportion of thorium to uranium in the specimen. Member I of the Kibish Formation has been dated to 130,000 years BP by this method, and thus both Omo I and Omo II are regarded as being of this age because their sites are stratigraphically equivalent.

Honan

Honan (Ho-nan in Pin-yin romanization), a small province in the north central part of the People's Republic of China, has an area of 64,400 square miles (166,800 square kilometres). The province stretches some 300 miles from north to south and 350 miles east to west at its widest point. It is bounded on the north by Shansi and Hopeh; on the east by Shantung and Anhwei; on the west by Shensi; and on the south by Hupeh. The Huang Ho (Yellow River) divides the province into two unequal parts—one-sixth north and five-sixths south of the river —and thus to some extent belies the name Honan, which means South of the River. In 1970 the population was estimated to be 50,300,000. K'ai-feng, the former capital, has been superseded by Cheng-chou, where the Peking–Hankow railway crosses the Huang Ho and meets the Lunghai Railway running from east to west.

History. Honan abounds in prehistorical and early historical interest. Some of the most important evidences of the Neolithic beginnings of Chinese civilization are found in the northern part of the province. It was at Yang-shao-ts'un in north Honan that a Swedish geologist and archaeologist, Johan Gunnar Andersson, in 1921 discovered an assemblage of Neolithic painted pottery, that, together with many later finds, marked the presence of a well-established primitive farming culture, which has been named Yang-shao. The early farmers occupied the lands at the confluence of the Huang Ho, Wei Ho, and Fen Ho, and it was here that Chinese civilization was cradled. The other main Honan sites of the culture are at Miao-ti-kou, Lin-shan-chai, P'an Nan, and Hsi Yin. These earliest of farmers, who were also part-time hunters and fishermen, lived in sunken circular or rectangular dwellings, sometimes of considerable dimensions. They grew foxtail millet, broomcorn millet, and kaoliang and had domesticated dog and pig. Cultivation with their primitive stone tools was comparatively easy in the easily worked loess (wind-borne) soil.

Cradle of Chinese civilization

Immediately to the east, at Lungshan in Shantung, a different culture was discovered, known as the Black Pottery culture, as distinct from the slightly earlier Yang-shao Painted Pottery culture.

It was on these Yang-shao–Lung-shan foundations that the early civilization of the Shang (Yin) dynasty arose (*c.* 1766–*c.* 1122 BC) in north and west Honan, south Hopeh, and west Shantung. Excavations near An-yang and, more recently (1950), in Cheng-chou and Hsing-t'ai, Hopeh, revealed an advanced culture, having a hierarchical class structure, advanced buildings, and elaborate ritual in which beautiful bronze vessels were used. Tung Tso-pin, the leading authority on oracle-bone inscriptions, has calculated from them that the Shang king Pan Keng moved his capital to An-yang in 1384 BC.

When the Shang kingdom fell to the Chou dynasty (1122–221 BC), An-yang lost its status as a capital. When the Chou capital, Hao (Kuoking), was destroyed in 771 BC by western tribes, Lo-yang (then known as Lo-i) took its place. During the period 771 BC to AD 938, the distinction of being the capital was shared alternately by Lo-yang and Chang-an (modern Sian in Shensi Province). Lo-yang was the capital during the following dynasties—the Eastern Chou (771 to 221 BC), Later (Eastern) Han (23 BC to AD 220), Wei (220 to 264), Western Chin (265 to 317), Northern Wei (386 to 534), and Later T'ang (*c.* 924 to *c.* 936). With the fall of the T'ang dynasty, K'ai-feng took over the role of the nation's capital and remained so until the Northern Sung dynasty was overthrown by the Mongol invaders in 1126. From that time on the national capital was never again in Honan. Both Lo-yang and K'ai-feng remained important during that period because of their strategic locations in the gateway leading from the North China Plain into the Huai Ho Basin, thence into the Yangtze Basin.

The natural environment. *Relief.* Honan can be divided topographically into two parts, the western highlands and the eastern plain. In the northwest the rugged T'ai-hang Shan and Chung-t'iao Shan form the steep eastern edge of the Shansi Plateau, rising in places above 5,000 feet. They are part of the T'ai-hang fold system of Permian times and have a general northeast to southwest trend. They mark the northern border of the province.

The western highlands

South of the Huang Ho there is a broad stretch of upland comprised of a number of moderately high mountain basins, the main ranges being the Hsiung-erh Shan and Fu-niu Shan. These mountains, which have an east–west trend, are the eastern extension of the great Nan Shan–Tsinling Shan axis that divides China geologically and geographically into north and south. The T'ung-pai Shan and Ta-pieh Shan form a further extension of this axis,

running in a southeasterly direction and marking the border between Honan and Hupeh. The T'ung-pai Shan is separated from the Fu-niu Shan by a gap of some 75 to 100 miles cut by the T'ang Ho and T'ao Ho, which are tributaries of the Han Shui. This gap gives easy access from the Honan Plain to the central basin of the Yangtze, a route much used from Han times onward in Chinese expansion southward.

To the east lie the plains. Until fairly recent geological times the mountains in the west (the western extension of the present Gulf of Chihli and Yellow Sea) formed the coast of a sea. That sea, now filled with silt brought down by the rivers and by the wind from the loess plateau, forms the North China Plain and the Huai Basin. It is part of the great Neo-Cathaysian Geosyncline (downward-sloping part of the Earth's crust), which extends from Heilungkiang to Kiangsi provinces. The floor of this geosyncline is sinking at a rate equal to that of deposition; it is estimated that the sediment of the plain is now 2,800 feet deep in places.

Drainage. Honan has three river systems: the Huang Ho in the north and northeast, the Huai Ho in the east and southeast, and the T'ang Ho and T'ao Ho in the southwest. The Huang Ho—known in Chinese literature simply as the Ho (or the River)—immediately after its confluence with the Wei Ho, at the Shansi border, turns eastward at T'ung-kuan to flow right across the north of Honan. Near T'ung-kuan it enters the San-men Hsia (San-men Gorge) of some 80 miles, thence issuing onto the plain. It is remarkable that from T'ung-kuan to the sea, a distance of some 600 miles, the Huang Ho receives only two comparatively small tributaries: the right-bank Lo Ho, on which Lo-yang stands, and the left-bank Ch'in Ho.

Enormous silt-carrying capacity of the Huang Ho

The Ho is subject to very great changes in summer and winter flow. The maximum recorded summer flow is 883,000 cubic feet per second, and the minimum recorded winter flow is 8,650 cubic feet per second. In time of maximum flow it carries an enormous load of silt, estimated at 1,600,000,000 tons per year, gathered mainly in its course through the loess plateau of Shensi and Shansi. In this area it carries an average silt concentration of 1.6 pounds per cubic foot, in comparison with the Colorado's 0.5 pound and the Nile's 0.06 pound per cubic foot. There is a Chinese saying that "If you fall into the Huang Ho you never get clean again." While the river is fast flowing in the San-men Hsia, it is able to carry its load of silt, but when it issues onto the plain its pace is checked —it can no longer carry the silt, and flooding occurs. Throughout historical times this menace has been met by building levees to contain the waters. Generally these dikes were built five to eight miles apart to give the river plenty of room in time of spate (flooding), but instead the load of silt has been spread, building up the riverbed through the centuries, until today it lies above the surrounding countryside. Dikes have been built higher and higher, and when they fail to hold—as happened in some part of the province almost every year—the river descended onto the plain, causing disastrous floods, the waters of which could not return to the high stream bed when the river's flow slackened. The result was waterlogging of the soil, crop destruction, and famine. Because the watershed between the Huang Ho and Huai Ho is almost imperceptible, the Huang Ho has radically changed its course several times in the last three millennia, flowing to the sea, first south, then north, of the Shantung Peninsula. The diversion has always been in north Honan between Cheng-chou and K'ai-feng. In 1938, in an attempt to arrest the advance of the invading Japanese army, the Huang Ho was deliberately diverted by blowing up the dikes near Cheng-chou and flooding 21,000 square miles of land, at an estimated cost of 900,000 lives. The river was restored to its former northern course in 1947 by United Nations action.

To meet a continual flood menace, the government published in 1955 a scheme known as the "Staircase Plan," calling for the building of 44 retention dams in the main river and 79,000 silt-precipitation dams in the tributaries. The key to the whole conservation plan was to be the construction of the San-men Dam in the San-men Hsia at a point where two rock islands divide the river into three channels. The dam, 295 feet high, was designed to retain a lake with a capacity of 1,270,000,000,000 cubic feet. The fourfold purpose of the dam was flood control, irrigation, hydroelectric power, and navigation. The hydroelectric plant was intended to supply the rapidly growing industries of K'ai-feng, Lo-yang, and Cheng-chou in Honan and Sian in Shensi Province. The dam was due for completion in 1962; in 1961, before this part of the work was completed, Russian advisers and technicians were withdrawn; there is no report of its final completion.

Huai Basin water-conservancy program

The Huai Ho itself and all its major left-bank tributaries have their sources in the mountains of western Honan. They flow eastward onto the Anhwei Plain, subjecting it to disastrous floods. In 1949 the Huai Basin was chosen by Mao Tse-tung for the first big water-conservancy program. Six dams were quickly built in the upper reaches of Huai tributaries in Honan, four on left-bank tributaries and two on right-bank tributaries. Since 1957 three very large dams at Lung Shan, Mei-Shan, and Fo-tzu-ling have been built. Dikes were strengthened, with the result that no serious disaster has since occurred.

Climate. Climatically, Honan lies in a transitional zone between the North China Plain and the Yangtze Valley. Although protected in some degree from the Mongolian winds by the T'ai-hang Shan, Honan has very cold winters; summers are hot and humid. Average January temperature in the north is 28° F (−2° C) and in the south 36° F (2° C). Average July temperature over the lowlands is 82° F (28° C), while in the western mountains it is a degree or two lower. The north enjoys 210 frostless days in the year and the south 250.

Rainfall is distributed more evenly throughout the year than it is in the rest of North China, although there is a marked spring–summer maximum. K'ai-feng has an average rainfall of 23 inches, of which only 3 inches fall in the autumn and winter months. There is a steady decrease in total rainfall from southeast to northwest and a marked increase in variability. Honan is therefore more subject to years of alternating heavy rain and drought than the provinces of the Yangtze Valley. In the past it has suffered from severe famine. It also experiences spring cloudbursts and occasional hailstorms, both of which can be very destructive. In times of drought, summer dust storms are worse even than those of winter.

Soils. Honan's soils are made up mainly of calcium carbonate (lime) in hardened layers of alluvium. Because of the comparatively low rainfall, there is little leaching. The higher land of the west is mainly mountain yellow-brown earth, better drained than the plains. The more fertile areas fringing the plain were the sites of early civilization. Alluvium is spread throughout the plain; it is yellowish and gray, porous, granular, and poor in organic matter. Since the bed of the Huang Ho lies above the surrounding land, much of the low-lying land on either side is waterlogged. Consequently, soil salinity and alkalinity affect the whole area. There are large areas of bleak, white saline sands. Since 1949 there has been much experimentation aimed at bringing these alkaline lands into production. It is reported that between 1954 and 1964 a fourth of the saline land between K'ai-feng and Cheng-chou was transformed into fertile farmland.

Salinity of the Huang Ho flood basin

Vegetation. The natural vegetation of Honan is deciduous forest and woodland over the plains, and deciduous and coniferous forest in the western highlands. Intensive settlement of the plains has long since led to the clearance of the trees to make way for cultivation. The mountains, however, retain some of their woodland. Since 1949 serious efforts have been made to educate the peasantry in the importance of reforestation. It has been reported that more than 50,000 acres of trees have been planted specifically for sand anchorage and as windbreaks.

Population. According to the census figures published by the State Statistical Bureau in November 1954, Honan had a population of over 44,000,000, making it the third highest in the nation to Shantung and Szechwan, and an average overall population density of 670 per square mile. There is no clear and precise demarcation between rural and urban population in that census. Generally, places of 2,000 or less whose population was engaged essentially in agriculture were classified as rural, but, if mining or some other industrial activity prevailed, the settlement was recorded as urban. Before 1949 Honan's urban population was very small indeed, and even in 1958 it was still only about 8 percent of the whole. There were only seven cities of over 100,000 in 1958: Cheng-chou (capital), 790,000; K'ai-feng, 320,000; Lo-yang, 500,000; Hsin-hsiang, 200,000; Chiao-tso, 250,000; Shang-ch'iu, 165,000; and An-yang, 153,000. There were 300 townships of under 5,000. Since 1958 there have been few official estimates of growth, but it is safe to say that the populations of cities such as Cheng-chou, Lo-yang, and K'ai-feng, with their great industrial development, have increased considerably.

The greatest concentration of rural population is in the eastern plain, where densities of between 800 and 1,000 per square mile are found. Nearly as great densities are found in the I Ho and Lo Ho basins and in the plain around Nan-yang, but in the more mountainous west and south they are considerably less. On the eastern plain, villages average about 400 inhabitants and are fairly close together, usually about one mile apart. In the mountains they are smaller and more widely dispersed. Houses are made mainly of mud-plastered walls and thatched roofs. There was considerable movement of rural people from Honan and other provinces of the plains to towns in the west in 1958–59, during agricultural collectivization and the Great Leap Forward.

Ethnic homogeneity of Honan

The ethnic composition of the population of Honan is remarkably homogeneous. The people are essentially Han Jen (northern Chinese). There are no autonomous minority groups such as are found in the western provinces. Mongol and Manchu invaders alike have been absorbed and Sinicized. In Later Han times a considerable influx of Jewish refugees into the province occurred and in the 10th and 11th centuries, when K'ai-feng was the imperial capital of the Sung dynasty, they formed an interesting and important part of the community. They retained their identity until the early 19th century but have since been absorbed.

Administration. On the victory of the Communists in 1949, the first administrative act of the People's government was to divide the country into six administrative areas. Honan, together with Hupeh, Hunan, Kiangsi, Kwangtung, and Kwangsi formed the Central South Administrative Area. In 1954 provincial government was established, and for local governmental purposes Honan has been subsequently divided into three municipalities (*shih*), ten special districts (*chuan-ch'ü*), 11 county-level municipalities (*shih*), and 110 counties (*hsien*).

This pattern of local government underwent considerable change in 1958–59 with the nationwide formation of communes. The first commune in China was formed in Honan in April 1958 as a result of experiments by a number of advanced agricultural-producer cooperatives who banded together into a much larger unit, largely to increase production. Many nearby localities immediately followed suit. By November 1958, 99 percent of the rural population was grouped in communes, with a marked effect on local administration.

Although there was no stereotyped blueprint, communes generally gathered a number of advanced cooperatives into one large unit. Their responsibility extended to every activity of local life—the propagation of Communist ideology, the organization of agriculture, the promotion of local industry, primary- and middle-school education, public health, recreation, and the training of local militia. The communes had considerable autonomy and differed much in actual practice. The outbreak of the Cultural Revolution in 1966 led to disorganization and confusion in local government. This was not resolved until the appointment of provincial Revolutionary Committees. The committee for Honan was established in January 1968, and consisted of 11 members, nine of whom were selected from the People's Liberation Army, one from the "revolutionary cadres," and one from the "revolutionary masses."

Effect of the Cultural Revolution

Social conditions. *Education and culture.* Since its imperial days K'ai-feng has remained the cultural and educational centre, although it has come to share that role with Cheng-chou. The first impact of Western learning came, as in the rest of China, through the primary and middle schools of Christian missions. Little real progress was made in the disturbed years between 1911 and 1949, and the vast mass of the people remained illiterate. Successful efforts were made in the first years of the People's government to overcome illiteracy, and a real attempt at universal primary education was launched.

In 1959 responsibility for primary- and middle-school education was placed with the communes, and stress was laid on part-time study and part-time work schools. The Cultural Revolution seriously interfered with education between 1966 and 1969. At its conclusion many agricultural middle schools were set up in Honan by local poor and middle peasants, giving prominence to proletarian politics and basic agriculture. The curriculum includes class struggle, farming knowledge, military training, and physical culture. The use of the abacus, stock-breeding, and the installation, operation, and maintenance of machinery are taught. The fields, machine shed, and animal sheds serve as classrooms.

In an essentially agricultural province, such as Honan, cultural life is centred in the rural commune. While families, for the most part, retain and own their own homes, cultural life is focussed in the community centre, with its reading room, library, and teahouses, in which the old tradition of storytelling has been developed and is very popular. The better lighting of the centre makes it attractive. Loudspeaker radio is used to ensure communication, usually on a basis of one loudspeaker to three families. Indoor and outdoor games are fostered, table tennis being very popular. Cheng-chou was one of the first to establish city communes, which are much more complex in their organization. One, which includes 20 streets and a population of 18,000 adults and 11,000 children under 16, has 56 factories and workshops and three agricultural brigades raising food.

Health. Modern Western medicine, like education, was introduced by Christian missions but made very little impact on the vast area of Honan. On attaining power in 1949, the People's government concentrated attention on public hygiene and preventive medicine. A doctor's training was cut from six to three years, and

Emphasis on the "barefoot doctor"

teams were dispersed throughout the province to teach hygiene, vaccinate, inoculate, and advise. Although a doctor's training has now reverted to six years, the old pattern and emphasis remain, and the "barefoot doctor" is the order of the day. In Honan, with great development in coal mining, attention has been focussed on the prevention of silicosis, which is being achieved mainly by improving working conditions. Kala azar, the debilitating disease carried by sand flies, is also receiving special attention.

The economy. *Agriculture.* In 1949 Honan was considered one of the more backward provinces. Its economy is essentially agricultural. It lies in the region of the wheat eaters, as distinct from the rice-eating region of the south.

From 60 to 70 percent of the total cultivated area lies in the plains to the east of the Peking–Hankow railway, and 20 to 30 percent in the upland regions. The only idle land is found in the mountains and in the saline lands of the northeast. The main food crops are winter wheat, millet, kaoliang, soybeans, barley, corn, sweet potatoes, rice, and green lentils. These account for 89 percent of the total crop acreage. Wheat is by far the most important, in both acreage and production, Honan ranking first in China's output. Millet, kaoliang (Chinese sorghum), corn (maize), and sweet potatoes each occupy about 6 percent of the crop area. Millet is widely distributed; corn is grown mainly north of the Lunghai Railway and kaoliang to the east. Soybeans are produced on the eastern side of the province, with a marked concentration in the south, near the Anhwei border. Kaoliang is a hardy crop—more resistant to waterlogging and aridity than other grains, growing well on infertile soil, and requiring little attention. Rice occupies only some 3 percent of the crop area. Its yield per acre, however, is almost three times as great as wheat. With rapidly improving irrigation, rice cropping is increasing. Double-cropping is common in Honan. The wheat crop is usually followed by barley or rapeseed. Fruit growing has received considerable impetus in recent years, partly for its own sake and partly for soil conservation, particularly in the idle sandy lands of the northeast and on mountain slopes. Dates, persimmons, and pears are the main fruits, with apples, walnuts, and chestnuts on the increase.

Chief centre of draft animals

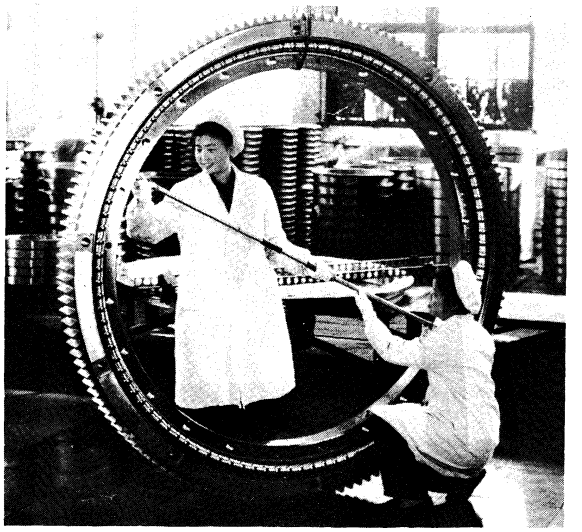
Honan produces more draft animals of good quality than any other province. The most important are yellow oxen and donkeys. Hogs are by far the most important food animals. Goats and sheep are raised in the western mountains and produce good mutton and wool.

The chief industrial crops, on about 10 percent of the total crop acreage, are cotton, tobacco, vegetable oils, and silk. Cotton is widely grown on about half the acreage, with its main concentration north of the Huang Ho around An-yang and Hsin-hsiang. Weak techniques of the past are being improved. Tobacco growing, introduced in Honan in 1916 by the British-American Tobacco Company, Ltd., has increased enormously since 1950. Vegetable oils are important, with Honan the largest producer of sesame in China, grown mainly in the east and south. Ramie, the most important of the leafy fibres, is grown in east Honan in the Huai Valley.

Honan is one of the oldest centres of sericulture (silkworm raising) in China. The industry dates back to the Later Han dynasty (AD 23–220). Both mulberry-leaf culture and oak-tree culture for silkworms were flourishing between the two world wars but suffered severely during the Sino-Japanese War. Since 1950 there has been a big revival on the slopes of the Fu-niu Shan, and the province has become an important exporter of silk.

Honan suffers very severely at times from locusts, which winter in the arid, sandy alkaline soils beside the Huang Ho. Between 1941 and 1943 they caused an 80 percent crop failure in the region. Extended and improved cultivation in these areas has helped control the pest.

Since 1959 considerable irrigation work has been carried out in the northwest, almost entirely by labour from the communes. Rural areas of Honan are now covered with a network of 40,000 miles of high- and low-tension electric lines that power pumps for 90,000 wells in the province. The total area now irrigated by pumps is reported to be more than 1,630,000 acres.



Workers in a ball bearing plant in the industrial centre of Lo-yang.
Eastfoto

Mining. Before 1949 there was very little industrial development in Honan, despite its very rich coal seams in the northwest. Both bituminous and anthracite coal are found along the slopes of the T'ai-hang Shan, and big reserves of good coking coal in thick, easily mined seams are found in the Fu-niu Shan between Hsü-ch'ang and P'ing-ting-shan. Iron ore is found at Ju-yang on the Ju Ho in the Hsiung-erh Shan, as well as some pyrite, bauxite, and mica. In recent years development has been rapid. Large coal mines at Chiao-tso supply the fast-growing industries of Lo-yang, Cheng-chou, K'ai-feng, and Hsin-hsiang but are still inadequate. The vast coalfield at P'ing-ting-shan was surveyed in 1953. Three mechanized mines, with a total annual production capacity of nearly 4,000,000 tons, were opened in 1964.

Site of China's first tractor factory

Industry. Lo-yang was chosen as the site for China's first tractor factory. No. 1 Tractor Plant was opened in 1958 with a designed capacity of 15,000 tractors a year. Since then, its output has burgeoned, and it is producing many models, ranging from tractors of 28 horsepower to 160-horsepower bulldozers. Lo-yang has become a heavy-industry centre. Cheng-chou lies in the heart of the cotton-growing area and is now the centre of the textile industry. It also has locomotive and tractor-repair workshops, food-processing factories, and the main thermal-power plant of the region. Its rapid growth is indicated by an increase in population from 100,000 in 1949 to 785,000 in 1958. K'ai-feng, imperial capital of the Sung emperors, declined when the river dikes were broken after the Yüan dynasty and the region ruined. Recent construction of large chemical-fertilizer works and a tractor-accessories plant have led to its revival. Hsin-hsiang, the most important city of north Honan, is the centre of the railway network of the area.

Transport and communications. Although the Huang Ho flows through north Honan, it serves it poorly as a line of communication. Within the province it was navigable only in the San-men Hsia until the construction of the San-men Dam. Even now it is useful over the plain only for small rivercraft. The Huai Ho and its tributaries flowing down from the western mountains are rapid in their upper courses and silted in their lower, so that they, too, serve only small craft. The Wei Ho, flowing north into the Hai Ho system, has been joined by canal to the Huang Ho. In 1964–65 it was successfully dredged in an experiment aimed at deepening the riverbed and so increasing flow and reducing waterlogging.

Cheng-chou is the junction of China's two greatest trunk railways, the Peking–Hankow–Canton line and the Lunghai line, which runs from the east coast via K'ai-feng, Cheng-chou, and Lo-yang to Sinkiang, Uighur

Autonomous Region, in the far west. The Peking–Canton line is now double-tracked throughout its entire length and carries a heavy load of both freight and passengers. The coalfields to the west are linked to it by branch lines.

The first modern roads in Honan date from the famine of 1920–21, when the American Red Cross built 850 miles of earth track to bring relief to the stricken provinces. Even in 1936 Honan had but 1,786 miles of road, of which only 167 miles were surfaced. By 1953 approximately 3,800 miles were open to traffic, mainly in the north centre and east. The most important and sole all-weather highway at that time ran from K'ai-feng via Hsuch'ang, P'ing-ting-shan, and Nan-yang to Hsiang-fan on the Han Shui in Hupeh. Since 1959 the great bulk of road building has been done with little modern technology by commune labour, some of it penetrating the more remote mountain region, as, for example, a road with a 240-foot tunnel in the T'ai-hang Shan between Hui-hsien and Ling-ch'uan.

Honduras

Honduras is a small republic of Central America situated between Guatemala and El Salvador, to the west, and Nicaragua to the south and east. The Caribbean washes its northern coast, the Pacific its narrow coast to the south.

With an area of 43,277 square miles (112,088 square kilometres) and a population (1970) of only 2,508,700, Honduras is one of the smallest countries of Latin America. The bulk of the population lives a rather isolated existence in the mountainous interior, a fact that may help explain the rather insular policy of the country in relation to Latin and Central American affairs. Its economy is primarily agricultural, bananas for export being particularly important, although maize, the chief staple, is by far the most important product in terms of value of annual output. The capital is Tegucigalpa, but—unlike most other Central American countries—there are other cities, such as San Pedro Sula, that are equally important industrially and commercially.

The landscape. Over 75 percent of the land area is mountainous, lowland being found only along the coasts and in the several river valleys that penetrate toward the centre of the interior. No clear-cut pattern of mountain trends is apparent, the interior taking the form of a dissected upland with numerous small peaks. Geological formations, however, have a general east–west orientation. Except for a narrow plain of alluvium bordering the Gulf of Fonseca in the south, the southwestern mountains consist of alternating layers of rock composed of dark, volcanic detritus and lava flows, both of Tertiary age (from 25,000,000 to 65,000,000 years old). The mountains in other regions are more ancient, granite and crystalline rocks predominating.

The four regions

Geographical regions. Four distinct geographical regions may be discerned: (1) The eastern lowlands and mountain slopes embrace about 20 percent of the total land area. Hot and humid, this area is densely forested, lumbering being an important economic activity. Subsistence agriculture and fishing are the main support of the scattered population of some 500,000 persons. (2) The northern coastal and alluvial plains and coastal sierras comprise about 13 percent of the land area and about 20 percent of the population. This is an economically important area, the clayey and sandy loam soils producing rich crops of bananas, rice, cassava, corn, and beans. Cattle, poultry, and swine are raised in considerable numbers. The nation's railroads are confined to this northern area, which has four of the five important ports of entry. (3) The central highlands take up 65 percent of the national territory and contain 70 percent of the population. The mountains are rugged and the valleys situated at altitudes of from 2,000–5,000 feet. The generally fertile soils, derived from lava and volcanic ash, produce coffee, tobacco, wheat, corn, sorghum, beans, fruits, and vegetables. Cattle, poultry, and swine are raised. (4) The Pacific lowlands and lower mountain slopes comprise only 2 percent of the land area and contain 5 percent of the population. The soils are fertile—composed of alluvium or volcanic detritus—and produce sesame seed, cotton, and small amounts of corn and sorghum.

Climate. The climate is generally hot, with high humidity in the tropical coastal lowlands becoming modified by altitude toward the interior. Lowlands below 1,500 feet have mean annual temperatures between 79° and 82° F (26° and 28° C). The north coast is occasionally affected from October to April by cool northern winds of continental origin. Mountain basins and valleys, from 2,000 to 4,000 feet, have mean annual temperatures 66° and 73° F (19° and 23° C). At Tegucigalpa, located on hilly terrain at an altitude of 3,200 feet, the rainy season starts in May and continues until the middle of November, with temperatures sometimes reaching 90° F (32° C) in May and dropping to 50° F (10° C) in December, the coolest month. Around 7,000 feet, mean annual temperatures are about 58° F (14° C). In the northern and eastern coastal and alluvial plains and on adjacent mountains, mean annual precipitation ranges from 70 to 110 inches or more, with a less rainy season from March to June; these areas occasionally have summer hurricanes with strong winds and heavy rains. Pacific plains and mountain slopes get 60 to 80 inches of rain annually, but there the months December to April receive little or no rain. Interior sheltered mountain basins and valleys get 40 to 70 inches annually, with December to April having little rain. Interior higher mountains have a longer wet season and receive considerably more rain.

Vegetation and animal life. In eastern Honduras the coastal and lagoon swamps have mangrove and palm forests, and west of these are low, rainy, sandy plains with pine-savanna (*Pinus caribaea*) forests, extending inland for 40 miles or more. West of the pine-savanna forests, in low valleys and on lower mountains, rainy all year, and on the low rainy northern mountains, are broad belts of dense evergreen broadleaf forests with many species of large trees, including mahogany, lignum vitae, Spanish cedar, balsa, rosewood, ceiba, sapota (yielding chicle used for the base of chewing gum), and Castilla rubber. The high rainy mountain slopes of highland Honduras support excellent oak–pine forests. The interior highland basins and valleys have open, dry deciduous woodlands and temperate grasslands. The Pacific plains and adjacent mountain slopes have deciduous tropical forest and savanna. Mangrove occupies the low coastal swamps.

Insects, birds, and reptiles are the most conspicuous animal forms. There are many species of butterflies, moths, beetles, bees, wasps, spiders, ants, flies, and mosquitoes, many of them beautifully coloured. Waterfowl in large numbers inhabit the coastal areas. Crocodiles, snakes, lizards (giant iguana and others), and turtles are found in the tropical forest areas. Bears, pumas, leopards, and panthers are more rare but may be found in the hills. Fish and mollusks are abundant in lagoons and coastal waters; by 1969 more than 1,300,000 pounds were exported annually.

The people. Honduras has been inhabited since well before the Christian Era: the ruins at Copán in western Honduras indicate that the area was the centre of Mayan civilization before the Mayas migrated to the Yucatán Peninsula. Although small, isolated groups of non-Spanish-speaking Indians—such as the Jicaques, Mosquito (Miskito, Mísquito), Zambos, and Payas—continue to exist, they are declining in numbers; the population is

predominantly mestizo (a mixture of Spanish and Indian). According to a census of 1950 the ethnic distribution was as follows: mestizos, 91 percent; Indians, 6 percent; blacks, 2 percent; and whites, 1 percent. The mestizos of Honduras are generally darker and more Indian in appearance than those of certain other Latin American countries such as Chile, Uruguay, and Argentina. Most of the Indians are found in the southwest, near the Guatemala border—near the most important Indian centres of the pre-Columbian period. A pronounced shift in population took place during the early part of the 20th century from the interior to the hot, humid north coast, where employment opportunities were provided by the United Fruit Company. There has been some reversal of this trend in later decades. The annual rate of increase of population is about four percent.

Almost 77 percent of the population is rural, living in small villages or isolated settlements. The mountainous, forested terrain and rather poor road transportation are conducive to local isolation, and, as a result, most Hondurans have never travelled more than a few miles from their home.

The economy. *Production.* Honduras possesses an agricultural economy, with only small-scale manufacture of such items as textiles and tobacco, chiefly for local consumption. In terms of contribution to the gross domestic product, agriculture, forestry, hunting, and fishing are followed by manufacturing, trade, services, and transport and communications.

Two large United States corporations—the United Fruit and Standard Fruit and Steamship companies—hold about 5 percent of the country's agricultural land and produce about 20 percent of the national income. Important export crops other than bananas include coffee beans, abaca fibre (manila hemp), tobacco, and coconuts. The extensive pine forests were attacked by blight in the 1960s, and mahogany—the major timber export—was declining in importance.

Mineral resources are considerable, though largely unexploited, and include antimony, iron, coal, mercury, and copper. Production of silver and gold has remained of some importance, and lead and zinc are produced in commercial quantities.

With a per capita gross national product of only $260, Honduras is a poor country, and the lot of the majority of Hondurans, who work on the land, is a hard one. The government has in recent years pursued more active economic policies, carrying out investment programs and granting incentives to private industry.

The Labour Code of 1954

In 1954 the trade-union movement obtained one of its most resounding triumphs, resulting in the promulgation of a labour code that has been considered one of the most complete instruments of its kind in Latin America. Labour–management relationships are regulated under the different articles of the code, which protects not only the worker but also the businessman. As a general rule, labour–management relationships are defined by means of collective contracts subscribed to by the labour unions and the management representatives of private enterprise. In some autonomous and semi-autonomous state agencies, there is the same labour–management relationship. The code has generally resulted in a higher standard of living for the worker and better operating conditions for the businessman.

Transportation. Honduras has less than 120 miles of public-service railroads. The two fruit companies own an additional 520 miles, which are confined to the north coast banana region and provide some passenger transport facilities.

A part of the Pan-American Highway, running from El Salvador to Nicaragua, cuts across southern Honduras for about 100 miles; a branch highway leaves it at Nacaome and runs north through Tegucigalpa to the north coast.

Air transportation is of great importance within Honduras and is frequently the normal means of conveyance for passengers and freight.

Administration and social conditions. Since acquiring independence in 1821, Honduras has been described constitutionally as a democratic, representative, unitary state with power divided among legislative, executive, and judicial branches. The country has had 16 constitutions, the latest having gone into effect in June 1965. Power, however, has frequently been mobilized and changed by violent, undemocratic means. Peaceful methods have included *imposición* ("rigged election"), *candidato único* ("one candidate"), and *continuismo* (continuing the president in power beyond his legal tenure). Although the legislature is given the power to pass laws, practically all important legislation is drafted by the executive and his assistants. The congress in theory has great authority to check the administrative activities of the president, but only in the period 1925–31, when several cabinet ministers appointed by the president were forced to resign through censure, was such authority effective. Strong, centralized dictatorial government was re-established in 1932. A theoretical counterweight to excessive executive power was devised in the 1950s and is embodied in the constitution of 1965: the chief of the armed forces, an almost autonomous official, is given the power of interposition against presidential orders, subject to final decision by congress.

Power of the executive

Honduras has a single-house legislature with single-member districts based on a ratio of one deputy for each 30,000 inhabitants. This numerical base may be changed by congress in accordance with increases in population. The congress convenes each year from May 26 to October 26, and its session may be prolonged by resolution initiated by a deputy or by the executive. Special sessions may be convoked by a permanent committee that represents congress during adjournment or upon petition by other deputies. All men and women who are citizens and over 18 years of age are permitted to vote, and a national electoral council supervises elections. The president is elected directly by popular vote for a period of six years with a second term prohibited.

For purposes of local administration, Honduras is divided into 18 departments and a central district.

The justices of the supreme court are elected by the congress for six years. The supreme court exercises centralized control over the lower courts, including the appointment of justices, and has original and exclusive jurisdiction to declare acts of the legislature unconstitutional. The departments are subject to the control of the central government, but the constitution establishes autonomy for municipalities.

By the 1970s Honduras, like most other Latin-American countries, had moved more and more in the direction of the interventionist, or welfare, state. A number of provisions in the constitutions of 1936, 1957, and 1965 gave the central government great power to direct and regulate social relations and the economic system. In February 1955 the Honduran basic labour code came into effect, granting the right to work, minimum wages, an eight-hour day and 48-hour week (reduced to 44 hours by the constitution of 1965), freedom to form labour unions, collective bargaining, conciliation, and the right to strike.

Education and cultural life. The Honduran educational system follows the European model of centralized control through the Ministry of Education. According to law, education is free and compulsory for all children. Efforts have been made to combat illiteracy, which in 1974 was still almost 40 percent for those 10 years of age and over. Related national efforts were reflected in the constitution of 1957, which dedicated 2 percent of the budgeted national income to the National Autonomous University of Honduras in Tegucigalpa (founded 1847), and in the constitution of 1965, which dedicated 3 percent. The university had an enrollment of about 8,000 in the mid-1970s.

The press

There is complete freedom of the press in Honduras, and daily newspapers are published in the principal cities of the country. Those of Tegucigalpa and San Pedro Sula are outstanding.

The progressive and rapid development of radio and television has provided the country with excellent facilities for speedy and effective communication. There are two private radio and television networks that cover the entire country. The state, private enterprise, and international organizations take advantage of these means for communicating to the Honduran people.

Cultural institutions in Honduras include the National School of Music, the House of Culture, and the San Pedro Cultural Centre, as well as many other state and private institutions. Among these others, especially noteworthy are the organizations dedicated to the production of theatrical works in both Spanish and English.

Hōnen

The founder of the Jōdo-shū, or Pure Land sect of Japanese Buddhism, Hōnen is one of the outstanding figures in the history of Japanese religion. Through his personal influence and the direct simplicity of his teaching, he played a seminal role in making Pure Land pietism one of the central forms of Buddhism in Japan. He was also called Genkū, Enkō Daishi, Ganso (Founder), and Hōnen Shōnin (Saint Hōnen).

Hōnen was born in 1133 at Inaoka, in western Honshu, the only son of Uruma Tokikuni, the regional military chief. His childhood name was Seishi-Maru. When he was nine years old, his father was attacked and killed by the headman of the village. The dying father instructed the son not to spend his life trying to avenge him but to enter the priesthood. After a period of local instruction in which he displayed marked ability, at 15 Hōnen was sent to Mt. Hiei, the monastic centre of the Tendai sect of Buddhism. The centre prospered externally, in wealth and prestige, but suffered from the internal power struggles of ambitious abbots and the moral and spiritual corruption of the priests.

Hōnen, along with other serious-minded young priests, however, came under the influence of the Pure Land doctrine, which taught salvation by the mercy of Amida (or Amitābha) Buddha, who dwells in the Western Paradise, to which he brings his devotees. Hōnen was haunted by the sense of the human futility of man "with blind eyes, capable of doing nothing" or, in the words of his disciple Shinran, "destined for hell, with nothing in his reach." He was greatly inspired by the *Ōjōyōshū* ("Essentials of Salvation"), by a 10th–11th-century Japanese Amida Buddhist, Genshin, and the *Kuan-ching-su* ("Commentary on the Meditation *sūtra*,") by a 7th-century Chinese Pure Land master, Shan-tao (Japanese Zendō). In 1175 Hōnen, then 43 years old, proclaimed his message that the one and only thing needed for salvation is *nembutsu* (calling the name of Amida Buddha).

Hōnen's basic teaching: the *nembutsu*

In his main work, the *Senchaku hongan nembutsu-shu* ("Book on the Choice of *nembutsu*"), written in 1198, Hōnen classified all the teachings of Buddhism under two headings: Shōdō ("Sacred Way") and Jōdo ("Pure Land"). According to him, Buddha, confident of man's inner character, had shown men the Sacred Way to Enlightenment by means of precepts, meditation, and knowledge, thus enabling them to be emancipated from this world of lust and delusion and to attain the other world of ultimate peace. Hōnen, convinced of his own "sinful and avaricious" nature, however, came to the conclusion that, while it was theoretically possible, it was practically impossible for him and others like him to follow the Sacred Way. The only alternative open for them was the way of Jōdo, which is based on implicit trust in the original vow of Amida Buddha, the lord of the Sukhāvatī (Sanskrit: "Pure Land"), who in his mercy assures salvation to the believer who clings to Amida's merciful hand and calls upon Amida's holy name—*namu Amida Butsu* ("Homage to Amida Buddha")—with all his heart. This is the *nembutsu* ("calling the name") of Hōnen's book.

Hōnen established his headquarters in the midst of the secular city of Kyōto, away from ecclesiastical establishments, and gathered together devoted disciples, including Shinran, who was to become the founder of the Jōdo Shinshū ("True Pure Land sect"). Hōnen and his followers accepted the legendary periodization of Buddhist history, according to which the first 1,000 years following the demise of the Buddha was the period of the "perfect law" (*shōbō*), in which the true teaching prospers; the second 1,000 years was the period of the "copied law" (*zōbō*), in which piety continues but true teaching declines, and the last 1,000 years is the period of the "latter end of law" (*mappō*), in which Buddhism declines and the world is destined to be overwhelmed by vice and strife. It is to be noted that, according to the accepted calculation of the Japanese Buddhists, the last period began in AD 1051. And, as though to substantiate this view of history, Japanese society during the 12th century suffered from political instability and social disintegration that resulted in the establishment of feudal government under the leadership of the warrior class. Understandably, Hōnen's simple teaching found eager followers among the various levels of Japanese society of that time.

The popularity of the faith in the Pure Land of Amida Buddha aroused jealousy from the established schools of Buddhism, and it so happened that two court ladies were converted to Hōnen's teaching and gave up the court form of Buddhism. Hōnen was thereupon charged with their seduction and was banished, together with his immediate disciples, from the capital in 1207 (some of his disciples were beheaded). Compelled to use a nonclerical name, he called himself Fujii Motohiko and proved to be an effective evangelist even during his exile to Shikoku island. He was permitted to leave Shikoku at the end of the year, but not to return to Kyōto until 1211, when he received a warm popular welcome. He died early the next year at the age of 80.

Banishment to island of Shikoku

Although he insisted on faith in Amida and the recitation of the name as the best way to salvation, Hōnen, an intrepid but nonaggressive person, was markedly tolerant and nonpolemical, urging his followers to respect the other Buddhas and other Buddhist ways of faith and practice. Observance of other forms of discipline, indeed, according to him, might be occasions leading toward Amida and his Paradise. Hōnen was also especially careful to warn against the temptation of accompanying the *nembutsu* with an immoral life or of believing that its recitation removes the stain of violations of the Buddhist life discipline or other immoral acts. He combined the cultured heritage of the established Buddhism of the past with the pioneering spirit of the new Buddhism of the 13th century. The Jōdo-shū founded by him continues to be one of the most influential schools of Japanese Buddhism; and the far more numerous Jōdo Shinshū founded by his disciple Shinran adds still more to the Pure Land influence initiated by him.

BIBLIOGRAPHY. The only significant work on Hōnen available in English is H.H. COATES and R. ISHIZUKA, *Hōnen, the Buddhist Saint: His Life and Teaching* (1925).

(Ma.Fu.)

Hong Kong

Hong Kong is a British crown colony situated on the coast of China's Kwangtung Province—China's "South Gate"—at the mouth of the Hsi Chiang Estuary. It consists of the island of Hong Kong and adjacent islets,

Hong Kong Harbour, seen from Victoria Peak, showing the business district of Victoria and Kowloon Peninsula across the bay.
J. Allan Cash—Rapho Guillumette

Stonecutters Island, Kowloon Peninsula on the mainland, and the New Territories—acquired on a 99-year lease from China, due to expire in 1997—which partly consist of mainland territory, and partly of more than 230 surrounding islands. About 90 miles to the northwest is the Chinese port city of Canton (*q.v.*) and about 40 miles to the west across the estuary is the old Portuguese enclave of Macau (*q.v.*).

The total land area of Hong Kong is 404 square miles (1,046 square kilometres), but this figure is not final, since land reclamation schemes occasionally add small bits of land to the total area. Hong Kong Island and its adjacent islets have a total area of 29 square miles; the Kowloon Peninsula and Stonecutters Island together have an area of three and three-quarter square miles; and the New Territories have a total area of about 366 square miles. There are extensive port facilities on the Kowloon Peninsula, while Victoria, the capital city, situated on Hong Kong Island, is built overlooking one of the world's finest natural harbours.

Between the end of World War II and 1971 the population of Hong Kong increased from about 1,500,000 (1947) to about 4,000,000—an increase indirectly attributable to the dramatic changes that occurred during this period in China itself. The increase has caused a serious housing problem but has also led to a modification of Hong Kong's historic function, which was to serve as an entrepôt for trade between China and Western countries. Because in recent years the economic policy of the People's Republic of China has made it increasingly difficult for Hong Kong to survive on trade alone, the city has been obliged to develop industry instead; by 1971 the percentage of Hong Kong's exports locally produced, which was 73 percent in 1960, had increased to 80 percent.

The development of industry

That Hong Kong has been able to maintain its present political status is due to the interplay of national interests. China wishes to keep Hong Kong as a point of contact with Western countries, as well as for economic reasons; yet Western countries, which also contain economic advantages from Hong Kong, use the colony as a station from which they can monitor information emanating from China. (For an asssociated physical feature, see HSI CHIANG; for historical background, see CHINA, HISTORY OF.)

The landscape. *Physiography.* The mainland and islands of Hong Kong form part of a drowned mountain range composed of volcanic and sedimentary materials atop a vast, subterranean expanse of granitic rock extending from southeastern China southwestward into the Indochinese Peninsula. The submersion is comparatively recent in geological terms since the overlying rocks date only from the Jurassic Period (136,000,000 to 190,000,000 years ago); hills rise directly from the sea with no intervening coastal flats. The numerous mountain peaks are mostly composed of weather-resistant volcanic rock. The highest peak, Tai Mo Shan, on the mainland, reaches an altitude of 3,140 feet (957 metres).

Geological structure

The colony has a wide variety of landform features. Erosion along the coast is marked and has produced many sea cliffs that were once steep hillsides, as well as many sea caves, rock tunnels and pinnacles, and other features. River courses are strongly etched into the landscape; hillsides are characterized by scars from landslides, gullies, and small terraces with steep sides.

The terrain of Hong Kong is mostly hilly, and in places very steep. In general, the colony can be divided into two distinctly different parts, with the Kowloon ridge as the dividing line. The harbour area and the commercial, industrial, and residential districts are to the south, while the agricultural area is restricted to the north and occupies some of the islands.

Drainage. Most of the longer streams in the New Territories flow to the northwest, while a large proportion of the surface water flows across the alluvial plain to drain into the Sham Chun River and Deep Bay in the northwest. The Sham Chun River, which forms the boundary between China and Hong Kong, is the longest river in the colony; being tidal, its water is brackish quite a long way up its course.

Soils. Around Deep Bay, which receives most of the rivers, the richest farmland in the colony lies amid fertile deposits that form part of the Chu Chiang (Pearl River) delta. Soils of this alluvial plain, much of which has been reclaimed during the present century, exhibit marine characteristics as much as three miles from the coast. Elsewhere, rapid weathering of granites and volcanic rocks, because of heavy rains and high temperatures, has either produced less fertile soils, which tend to be clayey and lateritic (leached and iron bearing), or has resulted in an altogether denuded terrain. In general, the natural residual soils are acid and of low fertility, needing the addition of lime, potash, and superphosphates for cultivation.

Climate. Hong Kong, lying at the northern limit of the tropical zone, has hot, humid summers, and cool, dry winters. Mean January and July temperatures are, respectively, about 60° F (16° C) and 82° F (28° C); the yearly average is 70° F (21° C). Normal annual rainfall is about 85 inches, of which more than half falls during June, July, and August and 90 percent between April and October. Typhoons occur mostly between July and October and occasionally in November; they bring torrential downpours and strong winds that often cause damage. In the winter, frost occurs occasionally in higher altitudes.

The typhoon season

Vegetation and animal life. Hong Kong has a year-long growing period. Centuries of cutting and burning have destroyed Hong Kong's original cover, leaving only about 11 percent of the land forested; bush fires consume large parts of this forested area during the annual dry season. Strict rules against cutting and intensive reafforestation programs have restored some of the stands of pine, eucalyptus, banyan, casuarina, and palm trees. Most of the land, however, remains under tropical herbaceous growth, including mangrove and other swamp cover. The heavily eroded badlands (barren areas) are an exception. Altogether, about 50 square miles of land are under cultivation.

Hong Kong's animal life consists of a mixture of mammals adapted to the tropics, and those adapted to a temperate or subtropical climate; there are at least 36 species of wild mammals, of which the most numerous are bats and various types of rodents. There are a few wild deer and monkeys, but since 1950 tigers and leopards are no longer to be seen.

Local cattle and buffalo are kept mainly for farm work.

Pigs and poultry are the principal animals reared for food.

Patterns of human settlement. As mentioned, the Kowloon mountain range at the northern end of the peninsula is the dividing line between urban and rural Hong Kong.

Hong Kong's urban development has been limited by a shortage of flat land. The principal urban areas are on Hong Kong Island and on Kowloon Peninsula, both of which are hilly. The built-up area on the island generally lies below a height of 600 feet; in Kowloon the built-up area has been extending northward towards the hills in recent years. As the total utilizable land of urban Hong Kong amounts to no more than 19 square miles, land reclamation has proved a profitable enterprise.

Land reclamation

Long continued and large-scale land reclamation has resulted in changes in the coastline. The filling material is usually stone and earth quarried from the adjacent hills; such quarrying has resulted in changes in local land forms. Because the coastal waters are relatively deep, the reclaiming of land from the sea is costly; but since the demand for land is great, and land prices are consequently extremely high, investment yields handsome returns. Many major streets, especially those on Hong Kong Island, are built on reclaimed land, as is much of Victoria's central business district; the industrial district of Kwun Tong, developed since 1958, is entirely built on reclaimed land.

Urban development on Hong Kong Island, especially in the western part, appears to have reached the saturation point. More vacant space, however, is available in Kowloon, where urban development has been proceeding rapidly in recent years. As Kowloon suffers less restriction from topography, its streets are comparatively wider, flatter, and straighter. Both cities are basically Chinese in character, with business sections having shops on the ground floor and living quarters above. The jumbling together of shops, small industries, and dwellings occurs in only a few scattered areas.

In the New Territories, rural settlements vary from hamlets to small towns. Most of the villages are compactly built, in the form of a square—a pattern which reflects past defense needs. The oldest villages, which have populations of Cantonese Chinese, have a history of continuous settlement from the 11th century; some are fortified with walls and moats. The Cantonese villages are mainly in the flat alluvial regions, and since floods are a constant threat, many houses are raised on earthen foundations; the pits left by the excavations are used as ponds. The villages of the Hakka people from N.E. Kwantung and Fukien provinces are usually in narrow valleys and on foothills; as a result the typical Hakka village, instead of being square, is long or round.

Features of the landscape

The *feng-shui* grove and the pond are characteristic features of both Cantonese and Hakka villages. The grove is generally planted above or around one side of the village as a kind of amulet to ward off evil, appealing to the *feng-shui*, the spirit of wind and water residing in the hills. The pond receives drainage and sewage from the village, which is usually on slightly raised ground. The water is used to irrigate fields, and its mud is used to fertilize the soil. Fish are also bred in the ponds.

The building of new roads and the advent of cooperative marketing created a number of large market towns in the New Territories. With the growing prosperity of vegetable farming, there has been a trend toward the establishment of scattered farmsteads so that farmers can live closer to their crops. A great number of recent immi-

MAP INDEX

Hong Kong, Area and Population

	area		population	
	sq mi	sq km	1961 census	1971 census*
Total Hong Kong†	404	1,046	3,133,000	3,948,000

*Provisional. †No first-order subdivisions are given because of inconsistencies of their boundaries and populations in various country sources.
Source: Official government figures.

grants from China have settled along the major highways.

The people. *Ethnic composition.* About 99 percent of Hong Kong's people are Chinese, many of them from neighbouring Kwangtung and Fukien provinces. About half the population, despite this immigration, was born in Hong Kong. As in China itself, a great variety of regional peoples and linguistic groups are represented, nearly all of them maintaining separate communities even in the urban areas. The most numerous, by far, are the Cantonese, whose dialect is universally understood and who are both rural and urban in their way of life. Other Chinese peoples include the Hakka, who are mainly hill farmers, and the Hoklo and Tanka. The latter two groups traditionally have comprised Hong Kongs's boat-dwelling population. In recent years, however, many thousands have moved ashore; some Hoklos have been landsmen for generations. Many of the current boat dwellers belong to neither group. The major non-Chinese elements in the population are from the British Commonwealth countries, the United States, Portugal, and Japan.

Religious groups. The religious persuasions of the people of Hong Kong are as complex as their political ideas. About 10 percent of the population are communicants of various Christian sects, but Islām claims only a few thousand adherents. Buddhism and Taoism have far outstripped other groups during the population growth of recent decades, and their many temples and monasteries play an important part in the life of the average Chinese. In each of the temples there is usually a principal deity after whom the temple is named, as well as other deities such as the sea gods and goddesses who were worshipped when Hong Kong was a major fishing port. The best known of the major deities is T'ien Hou, the Goddess of Heaven and patroness of sailors. A temple to her stands at nearly every entrance to a fishing harbour. Each year a celebration honouring her birthday is held with fanfare in the temple on the northern bank at the eastern entrance to Hong Kong Harbour.

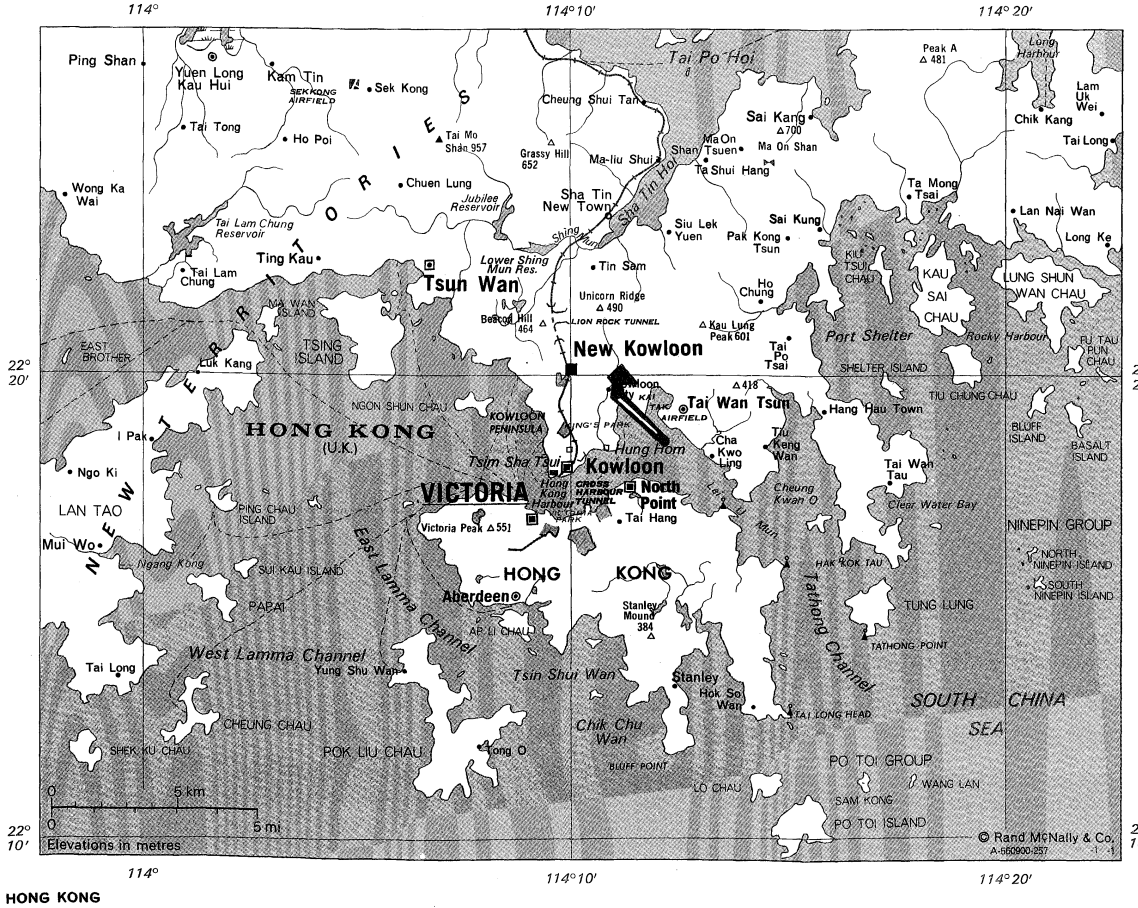
Buddhist and Taoist groups

Demography. Because of the influence of birth control and family planning programs, the birthrate, which in 1960 stood at 36 per 1,000 people, began to decline in 1961. By 1971 the figure had dropped to 19 per 1,000 but was still far ahead of the death rate, which was about 5 per 1,000. Infant mortality remains relatively high, however, standing at 18 per 1,000 live births. Nearly half the population is under 20 years of age.

About 87 percent of Hong Kong's people live in the urban areas of the colony, where industry has continued to attract the youth from the farming areas. Only a minority of the rural people are engaged in farming. In 1971, the total floating population of Hong Kong amounted to 80,000 people who were living in 10,000 boats.

The economy. The decisive factor forcing the change from a trading to an industrial economy was the adherence of Hong Kong in 1950 and 1951 to a United Nations' embargo placed on trade with China and North Korea during the Korean War. The transition was so rapid that few persons at first realized its significance. The needs of the free port are now met by a complex of light industry that flourishes in international trade competition without governmental subsidy or protection. Not only does the colonial government not protect local industry from competing imports but neither does it re-

Governmental economic policy



HONG KONG

taliate against countries that impose trade restrictions on Hong Kong's exports.

Resources. As the colony is not rich in natural resources, industry depends almost entirely on imports of raw material. A small iron mine is active at Ma On Shan, situated about 8 miles northeast of Kowloon in the New Territories, and there are deposits elsewhere of kaolin clay for pottery, graphite, lead, and other minerals. Most ore is shipped to Japan. The dependence on surface water has created serious shortages in the past, but agreement with China on the provision of a supply and the building of many new reservoirs and storage facilities are helping to overcome this problem. Electrical power is supplied to Hong Kong Island and the neighbouring islands of Ap Lei Chau and Lamma by plants at North Point and Ap Lei Chau; Kowloon and the New Territories are supplied by generating plants at Hok Yuen and on Tsing Yi Island. Fish is one of Hong Kong's major resources, used not only for domestic consumption but for export as well.

Sources of national income. The rapid industrial development in the 1950s was made possible almost entirely by money and technology contributed by Chinese industrialists mainly from Shanghai. Overseas investments, however, especially from Japan and the United States during the 1960s, began to have an effect upon the development of sections of the textile, garment, and electronic industries. One of Hong Kong's major economic assets has been its huge supply of labour, although this economic advantage is associated with serious social problems of overcrowding.

Manufacturing. The garment and textile industries contribute 45 percent of Hong Kong's exports and employ 45 percent of the industrial workers. Most of the yarn production is used for weaving fabrics on local looms and making garments for the world market. Other major light industries produce electronic equipment, toys, wigs, plastic flowers, and rubber products. Heavy industry includes shipbuilding and repairing, steel rolling and aluminum extrusion, and cement manufacture. Most of the industry is confined to Kowloon and Hong Kong Island, but some of the towns in the New Territories have a brisk industrial activity as well.

The decline in farming

Agriculture and fishing. Farming acreage continues to decline, even in the production of rice, the largest single crop. The majority of vegetables grown are the Chinese leaf types, and the local farms supply more than 40 percent of the colony's needs. As the growing season is year round, from four to ten crops per year are possible, depending on the crop. Many farmers also keep pigs and poultry. Large livestock farms are able to operate in areas unsuitable for crops. Dairy cattle are usually stall fed, and rarely leave their stalls.

The catching, processing, and exporting of marine fish is a major industry, forming an important element in Hong Kong's economy. Pond fish are also marketed. In Deep Bay, edible oysters are grown for export.

Financial services. The unit of currency is the Hong Kong dollar. At the end of 1971 there were 70 incorporated banks in Hong Kong with 431 branch offices; these included banks and other financial institutions from the Western nations. In the same year there were six stock exchanges which had ties with stock exchanges in Europe and the Americas.

Exports and imports

Foreign trade. The crowded harbour has long provided visual proof of Hong Kong's position in world trade. The United States is the main market for the colony's products, receiving 35 percent of Hong Kong's exports in 1971, compared to approximately 12 percent to the United Kingdom, the second largest purchaser. The major imports are foodstuffs and raw material for local industry. Alcoholic beverages and tobacco are the only major imports on which a tariff is levied. Imports come primarily from Japan, China, and the United States, in that order. Re-exported goods are important, accounting for some 20 percent of total exports. Much of this transshipment is of products from China, a factor that contributes to the relative harmony characterizing relations between the colony and its powerful neighbour.

The government seeks to create favourable conditions for private enterprise. Most semiskilled and unskilled workers in the manufacturing industries are usually paid for piece-work (*i.e.*, at a standard rate for each unit produced), although daily rates of pay are also common. Men and women receive the same rates for piece-work, but women are generally paid less when engaged on a time basis. There are no legal restrictions on hours of work for men, although most men employed in industry work ten hours a day or less. The restrictions on the hours of work for women were introduced in 1959.

With the exception of a small independent segment, workers' unions are either affiliated to, or associated with, one of two local federations. At the end of 1971 there were 276 workers' unions with a declared membership of about 198,000.

Transportation. The 22-mile Hong Kong section of the Kowloon–Canton Railway runs from the southern end of the Kowloon Peninsula to the Chinese border at Lo Wu, and thence into mainland China. Since 1949, passengers have had to change trains at the frontier and walk about 300 yards between the two terminals, although no transshipment is required for mail and cargo traffic. Traffic, especially of passengers, is frequent, and is heavier at weekends and on public holidays. A new railway terminus at Hung Hom (at the northern tip of Hung Hom Bay, Kowloon), is planned to replace the present one at Tsim Sha Tsui on the southern tip of the Kowloon Peninsula.

There are over 600 miles of roads in the colony, of which 200 miles are on Hong Kong Island, 170 miles in Kowloon, and the remainder in the New Territories. Nearly 150,000 vehicles are registered.

With the exception of the Kowloon–Canton Railway, public transport, which includes bus and tramway services, is operated by private interests. Of all the major metropolitan centres in the world, the cities of Hong Kong may doubtless lay claim to having the most crowded, noisy, and filthy buses.

Ferry services

A fleet of diesel-powered ferries, including several car ferries, connect Hong Kong Island, Kowloon, and the New Territories, as well as the outlying islands; another ferry service runs regularly between Victoria on Hong Kong Island and Tsim Sha Tsui on the southern tip of the Kowloon Peninsula. Both carry many millions of passengers each year.

Vessels arriving and leaving Hong Kong each year include thousands of oceangoing ships, river steamers, junks, and mechanized vessels of various kinds. An ocean-passenger terminal, containing more than 100 shops, together with restaurants and night clubs, was completed in 1966. The repair and maintenance of shipping is carried on at two major dockyards. Hong Kong is also a centre for the training of thousands of merchant seamen.

Major international airlines use the international airport at Kai Tak, about three miles from downtown Kowloon.

Administration and social conditions. *Governmental structure.* The governor, appointed by the British crown, is the Queen's representative and head of the executive branch of the colony. He presides over an executive council of five *ex officio* members (*i.e.*, persons who are members by virtue of their official positions) and eight unofficial members appointed by the governor. Of the eight unofficial members holding office in 1971, four were Chinese. Four of the five *ex officio* members also serve on the Legislative Council, of which the governor is president; in addition, the council consists of eight other official members and 13 unofficial members nominated by the governor. None of the members of the Legislative Council are elected. Laws are enacted by the governor with the advice and consent of the council, which controls finances and expenditure.

An urban council, partly appointed and partly elected, administers Victoria and Kowloon. The New Territories are divided into five administrative districts, each under a district officer. For local representation, villages are grouped into Rural Committees, of which there are 27.

The chairmen and vice chairmen of the Rural Committees, together with justices of the peace and counsellors, form the Full Council of the New Territories, which is called the Heung Yee Kuk ("Rural Consultative Council").

The courts consist of the Full Court, the Supreme Court, the District Court, the Magistrates' Court, the Tenancy Tribunal, and the Marine Court. The laws of England, with modifications, are in force. The judiciary, headed by the chief justice, is independent of the administration.

Social conditions. A large population crowded into a tightly restricted area is the primary conditioning factor in Hong Kong's way of life.

Although from 1955 to 1965 the number of persons accommodated in Hong Kong's public housing tracts, known as resettlement estates, increased from about 125,000 to more than 755,000, the squatter population in 1970 nevertheless remained at its 1955 level of about 360,000.

Elsewhere, entire households live in cubicles, bed spaces, attics, roofs, verandas, and similar quarters; well over half of all households share accommodations with others. The government is the largest landlord in the colony, but average rents remain high.

The most serious menace to health in Hong Kong has long been tuberculosis. This and other contagious diseases are spread by overcrowded and often unsanitary living conditions. The government works closely with voluntary health and welfare agencies in promoting large-scale public health programs. It operates a dozen general and special hospitals, and twice as many more are privately operated. Medical service at the government hospitals is not free but is cheap; private clinics are mostly expensive.

With education, as with housing and water supplies, the facilities available are outstripped by the population. All education is voluntary but not free, although even private schools receive public grants. Nearly 1,250,000 students attend schools at all levels. At the lower levels, more than half the schools are privately run. Facilities are particularly strained at college level. The University of Hong Kong, founded in 1911, is private, but receives public subsidies. The Chinese University of Hong Kong, established in 1963, is located at Shatin Shui in the New Territories, and represents the amalgamation of three older colleges. Both institutions are modelled on British systems, and enrollments are limited. Many students seek higher education in the United States, Japan, or Commonwealth countries.

The universities

Cultural facilities. There were 67 daily newspapers in 1971, including 63 Chinese and four English. There have been television services since 1957. Hong Kong is served by three broadcasting organizations, two of which are commercial; the other is a government-operated station. The colony has more than a hundred cinemas.

Prospects for the future. Hong Kong's cities, bustling, vastly overcrowded, and often dirty, are nevertheless actively engaged in commerce and industry. As a result, despite its problems, Hong Kong is experiencing an economic boom. Its future, however, is to a great extent dependent upon the economic and political relations existing between the People's Republic of China and other major powers. The New Territories, for example, are due to be returned to China in June 1997, when the agreement by which they were leased expires; whether the Chinese can wait this long, however, will depend upon how long they are willing to remain deprived of this lost land on the doorway of their South Gate.

Hooker, Richard

Richard Hooker, an Elizabethan and child of the English Renaissance, in *Of the lawes of ecclesiasticall politie*, proved himself to be one of the greatest masters of English prose and of legal philosophy. He created a distinctive Anglican theology and his conceptions of constitutional government were so well founded that they remain congenial to modern thought. Almost nothing is known of Hooker's private life except what is revealed in legal documents about his estate and references to him by his contemporaries.

Richard Hooker, engraving by E. Finden (1791–1857) after a print by W. Hollar (1607–77).

Years at Oxford

Hooker was born toward the end of 1553 or the beginning of 1554 near the city of Exeter. His family did not have the financial means to send young Richard to the university, but, with John Jewel, bishop of Salisbury, as his patron, in 1568 he entered Corpus Christi College at Oxford. At that time in the life of the Church of England, the dominant influence was Calvin's *Institutes of the Christian Religion*, and thus Hooker was trained in the traditions of Genevan Protestantism. Leading scholars at Oxford were, however, loyal to the Anglican *Book of Common Prayer* and used the vestments demanded by the ecclesiastical law of the realm. Hooker, always a staunch Anglican, went far beyond even liberal Calvinism and read widely the best scriptural interpretation of his day, the early Church Fathers, and even Renaissance Thomism (the philosophical school influenced by the thought of St. Thomas Aquinas). He thus avoided the limits of narrow academic Calvinism and became a man of wide Renaissance learning. Hooker said that he grew in his opinions and gave up narrow conceptions previously held.

While at Oxford he formed three friendships of lasting importance to him. The first was with John Reynolds, his teacher. Reynolds was a liberal Calvinist, and when, as a fellow of Corpus Christi College, Hooker defended him as a nominee for the presidency of the college against an orthodox Calvinist, both he and Reynolds were temporarily expelled from their fellowships. The second friend was George Cranmer, a lawyer and grandnephew of Thomas Cranmer, Henry VIII's theological reformer and archbishop of Canterbury. Cranmer later helped Hooker with comments on the *Politie*. The third friend was Edwin Sandys, the son of the Archbishop of York, who was knighted and became a member of the Inner Temple, the

great law confederation, and was a member of Parliament. He was very close to Hooker when he composed the *Politie*. Both Cranmer and Sandys were pupils of Hooker.

Master of the Temple

Hooker became a scholar of Corpus Christi College in 1573 and took his M.A. in 1577. In the same year he became a fellow of his college. In 1585 he was elected master of the Temple. The other candidate for this position was Walter Travers, an ardent Calvinist. Travers, an able man, had written a scholarly book, *Ecclesiasticae disciplinae defensio* ("Defense of Ecclesiastical Discipline"). Although he had not received Anglican orders, he was made lecturer (preacher) of the Temple Church. Hooker, a loyal Anglican, preached in the morning, and Travers, a firm Calvinist, in the afternoon. Thus it was said that the Temple Church congregations heard Canterbury in the morning and Geneva in the afternoon.

With the defeat of the Spanish Armada in 1588, the Church of England passed beyond the crisis of the threat of Roman Catholicism. Now the threat was that of Calvinism, not only in doctrine but in ecclesiastical organization as well. Small cells, or conventicals, of reformed worship were formed throughout the realm. Their very radicalism appealed, and their hold on general sympathy was so strong that even the bishops were lukewarm about suppressing them and allowed their growth to increase unchecked. Travers, in fact, set up an organization in the afternoon congregation on the model of the Reformed Church in the Low Countries and chided Hooker for not using the Reformed organization in the Temple Church. The difference between the two men was radical. Hooker did not approve of many of the decisions of the Roman Catholic Council of Trent (1545–63), which attempted to reform the Catholic Church following the Protestant Reformation, but he did approve of many of the medieval Scholastic philosophers and theologians, such as St. Thomas Aquinas, and he used their teaching with approval. This was anathema to Travers, who thought of the teaching of the Scholastics as sheer rubbish. Hooker does not seem to have lived in the parsonage of the Temple, but with John Churchman, a good friend of the Church of England. There were two reasons for this: first, the parsonage was not in good repair, and, second, Travers lived there.

On February 13, 1588, while still master of the Temple, Hooker married Joan Churchman, daughter of his friend and host. Izaak Walton, the English author and biographer, was responsible for the story, accepted for 300 years, that his future father-in-law tricked him into the marriage with his ill-favoured daughter. In 1940 it was proved by examination of the Court of Chancery records about Hooker's estate that the story was a tale devised to explain the incompleted state of the last books of the *Politie*. Joan Churchman brought with her a large dowry. At the time of his marriage Hooker had no known financial means, and yet at his death he left a considerable estate.

His masterpiece: the *Politie*

After he ceased to be master of the Temple in 1591, Hooker resided at his father-in-law's house and wrote his masterpiece, *Of the lawes of ecclesiasticall politie*. The *Politie* was the last link in a long strife, known as the admonition controversy: in June 1572 radical religious reformers had issued from a secret press *An Admonition to the Parliament*, which, though Queen Elizabeth forbade its consideration by Parliament, became the platform of the Puritans—those within the Church of England who wished for radical reforms along the lines developed in Geneva by Calvin. The leading bishops, now alarmed by the influence of the *Admonition*, knew that an answer was needed, and the Archbishop of Canterbury turned to John Whitgift, vice chancellor of the University of Cambridge, to reply to the *Admonition*. This Whitgift did and was answered in turn by Thomas Cartwright, professor at Cambridge and the leading Puritan clergyman. The controversy was continued in a whole series of books.

The *Admonition* was still much in the mind of England when Hooker left the Temple, and he set himself the task of replying to it. The *Politie* was to be a work of eight books, but the fifth book was the last one to appear in Hooker's lifetime. The tradition that his manuscripts were destroyed by Puritan ministers who were assisted by Hooker's wife does not seem to be correct. The incomplete condition of the last books of the *Politie* merely means that Hooker had not yet revised them at the time of his death.

In the *Politie*, Hooker defended the Elizabethan church against Roman Catholics and Puritans alike. He affirmed the Anglican tradition as being that of a threefold cord not quickly broken—Bible, church, and reason. Roman Catholics put Bible and tradition on a parity as the authorities for belief, while Puritans looked to Scripture as sole authority. Hooker avoided both extremes, allowing to Scripture absolute authority when it spoke plainly and unequivocally; where it was silent or ambiguous, wisdom would consult the tradition of the church; but he insisted that a third element lay in man's reason, which should be obeyed whenever both Scripture and tradition needed clarification, or failed to cover some new circumstance. The core of Hooker's thinking on the relations of church and state is unity. In his view, the Puritans adopted an impossible position; they claimed to be loyal to the Queen while repudiating the Queen's church. By law and by reason, an Englishman must be an Anglican, pledged to serve Elizabeth as the supreme magistrate of his country and the supreme governor of his church.

According to tradition Hooker served the churches at Drayton Beauchamp and Boscombe following his term as master of the Temple, but more probably he practiced pluralism, which means he received his salary as a vicar but allowed a lesser clergyman to perform the duties the parish required. In 1595 he accepted an appointment as vicar of Bishopbourne, near Canterbury and in 1597 the fifth book of the *Politie* was published. He died in 1600 and was buried at Bishopbourne.

Hooker Family

The Hookers, father and son, were virtually synonymous with English botany for nearly a century. Their many publications, some the product of joint effort, placed them in the forefront of plant taxonomy throughout the world. Although their major contributions involved the technical description and classification of new species, they also had great influence at the popular level. The accounts of their voyages and collecting trips, the introduction of new horticultural varieties, and the founding of The Royal Botanic Gardens at Kew, near London, stimulated the English-speaking world, directly and indirectly, to the most vigorous renewal of botany since the time of the Swedish botanist Carolus Linnaeus in the 18th century.

William Hooker

William Jackson Hooker was born in Norwich, England, on July 6, 1785, son of a merchant's clerk and descendant of Richard Hooker, noted theologian of the 16th century and author of *Of the lawes of ecclesiasticall politie* (1593). A fortuitous discovery in 1805 of a rare moss, which he communicated to James Edward Smith, founder of the prestigious Linnaean Society, redirected his interests from general natural history to botany. His early education at Norwich Grammar School was followed by a voyage to Iceland in 1809, a period of extensive study in England, and a trip to France, Switzerland, and Italy in 1814–15, where he met some of the leading continental botanists. He married Maria Turner, daughter of the botanist Dawson Turner, in 1815. Joseph Dalton Hook-

er, the second of their five children, was born on June 30, 1817, in Halesworth, Suffolk. Three years later, the elder Hooker accepted the chair of Regius Professor of Botany at Glasgow, a position he held until 1841. Until his death at Kew, Surrey, on August 12, 1865, he was actively engaged in promoting the importance of botany.

Beginning with William Hooker's *Journal of a Tour in Iceland in the Summer of 1809*, in 1811, more than 20 major works as well as numerous periodical articles appeared in the following 50 years. His main interest was in cryptogamic botany (*e.g.*, ferns, mosses, fungi), as evidenced by his publications: *British Jungermanniae*, 1816; *Musci Exotici*, 1818–20; *Icones Filicum*, 1829–31; *Genera Filicum*, 1842; and *Species Filicum*, 1846–64. He also published important floristic studies (*Flora Scotica*, 1821; *The British Flora*, 1830; *Flora Borealis Americana: or the Botany of the Northern Parts of British America*, 1840) and was a pioneer in the study of economic botany. The publications, together with his own herbarium, which he generously made available to all scholars, and the journals that he founded and edited, made him the centre of English botany. The climax of his career came in 1841 when he was appointed the first director of Kew Gardens. Under his leadership, Kew Gardens became the world's leading botanical institution. Now a vast complex, including laboratories, a museum, a library, and greenhouses, it is a national showpiece as well as his personal monument. Before his retirement in 1865, he founded the Museum of Economic Botany at Kew (1847).

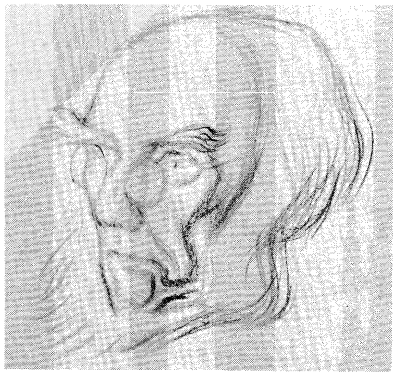
William Hooker, painting by S. Gambardella, 1843. In the collection of the Linnean Society of London.

Joseph Dalton Hooker, unlike his father, had the benefit of a formal education and was graduated from the University of Glasgow with an M.D., in 1839. Through his familiarity with his father's herbarium, he was well prepared for the first of his many travels—as surgeon-botanist aboard HMS "Erebus" on the Antarctic expedition of 1839–43. Thereafter, a steady stream of publications followed, punctuated by his own travels: *The Botany of the Antarctic Voyage of H.M. Discovery-Ships Erebus and Terror in 1839–1843*, 1844–60; *Rhododendrons of Sikkim Himalya*, 1849; *The Flora of British India*, 1872–97; *Handbook of the New Zealand Flora*, 1864; and *Journal of a Tour in Marocco and the Great Atlas*, 1878. His last major botanical expedition, to the Rocky Mountains and California (1877), led to the publication of several important papers concerning the relationship of American and Asian floras. His travels resulted in the discovery of species new to science, many of which were soon introduced to horticultural circles. Even more important, however, were the data, which gained him an international reputation as a plant geographer.

Joseph Hooker

In 1851 Joseph Hooker married Frances Henslow, the daughter of a botanist. Six children survived her death in 1874. By his second wife, Hyacinth Symonds Jardine, whom he married in 1876, he had two sons. He became assistant director of Kew in 1855, a position he retained until 1865, when he succeeded his father as director, serving in that capacity until his own retirement in 1885. Many honours came to Hooker, including the presidency of the Royal Society (1872–77) and, like his father, he was knighted for his many services. He remained active until shortly before his death on December 10, 1911, at Sunningdale, Berkshire.



Joseph Hooker, drawing by W. Rothenstein, 1903. In the National Portrait Gallery, London.

One of the most significant results of his travels was an attempt to explain the geographical distribution of plants and their seemingly anomalous variations. As a close friend to Charles Darwin and one well acquainted with the latter's early work, Hooker, along with the geologist Sir Charles Lyell, presided at the historic meeting of the Linnaean Society in July 1858. It was their function to adjudicate the priority claims concerning natural selection as the mechanism for evolution, which had been advanced simultaneously by Darwin and Alfred Russel Wallace. By lending his support to a scientific claim that was soon to be attacked on extra-scientific grounds, Hooker was among the first to demonstrate the importance and applicability of the evolutionary theory to botany in general and to plant geography in particular. The capstone to the younger Hooker's career came in 1883 with the publication of the final volume of the *Genera Plantarum*, written in conjunction with George Bentham. This world flora, describing 7,569 genera and approximately 97,000 species of seed-bearing plants, was based on a personal examination of the specimens cited, the vast majority of which were deposited at Kew. The volume is not only a monument to the Hookers but to the institution they administered for 44 years.

BIBLIOGRAPHY. J.D. HOOKER, "A Sketch of the Life and Labours of Sir William Jackson Hooker (with Portrait)," *Ann. Bot.*, 16:9–120 (1902), a careful study by the son and successor of the biographee containing data not otherwise recorded; MEA ALLEN, *The Hookers of Kew, 1785–1911* (1967), a popular but well written and carefully researched work, based on correspondence and archival materials at Kew; W.B. TURRILL, *Pioneer Plant Geography: The Phytogeographical Researches of Sir Joseph Dalton Hooker* (1953), the fundamental study of the younger Hooker by a leading plant geographer; and *Joseph Dalton Hooker: Botanist, Explorer and Administrator* (1963), popular but important because of the author's long association with Kew and his familiarity with Hooker's herbarium.

(Je.St.)

Hopeh

Hopeh (He-bei in Pin-yin romanization) is a province in northern China, located between the province of Shansi, on the west, and the Gulf of Chihli (Po Hai) and the Northeast (Manchuria), on the east. It is bounded on the north by China's Inner Mongolian Autonomous Region and on the south by the provinces of Shantung and Honan. Hopeh means "north of the (Yellow) river." Hopeh has an area of 74,300 square miles (192,400 square kilometres), or 2.0 percent of the national total. The esti-

mated population in 1970 was 43,000,000. The provincial capital was at Pao-ting until 1958, when it was transferred first to Tientsin and then, in 1967, to Shih-chia-chuang Shih, 160 miles southwest of Peking. The present capital is at the junction of three railways: the Peking–Canton line (the north–south trunk line), the Shih-chia-chuang–T'ai-yüan line to Shansi, and the Shih-chia-chuang–Te-chou line to Shantung. The large municipality of Peking, the national capital, lies within Hopeh Province but is independent of the provincial administration. Culturally and economically, Hopeh is the most advanced province in northern China.

Under the Manchu dynasty (1644–1911), Hopeh was known as Chih-li Sheng ("directly ruled province"), a name that was retained until 1928, when the Nationalist government moved the capital from Peking to Nanking, and the province was renamed Hopeh Sheng (Hopeh Province). From 1937 to 1945 Hopeh was occupied by the Japanese. After Japan's defeat the occupiers surrendered to the Chinese Nationalists in 1945. Chinese Communist forces took the province in January 1949, opening a new chapter in its long history.

Administrative levels

Hopeh Province and the separate municipalities of Peking and Tientsin form three of the 29 primary administrative divisions of the People's Republic of China. The province is subdivided into 11 secondary administrative units, consisting of the provincial capital and ten special districts (*chuan-ch'ü*). The subprovincial administrative areas are further subdivided into 142 counties (*hsien*), eight municipalities (*shih*), and two autonomous counties (*tzu-chih-hsien*). The traditional sub-*hsien* administrative unit was the *hsiang* (civil township, or rural district), which was supplanted in 1958 by the commune. The communes were envisaged as multiple-purpose basic units of rural organization and development: administrative, economic, social, even military. Numerous communes have established labour-intensive rural industries. The profits from these enterprises have helped to pay for primary and secondary education, social welfare, recreation, and medical care, thus achieving a certain degree of self-sufficiency.

LAND AND POPULATION

Relief. Hopeh Province consists of two almost equal sections: the northern part of the North China Plain and the mountain ranges along the northern and western frontiers. The former is sometimes called the Hopeh Plain. It is formed largely by the alluvial deposits of the five principal tributaries of the Hai Ho (Hai River), which flows past Tientsin to the sea. Two of them, the Yung-ting and the Pai, flow down from the northern highlands. The other three have their sources in the western part of Hopeh: the Ta-ch'ing, the Tzu-ya, and the Southern Grand Canal (Nan Yün Ho).

The Hopeh Plain slopes gently from west to east. It is bounded by the Yen Shan (Yen Mountains) on the north, the T'ai-hang Shan to the west, and the Gulf of Chihli to the east. The mountains have at their base a string of alluvial fans. This inner belt of the Hopeh Plain is generally well drained. The groundwater level is usually less than 33 feet from the surface and is easily tapped for domestic water and irrigation.

The Yen Shan range forms the northern rim of the North China Plain, displaying to the traveller an endless sea of rounded hills, with peaks averaging 4,900 feet above sea level. The Great Wall of China zigzags along its crests. Beyond these mountains the Mongolian Plateau stretches from the northernmost part of Hopeh Province to the Mongolian People's Republic. This part of Hopeh has an average elevation of 3,900 to 4,900 feet. The rim of the plateau is rugged and inhospitable to human settlement. Between the Yen Shan are large basin plains, cultivated and well-inhabited. Coal and iron are mined in the northern mountains.

To the west of the North China Plain sprawls the lofty north–south range of T'ai-hang Shan (Grand Run Mountains), separating the Hopeh Plain from the Shansi Plateau. Its general elevation is over 3,280 feet, but the highest peaks are 6,560 feet. The range is pierced by a number of west–east streams whose narrow valleys (the famous "Eight Gorges" of T'ai-hang) are the routes of highways and railroads between the Hopeh Plain and the Shansi Plateau.

Rivers

The major Hopeh rivers flow down from the loess-covered T'ai-hang Shan and the Shansi Plateau. They carry a heavy load of silt after the summer downpours, depositing it in the shallow channels downstream on the plain, gradually silting them up and causing widespread floods in low-lying areas. Under the People's Republic, vigorous measures for water control and soil conservation have been carried out, together with reforestation in the upland areas. Numerous dams, generally small to medium-size, have been built upstream and in the tributaries to conserve the water for irrigation and other uses; flood-retention basins and storage reservoirs have been built downstream. The Tu-liu-chen Canal, connecting the Ta-ch'ing Ho to the sea, helps to drain the extremely low-lying tract around the large Pai-yang Tien (Pai-yang Lake) and the Wen-an Wa (Wen-an Marsh). Water from the streams is utilized to wash away the excess salt in the alkaline soil and make it arable. Similar *chien-ho* ("reducing streams") have been completed for the Southern Grand Canal, and others have been under construction on the Pei Ho.

In the southernmost section of the province, the floodplains have a compact, sticky, waterlogged surface, which makes well digging difficult. The areas between the alluvial fans and the sea in this section are very flat, and there are a number of shallow lakes and marshes of varying degrees of salinity. The groundwater is generally alkaline and unfit for irrigation or domestic use.

The Hai Ho is only 35 miles long, from the city of Tientsin to the sea, but the drainage basin of its five tributaries covers over two-thirds of the province. Another major river is the Luan, draining northeastern Hopeh.

All the major Hopeh rivers empty into the Gulf of Chihli, a shallow sea with an average depth of only 100 feet. The water and nutrient matter brought down by the rivers nourish a rich marine fauna. In winter the surface water along the coast is frozen, but navigation is possible with the use of icebreakers. There are three important ports: Tientsin, which is about 30 miles up the Hai Ho; T'ang-ku, which has a new harbour at the river's mouth; and the major coal-handling port of Ch'in-huang-tao.

Climate and soil. The province has a continental climate. The January mean temperatures range from 25° F (−4° C) in the south to 14° F (−10° C) north of the Great Wall. The average July temperature is about 77° F (25° C) in the North China Plain, and 73° to 77° F (23° to 25° C) in the northern and western highlands. The annual precipitation (rain and snow) is more than 20 inches (500 millimetres) in most parts of the province. The summer months of June, July, and August are the rainy season.

The most common soil in the Hopeh Plain is dark-brown earth developed on loessic alluvium, modified by cultivation over several millennia. It is extremely fertile; the famous "good earth" has yielded crops with little fertilization for thousands of years. New alluvium is distributed in the areas along the rivers by frequent flooding. In the mountains the soils vary: the upland hills have leached dark-brown soils; the more humid mountainous areas of Yen Shan and T'ai-hang Shan have brown forest soils suited to fruit trees; the northernmost Chang-pei plateau has light-chestnut zonal soils.

The natural vegetation of the greater part of the province is broadleaf deciduous forest, but, after many centuries of human settlement, cultivation, and deforestation, little of the original vegetation remains except in the high mountains and other inaccessible areas. The northernmost Chang-pei plateau has steppe grass of the Mongolian Plateau type. The higher mountains have coniferous forests. In the saline areas along the coast and in the low-lying depressions, plants that flourish in a salty environment dominate. There is a conspicuous absence of forests in the lowlands and lower hills. The flora is predominantly of a northern character. It includes the willow, the elm, the poplar, the Chinese scholar tree

(*Sophora japonica*), the tree of heaven (*Ailanthus*), and drought-resistant shrubs.

Animal life

The North China Plain has been inhabited by man for several millennia. The present fauna include elements of the temperate forest (such as the forest cat *Felis euptilus*) and of the cold-winter steppe (such as the camel), as well as some tropical elements from the Indo-Malay region (such as the tiger and the monkey). The domestication of animals such as the dog, sheep, goat, cow, horse, donkey, mule, camel, and cat has led to the extinction or near-extinction of many wild species. The smaller mammals are better preserved, including moles, bats, rabbits and hares, rats, mice, and squirrels. Birds include the Mandarin duck (*Aix galericulata*), native to China. The Hopeh Plain was the home of *Sinanthropus pekinensis* (Peking man), one of the oldest known examples of fossil man, who lived about 400,000 years ago. The Peking man used tools and fire.

The people. The only complete census made in China in the first 70 years of the 20th century was that of June 30, 1953. It recorded 35,984,644 inhabitants in Hopeh Province, not including Peking Municipality (2,768,149), the national capital district. More detailed demographic data were not released. The population estimates of 1954 to 1957 were based on the annual reports of the provinces and municipalities, as collated by the State Statistical Bureau. On December 31, 1957, the registered population of Hopeh Province was estimated at 44,720,000, including Tientsin and Peking municipalities. The estimated population figures for 1970 were 43,000,000 for Hopeh, 4,300,000 for Tientsin Municipality, and 7,600,000 for Peking Municipality. These implied an increase of about 17,920,000 in 17 years. The ethnic composition of the population is almost entirely Chinese. Minority groups include 500,000 Hui (Chinese Muslims) and slightly over 10,000 Mongolians.

The population density of Hopeh in 1970 was approximately 597 inhabitants per square mile. This was less than that for Japan (726 per square mile) but greater than the population densities of the United Kingdom (573) and the state of New York (367). Since nearly one-half of Hopeh Province is mountainous, the density of population is really much higher than the average suggests. Its economic development, moreover, is far below that of New York, the United Kingdom, or Japan. At the start of the 1970s, the highest population densities in Hopeh were found in the Shih-chia-chuang and the Ting-hsien areas at the foot of T'ai-hang Shan, in the belt of alluvial fans, where irrigation by wells is widely practiced; there, densities of 1,036 to 1,300 persons per square mile were attained. This is a district settled since antiquity, on the ancient highway from the middle of the North China Plain (Chung-yüan, or the "Middle Plain") to Peking and on to the north of the Great Wall. The other areas along the alluvial fans of T'ai-hang Shan and Yen Shan also had very high densities, ranging from 777 to 1,036 persons per square mile. These piedmont plains have also been settled since ancient times. The rural settlement pattern is that of huge nucleated villages of more than 1,000 inhabitants. Farther east and south of the alluvial-fan belt are the low-lying districts subject to flood, which had somewhat lower densities (518 to 777 per square mile).

Among the poorer regions is an area along the Gulf of Chihli coast, in the shape of a gigantic crescent, where the population was around 250 per square mile. This section has many saline and alkaline tracts. The northwestern uplands of the province had a comparable population density, except for the arable basin plain (Hsüan-hua and Wei-hsien basins) and the intermontane valley plains (Ch'eng-te and Luan-p'ing), where it increased to between 250 and 500 per square mile. The Chang-pei plateau north of the Great Wall and the remote mountainous areas had the lowest densities, ranging from around 26 to 130 per square mile.

Before the Communist victory there was substantial migration from northwestern Hopeh to Inner Mongolia, but afterward most of this ceased. Peasants in southeastern Hopeh have also migrated in large numbers since the beginning of the 20th century to Manchuria, Inner Mongolia, and China's Northwest. This has apparently continued under the Communists, in a more organized way. With the expansion of large cities such as Peking and Shih-chia-chuang, there has also been an organized migration of peasants from the urban fringes to the Northeast (Manchuria) and the Northwest.

URBAN CENTRES AND ECONOMIES

City dwellers constitute about 20 percent of the total population of Hopeh, the highest proportion in North China, exceeded only by Kiangsu among the provinces south of the Great Wall. The Peking Municipality has an estimated population of 7,600,000 (1970), and Tientsin Municipality has 4,300,000 (1970).

Peking, Tientsin, and T'ang-shan

Major metropolitan complexes. The Peking–Tientsin industrial region, extending from the base of Yen Shan and T'ai-hang Shan to the sea, is the largest and most important in North China. It includes the important industrial cities of T'ang-shan and Ch'in-huan-tao, in eastern Hopeh, Pao-ting, and Shi-chia-chuang, in western Hopeh, and Liu-li-ho, in Peking Municipality. At the present stage of China's industrialization, manufacturing is predominantly concentrated in the large and medium-sized cities.

Heavy industry is closely associated with the major coal mines and railways. Through the foothills of Yen Shan and T'ai-hang Shan, from the Gulf of Chihli to Han-tan and Chiao-tso (in Honan), stretches a great crescent with rich coal deposits. The major coal mines of K'ai-luan, Ching-hsi (in the Western Hills of Peking), Ching-hsin (northwest of Shih-chia-chuang), and Han-tan supply fuel for the electric-power plants of Peking, Tientsin, T'ang-shan, Ch'ing-huan-tao, Pao-ting, Shih-chia-chuang, and Han-tan.

Tientsin, the second-largest city, was the capital of Hopeh Province until February 1967, when it was placed under the direct control of the central government. It is the primary industrial and commercial centre of North China and the second most important trade centre in all China. Tientsin was only a small trading centre in the 17th century, but since 1860 its development has been rapid.

Tientsin is also a major educational centre, with six institutions of higher learning at the start of the present decade. There was a Chinese museum, a museum of science and technology, a sports stadium, a large public library, a theatre, an aquatic park, and numerous public amusement centres (see also TIENTSIN).

T'ang-shan (812,000 inhabitants in 1958), the third city in the region, is a centre of heavy industry. Its development has been associated with that of the K'ai-luan coal mines, initiated by British capital and further developed under the Communists to become one of the largest coal mines in China. T'ang-shan's power plant supplies electricity to the K'ai-luan mines and to Peking and Tientsin. Heavy industry includes steel, cement, and railway-repair shops. Light industry in the city includes textiles, paper, flour mills, and ceramics. The larger factories often have their own workers' clubs, libraries, and clinics. There are literally hundreds of factory-run spare-time workers' schools. The city also has the famous T'ang-shan Institute of Railway Engineering.

Pao-ting and Shih-chia-chuang

Other important cities. Pao-ting (250,000 inhabitants in 1958), in central Hopeh, is an ancient city. During the Liao and Chin dynasties, from the 10th to the 13th centuries, it formed part of Peking's outer defense perimeter. It was the provincial capital from 1912 to 1958 and has long been a cultural and educational centre. Its most famous monument is the Ancient Lotus Pond, around which the Lotus Pond College was built during the reign of Yung-chen (1723–35); the college later became the Hopeh Library. The city has a large cultural museum and a museum of natural history, a medical college, an agricultural college, and more than ten secondary schools. Pao-ting functions as a commercial hub for the central Hopeh subregion and as an administrative and residential city. A period of industrial development began in the 1950s with the establishment of plants pro-

ducing agricultural machinery, flour mills, vegetable oils, leather goods, woolens, and bricks and tiles.

Shih-chia-chuang (623,000 inhabitants in 1958) is the present provincial capital. Its growth followed the completion of the Peking–Hankow railway and the Shih-chia-chuang–T'ai-yü'an line, which have a junction there. By the 1930s, there were a few small-scale industrial plants, a railway-repair shop, a coke oven, small textile mills, and flour mills. Under Japanese occupation (1937–45) a new rail line was built to Shantung Province, which joined the Tientsin–P'u-k'ou railway, the trunk line of eastern China. The population increased to 170,000. Despite this, industrial output declined during the occupation. After 1949 the old plants were reconstructed and expanded, and large, new plants were built, including cotton-textile, woolen, dyeing, food-processing, brick and tile, and fertilizer plants. Between 1953 and 1958 its population grew from 373,000 to 623,000, making Shih-chia-chuang fourth in population and industrial output in Hopeh, after Peking, Tientsin, and T'ang-shan.

Han-tan and Chang-chia-k'ou

The fastest growing urban–industrial centre in the province is the ancient city and new cotton-textile centre of Han-tan, whose population grew from 90,000 in 1953 to 380,000 in 1958. Located 100 miles south of Shih-chia-chuang, on the Peking–Canton railway and the Hai Ho inland navigation system, it serves as a central market for the economic subregion of south Hopeh. It became a rising centre of light industry during the 1950s with the building of cotton-ginning and textile plants and factories for food processing and agricultural machinery. The city is in the midst of a cotton-producing region, linked by railway with the coal-mining complex of Feng-feng, in the T'ai-hang Shan—a mining city of over 100,000 inhabitants. Han-tan was the capital of the state of Chao in the 4th century BC. The area was a Chinese Communist base during the Sino-Japanese War (1937–45) and the civil war that followed. A huge Martyrs' Monument in Han-tan commemorates this episode of its long history.

The former market town of Chang-chia-k'ou (Kalgan) on the Peking–Pao-t'ou railroad in northwestern Hopeh has become a rising industrial–commercial city. In 1953–58 its population grew from 229,300 to 480,000. It is a food-processing centre and also makes mining machinery. Chang-chia-k'ou is 19 miles by rail from Hsüan-hua and the Lung-yen iron mines, the largest south of the Great Wall. Another 12 miles farther south are the coal-mining districts of Hsia-hua-yüan, which supply fuel and electric power to the area. The power is carried over high-voltage lines to the Peking–Tientsin–T'ang-shan electric grid. Chang-chia-k'ou has been a centre for trade between the Chinese and the steppe peoples of Mongolia since time immemorial.

A basic policy of the government since 1957–58 has been the simultaneous development of large-scale industry by the national authorities and, at the local level, of small to medium plants. This is called the policy of "walking on two legs." After a period of economic difficulties in the early 1960s, a new upsurge of local industrial development began in 1966. The emphasis was upon industries supporting agriculture.

The province is served by seven major railways: the Peking–Canton and the Tientsin–P'u-k'ou lines, running north and south; the Peking–Shen-yang (Mukden) line, to the northeast and the sea; the Peking–Pao-t'ou line, to the Inner Mongolian Autonomous Region, northern Shansi, and the Northwest; the Peking–Ch'eng-te line, to Ch'eng-te and the western part of the Northeast; the Shih-chia-chuang–T'ai-yüan line, to Shansi Province; and the Shih-chia-chuang–Te-chou line, to Shantung.

Sea transport moves through Tientsin and the coal port of Ch'in-huang-tao. The province exports coal and salt to Shanghai; products of light industry to Dairen and the Northeast; and coal, metals, and consumer goods to the Shantung ports. From Dairen come petroleum, soybean cakes (fertilizer), paper, chemicals, and iron and steel; from Shanghai, staple foods and consumer goods; and, from Shantung, fruit and native products. Overseas exports consist chiefly of agricultural products in exchange for metals, machinery, and industrial raw materials.

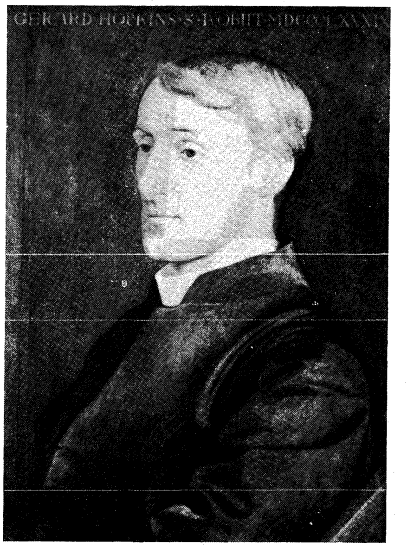
Hopkins, Gerard Manley

One of the most individual of all Victorian writers, Gerard Manley Hopkins created poems that combine subtlety of perception, force of intellect, and intensity of religious feeling, reflecting his vocation as a Jesuit priest. Rich in complex experiments in prosody and diction, his style was so highly original that it was unappreciated, except by a few friends, in his own lifetime. Not until nearly 30 years after his death was the first volume of his poems published, in 1918, and not until the 1930s was he generally recognized as one of the great poets of the English language.



Gerard Manley Hopkins, portrait by Harry Ellis Wooldridge (1845–1917). In a private collection.

Early education and conversion

Gerard Manley Hopkins was born at Stratford, Essex, on July 28, 1844. He was the eldest of the nine children of Manley Hopkins, an Anglican, who had been British consul general in Hawaii and had himself published verse. Hopkins won the poetry prize at the Highgate grammar school and in 1863 was awarded a grant to study at Balliol College, Oxford, where he continued writing poetry while studying classics. In 1866, in the prevailing atmosphere of the Oxford Movement, which renewed interest in the relationships between Anglicanism and Roman Catholicism, he was received into the Roman Catholic Church by John Henry (later Cardinal) Newman. The following year, he left Oxford with such a distinguished academic record that Benjamin Jowett, then a Balliol lecturer and later master of the college, called him "the star of Balliol." Hopkins decided to become a priest. He entered the Jesuit novitiate in 1868 and burned his youthful verses, determining "to write no more, as not belonging to my profession."

Until 1875, however, he kept a journal recording his vivid responses to nature as well as his expression of a philosophy for which he later found support in Duns Scotus, the medieval Franciscan thinker. Hopkins' philos-

ophy emphasized the individuality of every natural thing, which he called "inscape." To Hopkins, each sensuous impression had its own elusive "selfness"; each scene was to him a "sweet especial scene."

In 1874 Hopkins went to St. Beuno's College in North Wales to study theology. Here he learned Welsh and, under the impact of the language itself as well as that of the poetry and encouraged by his superior, he began to write poetry again. Moved by the death of five Franciscan nuns in a shipwreck in 1875, he broke his seven-year silence to write the long poem "The Wreck of the Deutschland," in which he succeeded in realizing "the echo of a new rhythm" that had long been haunting his ear. It was rejected, however, by the Jesuit magazine *The Month*. He also wrote a series of sonnets strikingly original in their richness of language and use of rhythm, including the remarkable "The Windhover," in recent years one of the most frequently analyzed poems in the language. He continued to write poetry, but it was read only in manuscript by his friends and fellow poets, Robert Bridges (later poet laureate), Coventry Patmore, and the Rev. Richard Watson Dixon. Their appreciation of the strangeness of the poems (for the times) was imperfect, but they were, nevertheless, encouraging.

Ordination to the priesthood

Ordained to the priesthood in 1877, Hopkins served as missioner, occasional preacher, and parish priest in various Jesuit churches and institutions in London, Oxford, Liverpool, and Glasgow and taught classics at Stonyhurst College, Lancashire. He was appointed professor of Greek literature at University College, Dublin, in 1884. But Hopkins was not happy in Ireland; he found the environment uncongenial, and he was overworked and in poor health. From 1885 he wrote another series of sonnets, beginning with "Carrion Comfort." They show a sense of desolation produced partly by a sense of spiritual aridity and partly by a feeling of artistic frustration. These poems, known as the "terrible sonnets," reveal strong tensions between his delight in the sensuous world and his urge to express it and his equally powerful sense of religious vocation.

While in Dublin, Hopkins developed another of his talents, musical composition; the little he composed shows the same daring originality as does his poetry. His skill in drawing, too, allowed him to illustrate his journal with meticulously observed details of flowers, trees, and waves.

His friends continually urged him to publish his poems, but Hopkins resisted; all that he saw in print in his lifetime were some immature verses and original Latin poems, in which he took particular pleasure.

Hopkins died of typhoid fever on June 8, 1889, and was buried in the Glasnevin Cemetery, Dublin. Among his unfinished works was a commentary on the *Spiritual Exercises* of St. Ignatius Loyola, founder of the Jesuit order.

After Hopkins' death, Robert Bridges began to publish a few of the Jesuit's most mature poems in anthologies, hoping to prepare the way for wider acceptance of his style. By 1918, Bridges, now poet laureate, judged the time opportune for the first collected edition. It appeared but sold slowly. Not until 1930 was a second edition issued, and thereafter Hopkins' work was recognized as among the most original, powerful, and influential literary accomplishments of his century; it had a marked influence on such leading 20th-century poets as T.S. Eliot, Dylan Thomas, W.H. Auden, Stephen Spender, and C. Day Lewis.

Poetic style

Hopkins sought a stronger "rhetoric of verse." His exploitation of the verbal subtleties and music of English, of the use of echo, alliteration, and repetition, and a highly compressed syntax were all in the interest of projecting deep personal experiences, including his sense of God's mystery, grandeur, and mercy, and his joy in "all things counter, original, spare, strange," as he wrote in "Pied Beauty." He called the energizing prosodic element of his verse "sprung rhythm," in which each foot may consist of one stressed syllable and any number of unstressed syllables, instead of the regular number of syllables used in traditional rhythm. The result is a muscular verse, flexible, intense, vibrant, and organic, that combines accuracy of observation, imaginative daring, deep feeling, and intellectual depth.

Hopkins' letters reveal a brilliant critical faculty, scrupulous self-criticism, generous humanity, and a strong will. His friends paid tribute to his personal integrity and to his rare "chastity of mind." Coventry Patmore wrote of him: "There was something in all his words and manners which were at once a rebuke and an attraction to all who could only aspire to be like him."

(J.C.Rd.)

Horace

An outstanding Latin poet, Horace (Quintus Horatius Flaccus) flourished in Rome's Augustan age, an era named after the emperor Augustus (sole ruler 31 BC–AD 14), whose friend and supporter the poet was. Although he wrote other works, his enormous influence upon Western literature rests principally upon his *Odes*, four books of short poems in lyric metres dealing with many themes, and his *Epistles*—hexameter poems (with six metrical feet) in the artificial form of letters, principally concerning conduct, although the two longer poems of the second book and the *Ars poetica* concentrate on literature and poetic criticism. Horace's fame rests chiefly upon the likable person revealed in his works. Autobiographical touches proliferate in his poetry: he seems to tell far more about himself, his character, his development, and his way of life than any other great poet of antiquity, and this, combined with the fact that he lived in one of the best documented periods of Roman history, creates the illusion that a good deal is known about him. Yet his autobiographical "disclosures" are not realistic but literary, a feature of his technique for creating an intimate atmosphere. What he tells about himself is part of the work of art he is creating; even his beliefs are impossible to pin down with any certainty, since apparent declarations of them are often no more than devices to create a mood or theme. Horace claimed that criticism in his poetry was for the good of society. As time went on he became convinced that the good poet must first be a good man and useful to the community as educator and civilizer.

Literary autobiographical "disclosures"

Family background and career. Born at Venusia (the modern Venosa) in Apulia, in southeast Italy, in December 65 BC, Horace was probably of the Sabellian hillman stock of Italy's central highlands. His father had once been a slave but gained freedom before Horace's birth and became an auctioneer's assistant. He also owned a small property and could afford to take his son to Rome

Horace, bronze medal, 4th century. In the Bibliothèque Nationale, Paris.

and ensure personally his getting the best available education in the school of a famous fellow Sabellian named Orbilius (a believer, according to Horace, in corporal punishment). In about 46 BC Horace went to Athens, attending lectures at the Academy. After Julius Caesar's murder in March 44 BC, the eastern empire, including Athens, came temporarily into the possession of his assassins Brutus and Cassius, who could scarcely avoid clashing with Caesar's partisans, Mark Antony and Octavian (later Augustus), the young great-nephew whom Caesar, in his will, had appointed as his personal heir. Horace joined Brutus' army and was made *tribunus militum*, an exceptional honour for a freedman's son.

Horace's survival and rise

In November 42 BC, at the two battles of Philippi against Antony and Octavian, Horace and his fellow tribunes (in the unusual absence of a more senior officer) commanded one of Brutus' and Cassius' legions. After their total defeat and death, he fled back to Italy—controlled by Octavian—but his father's farm at Venusia had been confiscated to provide land for veterans. Horace, however, proceeded to Rome, obtaining, either before or after a general amnesty of 39 BC, the minor but quite important post of one of the 36 clerks of the treasury (*scribae quaestorii*). Early in 38 BC he was introduced to Gaius Maecenas, a man of letters from Etruria in central Italy who was one of Octavian's principal political advisers. He now enrolled Horace in the circle of writers with whom he was friendly. Before long, through Maecenas, Horace also came to Octavian's notice.

During these years Horace was working on Book I of the *Satires*, ten poems written in hexameter verse and published in 35 BC. The *Satires* drew on Greek roots, stating Horace's rejection of public life firmly and aiming at wisdom through serenity. He discusses ethical questions: the race for wealth and position, the folly of extremes, the desirability of mutual forbearance, and the evils of ambition. His 17 *Epodes* were also under way. Mockery here is almost fierce, the metre being that traditionally used for personal attacks and ridicule, though Horace attacks social abuses, not individuals. The tone reflects his anxious mood after Philippi.

In the mid-30s he received from Maecenas, as a gift or on lease, a comfortable house and farm in the Sabine hills (identified with considerable probability as one near Licenza, 22 miles [35 kilometres] northeast of Rome), which gave him great pleasure throughout his life. After Octavian had defeated Antony and Cleopatra at Actium, off northwest Greece (31 BC), Horace published his *Epodes* and a second book of eight *Satires* in 30–29 BC. Then, while the victor, styled Augustus in 27 BC, settled down, Horace turned, in the most active period of his poetical life, to the *Odes*, of which he published three books, comprising 88 short poems, in 23 BC. Horace, in the *Odes*, represented himself as heir to earlier Greek lyric poets but displayed a sensitive, economical mastery of words all his own. He sings of love, wine, nature (almost romantically), of friends, of moderation; in short, his favourite topics. Some of the *Odes* are about Maecenas or Augustus: although he praises the ancient Roman virtues the latter was trying to reintroduce, he remains his own master and never confines an ode to a single subject or mood. At some stage Augustus offered Horace the post of his private secretary, but the poet declined on the plea of ill health. Notwithstanding, Augustus did not resent his refusal, and indeed their relationship became closer.

Themes of the *Odes*

The last ode of the first three books suggests that Horace did not propose to write any more such poems. (He was possibly disappointed with their reception following publication in 23 BC.) The last of his epistles (in Book II, published 20–19 BC)—literary "letters" that were more mature and profound versions of the *Satires*—certainly announces an abandonment of "frivolous" lyric poetry for this more moralistic kind of verse. Very shortly afterward, he set to work on three further epistles (much longer than any in the first book), all relating in different ways to poetic activities. In these, Horace abandoned all satirical elements for a sensible, gently ironical stance, though the truisms praising moderation are never dull in his hands. Two epistles comprise a second book, and the third, the *Epistles to the Pisos*, was also known, at least subsequently, as the *Ars poetica*. These last three epistles embody literary criticism in a loose, conversational frame, the "Epistle to Florus" (Book II, Epistle 2) choosing to explain why Horace abandoned lyric poetry for "philosophy." The best poems, Horace thought, edify as well as delight; the secret of good writing is wisdom (implying goodness); the poet needs teaching and training to give of his best. The "Epistle to Florus" may have been written in 19 BC, the *Ars poetica* (consisting of nearly 30 maxims for young poets' guidance) in *c.* 19–18 BC, and the last epistle of Book I in 17–15 BC. This last named is dedicated to Augustus, from whom there survives a letter to Horace in which the Emperor complains of not having received such a dedication hitherto. In the last epistle contemporary poetry is asserted against Rome's earlier literary background, but this was doubtless a defense of Horatian methods.

Poet laureate

By this time Horace was virtually in the position of poet laureate, and in 17 BC he composed the *Secular Hymn* (*Carmen saeculare*) for ancient ceremonies called the Secular Games, which Augustus had revived to provide a solemn, religious sanction for the regime and, in particular, for his moral reforms of the previous year. The hymn was written in a lyric metre, Horace having resumed his compositions in this form; he next completed a fourth book of 15 *Odes*, mainly of a more serious (and political) character than their predecessors. The latest of these poems belongs to 13 BC. In 8 BC Maecenas, who had been less in Augustus' counsels during recent years, died. One of his last requests to the Emperor was: "Remember Horace as you would remember me." A month or two later, however, Horace himself died, after naming Augustus as his heir. He was buried on the Esquiline Hill near Maecenas' grave.

During the latter part of his life, Horace had been accustomed to spend the spring and other short periods in Rome, where he appears to have possessed a house. He would winter sometimes by the southern sea and spent much of the summer and autumn at his Sabine farm or sometimes at Tibur (Tivoli) or Praeneste (Palestrina), both a little east of Rome. A short "Life of Horace," of which the substance apparently goes back to Suetonius, a biographer of the 2nd century AD, quotes a jocular letter he received from Augustus, from which it emerges that the poet was short and fat. He himself confirms his short stature and, describing himself at the age of about 44, states that he was gray before his time, fond of sunshine, and irritable but quickly appeased.

Influences, personality, and impact. To a modern reader, the greatest problem in Horace is posed by his continual echoes of Latin and, more especially, Greek forerunners. The echoes are never slavish or imitative and are very far from precluding originality. For example, in one of his satires Horace wrote what looks at first like a

realistic account of a journey made to Brundisium (Brindisi, on Italy's "heel") in 37 BC. Two of the incidents, however, prove to have been lifted—and cleverly adapted—from a journey by the earlier Latin satirist Lucilius. Often, however, Horace provides echoes that cannot be identified since the works he was echoing have disappeared, though they were recognized by his readers.

Another disconcerting element is provided by Horace's own references to his alleged models. Very often he names as a model some Greek writer of the antique, preclassical, or classical past (8th–5th centuries BC), whom he claims to have adapted to Latin, notably, Alcaeus and Archilochus and Pindar. Yet his style of writing is much nearer to that of the more "modern," refined, and scholarly Greek writers of the Hellenistic, Alexandrian period (3rd and 2nd centuries BC), though to these (as to certain important Latin predecessors) his acknowledgments are selective and inadequate.

If this continuous relationship with the literary tradition is borne in mind, together with certain other factors that preclude wholly direct expression, such as the political autocracy of the time and Horace's own detached and even evasive personality, then it does become possible, after all, to deduce from his poetry certain conclusions about his views, if not about his life. The man who emerges is kindly, tolerant, and mild but capable of strength; consistently humane, realistic, astringent, and detached, he is a gentle but persistent mocker of himself quite as much as of others.

Character and attitudes

His attitude to love, on the whole, is flippant; without telling the reader a single thing about his own amorous life, he likes to picture himself in ridiculous situations within the framework of the appropriate literary tradition—and relating, it should be added, to women of Greek names and easy virtue, not Roman matrons or virgins. To his male friends, however—the men to whom his *Odes* are addressed—he is affectionate and loyal, and such friends were perhaps the principal mainstay of his life. The gods are often on his lips, but, in defiance of much contemporary feeling, he absolutely denied an afterlife. So "gather ye rosebuds while ye may" is an ever-recurrent theme, though Horace insists on a Golden Mean of moderation—deploring excess and always refusing, deprecating, dissuading.

Some of his modern admirers see him as the poet of the lighter side of life; others see him as the poet of Rome and Augustus. Both are equally right, for this balance and diversity were the very essence of his poetical nature. But the second of these roles is, for modern readers, a harder and less palatable conception, since the idea of poetry serving the state is not popular in the West—and still less serving an autocratic regime, which is what Horace does. Yet he does it with a firm, though tactful, assertion of his essential independence. Not only is he unwilling to become Augustus' secretary, but, pleading personal inadequacy, he also gracefully sidesteps various official, grandiose, poetic tasks, such as the celebration of the victories of Augustus' admiral Agrippa. And he refers openly to his own juvenile military service against the future Augustus, under Brutus at Philippi. He himself ran away—he characteristically says—and threw away his shield. But that, equally characteristically, turns out to be copied from a Greek poet, indeed from more than one. It is not autobiography; it is a traditional expression of the unsuitability of poets—and of himself—for war. The whole poem absolves Horace of any possible charge of failing, because of his current Augustan connections, to maintain loyalty to his republican friends.

Attitude toward the Augustan regime

Horace's intellectual formation had to a large extent been completed before the Augustan regime began; yet he came to admire Augustus sincerely and deeply, owing him many practical benefits. But, above all, he deeply admired him for ending a prolonged, nightmare epoch of civil wars. So great was that achievement that Horace, at least, had no eye for any crudities the new imperial regime might possess. This was one of the ages when people wanted order more than liberty, though Augustus was an adept at investing his new order with a sufficient respect for personal freedom and a sufficient facade of republican institutions to set most men's minds at rest. He also restored the temples, and to Horace, though he probably did not believe in the gods whose names he called upon, the religious traditions and rituals of the Roman state seemed an integral, venerable part of Rome's greatness. The Emperor was on more delicate ground when he sought, by social legislation, to purify personal morals and to protect and revive the Roman family. But here, too, Horace, in spite of his own erotic frivolity, was with him, perhaps because of the famous austerity of his Sabine stock. And so the *Secular Hymn* contains a specific allusion (poetically not altogether successful) to these reforms.

Yet, before the hymn, Horace had already written the magnificent *Roman Odes,* numbers one to six of Book III—a great tribute to Augustus' principate, perhaps the greatest political poetry that has ever been written. But these *Odes* are by no means wholly political, for much other material, including abundant Greek and Roman mythology, is woven into their dense, compact, resplendent texture. This cryptic, riddling sonority is the work of a poet who saw himself as a solemn bard (*vates*), a Roman reincarnation of Pindar of Thebes (518–438 BC), a stately Greek lyricist. Pindar increasingly becomes Horace's model in the further state odes of his fourth and last book.

Horace's influence on posterity

After Horace's *Secular Hymn*, his works were known and appreciated by all educated Romans. Already at the time of Horace's death, his *Odes* were suffering the fate he deprecated for them and had become a school textbook. But their excellence was so great that they had few ancient lyrical successors, until some early Christian writers—Ambrose, Prudentius, and Paulinus—occasionally echoed Horace's forms, though with a difference in spirit. Thereafter, the medieval epoch had little use for the *Odes*, which did not appeal to its piety, although his *Satires* and *Epistles* were read because of their predominantly moralistic tones. The *Odes* came into their own again with the Renaissance and, along with the *Ars poetica*, exerted much influence on Western poetry through the 19th century. The English Victorian poet Alfred, Lord Tennyson, hailed the lines of the *Odes* as:

> Jewels five-words-long
> That on the stretch'd forefinger of all Time
> Sparkle for ever.

The many-facetted intricacy of these "jewels" has challenged translators throughout the centuries; in spite, or because, of their not wholly conquerable problems, every ode has been translated hundreds—perhaps thousands—of times. And still new versions, some of them admirable, continue to appear.

MAJOR WORKS

Among Horace's earlier poems, the following may be found particularly interesting: *Satires*, Book 1, fifth, sixth, and ninth satires; Book 2, sixth, seventh, and eighth satires; *Epodes*, ninth and 16th. Most of the *Odes* and *Epistles* are important. For a selection of translations of various epochs, see Michael Grant (ed.), *Roman Readings,* pp. 180–221 (1958, reprinted 1967); and for the *Odes, The Odes of Horace,* trans. by James Michie (1963).

BIBLIOGRAPHY. EDWARD FRAENKEL, *Horace* (1957, paperback 1966), is a fundamental work. GORDON W. WILLIAMS, *Tradition and Originality in Roman Poetry* (1968), and his shorter book *The Nature of Roman Poetry* (1970), deal extensively with Horace in an illuminating fashion. Other recent general studies are KENNETH J. RECKFORD, *Horace* (1969); and ANTONIO LA PENNA, *Orazio e la morale mondana europea* (1968). DAVID A. WEST, *Reading Horace* (1967), analyzes individual poems.

Hormone

Hormones are organic substances that are secreted by plants and animals and that function in the regulation of physiological activities and in the maintenance of a constant internal environment (homeostasis). They carry out their functions by evoking responses from specific organs or tissues that are adapted to react to minute quantities of them. The classical view of hormones is that they are transmitted to their targets in the bloodstream after discharge from the glands that secrete them. This mode of discharge (directly into the bloodstream) is called endocrine secretion. The meaning of the term hormone has been extended beyond the original definition of a blood-borne secretion, however, to include similar regulatory substances that are distributed by diffusion across cell membranes instead of by a blood system.

The hormones of vertebrate and invertebrate animals and of plants are characterized in this article. Comparative discussions of the hormone-producing (endocrine) glands of animals are found in ENDOCRINE SYSTEMS. The article ENDOCRINE SYSTEM, HUMAN deals with the endocrine system of man. The consequences of abnormal hormonal function in man are dealt with in ENDOCRINE SYSTEM DISEASES AND DISORDERS.

This article is divided into the following sections:

I. General features of hormones

RELATIONSHIPS BETWEEN ENDOCRINE AND NEURAL REGULATION

Hormonal regulation is closely related to that exerted by the nervous system, and the two processes have generally been distinguished by the rate at which each causes effects, the duration of these effects, and their extent; *i.e.*, the effects of endocrine regulation may be slow to develop but prolonged in influence and widely distributed through the body, whereas nervous regulation is typically concerned with quick responses that are of brief duration and localized in their effects. Advances in knowledge, however, have modified these distinctions.

Neurohormones

Nerve cells are secretory, for responses to the nerve impulses that they propagate depend upon the production of chemical transmitter substances, or neurohumors, such as acetylcholine and noradrenaline (norepinephrine), which are liberated at nerve endings in minute amounts and have only a momentary action. It now has been established, however, that certain specialized nerve cells, called neurosecretory cells, can translate neural signals into chemical stimuli by producing secretions called neurohormones. These secretions, which are often polypeptides (compounds similar to proteins but composed of fewer amino acids), pass along nerve-cell extensions, or axons, and are typically released into the bloodstream at special regions called neurohemal organs, where the axon endings are in close contact with blood capillaries (Figure 1A). Once released in this way, neurohormones function in principle similar to hormones that are transmitted in the bloodstream and are synthesized in the endocrine glands.

The distinctions between neural and endocrine regulation, no longer as clear-cut as they once seemed to be, are further weakened by the fact that neurosecretory nerve endings are sometimes so close to their target cells that vascular transmission is not necessary (Figure 1B). There is good evidence that hormonal regulation occurs by diffusion in plants and (although here the evidence is largely indirect) in lower animals (*e.g.*, coelenterates), which lack a vascular system.

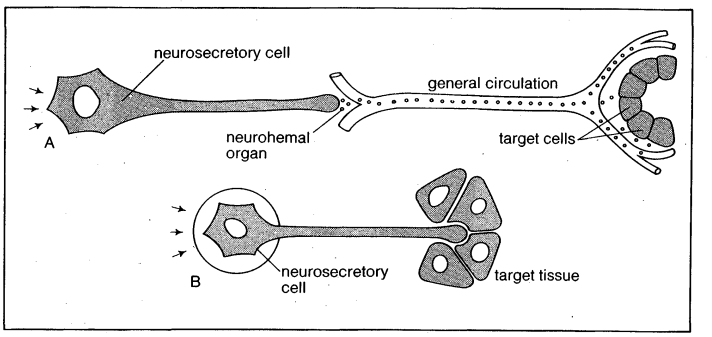

Figure 1: The release of neurohormones from neurosecretory nerve cells.
(A) Nerve signals (arrows) are translated into neurohormones, which enter the circulation at the neurohemal organ, reaching target cells via the bloodstream. (B) Release of neurohormone close to target cells without intervention of bloodstream.

THE EVOLUTION OF HORMONES

Hormones have a long evolutionary history, knowledge of which is important if their properties and functions are to be understood. Many important features of the vertebrate endocrine system, for example, are present in the lampreys and hagfishes, modern representatives of the primitively jawless vertebrates (Agnatha), and these features were presumably present in fossil ancestors that lived more than 500,000,000 years ago. The evolution of the endocrine system in the more advanced vertebrates with jaws (Gnathostomata) has involved both the appearance of new hormones and the further evolution of some of those already present in agnathans; in addition, extensive specialization of target organs has occurred to permit new patterns of response.

Role in chemical regulation

The factors involved in the first appearance of the various hormones is largely a matter for conjecture, although hormones clearly are only one mechanism for chemical regulation, diverse forms of which are found in living things at all stages of development. Other mechanisms for chemical regulation include chemical substances (so-called organizer substances) that regulate early embryonic development and the pheromones that are released by social insects as sex attractants and regulators of the social organization. Perhaps, in some instances, chemical regulators including hormones appeared first as metabolic by-products. A few such substances are known in physiological regulation: carbon dioxide, for example, is involved in the regulation of the respiratory activity of which it is a product, in insects as well as in vertebrates. Substances such as carbon dioxide are called parahormones to distinguish them from true hormones, which are specialized secretions.

II. The hormones of vertebrates

HORMONES OF THE PITUITARY GLAND

The pituitary gland, or hypophysis (Figure 2), which dominates the vertebrate endocrine system, is formed of two distinct components. One is the neurohypophysis, which forms as a downgrowth of the floor of the brain and gives rise to the median eminence and the neural lobe; these structures are neurohemal organs. The other is the adenohypophysis, which develops as an upgrowth from the buccal cavity (mouth region) and usually includes two glandular portions, the pars distalis and the pars intermedia, which secrete a number of hormones. The hormones secreted by the adenohypophysis are protein or polypeptide in nature and vary in complexity; as a result, their chemical constitution has not always been as fully characterized as has that of structurally simpler molecules of some other endocrine secretions. Functional analysis of these hormones also is difficult, for the

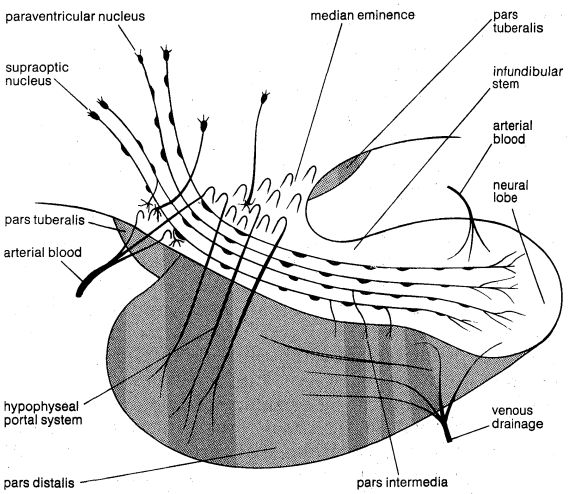

Figure 2: Elements in a generalized mammalian pituitary gland.
From E.J.W. Barrington, *Hormones and Evolution*, p. 29, fig. 4; The English Universities Press Ltd.

targets of certain hormones of the adenohypophysis, called tropic, or trophic, hormones, are other endocrine glands. The action of such tropic hormones can be understood only in the light of the mode of function of the endocrine glands they regulate.

Adenohypophysis. *Growth hormone (somatotropin; STH).* Growth hormone is protein, the primary structure of which has been fully established for the human and bovine forms of the hormone. It is probably universally distributed in gnathostomes (vertebrates with jaws), in which it is essential for the maintenance of growth, but its presence in agnathans (jawless vertebrates) has not yet been established with certainty. The physical and chemical properties of growth hormone (Table 1), which differ from species to species, are associated with marked differences in biological activity. Only part of the molecule, however, is actually responsible for its biological activity, for up to 25 percent of it can be lost without causing any decline in potency. Man responds to growth hormones obtained from other primates, but the rat responds to those from a wide range of species. Even more striking, growth of teleost (bony) fishes, which stops if the pituitary gland is removed, can be restarted by treatment with mammalian growth hormone; on the other hand, preparations of pituitary glands from these fishes have no effect on the growth of mammals. The growth hormones of lungfishes, which are closely related to the terrestrial vertebrates, and of sturgeons, which are primitive members of the evolutiontary line that led to bony fishes, affect mammalian growth, perhaps because these hormones have a more generalized molecular structure.

Table 1: Some Physicochemical Properties of Growth Hormones of Mammals

	human	monkey	bovine	sheep	pig	whale
Molecular weight	21,500	23,000	45,000	47,800	41,600	39,900

Effects of growth hormone

Growth is such a complex process that definition of the growth hormone's mode of action is difficult. One of its known effects is an increase in the rate of protein synthesis, which is to be expected, since growth involves the deposition of new protein material. In addition, growth hormone affects the metabolism of certain ions (including sodium, potassium, and calcium), promotes the release of fats from fat stores, and influences carbohydrate metabolism in ways that tend to cause an increase in the level of glucose in the bloodstream. The last action creates a demand for an increased output of insulin (a hormone secreted by the pancreas), which acts to return the blood-glucose level to normal. Prolonged treatment of dogs with growth hormone can overstrain the pancreatic tissue in which insulin is synthesized and bring about a diabetic condition, in which insulin is formed in inadequate quantities. It is unlikely, however, that this is a factor in establishing diabetes mellitus in man. Excess secretion of growth hormone does, however, have damaging effects in man, for it produces overgrowth of the skeleton. If this occurs in young people, before the closure of the epiphyses (ends) of the long bones, it results in gigantism. If it occurs afterward, it causes acromegaly, in which the disturbance of body form and functioning is more serious, with enlargement of the bones and soft tissues, and consequent distortion of the skull.

Prolactin. Prolactin is a protein hormone that in sheep has a molecular weight of about 23,000 (based on a molecular weight for hydrogen of one). It is doubtful that it is present in agnathans, but it is widely distributed in jawed vertebrates. In female mammals, prolactin initiates and maintains the secretion of milk, the mammary glands having been previously prepared for this function by the action of other hormones. In the female rat prolactin also maintains the secretion of the hormone progesterone, which is formed by the corpus luteum, an endocrine gland of the ovary; *i.e.*, prolactin, termed luteotropin in the rat, is a gonadotropin (see below *Hormones of the reproductive system*) in this animal, because its target is an endocrine gland. Evidence is accumulating that the molecular structures of prolactin and growth hormone are similar. This explains why they show some overlap in biological properties; in particular, administration of prolactin promotes some growth in many terrestrial vertebrates. Human growth hormone has prolactin-like luteotropic properties, and it is not yet certain that man actually has a distinct prolactin hormone.

Prolactin itself shows remarkable variety in biological action from one vertebrate group to another. It promotes the production of so-called crop-milk with which pigeons feed their young, and the associated changes in structure and arrangement of the wall of the crop provide a convenient means to assay the hormone. In certain newts (*Triturus* species) prolactin induces the change of behaviour that drives young animals into the water (water-drive action). In bony fishes, prolactin is concerned with the regulation of the level of sodium in blood plasma; it therefore is essential in some teleost species (*e.g.*, *Poecilia lattipinna*) for the maintenance of life in fresh water. Although other teleosts (*e.g.*, eels) can survive in fresh water after hypophysectomy, this means only that prolactin is but one factor in a complex regulatory mechanism involving several factors. Mammalian prolactin can regulate sodium metabolism when given to eels and can maintain the life of hypophysectomized *Poecilia*. Yet, although other convincing evidence suggests that the hormone must be present in the pituitaries of these teleosts, preparations of their glands tested on pigeons do not have a typical crop-stimulating action. This evidence is best accounted for by supposing that the prolactin molecule has undergone evolutionary changes in its molecular structure and biological properties and has also established specific adaptive relationships with target organs such as the crop and mammary glands.

Adrenocorticotropic hormone (ACTH; corticotropin). ACTH is present in all jawed vertebrates but has not yet been decisively demonstrated in agnathans. It regulates the activity of part of the outer region (cortex) of the adrenal glands (considered below under *Hormones of the adrenal glands*). In mammals its action on the adrenal cortex is limited to areas called the zona reticularis and zona fasciculata, in which important steroid hormones (*e.g.*, cortisol and corticosterone, known as glucocorticoids) are formed; ACTH does not affect the synthesis of the mineralocorticoid hormone aldosterone, which takes place chiefly in the outer cortical region (zona glomerulosa). Evidence strongly suggests that the action of ACTH is mediated by a substance known as CAMP (cyclic 3′,5′-adenosine monophosphate), the rate of synthesis of which

increases in adrenal tissue in the presence of ACTH; cAMP in turn promotes synthesis of enzymes necessary for the formation of cortisol and corticosterone. The relationship between ACTH and the adrenal cortex is an example of the negative feedback characteristic of endocrine systems; *i.e.*, a decrease in the level of glucocorticoids circulating in the bloodstream evokes an increase in the secretion of ACTH, which, by stimulating the secretory activity of its target gland (the adrenal cortex), tends to restore to normal the level of glucocorticoids in the bloodstream. The release of ACTH can also be influenced by the level of circulating adrenaline, which is not surprising in view of the close functional relationship between the hormones of the adrenal cortex and medulla.

Negative feedback

The ACTH of mammals is a polypeptide molecule consisting of 39 amino acids, only the first 20 of which are required for full activity. This region, often referred to as the active centre, is constant in composition in all mammals studied thus far; the remainder of the molecule varies slightly in amino-acid composition among different species. Since, however, the mammalian hormone is active in all vertebrates, ACTH structure probably varies little from one class to another. The concept that biological activity is localized in an active centre of a complex molecule is applicable to other polypeptide and protein hormones, including growth hormone, whose structure, as noted previously, can be partly lost without causing loss of activity. The concept of an active centre, however, raises the question of the function of the rest of the molecule. It may serve as the site of antigenic properties or of structural features important in establishing relations with specialized receptors in target cells.

Thyrotropin (thyroid-stimulating hormone; TSH). Thyrotropin regulates the thyroid gland through a feedback relationship similar to that for ACTH; thyrotropin increases the secretion of the hormones from the thyroid gland and, if its action is prolonged, evokes increase in cell number (hyperplasia) and increase in size of the gland. One consequence of an overactive thyroid in man is a bulging of the eyes (exophthalmos). The cause of this is obscure, although it has been thought to result from the action of a distinct exophthalmos-producing substance that, while closely associated with thyrotropin, can be chemically separated from it. Thyrotropin, which is probably absent from agnathans, is a glycoprotein; *i.e.*, a protein combined with carbohydrate. Its molecular weight is estimated to be about 26,000 to 30,000 in mammals. Some variability occurs in the degree of response obtained when a hormonal preparation from one species is tested on other species. This suggests, as with prolactin, that it has undergone molecular evolution.

Follicle-stimulating hormone (FSH). FSH is termed a gonadotropin because it is concerned with the regulation of the activity of the gonads, or sex organs, which are endocrine glands as well as the sources of eggs and sperm. FSH stimulates development of the graafian follicle, a small vesicle containing an egg, in the ovary of the female mammal; in the male, it promotes the development of the tubules of the testes and the differentiation of sperm. FSH, like thyrotropin, is a glycoprotein, with an estimated molecular weight (in man) of 41,000 to 43,000. The effects of FSH are discussed further in *Hormones of the Reproductive System*, below.

Luteinizing hormone (LH; interstitial-cell-stimulating hormone; ICSH). Luteinizing hormone is another gonadotropin, a glycoprotein with a molecular weight of 26,000 in man. In the female mammal it promotes the transformation, following release of the egg (ovulation), of the graafian follicle into the corpus luteum, an endocrine gland; its complex functional interrelationship with FSH is dealt with below in *Hormones of the reproductive system.* In the male, luteinizing hormone promotes the development of the interstitial tissue (Leydig cells) of the testes and hence promotes the secretion of the male sex hormone, testosterone. In males, luteinizing hormone (LH) may be associated with FSH in promoting the secretion of testosterone. The interrelationship of LH and FSH has made it difficult to establish with certainty that two separate hormones exist, particularly since both are glycoproteins. Although the existence of two hormones has been established in mammals, the situation in lower vertebrates is not yet certain. All vertebrates undoubtedly have gonadotropic activity in their pituitary glands; but, although FSH-like and LH-like effects are detectable, it is not yet clear that two distinct hormones always exist.

An unexpected property of mammalian FSH and LH is that both have a thyrotropic action (*i.e.*, stimulate secretion of thyroid hormones) in lower vertebrates. This so-called heterothyrotropic effect has led to the supposition that FSH, LH, and thyrotropin may have evolved by modification of a common ancestral glycoprotein molecule, resulting in an overlap of properties. Similar examples are pointed out in later sections.

Thyrotropic action of FSH and LH

Melanocyte-stimulating hormone (MSH; intermedin). This hormone, secreted by the pars intermedia region of the pituitary gland, regulates colour changes in animals by promoting the concentration of pigment granules in pigment-containing cells (melanocytes, chromatophores) in the skin of lower vertebrates; MSH acts in conjunction with the nervous system in bony fishes and reptiles. No response involving physiological colour change is found in birds and mammals, although the hormone is secreted by them, even in species in which a pars intermedia region is no longer distinguishable in the adenohypophysis. The reason for the presence of MSH in birds and mammals is not clear since the function of the hormone in these animals has not yet been established. MSH is known to influence the behaviour of mammals and the total amount of pigment in their skin, which darkens in man after administration of large doses of the hormone. This type of change, however, which results from a change in the total amount of pigment present, is called a morphological colour change, in contrast to the physiological one that occurs in the skin of lower vertebrates.

MSH is a polypeptide that exists in two forms. α-MSH contains 13 amino acids, which are found in the same sequence in all species studied thus far; β-MSH has 18 amino acids, in sequences that differ in different species. Remarkable are the facts that the 13 amino acids of α-MSH are identical with the first 13 amino acids of ACTH and that both α and β forms of MSH have a heptapeptide (seven-amino-acid) sequence that has some melanocyte-stimulating activity, and that is identical with an amino-acid sequence of ACTH (see Figure 3). This close correspondence in sequence can hardly be coincidental and suggests, as has been postulated above for FSH, LH,

and thyrotropin, that ACTH and α- and β-MSH may have differentiated within the adenohypophysis by evolutionary modification of a common ancestral molecule. A change in biological activity results from modifications in the amino-acid composition; β-MSH preparations from the pig and the horse, for example, are five times more effective than those of the ox in evoking pigment dispersion in frogs. MSH molecules do not show ACTH activity, which is dependent on the presence of amino acids that occur in the region of the molecule not found in MSH. On the other hand, ACTH does have a slight effect on pigment dispersion, presumably because its structure contains the heptapeptide sequence mentioned above.

Evidence shows that each of the adenohypophysial hormones is secreted by a specific cell type. The cell types can be differentiated by staining sections of the pituitary gland, and known changes in the output of an individual hormone, induced experimentally or correlated with phases in the life cycle, can be shown to correspond with changes in the appearance of the corresponding cell type.

Regulation of adenohypophysial activity

The regulation of the activity of the secretory cells of the adenohypophysis depends upon its association with the floor of the brain and results from the existence of a neurosecretory system located mainly, perhaps entirely, in the hypothalamic region there. Much remains to be learned about this system, which involves the passage into the adenohypophysis of neurosecretions from the hypothalamus called hypothalamic releasing factors. Chemical characterization of these factors shows them to be simple polypeptides, in which respect they resemble the hypothalamic polypeptide hormones (discussed in the next section). This neurosecretory system is best understood in mammals, in which good evidence has been found for the existence of a separate releasing factor for each hormone secreted by the pars distalis region of the adenohypophysis; a similar arrangement probably exists in other gnathostomes. The situation in agnathans is obscure, but the anatomical organization of the pituitary glands of these animals implies at least some form of chemical communication between the hypothalamus and the pituitary gland.

Chemical communication is achieved by two routes. One route is by the entry of neurosecretory-cell fibres from the hypothalamus into the adenohypophysis, so that the hypothalamic factors, when released, are either in immediate contact with the secretory cells (Figure 1B) or in blood capillaries very closely related to them. This route is characteristic of the pars intermedia region, in which neurosecretory fibres from the hypothalamus control the functioning of the secretory cells. If the pars intermedia is separated from its direct connection with the floor of the brain, for example, MSH secretion in amphibians increases, and prolonged darkening of the skin results. Secretory activity of the pars intermedia cannot then be regulated again until the nerve fibres have regenerated.

Direct innervation similar to that of the pars intermedia is also found in the pars distalis of bony fishes. Here neurosecretory fibres arise from a localized region of the hypothalamus, called the nucleus lateralis tuberis, and end in contact either with the various types of secretory cells or with blood capillaries related to them. The other route of chemical communication to the pars distalis is found in many fishes and in all terrestrial vertebrates; it is a vascular route that depends upon the median eminence, which lies at the front end of the neurohypophysis (see Figure 2). The median eminence is a neurohemal organ containing a capillary bed into which hypothalamic neurosecretory fibres discharge their releasing factors. These are then transmitted through blood vessels known as the hypophysial portal system, into the capillaries of the pars distalis, where each factor influences its specific target cells (compare Figure 1A).

Both hypothalamic neurosecretory routes have the same physiological significance; *i.e.*, they provide chemical communication between the adenohypophysis and the central nervous system, thus making it possible for the latter to regulate the activity of the gland (and also of the endocrine glands its tropic hormones influence) in response to the demands of both the internal and external environments. The hypothalamic neurosecretory system is also involved in the function of the negative-feedback mechanisms that regulate the secretion of the tropic hormones. As already mentioned for ACTH, the secretions of tropic hormones from the adenohypophysis are controlled by bloodstream levels of the hormones secreted by their target glands; the hormones of the target glands may act directly on specific adenohypophysial cells or indirectly by influencing the output of releasing factors from the hypothalamus.

Neurohypophysis and the polypeptide hormones of the hypothalamus. Another neurosecretory system, which involves the hypothalamic region of the brain and the neurohypophysis of the pituitary gland, originates in groups of neurosecretory cells in the hypothalamus called, in mammals, the nucleus supraopticus and the nucleus paraventricularis and, in lower vertebrates, the nucleus preopticus. Neurohormones from these regions pass along the axons of the neurosecretory cells to the neural lobe (see Figure 2) bound to a protein called neurophysin (molecular weight of 20,000 to 25,000). In the neural lobe, which is the neurohemal organ of this neurosecretory system, the hormones separate from neurophysin and are released into the bloodstream.

Effects of hypothalamic polypeptide hormones

In most mammals, the neurohormones are oxytocin and arginine vasopressin. Both have relatively simple and very similar molecular structures; each is composed of nine amino acids arranged as a ring, which is formed by the linkage of two molecules of the amino acid cysteine (a disulfide linkage $-S-S-$), and a short side chain Table 2). The two hormones differ in structure only at amino acids numbered 3 and 8. In some species of the family Suidae (pig, peccary, hippopotamus) arginine vasopressin is replaced by lysine vasopressin; in others, both may be present. The difference between the two vasopressin hormones is that one has the amino acid lysine (Lys) at position 8; the other has arginine (Arg). Both the vasopressins and oxytocin show some overlap of activity, which is a consequence of the similarities in their molecular structures. Preparations of the three hormones evoke responses from the mammalian kidney, from the epithelial-cell layer of the frog bladder, and from the smooth muscle in blood vessels, uterus, and milk glands. The slight variation in amino-acid composition, however, affects the levels of the responses; *i.e.*, the vasopressins differ slightly from each other in response, and oxytocin differs markedly from both. Each, therefore, is said to have a characteristic pharmacological spectrum, and all have some medical use.

The primary actions of oxytocin are the promotion of uterine contraction (of value in obstetrical medicine) and the release of milk during suckling. The stimulation exerted upon the nipples during suckling leads to the transmission of nerve impulses to the hypothalamus. These bring about the discharge of oxytocin, which causes contraction of the smooth muscle of the small ducts of the mammary glands and the release of milk. Although the vasopressins cause an increase in blood pressure in mammals through vasoconstriction (*i.e.*, contraction of blood vessels), this action requires a high concentration of hormone and is probably not a normal physiological effect. The primary action of the vasopressins is on the kidneys; it brings about a reduction in the output of urine. As a result arginine vasopressin is commonly called the antidiuretic hormone (ADH). A lack of this hormone in man results in a copious flow of urine, a condition called diabetes insipidus, which is readily alleviated by preparations containing arginine vasopressin from bovine sources.

The antidiuretic action of vasopressin is thought to depend upon its binding to the outer surface of the kidney tubule, resulting in an increase in the uptake of sodium from the urine into the tubule cells and, concurrently, an increase in the uptake of water. The amount of water, however, is greater than can be accounted for merely by increased diffusion of sodium into tubule cells, suggesting that ADH increases either the number of or the size of

pores on the surfaces of the cells. One stimulus that increases the release of vasopressin is a rise in the concentration of certain substances—chloride, for example—in blood plasma. These substances act directly upon the neurosecretory cells, although other receptors may also be involved. Another stimulus is a lowering of plasma volume, which probably acts chiefly through receptors in the vascular system, particularly in the heart and in the carotid blood sinuses. Both conditions necessitate increased retention of fluid; as soon as normal conditions are restored in the bloodstream, the secretion of ADH is reduced by negative feedback.

Origin of hypothalamic hormones

Oxytocin and the vasopressins are members of a series of hormones of which seven members have thus far been fully characterized. The existence of others is suspected (see Table 2). All show the same molecular structure but differ with respect to individual amino acids. The hormones comprising the series are believed to have been derived from each other by changes in genetic material (mutations) that resulted in one amino-acid substitution at a time; the starting point in the series is arginine vasotocin, which is the only one of the series found in agnathans. Two types of molecule are found in gnathostomes —a result, presumably, of a genetic duplication that established two lines of evolution. One line (basic vasopressor principles) is constituted mainly of arginine vasotocin, which is present in all gnathostomes except mammals; amino-acid substitution in the molecule gave rise to the vasopressins of mammals. The second line (neutral oxytocin-like principles) is represented by oxytocin, isotocin, glumitocin, and mesotocin. As shown in Table 2, each evolutionary line tends to have characteristic molecules, however, the molecular history in the second line is not clear. Oxytocin is thought to exist in some lower gnathostomes, and it is not yet certain whether it or mesotocin is phylogenetically the older molecule.

The functions of the hypothalamic polypeptide hormones in lower vertebrates are not yet clear, except to some extent in amphibians, in which arginine vasotocin evokes the so-called Brunn (water-balance) response; that is, water accumulates within the body as a result of a combination of increased water uptake through the skin and the wall of the bladder and decreased urinary output. This response, which also involves the uptake of sodium by the skin, is found only in the more terrestrial members of the Amphibia, in which it is an adaptation that enables them to conserve water. It is not yet known whether or not comparable adaptive specializations are associated with the molecules characteristic of the other groups of lower vertebrates. There is some evidence that hypothalamic polypeptides may be involved in the movements of water and ions (charged particles) in fishes. Changes in the functions of the polypeptide hypothalamic hormones during vertebrate evolution have occurred, partly as a result of evolution of their targets; *e.g.*, water balance in amphibians is mediated by a hormonal molecule that was already present in agnathans and was thus a part of the earliest hormonal endowment of vertebrates.

HORMONES OF THE THYROID GLAND

Biosynthesis. The two thyroid hormones, thyroxine (3,5,3′,5′-tetraiodothyronine) and 3,5,3′-triiodothyronine, are formed by the addition of iodine to an amino-acid (tyrosine) component of a glycoprotein called thyroglobulin. Thyroglobulin is stored within the gland in follicles as the main component of a substance called the thyroid colloid. This arrangement, which provides a reserve of thyroid hormones, perhaps reflects the frequent scarcity of environmental iodine, particularly on land and in fresh water. Iodine is most abundant in the sea, where thyroidal biosynthesis probably first evolved. Although the possibility that the thyroid hormones originated as metabolic by-products is suggested by the widespread occurrence in animals of the binding of iodine to tyrosine, the binding commonly results only in the formation of iodotyrosines, not the thyroid hormones. On present evidence, only the vertebrates and the closely related protochordates have a mechanism to synthesize significant amounts of biologically active thyroid hormones.

The synthesis of thyroid hormones in vertebrates begins with the active uptake by thyroid-gland cells of inorganic iodide circulating in the bloodstream; the inorganic iodide is oxidized (combined with oxygen) during a reac-

Table 2: The Structure and Distribution of the Hypothalamic Polypeptide Hormones of Vertebrates*

Basic Vasopressor Principles

1. Arginine vasotocin

Cys	Tyr	Ile	Gln	Asn	Cys	Pro	Arg	Gly(NH_2)
1	2	3	4	5	6	7	8	9

Exists in all fishes; possibly in all vertebrates, at some stage of development

2. Arginine vasopressin

Cys—Phe—Cys—Arg—|

Exists in most mammals except the pig family

3. Lysine vasopressin

Cys—Phe—Cys—Lys—|

Exists in mammals of the pig family

Neutral Oxytocinlike Principles

4. Oxytocin

Cys—Ile—Cys—Leu—|

Exists in mammals, birds, reptiles, amphibia (?), Dipnoi (?), and holocephalians (?)

5. 8 Ile oxytocin (Mesotocin)

Cys—Ile—Cys—Ile—|

Exists in reptiles, amphibia, and Dipnoi

6. 4 Ser, 8 Ile oxytocin (icthyotocin, isotocin)

Cys—Ile · Ser—Cys—Ile—|

Exists in teleost, holostean, and brachiopterygian fishes

7. 4 Ser, 8 Glu(NH_2) oxytocin (glumitocin)

Cys—Ile · Ser—Cys—Gln—|

Exists in elasmobranch fishes, particularly the skate

8. Unknown elasmobranch oxytocic principle (EOPI) (Val, Ser peptide[s]?).
Exists in *Squalus acanthias* and perhaps other sharks

*Amino acids indicated only by lines are the same as those present in arginine vasotocin.

tion catalyzed by an enzyme (iodide peroxidase). The product of this reaction (active iodine) combines with tyrosine components of the thyroglobulin molecule to form two compounds (3-monoiodotyrosine and 3,5-diiodotyrosine), which then join to form the active hormones. The synthesis of the thyroid hormones is inhibited by certain chemical agents called goitrogens, which reduce the output of thyroid hormones, thereby causing, through negative feedback, an increased output of thyrotropin and hence an enlargement of the thyroid gland (see below). Some goitrogens (*e.g.*, thiocyanates) reduce or inhibit the uptake of iodide; others (*e.g.*, thiourea, thiouracil) inhibit the peroxidase system and thus prevent the binding of iodine to thyroglobulin.

Release of the thyroid hormones into the bloodstream begins when the thyroid cells take up droplets of the stored thyroid colloid. The thyroglobulin in these droplets is then hydrolyzed (broken down in a reaction involving the elements of water) by an enzyme to form both iodotyrosines and the hormones. Normally, only the latter pass out of the cells in significant quantities. The iodine is removed from the iodotyrosines, which are not hormonally active, by an enzyme (deiodinase), and the iodine thus is conserved and used again. The hormones, usually bound to proteins (globulin and albumin) in the bloodstream, where they constitute the protein-bound iodine of the plasma, must be unbound from the proteins before they can function. The iodine is removed from the hormones largely in the liver and in the kidneys, and most of it returns to the thyroid gland, an economy that again emphasizes the need for conservation; some iodine, however, is lost in the alimentary tract.

Conservation of iodine

Synthesis of the thyroid hormones is regulated by the level of circulating hormones (*i.e.*, a negative-feedback mechanism) operating, as indicated earlier, partly by direct action on the thyrotropin-secreting cells of the pituitary gland and partly by indirect action on the hypothalamus and its thyrotropin-releasing factor. Thyrotropin attaches to the cells of the thyroid gland and may exert its effect by stimulating cAMP synthesis. It causes resorption of thyroid colloid and increases the rates of both glucose metabolism and protein synthesis as secretion of thyroid hormones increases in response to it. After the thyroid gland of the rat has been under thyrotropin stimulation for two or three hours, an increase in the size of the cells of the gland occurs, along with an increase in iodide uptake into them; prolonged thyrotropin action causes a marked enlargement of the gland (goitre), which in man may become externally apparent as a swelling. Goitres, which are of various types, result from a negative-feedback reaction that attempts to maintain output from the thyroid gland.

Effects. One established effect of the thyroid hormones in mammals is an increase in metabolic rate and in oxygen consumption, but the effects of the hormones undoubtedly are more wide-ranging than this. On the one hand, impairment of the thyroid function in mammals results in disturbances in the processes of growth and maturation. Both growth and maturation disturbances occur in the cretinous dwarfism resulting from thyroid deficiency in newborn infants; on the other hand, the metabolic effect is not apparent in lower vertebrates (*e.g.*, fish), even though treatment of these animals with thyroid hormones promotes an increase in the growth rate, provided pituitary growth hormone is also secreted. In addition, evidence suggests that, in lower vertebrates, the thyroid hormones are active during moments of stress in the life cycle (*e.g.*, migration and reproduction) and affect the activity of the central nervous system. Disturbance of thyroid output also affects reproduction in mammals, impairing the functioning of the ovary, for example, and causing irregularities of the ovarian cycle.

Effects of thyroid hormones on frog metamorphosis

The complex effects of thyroid hormones are well documented in the metamorphosis, or change in body form, of the amphibian tadpole into a frog. Metamorphosis, which involves a diversity of integrated morphological and biochemical changes, requires the presence of the thyroid gland and depends upon a delicate balance between the changing output of its hormones and changing sensitivities of the target tissues. Studies involving the tail of the frog tadpole show that the thyroid hormones directly promote the formation of the enzymes needed for reduction of the tail and suggest that the diverse effects produced in vertebrates by the thyroid hormones might depend upon their capacity to regulate protein metabolism, in which case the target cells would have to be adapted to respond by appropriate patterns of enzyme synthesis.

Ultimobranchial tissue and calcitonin. The discovery of calcitonin (thyrocalcitonin) in 1961 demonstrated the importance of comparative studies in endocrinology. It originally had been thought that this hormone, which is present in preparations made from mammalian thyroid glands, was secreted by the parathyroid glands, which in some species are combined with the thyroid gland. Later, the hormone was concluded to be a secretion of the thyroid gland itself. In fact, calcitonin is not a product of either of them. Its actual source is the ultimobranchial tissue, represented in vertebrates from fishes upward by the ultimobranchial gland, which develops from the hinder part of the pharynx. Ultimobranchial tissue is the source of distinctive cells (called light, C, or parafollicular cells), which are found in the thyroid gland of mammals; in birds, however, the ultimobranchial gland is separate, thus making it possible to remove the gland and to show that it is the source of the hormone. The molecular structure of hog calcitonin is that of a polypeptide, containing 32 amino acids and having a molecular weight of about 3,600. The calcitonin of the salmon, which is more potent than that of the pig, has the same number (but some different types) of amino acids, and the molecular weight is 3,427.

Effects of calcitonin

Calcitonin lowers the level of calcium in the blood (hypocalcemic action) when it rises above the normal level. Its secretion probably is regulated by a negative-feedback relationship between the gland and the blood plasma. The hormone affects bone, which is an active tissue. It undergoes not only growth but also remodelling as it adapts to the changing patterns of stress to which it is subjected; its calcium exchanges continuously with that of the plasma. The effect of calcitonin is to decrease the mobilization (resorption) of calcium from the skeleton into the blood plasma. In this respect, as is discussed in the next section, it is opposite in direction to the effect of parathormone of the parathyroid glands. Little is known of the action of calcitonin in the lower vertebrates, but its presence in fish raises interesting functional problems. Elasmobranch fishes (*e.g.*, sharks) lack bone, and many bony fishes have a type of bone that cannot be remodelled; the hormone, therefore, cannot act in these vertebrates as it does in higher ones. It is possible that in these fishes the hormone may control the level of plasma calcium by regulating its movement across cell membranes.

PARATHORMONE OF THE PARATHYROID GLANDS

The parathyroid glands, which are found only in terrestrial vertebrates (amphibians, birds, reptiles, and mammals), develop from certain pharyngeal pouches, which are embryonic remnants of the gill slits of fish. The parathyroid glands secrete a hormone called parathormone (PTH), which is a polypeptide of variable amino-acid composition. PTH, which consists of 83 to 85 amino acids in the human, regulates calcium metabolism in conjunction with calcitonin; its evolution in terrestrial vertebrates may have been an adaptation to the increased demand for continuous skeletal adjustments imposed by the evolution of terrestrial locomotion. Skeletal adjustments must be made without disturbing the delicate calcium balance of the rest of the body, for calcium is involved in maintaining the transport of substances through cell membranes; hence, it has an important role in muscle contractility, excitability of motor end plates in the nervous system, and coagulation of blood.

Removal of the parathyroid glands in mammals causes a fall in the level of calcium in the blood plasma, which, if sufficiently severe, is accompanied by convulsions and other symptoms resulting from increased excitability of the motor nerves. These symptoms can be corrected by

injection of appropriate preparations of parathyroid glands. The activity of the glands, like that of the ultimobranchial tissue, is regulated by negative feedback; *i.e.*, lowering of the plasma calcium level increases the output of parathormone (but decreases the output of calcitonin). The hypercalcemic effect (*i.e.*, increase in level of blood calcium) of the hormone depends largely upon its action on bone, since it promotes the transfer of calcium from this tissue into the plasma, probably by a direct action on the active bone-forming cells (osteocytes). In addition, however, parathormone promotes the formation of new bone tissue, and thus also increases its metabolic activity and the turnover of its structural material. Other effects of parathormone, at least in part, contribute to the elevation of plasma calcium; *i.e.*, PTH increases both the absorption of calcium by the intestine and its resorption by the kidney tubule. Since, however, the hypercalcemia induced by the hormone results in more of it passing into the kidney tubule, the net result may be increased excretion of calcium despite the increased resorption. Other actions of the hormone, less easy to relate to its well-defined influence upon calcium metabolism, include a regulatory influence upon the level of magnesium in blood plasma and upon the rate of removal of phosphate from urine.

In general, therefore, the action of parathormone is opposite in direction to that of calcitonin. Parathormone keeps the level of blood calcium up to its normal value; on the other hand, calcitonin ensures, through its hypocalcemic action, that the level does not rise far above this critical point. The combined actions of the two hormones serve to illustrate the importance of endocrine regulation in homeostasis. Vitamin D is a third factor in calcium regulation; its absence in young children results in skeletal malformations (rickets). Parathormone is unable to regulate the absorption and mobilization of calcium in the absence of vitamin D, which is also associated with the hormone in promoting mobilization of magnesium from bone and perhaps in the movement of phosphate within the kidney tubule.

Role of vitamin D in calcium regulation

HORMONES OF THE PANCREAS

Insulin. The vertebrate pancreas contains, in addition to the zymogen cells that secrete digestive enzymes, groups of endocrine cells called the islets of Langerhans. Certain of these cells (the B, or beta, cells) secrete the hormone insulin, inadequate production of which is responsible for the condition called diabetes mellitus. Insulin and the characteristic B cells are present in gnathostomes and in agnathans; in the latter, however, the islet cells are not associated with zymogen cells to form a typical pancreas. Insulin is a polypeptide molecule composed of two chains of amino acids, an A chain of 21 amino acids containing an intrachain disulfide linkage (— S — S —) and a B chain of 30 amino acids. The two chains are linked by two other disulfide linkages, the destruction of which destroys the activity of the molecule. It is thought that the molecule first appears in the B cell as a single-chain compound called proinsulin, which is disrupted by an enzyme-catalyzed reaction to form the two chains of the active hormone. As with other polypeptide hormones, extensive variation in amino-acid composition of the molecule occurs among different species, with the differences tending to be greater between the more widely separated species—*e.g.*, between fish and mammal. The variations in amino-acid composition have little effect on the biological activity of the molecules, but certainly influence their immunological reactions; this suggests that the two properties depend on the amino-acid sequences at different parts of the molecule.

Injection of insulin lowers blood-sugar (glucose) levels, but this so-called hypoglycemic effect is only one expression of the wide-ranging influence of insulin on storage and mobilization of energy, in which the target tissues of primary importance are muscle, adipose (fat) tissue, and liver. The actions of insulin on these tissues are varied. First, it promotes the use of the sugar glucose as an energy source; at the same time, it encourages the storage of excess carbohydrate as glycogen, the storage carbohydrate of animals. Second, insulin reduces the use of fat as an energy source and promotes its storage. Third, it reduces the use of protein as an energy source and promotes the formation of proteins from amino acids.

Insulin probably acts on carbohydrate metabolism in muscle by increasing the ability of glucose to pass through the muscle-cell membranes. This effect depends on a specific interaction between the cell membrane and the hormone; although the same effect occurs in adipose (fat) tissue, it does not occur either in the liver or in the central nervous system, despite the latter's complete dependence upon glucose for its energy supply. After the entry of glucose into a muscle cell, phosphate is added to the molecule, and two compounds form in succession, first glucose-6-phosphate, then glucose-1-phosphate; after these reactions, the metabolism of glucose is probably aided by two secondary actions of insulin (see also METABOLISM). The hormone stimulates the synthesis of an enzyme (glycogen synthetase), thus promoting the transformation of glucose-1-phosphate into glycogen; it also aids in the breakdown of glucose, thus providing energy to the cell. All of these effects contribute to the hypoglycemic (blood-glucose-lowering) action of the hormone. Insulin has other effects on muscle cells—it slows the breakdown of fat and increases the formation of proteins from amino acids. Insulin affects carbohydrate and protein metabolism in adipose tissue much as it does in muscle and also promotes storage of fat.

Effects of insulin in liver

The action of insulin in liver differs from that in muscle in that it has no direct influence upon the transport of glucose into liver cells; probably, however, insulin promotes the metabolism of glucose within liver cells in much the same way that it does in those of muscle, resulting in increased uptake of glucose from the bloodstream. In addition, insulin decreases gluconeogenesis (the formation of glucose in the liver from amino acids and other noncarbohydrate sources). The combination of these various effects causes a decrease in the level of blood glucose. Other actions of the hormone upon the liver include, as in adipose tissue, increases in fat deposition and in protein synthesis.

The diverse effects of insulin apparently are adaptively linked to regulating the storage and release of energy, but it is difficult to judge whether or not all of the effects result from a single mode of action of the hormone. The interaction of insulin with the muscle-cell membrane suggests that all of its effects might be produced by similar interactions between it and membranes within cells. The mechanism, however, has not yet been established with certainty.

The B cells of the islets of Langerhans respond directly through negative feedback to the level of glucose in the blood that reaches them; *i.e.*, an increase in blood glucose above the normal level (80 to 100 milligrams per 100 millilitres in man) brings about increased synthesis and release of insulin with the result that the level of blood glucose falls. As a consequence, the rate of insulin output then decreases. This, however, is only part of the complex hormonal mechanism that regulates carbohydrate metabolism. Another factor is the hormone glucagon, which is secreted in the islets of Langerhans by a second cell type, the A (alpha, or A_2) cells. (The function of a third type, the D (gamma, or A_1) cells, has not yet been established.)

Glucagon. Glucagon, which is present in gnathostomes but absent from agnathans, is a polypeptide molecule consisting of 29 amino acids. It strongly opposes the action of insulin, primarily through a hyperglycemic (blood-glucose-raising) effect that results from its promotion of the breakdown of glycogen (glycogenolysis) in the liver, a process that results in the formation of glucose. Glucagon exerts its action by increasing the availability of the enzyme required for the reaction by which glucose units are released from the glycogen molecule. It also reduces the rate of synthesis of glycogen, promotes the breakdown of protein, promotes the use of fat as an energy source, and evokes increased glucose uptake by muscle cells. The last effect, however, may be a

consequence of hyperglycemia induced by the increased secretion of insulin.

Another form of glucagon, called gastrointestinal glucagon, is secreted into the blood when glucose is ingested. Its only action appears to be to stimulate insulin secretion, an effect that may provide information to the islet cells of the pancreas about the entry of glucose into the bloodstream. It is also possible that pancreatic glucagon, which is secreted in the islets by the A cells, may directly stimulate the release of insulin from the adjacent B cells without actually entering the bloodstream.

Other hormones that affect insulin release

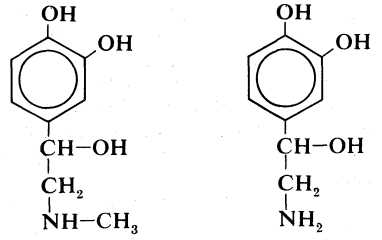
A number of other hormones also influence the release of insulin, mainly through their own actions upon blood-sugar levels. Growth hormone, thyroxine, adrenaline, and cortisol, for example, may increase insulin release because they can promote a rise in blood sugar through effects upon carbohydrate metabolism. In addition, growth hormone and cortisol can probably act directly upon the B cells.

The complexity and delicacy of the control of metabolism by insulin and other hormones in mammals illustrate again the importance of homeostasis, the control of which may not be as well organized in the lower vertebrates. Some of the responses in mammals, however, do occur in lower forms; for example, removal of pancreatic islet tissue from fishes produces hyperglycemia. Thyroxine induces hyperglycemia in amphibians, and corticosteroids promote gluconeogenesis in them. Far more information is needed, however, before the evolution of these remarkable regulating mechanisms can be determined.

HORMONES OF THE ADRENAL GLANDS

Chromaffin tissue of the medulla. The adrenal gland of mammals is composed of an outer region, the cortex, which consists of adrenocortical tissue that secretes steroid hormones (steroids are fat-soluble organic compounds), and an inner region, the medulla, which is composed of chromaffin tissue, so called because its cells contain granules that can be characteristically coloured by certain reagents. Chromaffin tissue secretes two hormones, adrenaline (epinephrine) and noradrenaline (norepinephrine), which are members of a class of compounds called catecholamines. Both chromaffin and adrenocortical tissues are present in gnathostomes and probably in agnathans (although the evidence on the latter point is not yet decisive), but the tissues vary in the degree to which they are associated, being completely separated in elasmobranch fishes.

Noradrenaline and adrenaline are each composed of a benzene ring containing two hydroxyl ($-OH$) groups and an amine (NH_2-containing) side chain (Figure 4).



adrenaline (epinephrine) noradrenaline (norepinephrine)

Figure 4: The structures of noradrenaline and adrenaline.

During the synthesis of these hormones, a sequence of enzyme-catalyzed reactions in the chromaffin granules of the secretory tissue transforms tyrosine into a compound commonly called dopa (dihydroxyphenylalanine), which then forms dopamine; dopamine then is hydroxylated (*i.e.*, an $-OH$ group is added) to form noradrenaline. Adrenaline is formed from noradrenaline by methylation (the addition of a methyl, or $-CH_3$, group), a reaction that occurs outside the granules of the chromaffin cells. Noradrenaline (but not adrenaline) is also formed in certain neurons (nerve cells), where it functions as one of the chemical transmitter substances.

After their release, both hormones are so rapidly metabolized that they probably remain in the bloodstream only for a few seconds. The first step in the breakdown, which usually occurs in the liver and kidneys, is methylation of one of the hydroxyl groups of the benzene ring; the products (metanephrine or normetanephrine), or compounds derived from them, are excreted in the urine. Small quantities (about 2 to 5 percent of the daily secretion of the gland in man) of nonmetabolized hormones are also found in the urine.

Effects of noradrenaline and adrenaline

Adrenaline and noradrenaline evoke diverse and widespread responses but differ from each other in certain of their effects (see Table 3 for their effects on man). Both influence the heart and blood vessels in ways which, although opposed to each other in a few respects, generally result in an increase in blood pressure and in output of blood from the heart. Both hormones also have metabolic actions; adrenaline, for example, like glucagon, stimulates glycogenolysis (breakdown of glycogen to glucose) in the liver, thus raising the level of blood sugar, and also increases oxygen consumption and the output of blood from the heart, probably contributing thereby to the regulation of body temperature in mammals. Adrenaline has effects upon the nervous system, recognizable subjectively in man by feelings of anxiety and of increased mental alertness.

Table 3: Effects of Adrenaline and Noradrenaline in Man

	adrenaline	noradrenaline
Heart rate	increase	decrease
Cardiac output	increase	variable
Total peripheral resistance	decrease	increase
Blood pressure	rise	greater rise
Respiration	stimulates	stimulates
Skin vessels	constriction	less constriction
Muscle vessels	dilation	constriction
Bronchus	dilation	less dilation
Eosinophil count	increase	no effect
Metabolism	increase	slight increase
Oxygen consumption	increase	no effect
Blood sugar	increase	slight increase
Central nervous system	anxiety	no effect
Uterus in late pregnancy	inhibits	stimulates
Kidney	vasoconstriction	vasoconstriction

Source: G.H. Bell, J.N. Davidson, and H. Scarborough, *Textbook of Physiology and Biochemistry*, 7th ed., 1968.

The chromaffin tissue is closely related to the sympathetic nerves of the autonomic nervous system, which innervates the components of circulation and digestion and controls their involuntary functions; in fact, the two may be said to form a sympatheticochromaffin complex. It is generally assumed that this complex acts to increase the capacity of the animal for effective action in emergencies. At such times, cardiac output increases, blood is distributed with maximum effectiveness, respiration is enhanced, and the nervous system is stimulated. The sympathetic nerves initiate these reactions and directly promote the release of adrenaline and noradrenaline because these nerves directly innervate the chromaffin cells. The hormones are thus able to develop and prolong an integrated set of responses; noradrenaline functions both as a neurohumor chemical transmitter of the sympathetic nervous system and also as a hormone of the chromaffin tissue.

The fact that adrenaline and noradrenaline, which have very similar structures (see Figure 4), can exert different actions is probably in part a consequence of the specialization of their target tissues. It has been suggested that the target tissues possess two different kinds of receptors, the alpha type, which responds to noradrenaline, and the beta type, which responds to adrenaline. Evidence for this theory is that adrenaline has a vasodilator effect (*i.e.*, it expands blood vessels), which can be blocked by certain drugs, and noradrenaline has an opposing vasoconstrictor effect, which can be blocked by other drugs.

The actions of both hormones are thought to be mediated by cAMP; alpha responses are associated with reduced synthesis of this mediator and beta ones with increased synthesis.

The interpretation of the function of these hormones in mammals has not yet been established as applicable to lower vertebrates in which the hormones are present, but they are known to influence metabolism and heartbeat in some genera. It is possible that in early stages of vertebrate evolution, the sympatheticochromaffin complex evoked more generalized physiological responses than it now does and that more precise action developed in mammals as part of their high level of homeostatic organization. Laboratory studies show that even in mammals the complex is not essential for life; animals from which it has been removed, however, are much less able to resist environmental stresses than are those whose complex is functional.

Adrenocortical tissue of the cortex. The adrenocortical tissue develops from coelomic epithelium (a cell layer surrounding the body cavity, or coelom). In this respect it resembles the endocrine tissue of the gonads, a resemblance emphasized by the fact that both the adrenocortical hormones (corticoids) and the sex hormones are steroids produced by similar metabolic pathways (the structures of some steroid hormones are found in Figure 5).

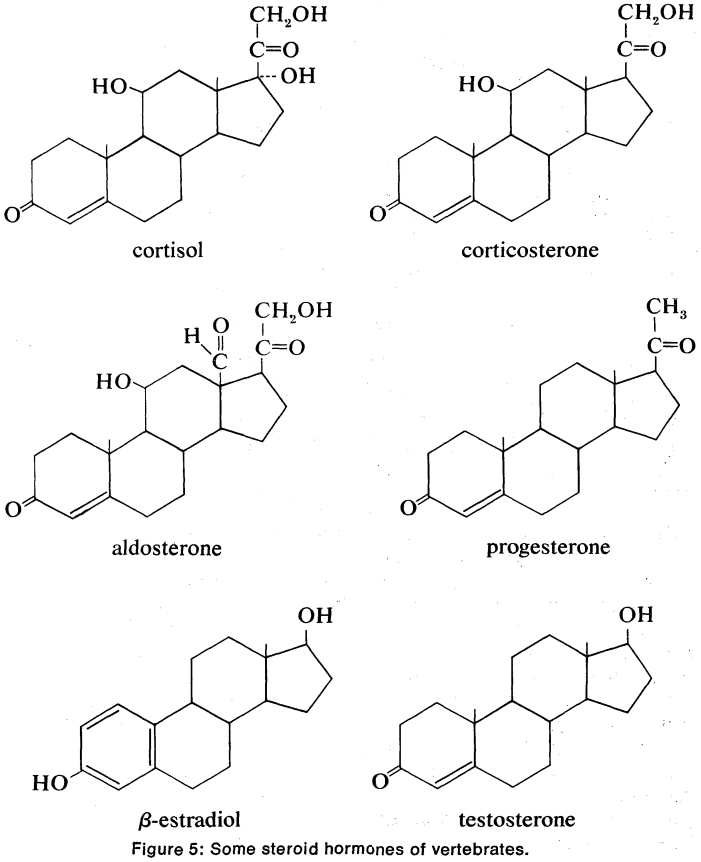


Figure 5: Some steroid hormones of vertebrates.

Active adrenocortical hormones

Many steroids have been isolated from the adrenal cortex, but in most vertebrate groups only three of them are active as hormones; they are cortisol (hydrocortisone; compound F), corticosterone (compound B), and aldosterone. Their biosynthesis is outlined in Figure 6.

The principal sterol of animals is cholesterol, which is formed by a complex series of reactions from a two-carbon compound (acetate). Progesterone, which is derived from cholesterol, can be used to form either corticosterone and aldosterone or cortisol. All three corticoids are bound to proteins during transfer in the bloodstream to their targets; cortisol, for example, is bound to a glycoprotein called transcortin. Some inactivation of the corticoids takes place in the kidney and in the alimentary tract, but most of it occurs in the liver. The metabolic products, which eventually appear in the urine, provide a basis for determination of the output of adrenocortical hormones in man.

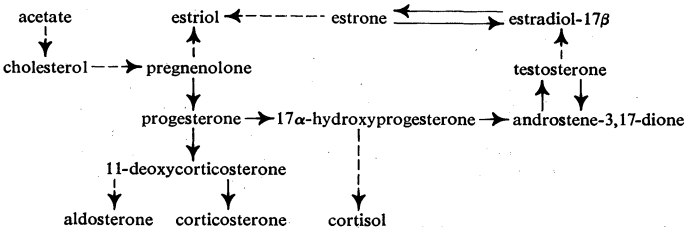

Figure 6: Metabolic pathways involved in the biosynthesis of steroid hormones. Broken lines indicate that more than one step is involved.

Adapted from D.M. Greenberg, ed., *Metabolic Pathways* (1960); Academic Press

The normal secretion of the hormones is best determined by direct measurement of the contents of the venous blood leaving the adrenal gland. In man, the daily secretion rates of the hormones, as determined by this procedure, are cortisol, 20 milligrams (one milligram = 0.001 gram); corticosterone, two to five milligrams; aldosterone, 75 to 150 micrograms (one microgram = 1,000,000th of a gram). Very small amounts of aldosterone are secreted, because the molecule has a high level of activity. Animal tissues maintained in culture fluid together with compounds from which the hormones are formed (*e.g.*, acetate, cholesterol, or progesterone containing radioactive isotopes of carbon or hydrogen) show that cortisol and corticosterone are produced in all vertebrates, including the agnathans, although the proportion of each is species-dependent; elasmobranch fishes are unique, however, in having 1-α-hydroxycorticosterone as the principal hormone. Aldosterone is produced by all terrestrial vertebrates. It has also been found in bony fishes, although its function in them has not yet been established as a hormonal one. The presence of aldosterone has not yet been established in elasmobranchs and agnathans, but whether or not this particular molecule occurs in them, the ability to synthesize corticoids must have evolved very early in vertebrate history.

In contrast to the chromaffin tissue of the adrenal medulla, the adrenocortical tissue is essential for life. Two primary functions of the corticosteroids are distinguishable in mammals. One, which contributes to the regulation of carbohydrate metabolism, is an action of cortisol and corticosterone, which are therefore called glucocorticoids. These hormones promote gluconeogenesis (formation of glucose) in the liver and are thus important in maintaining normal blood-sugar levels, particularly during glucose shortage; lack of them results in low levels of blood sugar and an increase in the sensitivity of the liver to insulin (whose effect there is to decrease gluconeogenesis). In addition, lack of the glucocorticoids is associated with a decrease in the entry of amino acids into muscles and an increase in their uptake by the liver, where enzymes required to convert amino acids to glucose must be synthesized.

In contrast to glucocorticoid action is the so-called mineralocorticoid action of aldosterone, which is manifested in mammals in the regulation of sodium metabolism. In the absence of aldosterone, sodium is lost from the body by excretion in urine; secondary consequences include a decrease in blood volume and in the filtration rate of substances through kidney structures called glomerule. Cortisol and corticosterone also play a minor part in mineral regulation, so that slight overlap in function occurs between the two corticoid types.

The action of aldosterone is exerted mainly upon the distal segment of the nephron (kidney tubule), where it promotes an increase in the permeability of the tubule membrane to the passage of sodium, and also an increase in the quantity of sodium removed into the blood from the fluid passing through the kidney tubule. At the same time, potassium and hydrogen pass into the fluid from the blood. Aldosterone also exerts other effects. It pro-

motes sodium retention in salivary glands, in sweat glands, and in the colon of the large intestine; it also promotes the excretion of magnesium in the urine. The effects of aldosterone result in an increase in the rate of synthesis of enzymes required to transport these substances through membranes.

Other actions of the corticoids are apparent in patients suffering from Addison's disease, which is caused by a general deficiency in corticoid production. A deficiency of corticoids causes disturbances in urinary output and fat metabolism, diminished resistance to stress, muscular weakness, and nervous disturbances manifested by depression and a general lack of mental alertness. The adrenocortical hormones, then, like the hormones of the chromaffin tissue of the medulla, are involved in resistance to stress. It has been postulated that the response to alarm stimuli initially involves both the sympathetico-chromaffin complex and the adrenocortical secretion; then a stage of full resistance occurs that may be followed by mental exhaustion if the alarm stimuli are prolonged. Although a close functional relationship is known to exist between the adrenocortical and chromaffin tissues in mammals, the function of the corticoids in the lower vertebrates has not yet been established. Indications are, however, that the general pattern of action may be similar; for example, the cortisol type of corticoid promotes gluconeogenesis in fish and removal of adrenocortical tissue impairs the metabolism of water and ions in the eel. Any interpretation of corticoid action in teleost, or bony, fishes has to incorporate prolactin, for, as has been noted previously, this hormone also influences the movement of ions.

Resistance to stress

In contrast to the chromaffin cells, the adrenocortical cells are not innervated. Both cortisol and corticosterone production are regulated by the action of ACTH from the pituitary gland on the zona reticularis and the zona fasciculata. The regulation of aldosterone secretion in the zona glomerulosa, however, is associated with the so-called renin–angiotensin system, which is best characterized in mammals. Renin, an enzyme with a molecular weight of about 40,000, is formed in the kidney and is released into the bloodstream, where it catalyzes the formation of angiotensin, a polypeptide molecule. Angiotensin acts upon smooth muscle and raises blood pressure. In man it reduces sodium excretion, probably by a direct action on kidney filtration, and may, in fact, be a true hormone, acting to aid sodium retention. In addition, however, angiotensin contributes to sodium retention by increasing aldosterone secretion. The exact physiological significance of the renin–angiotensin system is not yet known. In one form or another the system is probably widely distributed in vertebrates.

HORMONES OF THE REPRODUCTIVE SYSTEM

The hormones of the reproductive system of vertebrates (sex hormones) are steroids that are secreted, like those of the adrenal cortex, by tissues derived from the coelomic epithelium. Both types of secretory tissues also share biosynthetic pathways (see above *Adrenocortical tissue of the cortex*).

Female hormones. The sex hormones, together with the hypothalamic region of the forebrain and the pituitary gland, form a regulatory system, which is most complex in the female mammal. It is common for sexual activity of vertebrates to be cyclical and for the cycles to be coordinated with the seasons of the year; this ensures that the young are born at the most favourable time. In mammals, however, reproduction is complicated by the need to provide for the intrauterine life of the developing fetus and to ensure that interference by another generation of embryos cannot occur.

Estrogens. Two types of gonadal hormone, estrogens and progestins (Figure 6) are secreted in the female mammal. Estrogens are substances that evoke the cyclical onset of heat, or estrus, during which the animal is sexually active and receptive to the male. Estrus in this sense is not found in human females, but estrogens contribute to the events of the menstrual cycle, bringing about cyclical changes in the reproductive system that are comparable with those accompanying estrus in other mammals.

Hormones are secreted from the mammalian ovary by the ovarian follicle, or vesicle, including the granulosa cells immediately surrounding the ovum, or egg, and the cells of the theca, which forms a supporting outer wall for the follicle. The main estrogen secreted is called β-estradiol. The close relationship between the female and the male sex hormones is revealed by the fact that testosterone (the main male hormone) is an intermediate compound in the pathway that leads to the synthesis of estradiol, although another route, which avoids the formation of testosterone, is possible. Other estrogens are also known; the most familiar ones in man and other mammals, estrone and estriol, are much less active than estradiol, estriol being the weakest. Estrone can be converted to estradiol and vice versa in the ovary and in other tissues; *e.g.*, estradiol is converted, particularly in the liver, to estriol, which is an excretory product. The metabolism of these compounds is complex; they may be combined in part with other substances, or they may pass through the bile into the intestine for reabsorption and circulation through the body before excretion in the urine occurs. Their urinary concentrations provide an important clinical index of reproductive function.

Types of estrogens

Estrogens are concerned not only with reproductive behaviour but also with the general maintenance of the sexual organization of the female. When estradiol is administered to a mammal, the hormone becomes bound to uterine tissue, where it increases the rates of protein synthesis, of uptake of water and glucose, and, eventually, of growth of the lining epithelium and underlying muscular tissue (endometrium) of the uterus. Estradiol also evokes changes in the vagina, including hardening of the epithelium, a phenomenon that, in the laboratory rat, is used to determine its sexual condition. Estradiol and other estrogens have also been found in fishes and in other lower vertebrates. As with the corticosteroids, the sex hormones evolved very early in vertebrate history. Indeed, they have even been identified in invertebrates—in the eggs of the lobster, for example, and in the ovaries of starfishes, where, however, they may be no more than by-products of the metabolism of other steroids. Estrogenic activity is not necessarily restricted to steroids; for example, the estrogen mirestrol from a Thailand plant is not a steroid, nor is the very potent synthetic estrogen, stilbestrol, which is widely used in medicine.

Progestins. Progestins, of which the most important is progesterone, are concerned with the maintenance of pregnancy. Progesterone, therefore, evolved in viviparous mammals; *i.e.*, those that produce living young. Its chemical origin is demonstrable, since it is also an important intermediate compound in the biosynthetic pathways leading to corticoid and estrogen production. Mammals thus converted to hormonal use a substance that was synthesized by vertebrates long before the evolution of terrestrial vertebrates.

Some progesterone is probably formed in the ovarian follicle, but the main site of production is the corpus luteum, which is formed by a transformation of the follicle after ovulation; the secretory cells are formed from granulosa cells. The functions of the two important follicular phases, preceding and following ovulation, therefore, are continuous. The hormone is metabolized in several ways, but one important product is pregnanediol; formed mainly in the liver, it appears in part in the urine, where it can be measured to determine the degree of ovarian function.

The transformation of the follicle into the corpus luteum is an important turning point in the diphasic menstrual cycle of women and in the ovarian cycles of other mammals, from which the human cycle evolved. Progesterone prepares the uterus for the implantation of fertilized eggs, and it is also needed for the maintenance of pregnancy once implantation has taken place. It evokes a reduction in the ability of the uterine walls to contract, a proliferation of the glands of the endometrium, and the formation of glycogen. In addition, through its

Role of progesterone

feedback action upon pituitary secretion, progesterone inhibits further ovulation (see below), thus ensuring undisturbed fetal development. Ovulation in women occurs at about the middle of the monthly cycle, and the follicular phase is succeeded by the luteal phase. The vaginal bleeding at the end of the cycle is an indication that ovulation has not been followed by implantation of a fertilized egg and is immediately followed by the inception of a new cycle. If implantation does take place, the uterus provides metabolic support for the fetus until birth (see also MENSTRUATION).

The vertebrate reproductive cycle depends upon delicate interrelationships between the sex hormones and the pituitary gonadotropic hormones (FSH and LH). As mentioned, it is uncertain whether or not there are two distinct gonadotropins in lower forms, but their separate action is well defined in mammals. Broadly speaking, FSH (follicle-stimulating hormone), with some support from LH (luteinizing hormone), promotes growth and secretory activity of the follicle. The increasing output of estrogen from the ovary eventually tends, by feedback to the pituitary gland, to reduce FSH output and to stimulate the secretion of LH; it is a sudden peak release of the latter hormone that evokes ovulation in many mammals. In others, such as the cat and rabbit, however, ovulation occurs as a response to the stimulus of copulation. Although some progesterone may be secreted by the granulosa cells of the follicle, the development of the corpus luteum greatly increases its secretion. Luteotropic activity in one form or another (the action of prolactin, for example, in the rat) is important in the early stage of this phase. Progesterone, in conjunction with the estrogen that is also being secreted (in part, probably, by the corpus luteum), suppresses further ovulation. This interaction of the two hormones is the basis of the design of contraceptive pills.

The corpus luteum continues to function during pregnancy, supplemented (in eutherian, or placental, mammals but not in marsupials) by endocrine secretions of the placenta (the organ through which contact between mother and fetus is maintained). The hormonal activity of the placenta varies with the species; in man, for example, the placenta secretes two gonadotropins called human chorionic gonadotropin (HCG) and human placental lactogen (HPL). HCG, like the pituitary gonadotropins, is a glycoprotein, with a molecular weight of 25,000 to 30,000. HPL is a protein, with a molecular weight variously estimated at about 19,000 or 30,000. One or perhaps both of these hormones, which become detectable during the early weeks of human pregnancy, probably stimulate luteal secretion. After two months the human placenta begins to manufacture estrogen and progestin; as a consequence, the corpus luteum is no longer needed for the maintenance of pregnancy. Much of the estrogen, although synthesized in the placenta, is derived from a compound (dehydroepiandrosterone) formed in the adrenal glands of the fetus. The placenta and the fetus thus form an integrated endocrine complex, a striking index of the high level of specialization found in the regulation of mammalian reproduction. (See also PREGNANCY.)

The placenta probably secretes a luteotropin in all mammalian species, thereby contributing to prolongation of the life of the corpus luteum. In the mare and the monkey the placenta also secretes estrogen and progesterone, as in man, but in the mouse and rabbit it secretes only estrogen, and in the hamster and rat it secretes neither. In these last four species and in others like them, in which the placenta cannot substitute completely for the corpus luteum, ovariectomy (removal of the ovaries) of a pregnant female leads to the termination of pregnancy unless progesterone is administered to the female.

The interrelationships between the ovarian and the pituitary hormones are based upon negative feedback involving both the cells of the pituitary and those of the hypothalamus, which contains centres that are excited or inhibited by gonadotropin released from the pituitary gland. It is the hypothalamic involvement that enables vertebrate reproductive cycles to be adjusted by the central nervous system relative to external stimuli, particularly the seasonal fluctuations of daylight and other environmental factors that determine the onset of reproduction in many vertebrate species.

Male hormones. The sex hormones of the male follow a much simpler pattern than do those of the female, although the same principle of interaction exists between the pituitary gland and the gonads. The latter organs, the testes, secrete steroids called androgens, which are responsible for the maintenance of male characteristics and behaviour. FSH (follicle-stimulating hormone) from the pituitary gland stimulates the growth of the seminiferous tubules that constitute much of the structure of the testes and promotes within them the cell divisions that result in the production of mature sperm. LH (luteinizing hormone) from the pituitary gland promotes the development within the testes of endocrine tissue, which is composed of groups of cells (interstitial tissue) between the seminiferous tubules. The interstitial tissue of certain bony fishes, however, is represented by cells, called lobule boundary cells, situated within the tubule tissue.

Androgens

Under the influence of LH (often called ICSH, or interstitial-cell-stimulating hormone, in males), the interstitial tissue secretes the steroid hormone testosterone, which is the most important vertebrate androgen. The fact that it is an intermediate compound in the metabolic pathway of estrogen synthesis accounts for the origin of some forms of abnormal sexual organization in man; for example, the testes may secrete predominantly estrogen instead of androgen, resulting in markedly female appearance and behaviour in a male. Although testosterone may be secreted by the adrenal cortex, occasionally producing sexual disturbances, the amount of secretion is not normally significant. Testosterone, which is bound to a protein as it circulates in human blood, can be converted to the compound (androstenedione) from which it is formed, especially in the liver and in muscle; both compounds are metabolized, mainly in the liver, to substances that are excreted in urine. Very small quantities of testosterone can also be excreted in urine, and the quantities of testosterone and compounds derived from it frequently are measured to provide an index of testicular condition.

In addition to promoting male characteristics, male behaviour, and the maintenance of the spermatic tubules, testosterone, in the presence of normal amounts of growth hormone, also promotes growth of the bony skeleton. The reason for rapid growth at puberty is that the secretion of androgen markedly increases. The hormone brings about the closure of the epiphyses (ends) of the long bones, which completes the process of growth (estrogens have a similar action in the female). Thus, as often occurs among animals, growth ceases before full reproductive activity is attained, and competition between two processes, both of which make heavy demands upon the resources of the body, is avoided.

HORMONES OF THE DIGESTIVE SYSTEM

In vertebrates, the muscular and secretory activities of the alimentary canal and its associated glands are regulated by nervous and hormonal mechanisms. The hormones comprise a self-contained complex that functions at a relatively primitive level of organization and is distinguished by peculiar features; for example, specialized glandular tissues that secrete the hormones cannot be identified, although certain cells that can be seen in the wall of the alimentary canal are thought to be involved in their production. In addition, the digestive hormones regulate the system that produces them and are largely independent of the rest of the endocrine system, although certain relationships may not yet have been discovered.

Functions of digestive hormones

The functions of digestive hormones are best understood in mammals, in whom at least three are well characterized; the existence of others has been postulated. The three hormones—gastrin, secretin, and cholecystokinin/pancreozymin (CCK-PZ)—are polypeptide molecules whose amino-acid sequences are known. When food enters the stomach, the wall of its pyloric end (the area at which the stomach joins the small intestine) releases a hormone called gastrin, which promotes the flow of acid

from the gastric glands in the stomach. These glands also release pepsinogen, which is the inactive form of the protein-digesting enzyme pepsin, but this process is primarily under nervous control. The entry of the acidified stomach contents into the first part of the small intestine (duodenum) releases secretin and cholecystokinin/pancreozymin. Secretin evokes the discharge of fluid and bicarbonate ions from the pancreas (hydrelatic action) and promotes the secretion of bile from the liver (chloretic action). Cholecystokinin/pancreozymin, so-called because its two main actions were formerly attributed to two separate hormones, evokes the release of enzymes from the pancreas (ecbolic action) and causes contraction of the gallbladder (cystokinetic action), thereby promoting the entry of bile into the duodenum.

Little is known regarding hormonal control of alimentary activities in lower vertebrates; however, hydrelatic, ecbolic, and cystokinetic activities are present in preparations of the alimentary tracts of both agnathans and gnathostomes, indicating that substances able to regulate digestive activity appeared very early in the evolution of the vertebrate alimentary tract. Evidence suggests that the appearance of these hormones may have resulted in molecular diversification similar to examples previously discussed. The structure of the glucagon molecule from the pancreas, for example, is similar to that of secretin in that each molecule includes the same 15 amino acids located in the same positions. It has therefore been suggested that the two hormones may have evolved from a common ancestral molecule.

ENDOCRINE-LIKE GLANDS AND SECRETIONS

In addition to the well-defined hormones, other substances, which are found in blood and in tissues and are of uncertain function, may be concerned in various ways with physiological regulation in vertebrates, although their hormonal status has not yet been established.

Blood contains substances called kinins, which are polypeptides that originate in the blood and perhaps elsewhere; bradykinin, for example, causes contraction of most smooth muscles and has a very potent action in dilating certain blood vessels. Its function, which is not yet established, may be to regulate the rate of blood flow or to participate in the inflammatory response of an animal to injury.

Some endocrine-like glands are associated with organs. One example in mammals is the carotid bodies, which are found on the carotid arteries that supply blood to the head. The carotid glands are stimulated by a decrease in the oxygen content of the blood and are considered to be the source of a substance, the nature of which has not yet been established with certainty, that promotes the process of red-blood-cell formation (erythropoiesis).

The pineal organ is an endocrine-like body found in the brain of all vertebrates. In lower vertebrates, it contains sensory and supporting cells and functions as a light-sensitive organ; in higher vertebrates, beginning with amphibians, the pineal gland has secretory functions, and in mammals, it is exclusively a secretory organ, producing from an amino acid (tryptophan) the compound serotonin (5-hydroxytryptamine, or 5HT) and a derivative of serotonin called melatonin. Preparations of melatonin, when given to amphibians, stimulate the concentration of pigment granules in chromatophores, an effect comparable with that of intermedin (MSH) but much more powerful. The normal physiological function of melatonin in higher vertebrates has not yet been established, although involvement in the regulation of reproduction is suspected. Serotonin is widely distributed in animals, especially in the brain and alimentary tract of vertebrates; it may function as a neurohumor in the invertebrate mollusks, but its significance in other animals is not yet certain.

The thymus is essential for the normal development in mammals of the system responsible for immunological responses. Its removal in newborn mice results in a deficiency of one type of white blood cells (lymphocytes) and a consequent likelihood of early death from infection. Preparations of thymus glands from various species contain a protein component, called thymosin, that promotes the development of lymphocytes. Although thymosin is sometimes regarded as a possible thymus hormone, the evidence is not yet complete.

Urohypophysis and corpuscles of Stannius

The urohypophysis, an organ found only in elasmobranch and bony fishes, probably developed independently in each group. The neurosecretory cells comprising the urohypophysis are concentrated at the hind end of the spinal cord, where they are associated with a vascular plexus to form a neurohemal organ. The urohypophysis resembles the neurosecretory system of the hypothalamus and the neural lobe (see above *Neurohypophysis and the polypeptide hormones of the hypothalamus*), but its functions have not yet been established.

The corpuscles of Stannius, found only in bony fishes, are sac-like bodies in the kidney. Although they were once thought to be a form of adrenocortical tissue, they differ from it in embryological origin as well as in cytological characteristics; moreover, although the corpuscles of Stannius are capable of limited steroid biosynthesis, they cannot convert cholesterol into corticoids, a process that occurs in adrenocortical tissue. Evidence suggests that these corpuscles secrete some substance, as yet uncharacterized, which plays a part in maintaining ionic homeostasis, perhaps in conjunction with the corticoid hormones.

III. The hormones of invertebrates

Some form of endocrine regulation probably occurs in all invertebrates; in arthropods (as exemplified in insects and crustaceans) it attains a level of complexity similar to that of vertebrates.

HORMONES OF INSECTS

Insects secrete hormones from neurosecretory cells and also from endocrine glands. Important neurosecretory centres occur in the pars intercerebralis region of the brain. The several cell types found in these centres indicate that more than one hormone is produced there.

Neurohormones. One of the brain hormones is thoracotropic hormone. This is released from nerve endings located in a neurohemal organ called the corpus cardiacum; the relationship between the corpus cardiacum and the brain closely parallels that between the neural lobe of the pituitary gland and the hypothalamic region of the brain of vertebrates. The thoracotropic hormone is transferred in the blood to the thoracic glands in the body region called the thorax. It stimulates the production and release from the glands of ecdysone, a hormone that initiates molting, which is the periodic shedding of the outer skeleton that typically occurs in insects and other arthropods. The thoracotropic hormone is probably a polypeptide molecule.

A neurosecretion of the insect brain distinct from the thoracotropic hormone and called bursicon acts directly on the adult cuticle (skin) of arthropods to stimulate darkening and hardening processes. Bursicon is almost certainly a polypeptide, with a molecular weight of about 40,000. The brain of insects also produces a third neurohormone, which has a hyperglycemic (increase in level of blood glucose) effect in a tissue mass called the fat body, and a fourth neurohormone, which acts on the malpighian tubules (excretory organs) and rectum to facilitate the removal of excess fluid taken in with food; these two hormones, which may actually be one hormone with two effects, are also probably polypeptides. Another more active hyperglycemic hormone is formed within the corpora cardiaca, perhaps under the control of cerebral neurosecretion.

Molting hormones. Ecdysone is a steroid compound derived from cholesterol. Two forms are found in insects—α-ecdysone and β-ecdysone; ecdysones of unknown biological significance are also present in plants. Unlike vertebrates, insects cannot synthesize cholesterol, and they thus must obtain it from their food. Evidence concerning the mode of action of ecdysone indicates that it has a direct action upon the synthesis of the ribonucleic acid (RNA) that controls protein synthesis in the cell.

The distinction in insects between molts that occur

Juvenile hormone

within the larval stage of development and those that result in the transformation of larvae to other stages (pupae, adults) in the life cycle is controlled by another hormone, called juvenile hormone, which is secreted in epithelial glands, called the corpora allata, near the brain. The hormone controls the appearance of juvenile characters in larval stages, presumably by suppressing the activity of genes concerned with the expression of adult characters; reduction in the amount of or absence of the hormone at later molts results in the appearance of mature characters. The hormone nevertheless may continue to function in adults and often is necessary for normal egg production in females. Juvenile hormone is a lipoidal (fatlike) compound of similar structure from all sources. Many synthetic compounds mimic its effect, as do certain natural products—*e.g.*, substances in the balsam fir tree (*Abies*). Substances that mimic the action of juvenile hormone sometimes are used as insecticides, for if they are present in abnormal amounts in the later stages of the life cycle, they kill the insects.

Pheromones. Pheromones are important as insect sex attractants and as regulators of the social organization of social insects; *e.g.*, bees. The sex attractant of the female silk moth (*Bombyx mori*) is called bombykol. A related compound, gyptol, is the sex attractant of the female gypsy moth (*Porthetria dispar*), and gyplure is a synthetic compound that acts as an even more powerful attractant. The use of these compounds in the chemical control of insect pests is probably more promising than is the use of juvenile hormone (see also PEST CONTROL).

The odour of the sex attractant of the honeybee (*Apis mellifera*), 9-oxodecenoic acid, stimulates the olfactory receptors of the drones (males). Secreted by the queen bee in the hive, the pheromone inhibits the development of the ovaries of the worker bees (sterile females) but is entirely effective only when it acts in conjunction with another inhibitory pheromone, 9-hydroxydecenoic acid. Removal of the queen from the hive results in the building of new queen cells by the workers and the development of functional ovaries in the drones. The mechanism by which these inhibitory substances function is not yet understood; some effect upon the nervous system presumably is involved.

HORMONES OF CRUSTACEANS

The endocrine systems of crustaceans resemble those of insects; important differences occur, however, implying extensive independent evolution in the two groups. The main sources of neurohormones are groups of cells (the X-organs) located in the optic ganglia of the eyestalks; the most important neurohemal organ is the sinus gland beside the eyestalks. Less important neurosecretory centres and neurohemal organs also occur. The pericardial organ of decapods, for example, is a group of nerve fibres and nerve endings in the walls of the pericardium, which encloses the heart; the pericardial organ secretes a substance, perhaps a polypeptide neurohormone, which accelerates the heartbeat.

In crustaceans, neurosecretory control is exerted over many functions, including the movement of pigment in the chromatophores, which determine body colour, and in the retina of the compound eye. Neurosecretions also regulate molting and the metabolic functions associated with it by actions exerted upon the so-called Y-organ in the head; this organ so closely resembles the thoracic gland of insects that the two may share a common ancestry. In crustaceans, however, the neurosecretion inhibits secretions from the Y-organ, and the molt is initiated by the withdrawal of the inhibitory hormone (in insects, the thoracotropic hormone from the corpus cardiacum stimulates the secretion of the molting hormone, ecdysone, from the thoracic gland). Neurosecretory hormones of crustaceans have diverse chemical and biological characteristics but apparently are polypeptides, as are the neurosecretory hormones of vertebrates.

Androgenic gland

Unlike insects, crustaceans have an androgenic gland, which typically is located on the genital duct (vas deferens) of the male. The androgenic gland secretes a hormone, possibly steroid in nature, that controls both the differentiation of the gonad of the male into a testis and the male characteristics of its limbs. The absence of the androgenic gland in the female results in the formation of an ovary, which subsequently synthesizes one or more hormones that, in female amphipods, promote the development of brood chambers (in which the young are hatched) and other structures associated with reproduction.

OTHER INVERTEBRATE HORMONES

The characterization of the hormones of other invertebrates awaits further study. Evidence indicates that the brain of polychaete worms produces neurosecretions that regulate growth and reproduction; in *Nereis* and *Nephtys* the neurosecretory fibres apparently have a close and presumably functional relationship with an epithelial gland (infracerebral organ), which is formed from coelomic epithelium and is situated on the wall of the brain.

Neurosecretory cells probably are present in mollusks such as gastropods and lamellibranchs. Experimental studies indicate an endocrine relationship in gastropods between the gonad (ovotestis) and possible neurosecretory cells in the tentacles and the brain; one ganglion of the gastropod *Lymnaea* may secrete a neurohormone with a diuretic (urine producing) action. Epithelial glands in mollusks are important; in the cephalopods, which are the most advanced invertebrates in some respects, optic glands on the optic stalks (eyestalks) secrete a hormone that promotes development and maturation of the gonads. In immature cephalopods the activity of the glands is inhibited by the central nervous system, apparently by a chemical mediator that diffuses from nerve fibres.

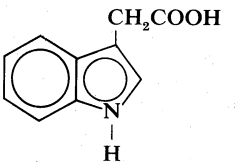
The nerve net, which constitutes the very primitive nervous system of the coelenterates, probably the most primitive multicellular animals, apparently contains neurosecretory cells; indirect but convincing evidence suggests that the cells release a secretion that promotes growth and inhibits sexual reproduction.

IV. The hormones of plants

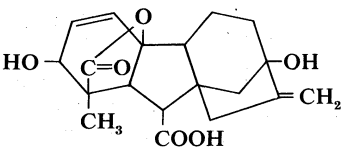
Growth in plants is regulated by four categories of phytohormones—auxins, gibberellins, cytokinins, and inhibitors.

GROWTH PROMOTORS

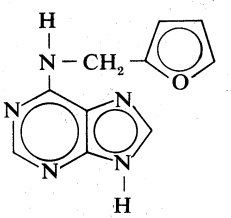
Auxins. The distribution of auxins, which promote the lengthwise growth of plants, is correlated with the distribution of the growth regions of the plant. The most important auxin, whose structure is represented in Figure 7, is β-indolylacetic acid (IAA), which is formed either from the amino acid tryptophan or from the breakdown of carbohydrates known as glycosides. The hormone affects plants by its action on chemical bonds of



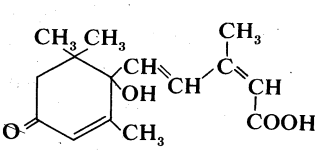
β-indolylacetic acid



gibberellic acid



kinetin (6-furfurylaminopurine)



abscisic acid

Figure 7: The structures of plant hormones.

carbohydrates comprising plant cell walls. The process permits the cells to be irreversibly deformed and is accompanied by the entry of water and the synthesis of new cell-wall material. Many animal hormones may exert their effects by influencing protein synthesis, and evidence suggests that auxins may act in a similar way.

Many other naturally occurring and synthetic compounds called auxins also have growth-promoting properties, but they are not always as active as IAA. Some of these compounds, however, resist the enzymatic destruction that is the normal fate of IAA within the plant; this feature is of great value in research and in horticulture, because auxin action can be prolonged. Other auxin-like compounds are used as selective weed killers (*e.g.*, to disturb the leaf growth of dicotyledonous plants either in fields containing monocotyledonous cereal crops or on lawns) and as agents that remove leaves from dicotyledonous plants (defoliating agents).

Effects of indolylacetic acid

The hormonal characteristics of IAA are readily demonstrated in grass seedlings, in which the hormone is synthesized at the tip of the coleoptile (the protective sheath of the emerging plumule, or embryonic bud) and passes downward to its point of action in the growing region, where it evokes elongation of the coleoptile cells; growth stops if the tip is removed. The movement of the hormone downward from the tip of the coleoptile depends upon an interaction between the hormone and the cells through which the movement normally takes place.

In addition to promoting normal growth in plant length, auxins influence the growth of stems toward the light (phototropism) and against the force of gravity (geotropism). The phototropic response occurs because greater quantities of auxin are distributed to the side away from the light than to the side toward it; the geotropic response occurs because more auxin accumulates along the lower side of the coleoptile than along the upper side. The downward growth of roots is also associated with a greater quantity of auxin in their lower halves. This effect, which is the opposite to that found in coleoptiles, is attributed to an inhibitory action of auxins on root growth, but this aspect of auxin action is not yet fully understood. Auxins have actions other than those associated with promoting growth; *e.g.*, they play a role in cell division, in cell differentiation, in fruit development, in the formation of roots from cuttings, and in leaf fall (abscission). In experimental conditions, auxins tend to inhibit the progress of plant aging, perhaps because of their stimulating effect upon protein synthesis.

Gibberellins. Gibberellins are named after the fungus *Gibberella fujikuroi*, which produces excessive growth and poor yield in rice plants. One gibberellin (Figure 5) is gibberellic acid (GA_3), which is present in higher plants as well as in fungi; many related compounds have structural variations that correlate with marked differences in effectiveness.

Gibberellins, abundant in seeds, are also formed in young leaves and in roots; they move upward from the roots in the xylem (woody tissue) and thus do not show the movement characteristic of auxins. Evidence suggests that gibberellins promote the growth of main stems, especially when applied to the whole plant. Unlike the auxins, gibberellins have little effect upon pieces of coleoptile in tissue culture. Gibberellins promote the growth of dwarf peas and are involved in the bolting (elongation) of rosette plants such as the carrot. Elongation of rosette plants occurs after exposure to certain environmental stimulation (*e.g.*, cold, or long periods of daylight), which is accompanied by an increase in the gibberellin content of the affected plant. In experimental conditions gibberellins tend, like auxins, to retard senescence.

Cytokinins. Cytokinins are compounds derived from a nitrogen-containing compound (adenine). One cytokinin is 6-furfurylaminopurine (kinetin, see Figure 7); other compounds derived from adenine with effects similar to those of kinetin, and certain compounds derived from another nitrogen-containing compound, urea, are conveniently referred to as cytokinins, although not all are natural products. Cytokinins are synthesized in roots, from which, like the gibberellins, they move upward in the xylem and pass into the leaves and the fruit. Required for normal growth and differentiation, cytokinins act, in conjunction with auxins, to promote cell division and to retard senescence, which, at least in its early stages, is an organized phase of metabolism and not just a breakdown of tissue. An example of senescence is the yellowing of isolated leaves, which occurs as proteins are broken down and chlorophyll is destroyed. Cytokinins, which prevent yellowing by stabilizing the content of protein and chlorophyll in the leaf and the structure of chloroplasts, are used commercially in the storage of green vegetables.

GROWTH INHIBITORS

Growth inhibitors of various types have been identified in plants. The best characterized one is abscisic acid (Figure 7), which is chemically related to the cytokinins. It is probably universally distributed in higher plants and has a variety of actions; for example, it promotes abscission (leaf fall), the development of dormancy in buds, and the formation of potato tubers. The mode of action of abscisic acid has not yet been clarified but is thought to involve the direct inhibition of the synthesis of RNA and protein.

Another growth inhibitor is ethylene, which is a natural product of plants, formed possibly from linolenic acid (a fatty acid) or from methionine (an amino acid). Ethylene promotes abscission in senescent leaves, perhaps by facilitating the destruction of auxin. Its effects extend beyond that of inhibiting growth; in fruit, for example, ethylene is regarded as a ripening hormone. Involved in its action in fruit is another factor, perhaps auxin or another growth-regulating hormone, which influences the ethylene sensitivity of the tissues.

Hormonal interaction

The hormonal interaction conspicuous in animals is found also in plants; one example is the control of abscission, which requires the synthesis of enzymes at an abscission zone, at the base of the structure concerned, to catalyze reactions involving breakdown of cell walls. Auxin reaching the abscission zone from the tip of the structure promotes abscission; if auxin reaches the structure from the opposite direction, however, it tends to inhibit the process, probably by its influence on metabolism. Other hormones are also involved in abscission; ethylene stimulates the synthesis of the enzymes, and abscisic acid accelerates the associated senescence. Gibberellin tends to inhibit abscission by promoting growth.

Another example of hormonal interaction occurs during the germination of cereal seeds. The embryo (germ) is first activated by uptake of water, which enables it to produce gibberellin. Gibberellin acts on the living cells (aleurone layer) surrounding the food reserves (endosperm). This action induces the aleurone cells to produce enzymes that break down starch to sugars and release tryptophan from the protein of the endosperm. The tryptophan migrates to the coleoptile tip and is transformed into indolylacetic acid, which in turn moves to the growth zone and weakens the cell walls, thus permitting water uptake.

The target tissues probably play a role in such sequential actions, and it is likely that changes in their responsiveness to hormonal action, perhaps correlated with environmental stimuli, contribute to adaptive integration. The similarities in the hormonal mechanisms of plants and animals, two groups that are so profoundly different in their structure and mode of life, effectively illustrate the fundamental uniformity of biological organization.

Horse

Zoologically, the horse is a mammal of the family Equidae. It comprises a single species, *Equus caballus*, whose numerous varieties are called breeds. The earliest traces of the ancestors of the horse have been found in rocks from the Eocene epoch (50,000,000 years ago); evidence suggests a small fox-like animal that walked on four toes but possessed a fifth in the form of a useless vestige. Fossil skeletons of this animal, called *Eohippus*, were found in the Mississippi Valley area of the U.S., from which the animal disappeared in an unexplained manner after first giving rise to the line that produced *Orohippus, Protohippus, Hipparion*, and, finally, *Equus caballus*. In this series the animal developed in size and shape and came to stand on one toe enveloped in a protective hoof.

GENERAL FEATURES

Historic background. *Equus caballus* first appeared in Central Asia as a sturdy, sand-brown animal called Przewalski's horse (*E. caballus przewalskii*). It spread eastward, giving rise to Chinese and Mongolian breeds, and farther westward there arose the mouse-coloured European Tarpan. Wild horses migrated to the southwest, to Asia Minor, and from there to Egypt and the Mediterranean countries, establishing local breeds in those parts of the world. In 1519 the Spanish explorer Hernando Cortéz transported the horse to the New World.

Utility of the wild horse

In prehistoric times the wild horse was probably first hunted for food. When its domestication took place is unknown, but it certainly was long after the domestication of the dog or of cattle. It is supposed that the horse was first used by a tribe of Indo-European origin that lived in the steppes north of the chain of mountains adjacent to the Black and Caspian seas. Influenced by climate, food, and man, the horse rapidly acquired its present form.

Significance. The relationship of the horse to man has been unique. The horse was man's partner and friend, carrying him above his fellowmen on foot and giving him power and speed. It plowed his fields and brought in his harvest, hauled goods and conveyed passengers, followed game and, later, tracked cattle, and carried combatants into battle and adventurers to unknown lands. It has provided recreation in the form of jousts, tournaments, carrousels, and in the sport of riding. The widespread influence of the horse is expressed in the English language in such terms as chivalry, cavalier, and cavalry, which generally connote honour, respect, good manners, and straightforwardness. (For an account of the training and use of the horse in riding, see RIDING AND HORSEMANSHIP; for the racing of horses see HORSE RACING.)

The horse is the "proudest conquest of Man," according to the French zoologist Le Comte de Buffon. Its place was at its master's side in the graves of the Scythian kings or in the tombs of the Pharaohs. Many of man's early cultures were centred on possession of the horse. Superstition read meaning into the colours of the horse, and a horse's head suspended near a grave or sanctuary or on the gables of a house conferred supernatural powers on the place. Greek mythology created the centaur, the most obvious symbol of the oneness of horse and rider. White stallions were the supreme sacrifice to the gods, and the Greek general Xenophon recorded that "Gods and heroes are depicted on well trained horses." A beautiful and well trained horse was, therefore, a status symbol in ancient Greece. Kings, generals, and statesmen of necessity had to be horsemen. The names of famous horses are inseparably linked to those of their famous riders: Bucephalus, the charger of Alexander the Great; Incitatus, foolishly made a senator by the Roman emperor Caligula; El Morzillo, Cortéz' favourite horse, to whom the Indians erected a statue; Roan Barbery, the stallion of Richard II, mentioned by Shakespeare; Copenhagen, the Duke of Wellington's horse, which was buried with military honours.

The horse in art

The horse has occupied a special place in the realm of art. From the Stone Age drawings to the marvel of the Parthenon frieze, from Chinese T'ang dynasty tomb sculptures to Leonardo da Vinci's sketches and Verrocchio's Colleoni, from the Qur'ān to modern literature, the horse has inspired artists of all ages and in all parts of the world.

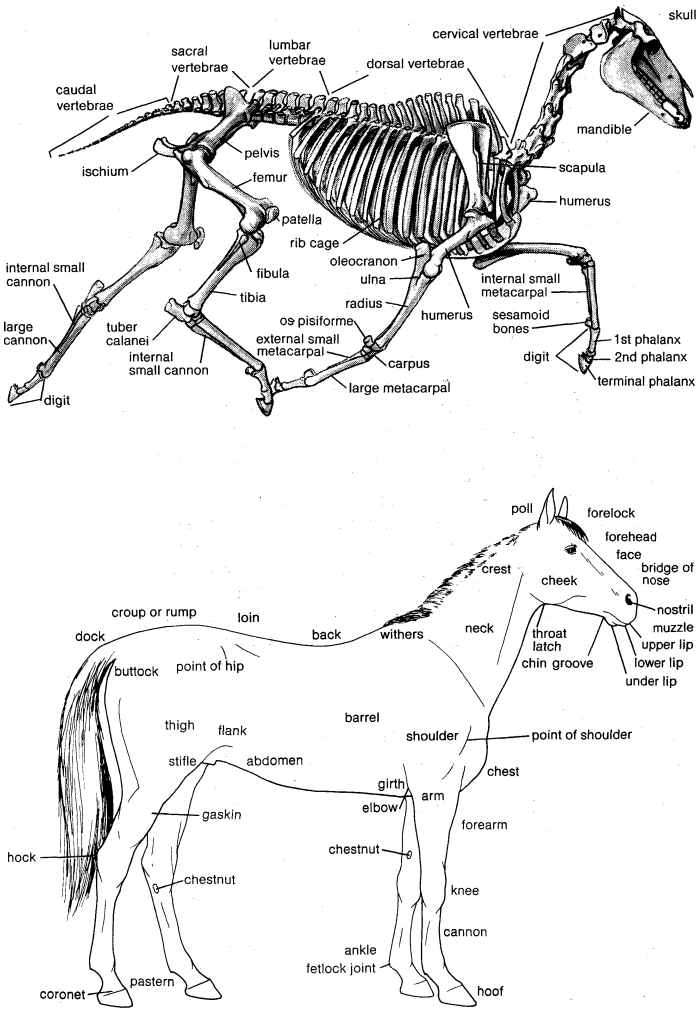
The horse in life serves man in his travels, wars, and labours and in death provides him with many commodities. Long before their domestication horses were hunted by primitive tribes for their flesh, and horsemeat is still consumed by man in parts of Europe and in Iceland and is the basis of many pet foods. Horse bones and cartilage are used to make glue. Tetanus antitoxin is obtained from the blood serum of horses previously inoculated with tetanus toxoid. From horsehide a number of articles are manufactured, including fine shoes and belts. The cordovan leather fabricated by the Moors in Córdoba, Spain, was originally made from horsehide. Stylish fur coats are made of the sleek coats of foals. Horsehair has wide use in upholstery, mattresses, stiff lining for coats and suits; high-quality horsehair, usually white, is employed for violin bows. Horse manure, which today provides the basis for cultivation of mushrooms, was used by the Scythians for fuel. Mare's milk was drunk by the Scythians, the Mongols, and the Arabs.

FORM AND FUNCTION

A mature male horse is called a stallion, the female a mare. A stallion used for breeding is known as a stud. A castrated stallion is commonly called a gelding. In former times stallions were employed as riding horses, while mares were kept for breeding purposes only. Geldings were used for work and as ladies' riding horses. In recent years, however, geldings generally have replaced stallions as riding horses. Young horses are known as foals; male foals are called colts and females fillies.

Anatomical adaptations. The primitive horse probably stood 12 hands tall (about 120 centimetres, or 48 inches) at the withers, the high point on the back at the base of the neck, and was dun coloured. Domestic horses gone wild, such as the mustangs of western North America, tend to revert to those primitive features under random mating; they generally are somewhat taller (about 15 hands), usually gray, dun, or brownish in colour, and move in herds led by a stallion.

The horse's general form is characteristic of an animal of speed: the long leg bones pivot on pulley-like joints that restrict movement to the fore and aft, the limbs are levered to muscle masses in such a way as to provide the most efficient use of energy, and the compact body is supported permanently on the tips of the toes, allowing fuller extension of the limbs in running (see illustration).



(Top) Skeleton of the horse; (bottom) points of the horse.

The rounded skull houses a large and complex brain, well developed in those areas that direct muscle coordination. While the horse is intelligent among subhuman animals, it is safe to say that the horse is more concerned with the functioning of its acute sensory reception and its musculature than with mental processes. Though much has been written about "educated" horses that appear to exhibit an ability to spell and count, it is generally agreed that in such cases a very perceptive animal is responding to cues from its master. But this ability is remarkable enough in its own right—for the cues are often given unconsciously by the human trainer, and detection of such subtle signals requires extremely sharp perception.

The horse, like other herbivores, has typical adaptations for plant eating: a set of strong, high-crowned teeth, suited to grinding grasses and other harsh vegetation, and a relatively long digestive tract, most of which is intestine concerned with digesting cellulose matter from vegetation. Young horses have milk (or baby) teeth, which they begin to shed at about age two and a half. The permanent teeth, numbering 36 to 40, are completely developed by age four to five years. In the stallion these teeth are arranged as follows on the upper and lower jaws: 12 incisors that cut and pull at grasses; 4 canines, remnants without function in the modern horse and usually not found in mares; 12 premolars and 12 molars, high prisms that keep moving out of the jaw to replace the surfaces worn off in grinding food.

Diversification into three types

Under domestication the horse has diversified into three major types, classified on the basis of size and build: draft horses, heavy limbed and up to 20 hands high (200 centimetres or 80 inches); ponies, by convention horses under 14.2 hands high (about 144 centimetres or 57 inches); and light horses—the saddle or riding horses that fall in the intermediate size range. Domestic horses tend to be nearsighted, less hardy than their ancestors, and often high strung, especially among thoroughbreds, in which intensive breeding has been focussed upon speed to the exclusion of other qualities. The stomach is relatively small, and, since much vegetation must be ingested to maintain vital processes, foraging is almost constant under natural conditions. Domestic animals are fed several (at least three) times a day in quantities governed by the exertion of the horse.

Senses. The extremely large eyes placed far back on the elongated head admirably suit the horse for its chief mode of defense: flight. And its long neck and high-set eyes, which register a much wider range than man's, enable it to discern a possible threat even while eating low grasses. The horse's vision is binocular, like man's, but only in the narrow area directly forward, and evidence suggests that it does not register colour. While visual acuity is high, the eyes do not have variable focus, and objects at different distances register only on different areas of the retina, which requires tilting movements of the head. The senses of smell and hearing seem to be keener than man's. As the biologist George Gaylord Simpson has put it in *Horses* (1961): "Legs for running and eyes for warning have enabled horses to survive through the ages, although subject to constant attack by flesh eaters that liked nothing better than horse for supper."

Colour and pattern. From the dun of the primitive horse have sprung a variety of colours and patterns, some highly variable and difficult to distinguish. Among the most important colours are black, bay, chestnut (and sorrel), palomino, cream, and white.

The black colour is a true black, although a white face marking (blaze) and white ankles (stockings) may occur. The brown horse is almost black but has lighter areas around the muzzle, eyes, and legs. Bay refers to several shades of brown, from red brown and tan to sandy. Bay horses have a black mane, tail, and (usually) stockings. Chestnut is similar to bay but with none of the bay's black overtones. Lighter shades of chestnut are called sorrel. The palomino horse runs from cream to bronze, with a flaxen or silvery mane and tail. The cream is a diluted sorrel, or very pale yellow, nearly white. White in horses is variable, ranging from aging grays (see below) to albinos with blue eyes and pink skin and to pseudoalbinos with a buff mane or with brown eyes. The chief patterns of the white horse are gray, roan, pinto, and appaloosa. Gray horses are born dark brown or black and develop white hairs as they age, becoming almost all white in advanced years. Roan refers to white mixed with other colours at birth: blue roan is white mixed with black; red roan is mixed white and bay; and strawberry roan is white and chestnut. The pinto is almost any spotted pattern of white and another colour; other names, such as paint, calico, piebald, skewbald, overo, and tobiano, refer to subtle distinctions in type of colour or pattern. Appaloosa is another extremely variable pattern, but the term generally refers to a large white patch over the hips and loin, with scattered irregular dark spots.

Nutrition. The horse's food, which in general consists of hay and grain, is usually not given immediately before or after work. Fresh water is important, especially when the horse is shedding its winter coat, but the animal is never watered when it is overheated after working. Oats provide the greatest nutritional value and are given especially to foals. Older horses, whose teeth are worn down, or those with digestive troubles, are provided with crushed oats. Chaff (minced straw) is added to the oat ration of animals that eat greedily or do not chew the grain properly. Crushed barley is sometimes substituted in part for oats. Hay provides the bulk of the horse's ration and may be of varying composition according to locale. Mash is bran mixed with water and with various invigorating additions or medications. It is given to horses with digestive troubles or deficient eating habits. Maize, or corn, is used as a fattening cereal, but it makes the horse sweat easily. Salt is needed by the horse at all times and especially when shedding. Bread, carrots, and sugar are tidbits used to reward an animal by the rider or

trainer. In times of poverty horses have adapted to all sorts of food—potatoes, beans, green leaves, and in Iceland even fish—but such foods are not generally taken if other fare is available. A number of industrial products are available to modern breeders and owners that contain balanced additions of minerals, vitamins, and other chemical elements, together with the customary natural foods.

Behaviour. The horse's nervous system is highly developed and gives proof to varying degrees of the essential faculties that are at the basis of intelligence: instinct, memory, judgment. Foals, which stand on their feet only a short while after birth, and are able to follow their mothers within a few hours, even at this early stage in life exhibit the traits generally ascribed to horses. They have a tendency to flee to evade danger. They express fear sometimes by showing panic, sometimes by immobility. Horses attack rarely and do so either when flight is impossible or when driven to assault a person who has treated them brutally.

Habit and instinct

Habit governs a large number of their reactions. Instinct, together with a fine sense of smell and hearing, enables them to sense water, fire, even distant danger. An extremely well-developed sense of direction permits the horse to find its way back to its stables even at night or after a prolonged absence. The visual memory of the horse prompts it to shy repeatedly from an object or place where it had earlier experienced fear. The animal's auditive memory, which reminded ancient army horses or hunters to follow the sounds of the bugles, is used in training. When teaching, the instructor always uses the same words and the same tone of voice for a given desired reaction. Intelligent horses soon attach certain movements desired by their trainers to particular sounds and even try to anticipate their rider's wishes.

While instinct is an unconscious reaction more or less present in all individuals of the same species, the degree of its expression varies according to the individual and its development. Most horses can sense a rider's uncertainness, nervousness, or fear, and are thereby encouraged to disregard the rider or even deliberately disobey him. Highbred animals, which give evidence of greater intelligence than those of low breeding, are capable not only of acts of vengeance and jealousy against their riders but also of expressions of confidence, obedience, affection, and fidelity. They are less willing than a lowbred horse to suffer rough handling or unjust treatment.

Cunning animals have been known to employ their intelligence and physical skill to a determined end, such as opening the latch of their stalls or the lid of a chest of oats.

Reproduction and development. The onset of adult sex characteristics generally begins at the age of 16 to 18 months; and the horse is considered mature, according to the breed, at approximately three years and adult at five. Fecundity varies according to the breed and may last to beyond age 20 with thoroughbreds and to 12 or 15 with other horses. The gestation period is 11 months, 280 days being the minimum in which the foal can be born with expectation to live. As a rule a mare produces one foal per mating, twins occasionally, and triplets rarely. The foal is weaned at six months.

The useful life of a horse varies according to the amount of work it is required to do and the maintenance furnished by its owner. A horse that is trained carefully and slowly and is given time necessary for development may be expected to serve to an older age than a horse that is rushed in its training. Racehorses that enter into races at the age of two rarely remain on the turf beyond eight. Well-kept riding horses, on the contrary, may be used up to 20 years and beyond.

Life expectancy

The life-span of a horse is calculated at six to seven times the time necessary for his physical and mental development; that is, at 30 to 35 years at the utmost, the rule being rather about 20 years. Ponies generally live longer than horses. There are a number of examples of horses that have passed the usual limit of age. The veterinary university of Vienna conserves the skeleton of a thoroughbred mare of 44 years of age. Unauthenticated reports have been made of horses living to the age of 40 and 50.

Diseases and parasites. Horses are subjected to a number of contagious diseases, such as influenza, strangles, glanders, ringworm, and swamp fever. Their skin is affected by parasites, including certain mites, ticks, and lice. Those with sensitive skin are especially subject to eczemas and abscesses, which may result from neglect or contamination. Sores caused by injuries to the skin from ill-fitting or unclean saddles and bridles are common ailments. The horse's digestive tract is particularly sensitive to spoiled feed, which causes acute or chronic indigestion, especially in hot weather. Worms can develop in the intestine and include the larvae of the botfly, the pinworms, tapeworms, and roundworms (ascarids). Overwork and neglect may predispose the horse to pneumonia and rheumatism. The ailment known as roaring is an infection of the larynx that makes the horse inhale noisily; a milder form causes the horse to whistle. Chronic asthma, or "broken wind," is an ailment that is considered to be all but incurable. A horse's legs and feet are sensitive to blows, sprains, and overwork, especially if the horse is young or is worked on hard surfaces. Lameness may be caused by bony growths, such as splints, spavins, and ringbones, by soft-tissue enlargements, known as windgalls, thoroughpins, and shoe boils, and by injury to the hooves, including sand crack, split hoof, tread thrush, and acute or chronic laminitis.

BREEDS OF HORSES

The first intensively domesticated horses developed in Central Asia. They were small, lightweight, and stocky. In time, two general groups of horses emerged: the southerly Arab-Barb types (from the Barbary coast) and the northerly, so-called cold-blooded types. When, where, and how these horses appeared is disputed. Nevertheless, all modern breeds—the light, fast, spirited breeds typified by the modern Arabian; the heavier, slower, and calmer working breeds typified by the Belgian; and the intermediate breeds typified by the thoroughbreds—may be classified according to where they originated (Percheron, Clydesdale, and Arabian), by the principal use of the horse (riding, draft, coach horse), and by their outward appearance and size (light, heavy, pony).

Light horses. *Arabian.* Known for its stamina, intelligence, and character, the Arabian breed is first mentioned in 400 BC and is said to have stemmed from five mares given to Muḥammad by his followers, but the Arabs doubtless had horses earlier. The Arab is a compact horse with a small head, protruding eyes, wide nostrils, marked withers, and a short back. It usually has only 23 vertebrae, while 24 is the usual number for other breeds. Its legs are strong with fine hooves. The coat, tail, and mane are of fine silky hair. While many colours are possible in the breed, gray prevails. The most famous stud farm is in the region of Najd, Saudi Arabia, but many fine Arabian horses are now bred in the United States.

Thoroughbred lineage

Thoroughbreds. The history of the English Thoroughbred is a long one. Records indicate that a stock of Arab and Barb horses was introduced into England as early as the 3rd century. Conditions of climate, soil, and water favoured development, and selective breeding was long encouraged by those interested in racing. Under the reigns of James I and Charles I, 43 mares (the Royal Mares) were imported into England, and a record, the General Stud Book, was begun in which only those horses are inscribed that may be traced back to the Royal Mares in direct line, or to only three other horses imported to England: the Byerly Turk (imported in 1689), the Darley Arabian (after 1700), and the Godolphin Barb (about 1730). The English Thoroughbred has since been introduced to most countries, where it is bred for racing or used to improve local breeds. The Thoroughbred has a small fine head, a deep chest, and a straight back. Its legs have short bones that allow a long easy stride, and its coat is generally bay or chestnut, rarely black or gray.

Asian. Asian breeds were strongly influenced by Arabian or Persian breeds, which together with the horses of

the steppes produced small, plain looking horses of great intelligence and endurance. Among them are the Tartar, Kirghis, Mongol, and Cossack horses. A Persian stallion and a Dutch mare produced the Orlov trotter in 1778, named after Count Orlov, the owner of the stud farm where the mating took place.

Anglo-Arab. The Anglo-Arab breed originated in France with a crossing of English Thoroughbreds to pure Arabians. The matings produced a horse larger than the Arab and smaller than the Thoroughbred, of easy maintenance, and capable of carrying considerable weight in the saddle. Its coat is generally chestnut or bay.

Standardbred and Saddle horses. From the English Thoroughbred stem the American Thoroughbred; the American Standardbreds, especially good at the pace and trot gaits; the American Saddle horses with three and five gaits. These are very fine animals with small heads and spectacular high-stepping movements. The three-gaited horses perform the walk, trot, and canter; the five-gaited horses in addition perform a rack and a slow gait. Since they are used mainly for shows, their hooves are kept rather long and the muscles of their tails are often clipped so that the base of the tail is carried high. Chestnut and bay are the usual coat colours.

Also influenced by the Thoroughbred is the Tennessee Walking horse, used as a comfortable riding horse to cover great distances at a considerable speed. Its specialty is the walking pace, a very long and swift stride, which allows the horse to move at a rate of 8–10 miles (16 kilometres) per hour. Bay is the most common colour.

The Quarter Horse was bred for races of a quarter of a mile and is said to descend from Janus, a small Thoroughbred stallion imported into Virginia toward the end of the 18th century. It is 14.2 to 15 hands high, with sturdily muscled hind quarters, essential for the fast departure required in short races. It serves as a polo pony equally well as for ranch work.

The Morgan horse originated from a stallion given to one Justin Morgan around 1795. This breed has become a most versatile horse for riding, pulling carriages, farm labour, and cattle cutting. It was the ideal army charger. It is 15 hands high, robust, good-natured, willing, and intelligent. Its coat is dark brown or liver chestnut.

The Appaloosa

Appaloosa is a colour breed (see above) said to have descended in the Nez Percé Indian territory of North America from wild mustangs, which in turn descended from Spanish horses brought to the new world by explorers. The Appaloosa is 12 to 14 hands high, of sturdy build and of most diverse use; it is especially good in farm work. The English Hackney is a light carriage horse, influenced by the Thoroughbred, capable of covering distances of 12 to 15 miles (19 to 24 kilometres) per hour at the trot and canter. It measures 15.2 to 15.3 hands high and is appreciated for its high knee action. The English Hackney Bellfounder, imported to the United States in 1822 together with the Thoroughbred Messenger, contributed to the American Standard Breed.

The Cleveland Bay carriage horse, up to 17 hands high and generally bay in colour, is similar to the Yorkshire Coach horse. Both breeds are now used for the sport of driving.

Other versatile breeds include the German Holstein, Hanoverian, and East Prussian (Trakehner), which serve equally well for riding, light labour, and carriage. These horses, 16 to 18 hands high and of all colours, are now mostly bred for sport.

The Andalusian, a high-stepping, spirited horse, and the small but enduring Barb produced the Lipizzaner, named after the stud farm founded near Trieste, Italy, in 1580. Originally of all colours, the Lipizzaner is gray or now, exceptionally, bay. It is small, rarely over 15 hands high, of powerful build but slender legs, and long silky mane and tail. Intelligence and sweetness of disposition as well as gracefulness destined it for academic horsemanship, notably as practiced at the Spanish Riding School of Vienna.

Heavy breeds. The horses used for heavy loads and farm labour descended from the ancient war horses of the Middle Ages. The English Shire (the world's largest horse) and Clydesdale, the French Percheron, the Belgian horse, the German Noriker, and the Austrian Pinzgauer are now little used for their original purpose, being almost entirely replaced by the tractor. They measure well over 17 hands high, some 19 hands and more. They are of all colours, sometimes spotted, and generally have a very calm temperament.

Originating in the South Tyrol, the Haflinger is a mountain horse, enduring, robust, and versatile, used for all farm labour, carriage, sledge, and for pack hauling. It is rarely over 14.2 hands high and is chestnut with a flaxen mane and tail.

Ponies. Ponies are any horses other than Arabians that are shorter than 14.2 hands. They are generally very stur-

Representative horse breeds.
(Top) The Belgian, a heavy breed; (centre) an Indian pony; (bottom) the American saddlebred, a light breed.

dy, intelligent, very energetic, and sometimes stubborn. The coat is of all colours, mainly dark, and the mane and tail are full. Ponies are used for pulling carriages and pack loads and as children's riding horses or pets. There are numerous varieties, including the Welsh, Dartmoor, Exmoor, New Forest, Highland, Dale, Fell, Shetland (under seven hands high), Iceland, and Norwegian. Ponies of the warmer countries include the Indian, Java, Manila, and Argentine.

HORSE SOCIETIES AND SHOWS

International standards

With the development of riding as a sport, organizations devoted to horses formed, and international standards were set up for various competitions. The chief governing body, the International Equestrian Federation, heads the various national federations that are subdivided into associations and clubs. It is the object of these organizations to promote and maintain interest in riding, to further the art of riding, to encourage instruction and progress of horsemanship, and to safeguard the welfare of the horse. The national federations organize horse shows and competitions, appoint judges, and delegate riders from their countries to international events. The selection of individual riders or a team for the Olympic, Pan-American, or regional games is done by the national federations.

Horse shows range from small local shows to international competitions and are held for many kinds of activity with a horse. The object of a horse show is to set a standard of presentation of horse and rider or trainer. The international competitions are open for dressage (deportment and obedience), jumping, and combined training. The International Federation acknowledges national events, held under the regulations of the national federation of the host country; friendly events, in which competition is open to riders from an invited nation; and official international events (Concours Hippique International Officiel) or Championships, which are authorized by both the national and the International Federations, are limited to once a year in Europe and twice a year in the rest of the world. At the 23rd Olympiad, 688 BC, a four-horse chariot race was on the program for the first time, and at the 33rd games, some 40 years later, mounted-horse races were included. The Olympic Games now include three equestrian events: dressage, stadium jumping, and combined training. Besides uncountable local horse shows, often in connection with agricultural fairs, a large number of international horse shows are held each year in Europe, the U.S., and Canada. Apart from the associations affiliated with the national federations, numerous organizations and clubs exist for racing, breeding, polo, hunting, or schooling.

BIBLIOGRAPHY. G.G. SIMPSON, *Horses* (1951; paperback edition, 1961), a very readable and popular account of the horse family today and through 60,000,000 years of development, with a good bibliography; M.C. SELF, *The Horseman's Encyclopedia*, rev. ed. (1963), an invaluable collection of information on domestic horses. Breed associations issue pamphlets on selected breeds of horses.

Horse Racing

Although horse racing is one of the oldest of all sports, its basic concept has undergone virtually no change over the centuries. It has developed from a primitive contest of speed or stamina between two horses into a spectacle involving large fields of runners, colourful costumes, rigid protocol for contestants and spectators alike, sophisticated electronic equipment, and immense sums of money; but its essential feature has always been the same: the horse that finishes first is the winner.

This article covers the history of horse racing, including its beginnings and the development of the sport and of the Thoroughbred racing horse; racecourses; racing rules and procedures; and strategy. There are also short sections on steeplechasing, Quarter Horse racing, and harness racing and a section on wagering, including parimutuel and off-track betting (see also RIDING AND HORSEMANSHIP).

Horse racing remains one of the most popular sports and continues to grow in attendance and financial statistics, but, relatively speaking, it has had to surrender an increasing share of public attention to newer sports and other leisure activities.

It is difficult, now, to appreciate the pre-eminence once enjoyed by racing. Throughout the bulk of recorded history of many countries the horse was the primary means of transportation, a vital adjunct to agriculture, and the mainstay of armies. Even those who did not actually ride were thoroughly familiar with horses as an integral part of everyday living. The attention that today is lavished on automobiles, football teams, and other agents of sport formerly was concentrated on horses.

It was only natural that pride in one's own animal would engender the desire to match it against another and that community pride would be manifested by matching the champion local horse against that of a neighbouring village. And, it was only human to wager on the result.

In its rude form, a horse race required no special arena or time away from regular work to train teams of participants. And, apart from wagering, it entailed no special expense. Two horses and two riders provided all the ingredients necessary.

Today, horse racing survives in its rude form, and coexists as an enormous, highly technical industry.

History

ORIGINS AND EARLY HISTORY

The origin of horse racing cannot be determined with precision, and the subject does not lend itself to categorical treatment. Conclusions based on archaeological findings are subject to revision from time to time in the light of additional findings and developments in the techniques for interpreting them.

Evidences of racing. For many years the chariot race described in Homer's *Iliad* was regarded as the first recorded instance of the sport. Subsequent discovery of inscribed tablets in Asia Minor, however, indicates that Assyrian kings maintained elaborate stables under the supervision of "professional" trainers 1,500 or more years BC; *i.e.*, centuries before the Trojan War.

Evidence predating the *Iliad*

At the Olympic Games in Greece, there was racing among chariots drawn by teams of four horses during the 7th century BC, prior to which the two-horse hitch had prevailed. It was not until about 40 years after the appearance of the four-horse hitch that racing among mounted horses (ridden bareback) was introduced, and for years this was regarded as having marked the approximate origin of horseback riding. Other evidence, however, indicates that man was riding horseback in Egypt about 1345 BC and in Babylonia during the 3rd millennium BC, although in the latter case the claim is submitted only to the extent that the animal ridden was an "equine quadruped," with the observation that it well might have been an onager, the ass having been domesticated before the horse.

Arguments for precedence of mounted racing. Some researchers have speculated that long before the horse reached the degree of training necessary for actual participation in battle it was used for transportation to the site of battle, whereupon the warrior dismounted.

That chariot racing preceded mounted horse racing by as much as several millennia is disputed by some horsemen. Archaeologists contend that for thousands of years the horse was too small to bear man's weight on his back; the only truly wild horse known in the 20th century, Przewalski's horse (*Equus caballus przewalskii*), is a small pony, found in western Mongolia, about 12 hands (48 inches or 120 centimetres) high. Horsemen, however, argue that donkeys no more than 12 hands high carry men on their backs and point out that, in any case, during the course of evolution both horse and man have come in various sizes that conceivably could have accommodated a variety of matchups. The gist of the horsemen's contention is simply that it is not natural that riding in wheeled vehicles should have preceded riding astride by so long a period, if at all. At whatever time the

horse was domesticated (after the ox and the ass), it would have been virtually instinctive on the part of man to mount and ride it. The chariot itself, with its relatively complicated harness attachments, would not have been necessary. A braided vine or rawhide thong (evidence of which is not likely to be found in excavations nor easily interpreted if found) would have been all the equipment needed. Archaeological evidence by and large has been found on the sites of what formerly were relatively stable, civilized areas, horsemen point out, whereas nomadic tribes, which were the least likely to have left traces of their activity, are the most likely to have originated mounted horsemanship.

Spread of racing stock. While many of the horses that performed at the Olympic Games probably were bred in Greece, many others came from Asia Minor or North Africa or were close descendants of horses imported from those areas. Arabians, Barbs, and Turks, since time immemorial, were the most greatly prized equine stock for purposes of speed. As the nucleus of culture and power shifted from Greece to Rome, the horses went along, and from Rome their influence was disseminated throughout Europe. Much later, from Spain, some of this same blood crossed the Atlantic to the Americas.

Horses from Asia Minor and North Africa

BEGINNINGS OF ORGANIZED RACING

Origins. As is true of impromptu racing, there is no specific date to mark the beginning of organized racing. It developed at different times in different countries. Presumably, areas such as China, Persia, Arabia, other countries of the Near East, and North Africa, where horsemanship was highly developed, were among the first to have organized racing.

Greece and Rome. Modern racing, in the sense that the general public became part of the proceedings, was foreshadowed in ancient Greece and Rome. During the heyday of the Roman Empire, there were chariot races, mounted races, and so-called Roman races in which riders stood with one foot on each of two horses. Public registries were kept for recording bloodlines of horses as well as racing records; and exceptional horses were accorded the honour of burial with a stele citing their records—one such having indicated 1,300 victories, 88 second- and 37 third-place finishes. There was ample opportunity to race: from 12 races a day under Augustus (27 BC–AD 14), the programs increased to 100 under the Flavians (AD 69–96), morning until sundown, with the distances of the races having been reduced to accommodate the increased numbers. There were professional racing officials, starting chutes, disputes at law, accusations of doping, widespread gambling (off-track as well as on, judging from the carrier pigeons that were released after certain races), and riots among the spectators.

Great Britain. Racing of the variety that came to be known as "the sport of kings" originated in England, although the fact that, long after the Roman invasion, Englishmen continued to import horses from the Continent, the Near East, and North Africa suggests that a similar form of sport was being carried on in other countries. An Arabian filly described as a racehorse reportedly was sold for the equivalent of £67,200 in the year 1290.

For centuries the avowed purpose of improving the breed of horses was to upgrade the cavalry; but in England, as the war horse gravitated toward the massive charger capable of carrying a man in heavy armour, a distinct type of horse, lighter and faster and selected for the specific purpose of sport, emerged. A description of London, about 1174, mentions racing at Smithfield every Friday; horses for sale were ridden in competition by professional riders to display their speed to buyers.

Like many other participants in the Crusades, Richard the Lion-Heart had acquired a great admiration for the Arabian horse, and it was during his reign (1189–99) that the first known racing purse was offered, 40 pounds in ready gold, run for over a three-mile (4.8-kilometre) course, with knights as riders. Richard's successor, John, was the first English king reported to have "running horses" in his stables. The Lanark (Scotland) Silver Bell has been run for since the late 12th century; and at some time prior to 1500 an annual "meeting" (one race each year) was instituted at Chester, as the report of the 1512 race stated that the event had been contested "time out of mind."

The patronage of English kings

Henry VIII in the 16th century imported "coursers" from Italy and Spain (which suggests that the horses were Barbs) and established royal studs in several locations. James I, who previously had patronized racing in Scotland, sponsored meetings in England during his reign (1603–25). Charles I, who reigned 1625–49, had a stud of 139 horses at the time of his death; and Charles II, who reigned 1660–85 and is known as "the father of the British turf," actively participated in races as a rider and offered King's Plates (silver cups or other prizes) to be run for. His patronage established Newmarket as the headquarters of racing.

North America. An emissary of Charles II, Richard Nicolls, earned the cognomen "father of the American turf." The first governor of the colony of New York, in 1665 he offered a silver cup, to be run for each spring and fall over a course laid out on Hempstead Plain, Long Island. This was the first known race trophy in North America and the beginning of so-called course racing. There had been previous racing in other American colonies, notably Virginia, but it was of the informal frontier variety.

France. There is documentation of racing, of a type associated with rural festivals, in France during the 14th century; a formal race, resulting from a bet between Prince d'Harcourt and another nobleman, was reported in 1651. During the long reign of Louis XIV (1643–1715), racing on which gambling was based was prevalent. Louis XVI (reigned 1774–93) organized a jockey club; and decrees issued by the royal printing house included rules of racing, among which were specifications concerning certificates of origin and extra weight to be carried by "foreign" horses—an early example of discrimination in favour of native stock. Napoleon established a series of regional competitions for money prizes, with a runoff for a "Grand Prix" at Paris.

Match racing. As noted, racing by fields of horses for prizes dates back to ancient times, but as the sport began to re-evolve into its present format, during the 16th century, matches were the most common form of competition. In a match, the owners of the competing horses themselves provided the prize (purse).

A typical early match was simply an agreement between two owners to run their horses against one another for, say, "200 guineas each, half forfeit," which represented a wager, pure and simple, with a penalty provided should either owner withdraw his horse. "Official" records of such agreements (some of which involved sums considerably larger than 200 guineas) were entered in books by unbiased third parties, and specialists at this function emerged in various racing centres as "keepers of the match book." In 1727, John Cheny, keeper of the match book at Newmarket, published *Cheny's Horse Matches*, which was a consolidation of the match books of various racing centres. The work was carried on as an annual volume by a succession of publishers under different titles—some volumes carried results of cock fighting and cricket matches as well as of horse racing—until it was taken over in 1773 by James Weatherby. As the *Racing Calendar*, devoted to horse racing only, it has been published by the Weatherbys ever since.

Origins of racing calendars

Although three or more horses could participate in early matches, the usual number was two; and in modern times the term match race applies only to contests between two horses.

A defection from a two-horse race, of course, resulted in cancellation of the contest. To discourage casual forfeiture, such terms as one-fourth forfeit were replaced in some races by the phrase play or pay, which meant that an owner whose horse failed to fulfill the engagement forfeited his entire stake. A similar change took place in the rules of betting, which originally provided that a wager on a horse that did not actually start should be refunded but later stipulated "play or pay," which meant that the bet was firm whether or not the horse ran.

Open field racing. Because of their essentially private nature, match races progressively lost favour to more open events, involving larger fields of runners. The races for the King's Plates, which dated back to the time of Charles II, were especially popular. Townships and individual sportsmen also offered prizes to be run for by any horses that met certain qualifications; and general sweepstakes, to which a number of owners could nominate horses at a fee, came into vogue.

There developed a wide spectrum of eligibility conditions for races, based on age, sex, birthplace, qualification of riders, previous usage, and previous accomplishment or (as was more common) lack thereof. Some of the conditions, *e.g.*, those based simply on age and sex, were designed to attract larger fields of runners. Other conditions were designed to broaden the base of the sport by encouraging participation of those who might have eschewed open competition or to provide for more interesting contests among horses of essentially similar class, or both. Examples of such conditions were "owners to ride," or "for Horses, etc., bred in the county of Glamorgan . . .," or "for Horses, etc.; that never won Plate or Match of 50 pounds. . . ."

Eligibility conditions and racing rules

The articles for the King's Plates in England were among the earliest racing rules of national scope. George II's Act of 1740 was relatively simple in that it provided for only one type of race but remarkably comprehensive in the contingencies it covered. Horses were required to be the bona fide property of persons who entered them (a precaution against "ringers" [*i.e.*, horses entered into competition with false identification] of superior ability); certificates as to ownership and age were required; penalties were specified for rough riding; and riders were not allowed to dismount before arriving at the place of weighing-in.

First records of jockeys. Although jockeys were identified in contemporary accounts of certain important races, they were ignored in the early official records. No doubt this was in part a reflection of the succinct format of early records, but it also reflected prevailing opinion that the jockey was not an especially important factor in determining the outcome of a race. Certainly this was true of four-mile (6.4-kilometre) heat racing, in which the strength and stamina of the horse were more important than quick thinking and judgment by the rider. If a horse became boxed in during a four-mile heat, there was plenty of time in which to extricate him; and even should the heat be lost, there were other heats in which to make amends. In dash racing, by contrast, depending on the distance, the loss of a few yards could mean the race. Jockeys more or less crept into the official records. First, the names of the winning trainer and winning rider only were added to race reports. By the late 1850s it had become customary for the *Racing Calendar* to record all riders.

One of the first jockeys to appear in official English records was for many years identified simply as "Nat," until finally, in 1841, the *Racing Calendar* recorded his full name: Elnathan Flatman. A famous jockey in early American records was a slave listed only as "Abe."

Development of the Thoroughbred. The widely circulated version that the Thoroughbred breed was founded by three "Oriental" stallions and 43 "royal" English mares is misleading. The word founded is dubious to the extent that it suggests establishment according to some preconceived plan. The Thoroughbred breed simply evolved. In the beginning, it was the horses that made the pedigrees rather than vice versa; and it was not until many generations later that certain horses were determined—in retrospect—to have been founders. The breed emerged from considerably more than 43 mares, not all of which were "royal" (a designation given to a group of mares imported by Charles II and applied also to their descendants), and considerably more than three stallions, not all of which were "Oriental."

Emergence of the breed

The Thoroughbred did begin as a mixture of Arabs, Turks, and Barbs with native English stock; although it might have had remote Arabian antecedents, the Barb was generally acknowledged as a distinct breed indigenous to Algeria and Morocco rather than to the Orient. Barbs were especially popular in England and more easily obtainable, through Spain and Italy, than the other breeds. Since a stallion has so many more offspring than a mare, this foreign blood was more widely disseminated by sires; but there also were elements of it, resulting from previous importations, among the "native" English broodmare population.

Bloodlines and studbooks. As the English sporting horse emerged as a distinct type, the term bred horse came into being, and it became customary to include pedigrees of horses in papers of sale. There had been private studbooks, one dating back to 1605, but the records were not invariably reliable.

In 1791, Weatherby, publisher of the *Racing Calendar* mentioned above, offered a small collection of pedigrees he had extracted from *Racing Calendars* and sale papers as *An Introduction to a General Stud Book*. It was revised several times over a period of many years, increasing in scope with the revisions, and it became Volume I of the *General Stud Book*. This volume purported to be nothing more than a collection of pedigrees of horses (with a view toward correcting "false and inaccurate" pedigrees but with no claim that it was free of error). Horses were included "from the earliest records," which in some cases dated back a century, suggesting that Weatherby relied at least to some extent on private studbooks for his information.

The term bred horse, or blooded horse, also was used in other countries, and although it was not formally defined, horsemen evidently had an understanding as to its meaning. Conditions for a Pennsylvania race in 1764 specified more entrance money for "full-blooded" horses than for three-quarters blooded, and half-breds received a further discount. In colonial North America, where the progress of racing and breeding followed that of the mother country so closely as to be virtually contemporaneous, the degree of breeding almost certainly referred to the English pattern; Bulle Rock, the first documented "bred" horse in America, was imported from England in 1730.

Studbooks were established in other countries, including in some cases native stock but relying heavily in all cases on horses of "English" breeding. Volume I of the *Stud Book Français*, begun in 1838 but, like the British book, revised over a period of years before it became firm, had two classifications of "purebred" horses: "Orientale," which included pure Arabs, pure Turks, and pure Barbs; and "Anglais," which included mixtures according to the English pattern. The latter category, by far the larger, was determined according to type of breeding rather than place of birth; and most of the horses were native to France.

The mixed breed was destined to predominate, and the modern *Stud Book Français* is presented simply as a register of "chevaux de pur sang Anglais" ("horses of pure English blood").

Because the top (tail-male, through male issue) and bottom (tail-female, through female issue) lines are the longest lines in a pedigree, horsemen pay particular attention to those lines, especially the top one since, as already noted, the influence of an individual stallion is far more widespread than that of a mare.

Male and female pedigree lines

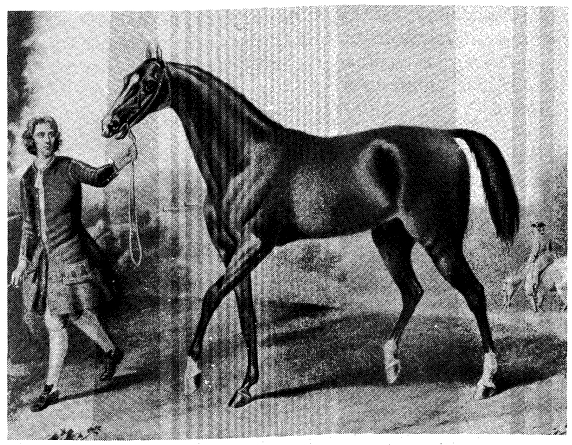
By sheer coincidence it developed that every horse registered in the studbooks of all countries traced in direct male line to one of three stallions, viz:

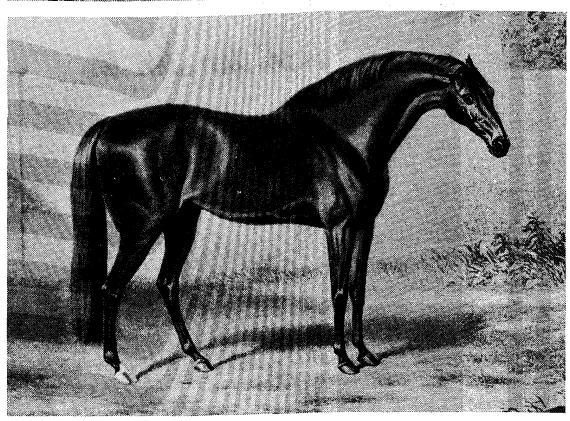
The Byerly Turk, used as a charger by the English Captain Byerly (also spelled Byerley) at the Battle of the Boyne in 1690.

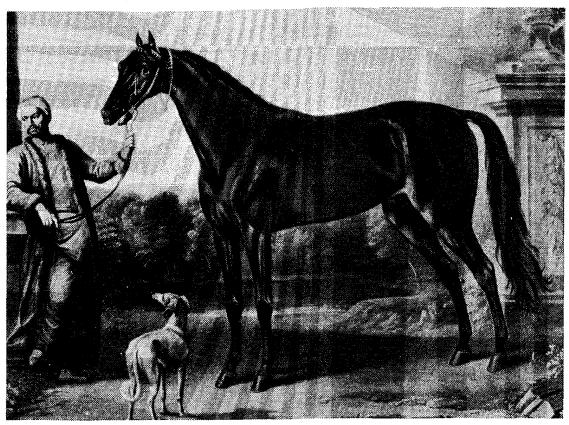
The Darley Arabian, imported as a young horse, about 1704, from Aleppo to England by Richard Darley of Yorkshire.

The Godolphin Barb (also called Arabian) brought to England from France about 1730 by Edward Coke, who, according to a popular account, discovered the horse pulling a cart through the streets of Paris. After Coke's death, the horse passed into the ownerhip of the Earl of Godolphin.

By another coincidence, the male lines of each of these three sires survives through a single descendant. All tail-male descendants of the Godolphin Barb trace to him







Three foremost stallions.
(Top) The Darley Arabian. (Centre) The Godolphin Barb. (Bottom) The Byerley Turk. Every horse registered in the stud books of all countries can be traced to one of these stallions in direct male line.
Fores Ltd.

through his grandson, Matchem (1748–81); those of the Byerly Turk through his great-great-grandson, (King) Herod (1758–80); and those of the Darley Arabian through his great-great-grandson, Eclipse (1764–89). Actually, the Matchem line could be identified by other names since there probably is not a modern horse tracing to him that does not do so through West Australian, six generations removed from Matchem. The male-line descendants of Eclipse comprise the vast majority of the Thoroughbred breed, and his most prolific branch is that of an oddly named son, Potooooooooo. The name supposedly resulted from the inability of a stable lad to spell potatoes, but this sire is listed in modern pedigrees as Pot-8-0's. Eclipse was bred by the Duke of Cumberland, who at one time owned Herod.

In tracing pedigrees only through tail-male or tail-female lines, connections between stallions and their daughters or mares and their sons are disregarded. While all Thoroughbreds today descend from one of the three so-called foundation sires, in tail-male line, they also descend from other sires in other lines of their pedigrees. For example, Herod, Matchem, and Eclipse, in other than their top lines, trace to D'Arcy's Yellow Turk and to the Leedes Arabian, whose tail-male lines have died out.

When the Australian Bruce Lowe and the German Hermann Goos (independently of each other) traced every mare in tail-female line back to her so-called taproot as registered in volume I of the *General Stud Book*, they found only 43 female "families" that still survived in unbroken chains of dam-to-daughter at the time of their research, in the latter part of the 19th century. No account was taken of taproot mares whose bottom lines had died out but who nevertheless had descendants through lines that at some point(s) traced through a son. Moreover, Lowe's family numbering system ignored female families in other countries, whose taproots were not recorded in the first volume of the *General Stud Book*.

For many years there had been reciprocity among the studbooks of various countries, but in 1913 the English Jockey Club passed a measure, sponsored by the Earl of Jersey, that declared that only horses that traced in all their lines to animals previously registered in the *General Stud Book* would be accepted for future registrations therein. The effect of the Jersey Act, as it was called, was to disqualify as Thoroughbreds many horses bred outside of England or Ireland, including the majority of North American horses. The ostensible purpose of the Act was to protect the British Thoroughbred from infusions of American "sprinting" blood, but the background suggests more mundane motives. Political repression had caused a shutdown in 1911 and 1912 of racing in New York, which was the major American racing centre and bloodstock market. During the uneasy years that preceded the shutdown, American owners and jockeys had gone to England in increasing numbers; after the shutdown an invasion of American bloodstock into England was a threat. As just one example, James Ben Ali Haggin (whose private catalog for 1903 had included approximately 2,000 horses) had been in the habit of shipping trainloads of horses to the New York sales, and he already had sold horses in England, including Grand National winner Rubio for $75. By himself, Haggin could have flooded the English market, and there were other American breeders with horses to sell but no buyers at home.

Exclusion of American horses

Apart from its economic significance, for decades the Jersey Act rankled national pride and rather defied logic. Americus, for example, had been sent to England and duly registered in the *General Stud Book* before the Act. He was therefore a Thoroughbred, but both of his parents and numerous half-siblings, which had remained in America, as of 1913 suddenly were not. Americus (through a daughter) became the ancestor of such distinguished English Thoroughbreds as Mahmoud and Nasrullah.

The ticklish question finally was resolved in a proper setting, on the racetrack. Following a rash of victories in prestigious English races by French horses with "tainted" American ancestry, in 1949 the Jersey Act was rescinded. Animals with "eight or nine crosses of pure blood" became eligible for admission into the *General Stud Book*. This did not open the book automatically to all American Thoroughbreds, but it eliminated the ill feeling.

In 1954, the Derby and St. Leger were won by Never Say Die, a son of Nasrullah, mentioned above, out of a granddaughter of America's most famous horse, Man o'War, who, throughout his long life (1917–47) was not regarded as a Thoroughbred by English standards. In 1962 Never Say Die was champion English sire.

Jockey clubs and racing commissions. Provincial jockey clubs or similar organizations that regulated local turf affairs developed, along with racing, at various times in various places. The Jockey Club formed at Newmarket about 1750 wrote its own rules of racing; in contrast to the articles for King's Plates, which dealt with that form of racing only, these rules took into account different kinds of contests involving horses of different ages and

The Jockey Club rules and stewards

were correspondingly more detailed. These rules originally applied to Newmarket only but were printed in the *Racing Calendar* and served as models for rules everywhere. They gradually were adopted throughout the United Kingdom, and as the Jockey Club acquired ownership of the *Racing Calendar* and the *General Stud Book* (although both continued to be published by the Weatherbys) its authority became supreme. For a time it was policy to delegate authority to a Jockey Club steward of exceptional stature; those who held this position—Sir Charles Bunbury; Lord George Bentinck; and Admiral Henry John Rous, who died in 1877 and had no successor—were known as dictators of the English turf.

The Jockey Club in England continues to exercise virtually complete control of racing and breeding, and it also owns the Newmarket racecourse and the training grounds that surround it.

La Société d'Encouragement pour l'Amélioration des Races de Chevaux en France was founded before its English counterpart, in 1833. It administers racing, owns major tracks and training centres, including that at Chantilly, which is probably the finest in the world; but the *Stud Book Français* is published by the Ministry of Agriculture, and it was only in 1969, after the demise of *La Chronique du Turf*, that the society took over publication of that country's racing calendar.

In other countries the scope and authority of national jockey clubs vary; in North America there is a proliferation of organizations that bear that title. Some are simply commercial corporations that administer business operations of one track only. Control of actual racing in the United States is widely diffused, as rules are promulgated by individual commissions in each of the states that have racing. The commissions are organized into a National Association of State Racing Commissioners (which includes member bodies from Canada, Mexico, and elsewhere in North America), but each state retains its own authority.

The (North American) Jockey Club, headquartered in New York, at one time exercised wide (but not complete) control over American racing. A court ruling that took away its licensing power reduced its authority; but it still has considerable influence as keeper of the *American Stud Book* (which includes foals from Canada, Puerto Rico, and parts of Mexico), and it also publishes rules of racing that are used as a model by many states and have been formally adopted in at least one state.

There are numerous other racing organizations in many countries, as well as associations among owners, breeders, operators of race tracks, jockeys, trainers, veterinarians, and others closely identified with the sport.

TYPES OF RACES

Organized races. *Heat racing.* The original King's Plates were standardized races—all were for six-year-old horses, carrying 168 pounds (76 kilograms), at four-mile (6.4-kilometre) heats, a horse having to win two heats to be adjudged the winner. Beginning in 1751, five-year-olds (set to carry 140 pounds) and four-year-olds (126 pounds) were admitted to King's Plates, with a reduction in distance of the heats to two miles (3.2 kilometres). The desire to race younger horses had long since manifested itself in other kinds of races. Racing for four-year-olds was well established, and a race for three-year-olds, carrying 112 pounds (51 kilograms) in one three-mile (4.8-kilometre) heat, was run in 1731.

The Industrial Revolution was a significant factor in the demise of heat racing. In an agrarian economy a horse could be raised until it reached the age of four or five at no great additional expense, and if the horse turned out to be a failure on the racecourse it could be diverted to some other useful function. In an industrial economy such a horse represented virtually a total loss.

Heat racing persisted as the most popular form of the sport much longer in America, where Virginia was the horse capital, than it did in England. Heat racing, in which four-year-olds competed at the "full" distance of four miles, continued as a popular form until the U.S. Civil War (1861–65).

Dash racing. By that time heat racing had long since been overshadowed in Europe by dash racing, a "dash" being any race decided by only one heat, regardless of its distance. Some early dashes were at eight miles (12.8 kilometres), although the horses generally cantered until within a few furlongs of the finish.

The English classics

The modern age of racing is generally considered to have been marked by the inauguration of the English classic races: the St. Leger in 1776 (although it was not run under that name until two years later), the Oaks in 1779, and the Derby the next year. All were dashes for three-year-olds only. Sir Charles Bunbury, who was a strong advocate of dash racing for young horses, won the inaugural of the Derby with Diomed. Ironically, the horse later was exported to America where he founded a dynasty that dominated the golden age of four-mile-heat racing in that country.

Handicaps. *Weight handicaps.* During the 19th century, races of the English classic pattern—dashes for three-year-olds, at level weights except for the sex allowance (see below)—spread all over the world.

In the early match races the weight to be carried by each horse was a matter of agreement between the owners. In racing for fields of horses the weights generally were determined by age. Older horses had to concede weight to their juniors up to age seven, for example, at which point they were considered "aged" and the weights levelled off. (There were exceptional cases, such as the renowned American campaigner, Walk-in-the-Water, who raced on through age 18; at 15 and beyond, he received a concession from his juniors.)

There also were races in which weight was based upon height, but this proved to be an unsatisfactory criterion.

Scales of weights for age

As racing of younger horses became more prevalent, finer distinctions as to weight were necessary. A preliminary scale of weights for age, published by Admiral Rous in 1850, embodied sharply ascending weights for two-year-olds as the racing season progressed, April through November, while the weights for older horses were relatively stable throughout the year. Among the earliest acknowledgments that two-year-olds were regarded as racehorses in the U.S. was an 1843 rule that prescribed for them "a feather."

Gradually, scales of weights for age evolved into the elaborate modern tables that specify weights, month by month, according to age of the horses and distance of the races. Each country (and in the United States, each state) has its own scale, but the following examples are representative. A three-year old of the Northern Hemisphere, racing against a four-year-old at 6 furlongs (one furlong = ⅛ mile) receives a 15-pound (seven-kilogram) concession in January, but only a two-pound (one-kilogram) concession in November, when it has almost caught up in development. At a given time of year, say, November, the concessions increase from two pounds at 6 furlongs to four pounds (two kilograms) at 1½ miles or more. In general, the scales reckon a horse as being fully aged at five years, or earlier, so far as sprint racing is concerned.

The sex allowance provides that fillies receive a three- or five-pound (one- or two-kilogram) concession from males, and in many countries geldings also receive a weight concession, to encourage elimination of mediocre horses from stud duty.

Ages are reckoned from January 1 in the Northern Hemisphere and either July 1 or August 1 in the Southern. (May 1 formerly was the universal birthday in the Northern Hemisphere.)

The weight scale is designed to determine the intrinsically best horses, and all classic races are run under its provisions. Various devices were developed to neutralize the weight scale, however, in order to provide for more closely contested races or to attract larger fields (thereby stimulating wagering), or both.

Allowance and claiming races. "Condition" or "allowance" races provide for weight penalties or allowances based on previous performance. The "selling plate," or "claiming race," is essentially a method of requiring owners to classify their own horses by setting a price on

them. In early versions, the winning horse was sold at auction. In the modern version, any owner who has a horse in the race (or has started a horse at the meeting) may claim any other horse for the stated price (drawing lots if more than one owner claims the same animal). If any owner runs a horse below its true class, he stands to win the race but lose the horse.

Handicap races. The handicap race represents an outright repudiation of the classic concept that the best horse should win; imposts are assigned on the basis of past performance with the specific objective of giving all horses an equal chance of winning—although this objective is by no means invariably achieved. Racing form fluctuates, and assignment of weights is at best a difficult art, and at worst it can be a farce. In some countries, weights for all handicaps are assigned by a central authority, such as a representative of the jockey club, but in others each track employs its own handicapper and owners of star attractions thus are able to shop around for the most lenient weight assignments.

Assignment of handicap weights

In some countries, the purses of handicaps generally are not large enough to attract the classic winners or other top horses. In countries that offer handicap purses that are sufficient to attract the best horses, such races provide more emphatic tests of intrinsic merit than do classic events. Obviously, it requires a better horse to win against all comers while conceding weight than it does to win against members of only one foal crop at level weights. Unlike many classics, handicaps as a rule are not restricted as to age or sex.

The Melbourne Cup, a handicap inaugurated in 1861, is generally regarded as the most important race of the Southern Hemisphere. It has been won by such epic horses as Carbine, under 145 pounds, and Phar Lap, under 138. In America, the Metropolitan, Brooklyn, and Suburban handicaps—all of which date back to the 19th century—were at one time the most valuable events in the country, and remain reasonably comparable in value to classic events. Only three horses—Whisk Broom II, Tom Fool, and Kelso—have managed to win this "handicap triple," compared to nine winners of the American Triple Crown for three-year-olds. As it happens, not one of the three handicap triple winners ran in any one of the three-year-old classics.

The pioneer among existing races of $100,000 or more in value is the Santa Anita Handicap, which for its first running, in 1935, attracted horses from thousands of miles away. The field included four classic winners of former years (and still another had been withdrawn shortly before the race), but the winner was an Irish-bred former steeplechaser, Azucar.

As is to be expected, handicaps are exceptionally popular as betting media.

Phar Lap, who was bred in New Zealand, won several classic races in Australia, and Kelso's failure to participate in the American classics for three-year-olds was the result of an interruption in his training. As geldings, however, had they raced in Europe (or in any of several countries elsewhere), neither Phar Lap, Kelso, nor Azucar would have been allowed to run in classic races. The restriction against geldings in certain important races in New York was lifted as recently as 1957; and Kelso, the leading money earner in history ($1,977,896), derived a considerable measure of his fame and income from five successive victories in the Jockey Club Gold Cup, a classically conceived weight-for-age event for which he would not have been eligible a decade earlier.

Races for older horses. That three years is the classic age of lucrative purse opportunities is based more on expediency than on sporting considerations. Statistics tend to confirm the implicit message of weights, that a racehorse achieves peak ability at age five. There has been a modern trend toward giving horses older than three more opportunities to race for larger purses. The Prix de l'Arc de Triomphe, in France, is generally acknowledged as the world championship event not only because of its enormous value (more than $200,000 to the winner) but also because it admits older horses. It is not a handicap, as weights are based on age and sex only, but they are adjusted from time to time to maintain balance between frequency of victory and frequency of participation by horses of various age groups. The Arc is not open to geldings, however.

A partial listing of other famous races that admit horses older than three would include, in addition to events already mentioned, the Gran Premio Internacional Carlos Pellegrini in Argentina, Caulfield and Sydney cups in Australia, Grande Premio São Paulo Internacional in Brazil, King George VI and Queen Elizabeth Stakes in England, Gran Premio del Jockey Club and Gran Premio di Milano in Italy, Emperor's Cup and Arima Memorial Stakes in Japan, Wellington Cup in New Zealand, Rothman's July Handicap in South Africa, and Gran Premio Clasico Simón Bolívar in Venezuela. Of the approximately 60 races in the United States with purse values of $100,000 or more, about half are open to horses older than three years.

Purse money and stakes fees. The King George VI and Queen Elizabeth Stakes and the Rothman's July Handicap are examples of sponsored races for which much of the purse money is put up by commercial firms. In the United States, this practice has not caught on, and most of the purse money for the richest events is provided by the owners themselves, in the form of stakes fees. The $352,320 purse of the 1970 Garden State Stakes (which is an event for two-year-olds) included $227,320 in owners' stakes fees.

Distribution of purses

Methods of distributing purses vary widely. As winner-take-all matches were replaced by racing among fields of horses, the provision "second to save his stake" was inserted into conditions for some races. Then, a second prize of stated value, greater than the owner's stake, was offered (in early races, hogsheads of claret and, in America, casks of tobacco were frequent ingredients of race prizes). Gradually, in further efforts to encourage larger fields, third and fourth prizes became common. Fifth money is not unusual today, and in some races at least a token portion of the purse is awarded to every horse that starts.

As an overall average, North American purses, for example, in 1970 were allocated 61 percent to the winner, 20 percent to second, 11 percent to third, 6 percent to fourth, 2 percent to fifth, and an inconsequential percentage to horses out of the first five. Slightly more than half (54.5 percent) of the horses that started in North America in 1970 won at least one race, and as a group these horses also gathered in the lion's share of minor purse awards—when they didn't win, they usually finished close up—with the result that they earned 94.1 percent of the total purse money.

THE HORSES AND THE HORSEMEN

Breeding theory and practice. Over the centuries the guiding principle for breeding Thoroughbreds has been, as expressed by an old cliché: breed the best to the best and hope for the best. Performance of progeny is the most reliable guide to what is best for breeding purposes, of course, but in the case of horses untried at stud, their own racing ability, pedigree, and physical conformation are the only available yardsticks. Emphasis is on racing ability, especially in evaluating potential stallions. Although for many years the stallion was regarded as by far the dominant partner in an individual mating, the modern school of thought credits the mare for approximately half the inherited quality of the offspring.

Breeding systems

When Lowe numbered the female families, he did so in order of the frequency of victories in the English Derby, St. Leger, and Oaks, members of the number one family having scored the most victories, and so forth. Families that had produced no winners of the designated races were assigned the higher numbers, according to Lowe's estimate of their worth. He also designated certain tail-female lines as "running families" or "sire families." As time went on, the rankings in number of classic victories were subject to change, and new families were introduced; but the original family numbers were retained. Matching bloodlines according to Lowe numbers was at one time practiced as a breeding system, but today the

numbers are generally regarded simply as convenient identifications of female lines.

Lieutenant Colonel J. Vuillier, a French cavalry officer, propounded in the 1920s what he called a "dosage system," based on the theory that each ancestor provided a fractional portion of the makeup of a horse. Having noted that 15 stallions and one mare (Pocahontas) appeared most frequently in the pedigrees of successful racehorses, he advocated matings that provided for optimum dosages of the blood of each. The system continues to attract some followers; and the late Aga Khan III, who enjoyed enormous success in racing and breeding, was said to have employed a modification of the Vuillier system.

The most successful breeders appear to be those who apply the best-to-the-best formula, with common sense and judgment added—instead of mating just any top class stallion to any top class mare, they take into account the individual characteristics of each animal.

To the phenomenally successful Italian breeder, Federico Tesio, whose products included undefeated champions Nearco and Ribot (he named many of his horses after artists), breeding horses appears to have been as much an art as a science. Nor did he discount romance, having attributed the merit of Derby and Oaks winner Signorinetta to the strong attraction her parents had manifested for each other.

Outstanding horses. Eclipse, from whom the majority of Thoroughbreds descend in tail-male, antedated the classics and did not begin racing until he was five years old. He was undefeated in 18 races, including a number of walkovers in which no rivals appeared to compete with him.

St. Simon (1881) did not run in any of the three-year-old classics, and he, too, was undefeated—in nine races, including the Ascot Gold Cup. At stud he was extraordinarily prolific and successful. He covered mares through age 27 and got an average of 25 foals per crop. He was champion sire nine times, including a sequence of seven consecutive seasons.

St. Simon's maternal grandsire, King Tom, was a son of Pocahontas (1837), the only mare included in the Vuillier dosage system. Among her other sons was Stockwell (1849), a seven-time champion sire who was known as the "Emperor of Stallions." Although she was a non-winner on the racecourse, Pocahontas produced 15 foals of which 10 achieved fame, and it would be difficult if not impossible to find a Thoroughbred anywhere in the world today that does not trace to her in some line of its pedigree. (This rather aptly illustrates the fallacy of some breeding systems based on bloodlines; every classic winner descends from Pocahontas, but so does every non-winner.)

Pocahontas and her descendants

Pocahontas' sire, Glencoe (1831), was exported to North America, where he was champion sire eight times. He begat 50 known foals when he was 23 years old and was a genetic oddity: early records did not in every case indicate sex; but of Glencoe's 481 American foals whose sex was recorded, 317, or about two-thirds, were fillies.

The longest tenure as leading sire was that of Lexington (1850), who led the North American rankings for 16 seasons, 14 of them in succession. The modern record—the most remarkable of all in view of the vastly larger arena in which he was competing—is held by Bold Ruler, who was leading North American sire seven successive seasons (1963–69). He succeeded his own sire, Nasrullah, who held the unique distinction of having been leading sire in England (once) and in North America (five times).

The most remarkable racing record was compiled by the Hungarian mare Kincsem (1874), undefeated winner of 54 races in six countries: Austria, Czechoslovakia, England, France, Germany, and Hungary. She finished in a dead heat with Prince Giles in the 1878 Grand Prix at Baden-Baden, but the rules required a runoff, which she won by five lengths. Other famous undefeated runners include Barcaldine, Ormonde, Hurry On, The Tetrarch (who ran only at two), and Bahram in England; Ajax, Pharis, Le Pacha, and Caracalla in France; and Colin in the United States. The American horse Kingston (1884) won 89 races in 138 starts, and the mare Pan Zareta (1910) won 76 races in 151 starts.

World record holders and winners of selected famous English, French, and American races are listed in SPORTING RECORD in the *Ready Reference and Index*.

Triple crowns and classics

The highly-prized trilogy known as the English Triple Crown, consisting of the 2,000 Guineas, Derby, and St. Leger, has been won 15 times since 1853. The American Triple Crown, consisting of the Kentucky Derby, Preakness Stakes, and Belmont Stakes, has been won nine times since 1919. In France, where (with notable success) stamina is encouraged, the emphasis is on the classic double of the Prix du Jockey Club (French Derby) and the $1\frac{15}{16}$-mile Grand Prix de Paris, which has been won 19 times since 1875.

Sceptre (1899) won four English classics: the 1,000 Guineas and Oaks restricted to fillies, and the 2,000 Guineas and St. Leger from males. Seven other fillies swept the classics for their sex and won the St. Leger as well, among them Pretty Polly, winner of 22 races in 24 starts and subsequently a landmark broodmare.

The Ranger, winner in 1863 of the Grand Prix de Paris, was an English horse, but two years later France returned the favour with interest as Gladiateur won the Grand Prix de Paris in his own country and crossed the channel to sweep the English Triple Crown. (He also won two other coveted English races, the Goodwood Cup and Ascot Gold Cup.)

Over the years, competition between England and France became quite keen; and with the development of jet transportation, competition in classics has become worldwide.

Outstanding riders. English jockey Fred Archer, riding from 1870 to 1886, achieved 2,748 victories, and the 20th century was well along before his record was surpassed. Among those victories were 21 classics, and Archer compiled his total from 8,004 mounts for a winning average of 34 percent.

Personal records of the American Negro jockey Isaac Murphy, who had relatively few mounts (partially due to a weight problem that later led to his retirement) showed 628 victories in 1,412 races for a phenomenal 44 percent winning average. His official career was from 1876 to 1896, but when 14 Murphy had ridden a few races in 1875 under his original name of Isaac Burns.

Richards, Longden, and Shoemaker

Gordon Richards, who surpassed Archer's record for total victories in 1943, continued to ride through age 50, retiring with 4,870 victories. Sir Gordon, who was knighted by Queen Elizabeth II, was seasonal champion 26 times in 34 years, including a streak of 22 championships in 23 years. Richards' idol, Steve Donoghue, rode Triple Crown winners Pommern and Gay Crusader and won the Derby four other times in five years with Humorist, Captain Cuttle, Papyrus, and Manna (1921–25). Another of Donoghue's records was that in 33 years of riding he never was summoned before the stewards for disciplinary purposes.

John Longden, who surpassed Richards' record in 1956, retired in 1966 at age 59 with 6,032 victories. During his 40-year career Longden accepted 32,406 mounts in North America in addition to several in other countries (six of his victories were scored outside North America).

In 1970, William Shoemaker, at age 39, overtook Longden and finished the year with a career total of 6,072 victories. Shoemaker had amassed his total in only 22 seasons, during which he had 24,661 mounts and a winning average of 25 percent. His 485 victories in 1953 are a record for a single season, and, all told, his mounts through the end of 1970 had earned about $43,800,000, to average almost $2,000,000 per season. During 1971, Shoemaker continued to add to his records and by the end of 1972 he had set a new record of 577 victories in stakes races, the only significant gross record he did not already hold, breaking the previous record which had been held by the famed rider Eddie Arcaro, who retired in 1961. Shoemaker's success was a contradiction to the old belief that "live" weight on a horse is better than "dead" weight. A natural 100-pounder, Shoemaker had a special saddle pad with extra pockets for lead weights.

Among other jockeys are nine-time English champion Lester Piggott, who in 1972 rode his 20th English classic winner to come within striking distance of Archer's record; and young Yves Saint-Martin, who had nine French championships to his credit at age 30.

Riding styles

Among jockeys who influenced style, Tod Sloan, who flourished during the 1890s, did much to popularize short stirrups and the high crouch; but the style had been used previously, notably by black exercise boys and by North American Indians. John Randolph of Virginia (1773–1833) was said to have ridden "like a monkey on a stick," which description later was applied to Sloan. Similarly, although Arcaro did not originate the style, many other riders adopted his method, called "ace-deuce," of riding with the right stirrup shorter than the left.

History is crowded with references to women riders, but women as licensed professional jockeys in official horse races did not make their debut until 1969. A year later there were about a dozen of them in North America, none of whom had proved to be more than a reasonably competent journeyman rider.

Trainers, owners, and breeders. At the time of his death in 1970, the American trainer Hirsch Jacobs had saddled winners of 3,596 races. The former handler of racing pigeons had started out in horse racing with mostly cheap claimers; but, in partnership with Isidor Bieber, he developed a racing–breeding empire worth millions of dollars.

Official records of breeders were not maintained in the United States until 1918; but John E. Madden, who topped the standings for the first ten years such records were kept, bred winners of 3,477 races in just those years, and he had bred numerous winners previously.

Through the end of 1970, owner Marion H. Van Berg (who died in 1971) had won a total of 4,691 races. His stable, which he operated in divisions, included as many as 245 horses in the course of a season, not all of them full-time, as he was active in the claiming ranks. The 393 races won by the Van Berg stable in 1969 were a numerical record for a single season, but the financial record is held by Sigmund Sommer, whose stable earned a total of $1,605,936 in 1972.

Horses owned by Calumet Farm, most of them homebred, through 1970 had earned almost $20,000,000. The Calumet runners have included former world's leading money earners Armed, Whirlaway, and Citation, the latter two also winners of the Triple Crown. Horses bred by Calumet Farm through 1970 had earned almost $30,000,000.

Earnings. Offsetting the enormous gross purse distribution in North America is the fact that training expenses are generally higher. Moreover, the average annual earnings per runner of approximately $4,000 reflects $100,000 purses to which the truly average horse cannot aspire; and median earnings are less than half the average, about $1,600.

Nevertheless, as of July 1973, 12 horses had earned more than $1,000,000 each, and another was approaching that sum. The hope of acquiring such a horse has had a pronounced influence on prices for bloodstock.

Nijinsky, Canadian-bred winner of the English Triple Crown, was syndicated into 32 shares at $170,000 each, for a total valuation $5,440,000 at age three, before his third classic victory. American Triple Crown winner Secretariat was syndicated for a new record total of $6,080,000 before his first classic victory. The record price at public auction is $725,000, bid for the seven-year-old Typecast, who was classified as a race mare at the time of sale but was retired to stud without having raced for her purchasers. Top price for a brood mare as such was $450,000 paid for What A Treat, in foal to Vaguely Noble (and the foal she was carrying was sold subsequently for $326,400).

Even untried yearlings command enormous sums. A colt by Bold Ruler (sire of Secretariat) was sold in 1973 for $600,000. A daughter of European champion Sea-Bird, out of Hyperion's daughter, Libra, brought the record price for a yearling filly of $405,000 in 1968.

The sport of kings

The sport of kings—or king of sports, as racing came to be known as it developed from a diversion of the leisure class into a huge public entertainment business—is conducted on a sufficient scale to warrant a separate report in *The Bloodstock Breeders' Annual Review* in: Argentina, Australia, Austria, Barbados, Belgium, Brazil, Canada, Czechoslovakia, Chile, Colombia, Denmark, France, Germany, Greece, Holland, Hong Kong, India, Ireland, Italy, Indonesia, Jamaica, Japan, Kenya, Malaysia, Malta, Mexico, The Netherlands, New Zealand, Norway, Panama, Peru, Poland, Puerto Rico, Rhodesia, South Africa, Spain, Sweden, Switzerland, Trinidad, Turkey, Uruguay, the United States, the U.S.S.R., Venezuela, and Yugoslavia.

Nations in which racing is a major attraction

The occasions of certain races are regarded as public holidays. Estimates of attendance on Derby day at Epsom, where the public is admitted onto portions of the grounds at no fee, have ranged as high as 500,000. Official (paid) attendance at the 1969 Japan Derby was 168,000, and more than $13,000,000 was wagered on that race alone. Japan observed the 100th anniversary of organized racing in 1961. Among its unusual features is an Equestrian Park, at which there is a school for jockeys; the two-year course includes academic as well as equestrian subjects.

RACECOURSES

Proprietorship. Proprietorship of the sport varies from complete state operation and control, as in the Soviet Union—where the national government owns the tracks and the horses and employs the trainers, jockeys, grooms, and other necessary personnel—to complete private enterprise, as in most of the United States—where racetracks are operated for profit as a business, jockeys and trainers are independent contractors, and horses are owned by individual citizens. There are in-between versions of these arrangements. The government (provincial or national) might own the tracks and citizens might operate the racing stables (in some cases, leasing horses from the government). Some tracks are owned by a township (Doncaster, for example), others by a jockey club or equivalent organization (Newmarket, Longchamp), and still others are owned by private corporations but operated on a nonprofit basis (Australia, the New York Racing Association).

Stands and paddocks. The stands at racecourses range from elegant palaces with every imaginable facility (*e.g.*, Longchamp, Ascot, various tracks in the Americas, Japan, Australia), to relatively modest but functional structures (Cologne, The Curragh), to simple sheds for protection from the elements.

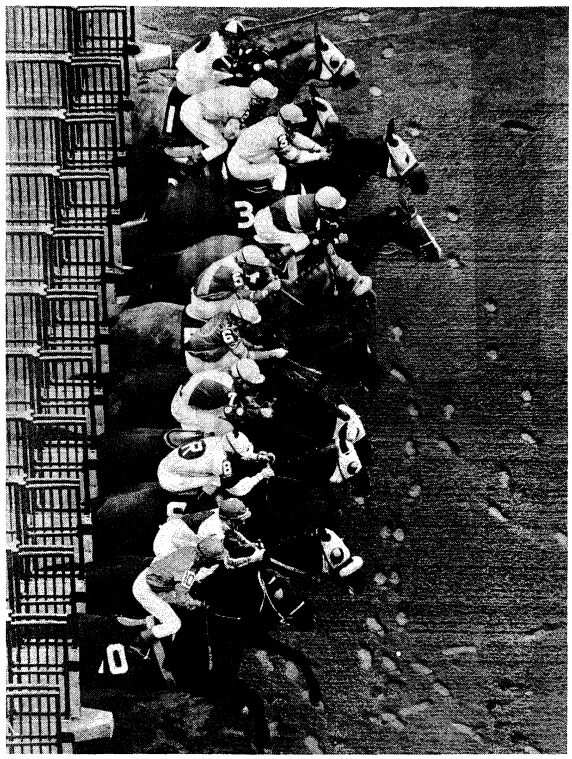
Paddocks at some tracks are ignored areas behind the stands where horses are saddled, while at other tracks they are garden-like enclosures surrounded by stands for spectators.

Track surfaces and layouts. The running surfaces of European tracks (and of tracks in some former dominions of European countries) are generally grass; in the Americas, dirt is the most common running surface although grass courses are quite popular, and in other countries there is racing on grass, dirt, and sand (the latter surface is used for training only in many countries). There are a few tracks in the United States with a synthetic surface designed to be impervious to weather, but some horsemen complain that it "grabs" the horses' hooves and insist that it be sprinkled with sand.

Some older tracks (mostly in Europe) conform to the natural terrain, having been laid out on previously existing race grounds, with facilities for spectators added later. Newer tracks are mostly elliptical, essentially flat, and a mile is the most common circumference.

The English Triple Crown offers a variety of tests—over a straightaway with a dip at Newmarket, the undulating, turning course at Epsom, and the flat, pear-shaped course at Doncaster—at distances from a mile (1,600 metres) to more than 1¾ miles (2,800 metres).

The course at Newmarket offers probably the truest run races, as it can accommodate a run of 2¼ miles



A field of horses breaking from the electrically operated starting gate at Aqueduct, Long Island, New York. As at most other U.S. tracks, the Aqueduct races are run on a dirt track.
Photo Trends

(3,600 metres) with a gentle change of direction of less than 90 degrees. Much of a race on this course is out of view of the spectators, however. The American Triple Crown events are all run on flat, elliptical tracks at distances that vary by only 2½ furlongs (5/16 miles or 500 metres). On the other hand, the English classics are spaced out in the calendar from April or May to September, while the American races frequently are bunched between the first Saturday in May and first Saturday in June, which requires that a horse maintain peak form with no letup for five weeks.

The Triple Crown courses

Grass courses require meticulous care and cannot take the constant pounding to which dirt tracks are subjected. Race meetings at a given European track generally are brief, some lasting only several days, and the track is reserved for racing only. Training is accomplished on gallops, or training tracks, set aside for that purpose; horses are vanned to the track to race and returned to their home yards at the training centres afterward. In the U.S., where it is not uncommon for a track to be used for 100 or more days of racing a year (some double as harness tracks), stabling is provided at the track, which is also used for training. (There are training tracks in some areas, but the main tracks are used, too.)

RACING RULES AND PROCEDURES

The rules of racing, representing as they do centuries of experience, are quite complex in their entirety. Briefly, eligibility of horses having previously been checked by entry clerks, the race procedure begins when jockeys weigh out and report to the paddock for instructions from trainers. An official in the paddock verifies the identity of the horses. After the jockeys mount, the horses enter the track and parade past the stewards for inspection. At some tracks this is a colourful spectacle as horses gallop onto the track one by one; but at the typical North American track they simply amble past the stands, more often than not accompanied by a lead pony, and do not break off into their warm-up gallop until they reach the far side of the track.

The use of electric starting gates is practically universal, although some starts still are effected from a barrier that springs upward when actuated by the starter, or in the "walk-up" fashion, whereby the starter gives a verbal order when the horses are reasonably well aligned. During the course of the race, patrol judges and stewards, supplemented by a motion-picture film patrol at most tracks, are alert to detect rule violations. The finish is photographed by a special camera, and if it is close, development of the film is awaited before listing the order of finish. The result does not become official until the jockeys have weighed in and riders of horses that finished in the money are certified by the clerk of scales to have carried proper weight.

Photo finishes and patrol films

At the time of weighing in a jockey may claim foul against a horse that interfered with his mount or against another jockey (or the owner or trainer may do so). If a horse that finished among the first three is involved, the stewards study films of the race and reach a decision prior to declaring the result official. If the infraction does not affect the order of finish for wagering purposes, official action usually is postponed so as not to delay the program. Patrol films are reviewed the next morning and used as educational tools for jockeys and officials, and also as a basis for disciplinary action.

For wagering purposes, the result of a race is official when so declared by the stewards; however, urine or saliva samples, or both, are extracted from winning horses (and others that might be designated by the stewards); and if a horse subsequently is determined to have won while under the influence of a prohibited substance, he is disqualified from the purse distribution.

Most time records are clustered in North America, opportunity being an obvious factor, as in no other area is there half as much racing as in the combined United States, Canada, northern Mexico grouping.

Although the difference is not enough to account for the generally faster North American running times, the method of timing Thoroughbred races in North America is less precise than that of most other countries, where horses are timed to the nearest 1/100 of a second, from a standing start. In North America they are timed to the nearest 1/5 of a second, from a running start—the length of the run between the starting gate and the official starting point varying from track to track (and, occasionally, varying according to the distance of the race at any one track).

The timing of races

RACING STRATEGY

The typical Thoroughbred is capable of running only a quarter of a mile or so at very top speed; and much of the strategy of racing lies in determination of the best moment at which to unleash this burst. Operating factors are distance of the race, size of the field, layout of the track, and nature of a particular horse and of the opposition. The burst cannot be delayed too long in a sprint, nor should it be turned on when there is heavy traffic ahead or while going wide around a turn and thus losing ground. On the other hand, if a fast horse is allowed to run in front unchallenged, he might exert himself so little as to be fresh enough to repel any challenges at the end. Sprinters have been known to win distance races in this manner, and for important races slow beginners often are accompanied by pacesetters, whose role is to challenge the fast horses in the early going and keep up the pace. Some horses are inclined to pull themselves up upon reaching the front; timing the move on such a horse so as to coincide with the finish pole is an art.

Training, simply expressed, is maintaining a horse in the best condition to run. Exercise and feeding programs and knowledge of the individual horse are factors involved. A good trainer selects a jockey who suits the horse and, perhaps more important, enters the horse in suitable races. A trainer of a horse for a classic race not only must develop the horse into peak condition but must time the development so that the horse reaches its peak on a certain day, which is the most difficult art of all.

Other types of racing

STEEPLECHASING

Steeplechasing, racing over jumps or obstacles, derives its name from impromptu contests over natural country

in which church steeples served as landmarks. This form of racing is quite ancient; Xenophon (431–*c.* 355 BC), much of whose writings on horsemanship remains pertinent today, was a strong advocate of riding over the countryside, jumping obstacles. Steeplechasing was long a favourite sport of cavalry officers, which tradition is reflected by the fact that steeplechasers, as a rule, carry much higher weights than flat racers.

The most famous steeplechase is the Grand National at Aintree, Lancashire, over a distance of four miles and 856 yards (7,180 metres), with 30 obstacles. Huge fields (there were 66 starters in 1929) and the hazards of the course have caused numerous injuries and some deaths, and there has been occasional agitation to outlaw this race. It has been won several times by horses that carried 175 pounds (79 kilograms).

Importance of stamina

Because of the stamina required, mature horses are preferred for steeplechasing, and racing through age ten and beyond is not uncommon. Speed is desirable but not if it is accompanied by impetuosity or temperament; and many steeplechasers are "half-bred," the term being loosely applied to any horse that is not a pure Thoroughbred although it may be three-quarters or seven-eighths so. Large horses also are generally preferred, although there are exceptions. Battleship, winner of both the English (at age 11) and American Grand Nationals was quite small; he was further unusual in that he was a stallion, whereas most steeplechasers are geldings.

Fred Winter, who rode two Aintree winners, also scored an epic victory in the Grand Steeplechase de Paris aboard Mandarin after the horse had lost its bridle.

While steeplechasing is a "poor relation" to flat racing in many countries, it is quite popular in England, France, and Ireland, especially the latter country, where Arkle, winner of 27 races in 35 starts and earner of the phenomenal sum (for a steeplechaser) of £75,207½, became a national hero second to none.

QUARTER HORSE RACING

Quarter racing, the racing of horses for short, traditionally one-fourth-mile (400-metre) distances, is indigenous to North America and was the earliest form of sport in the Colonies, having begun shortly after the settlement at Jamestown, Virginia, was established in 1607. The original quarter racers ran brief distances over whatever pathways through the forest were available. Generally, such pathways could accommodate only two horses (although racing through streets of a settlement later became common).

The Quarter Horse breed

Although they were for years recognized as a distinct type, registration of Quarter Horses as a breed did not begin until 1941. It is the largest equine registry in the world, with approximately 90,000 foals registered annually. Of these, about 12 percent are racing Quarter Horses, with the remainder divided between performing horses (ranch work) and pleasure horses.

Modern Quarter Horse racing is conducted at about 100 tracks throughout North America. Basically, the rules and procedures are the same as those that apply to Thoroughbred racing, but the races themselves are quite different. All are on a straightaway, varying in distance from 220 to 660 yards (200 to 600 metres), and vying for position along the rail or establishing pace plays no part. The horses run straight ahead, all out all the way. The combination of large fields and short distances produces close contests in which photo finishes are more the rule than the exception.

The All-American Futurity at Ruidoso Downs, New Mexico, a 400-yard (370-metre) event to which entry is gained through qualifying trials, in 1971 had a gross purse of $753,910 if breeders' awards are included. It is divided into three divisions, according to best qualifying times, and all qualifiers receive a share of the purse. Value to the winner of the championship division in 1971 was $200,841, from a total of $502,782 allocated to that division.

Unlike North American Thoroughbred races, Quarter Horse races are timed to the nearest 1/100 of a second, from a standing start. (W.H.P.R.)

HARNESS RACING

History. Harness racing—racing, trotting, and pacing horses in harness, pulling the drivers in light, two-wheeled vehicles called sulkies—an organized sport in 46 countries of the world, has an ancient past and an active and flourishing present. Between the two is a chasm of nearly 2,000 years of obscurity.

Archaeological excavations in the early 1930s in Boğazköy, Turkish Asia Minor, unearthed baked-clay tablets containing, intact, some 900 lines of detailed description of the training of racehorses by one Kikkulis, head trainer for Suppiluliumas, King of Mitanni, a country later known as Cappadocia, around 1350 BC.

These tablets, when translated and presented before the Académie des Inscriptions et Belles-Lettres in 1934, revealed a highly organized and sophisticated program for the general preparation of horses for training at speed at both the trot and the gallop. Specific and minute in detail, they included a 144-day program, starting in spring, which led either to the racecourse, hunting field, or battlefield. It was obvious, from the tablets, that the trotting horse occupied the royal place of honour in the racing affairs of that part of the Assyro-Babylonian Empire, the leading horse-producing area of its day.

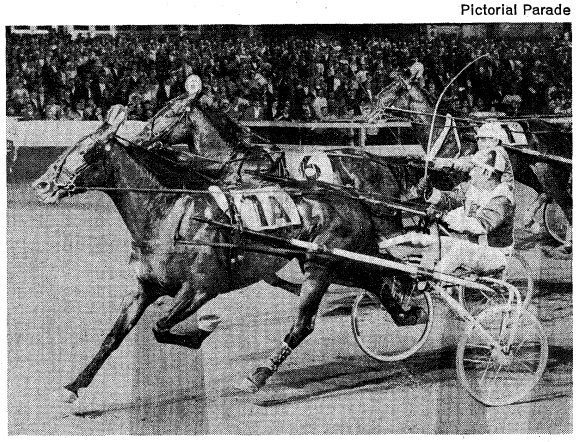
With the disappearance of the ancient racing trotters of Mitanni–Cappadocia, however, the trail of the trotting racehorse is lost until it reappears informally in Holland in the 16th century, on the road in England in the 18th, and in full glory as a racing phenomenon in the United States in the early 19th century.

Reappearance of the trotting horse

Dutch trotters competed as early as 1554 at Valkenburg, when 3,000 horses were brought together at a fair and trotting matches were held among the fastest. Holland's "Golden Whip," most famous of Dutch trotting events, dates back to 1777 at Soestdijk.

About the same time as this trotting activity among Dutch Fresian horses in the late 18th century, Count Grigory Orlov was developing a powerful trotting strain at his stud in Russia, and from his stallion Barss came the Orlov trotter that remains today as the foundation of Russian trotting stock.

Pictorial Parade



Harness Racing.
Trotters streaking to the finish. In the lead is Flamboyant, winning the Realization Trot at Roosevelt Raceway, New York, June 1968.

England's Norfolk Trotter, which emerged as a breed around 1750, was purely a road horse, bred for use on the highways of the day. Its speed led to its being used for road racing as a diversion for its owners, and most of its matches were trotting a given distance within a specified amount of time.

American trotting, too, had road racing as its earliest heritage; but by the end of the first decade of the 19th century, trotting racetracks were in use in the United States. A mile in 2:59 was recorded by a horse called Yankee over the track at Harlem, New York, in 1806, and was lowered to 2:48½ on August 25, 1810, by an unnamed trotting gelding "from Boston" at the Hunting Park track in Philadelphia.

The American Standardbred. By 1840, trotting was an organized sport in New York and New England, and a new era was underway. This era culminated, in 1879, with establishment of the American Standardbred horse in the United States, based on a standard of time performance—2 minutes 30 seconds—for one mile. It marked creation of the first pure breed and variety of trotting racehorse, as opposed to the road horse, since the Cappadocian trotters of 1350 BC.

Eight years before the Standardbred was established came the formation, in 1871, of the Grand Circuit of American harness racing. Originally known as the Quadrilateral Trotting Combination, it grew from four to 23 tracks, celebrated its centennial in 1971, and is the oldest organized sports group in the United States.

Messenger and Hambletonian

The creation and evolution of the American Standardbred and that horse's impact on world trotting rested on the prepotency of the English Thoroughbred stallion Messenger, imported to Philadelphia in 1788. Messenger combined the blood of the three founding fathers of the Thoroughbred horse—the Darley Arabian, Godolphin Arabian, and Byerly Turk—and he became a major contributor to the American Thoroughbred through his undefeated grandson American Eclipse, the descendants of which included a number of great runners such as Whirlaway, Equipoise, Gallant Fox, Exterminator, and Man o'War.

It was as a sire of Thoroughbred runners that became trotting stallions, however, that Messenger attained immortality. Ten of his sons became leading trotting sires of the early 19th century, and his great-grandson, Hambletonian 10, foaled in 1849, sired 1,331 sons and daughters between 1851 and 1875 and obliterated all other strains of the trotting horse in America. He founded a line so dominant that all American Standardbreds today and many trotters in the rest of the world can be traced to him.

Development of the sport. Trotting, meanwhile, was spreading rapidly. The sport was introduced in France, at the mountaintop course at Cherbourg, in 1836; Italy's Padovanella dates back to the same era; Austria and Germany became active in the racing of trotters late in the century; and Sweden began harness racing in the 1880s.

By this time American trotting had moved from the agricultural fairs where it thrived in the mid-1800s to regular harness racetracks, and the rise of colourful and charismatic champions like Lady Suffolk, nicknamed the "old gray mare"; Flora Temple, the "bob-tailed mare" of the well-known song "Camptown Races"; the legendary Goldsmith Maid and Dexter; and particularly the popular Maud S. led to an extremely active interest in American breeding stock in Europe and around the world.

One rival of Lady Suffolk—the gelding Americus—had been sent on a highly successful invasion against English road trotters in the 1850s; and in the same decade the trotting mares Lady Pierce and Miss Bell had been exported to France. Both raced well there, and Lady Pierce produced a line that led to Fuschia, greatest early trotting progenitor of the French breed.

In the last decade of the 19th century, American blood was introduced into virtually all trotting nations of the world—2,000 American Standardbreds had been exported by 1898 and 3,000 by 1903—and the American influence has remained a factor ever since.

The French and Russians, who had established trotting breeds of their own in the strong demisangs (half-bloods) of Normandy and the Orlovs, resisted the American influx; and the French closed their studbook to foreign horses in 1937. Elsewhere, however, American blood predominated; and in Italy, Germany, Scandinavia, the Low Countries, Argentina, and across the world in Australia and New Zealand, most present-day horses of major rank can be traced to American heritage.

Trotting and pacing gaits

Trotters and pacers. To talk of trotters exclusively covers the subject in Europe, where pacers are not raced; but in the United States and Australasia today the pacing horse is predominant, at least in numbers. The pacing horse, sometimes known as a "sidewheeler," moves both legs on one side of its body at the same time, in contrast to the diagonal gait of the trotter, which strides with its left front and right rear leg moving forward simultaneously, then right front and left rear together.

The infusion of American blood into Australia and New Zealand began in the 1880s; and, with little harness-racing background on which to draw and pacers far easier to train, that branch of the Standardbred family attained immediate popularity with trainers and owners. It still prevails.

The American pacer descended a different path from that of his trotting cousin. His heritage fuses the blood of the Narragansett pacer—a saddle horse that disappeared from the scene by 1850—and the Canuck of French Canada. While the American trotter had his beginnings in the East, the great growth of the pacer came in the Midwest and South—primarily Ohio, Indiana, Kentucky, and Tennessee—and he was a despised horse until he attained popularity in the late 1800s.

The arrival of the "Big Four"—Mattie Hunter, Sleepy Tom, Rowdy Boy, and Lucy—on the Grand Circuit of the late 1870s; the coming of the first two-minute harness horse, the pacer Star Pointer, in 1897; and the overwhelming national popularity of the first sports hero of the 20th century, Dan Patch, did much to foster the popularity of pacers.

Harness racing's first zenith, in the late 1800s, was followed by a sharp decline with the advent of the automobile and the passing of the road horse.

Revival with pari-mutuel betting under lights. But the European trotting derbies and traditional American Grand Circuit and county-fair races persisted and survived. With the introduction of regularly scheduled pari-mutuel racing under lights at Roosevelt Raceway in New York City in 1940 (there had been night racing as early as the 1890s and a meeting under lights in Toledo, Ohio, in 1927) and the introduction of the mobile starting gate (a pair of retractable metal wings mounted on the rear of an automobile or light truck that moves off slowly, getting the horses off to an even start, and then accelerates away and off the track), also at Roosevelt, in 1946, a new era was ushered in on the sports scene.

Introduction of the mobile starting gate

Tracks proliferated; breeding boomed; international trade and competition accelerated; attendance, pari-mutuel turnover, and purses soared. Attendance at American harness tracks rose from 5,700,000 in 1948 to 27,200,000 in 1971; state revenue rose from $8,500,000 to $162,000,000; purses went from $9,800,000 to $97,600,000; horses starting from 9,300 to 37,600; and members of the United States Trotting Association from 7,300 to 34,600.

The two leading money winners of all time are the trotting mares Une de Mai of France and Fresh Yankee, Canadian-owned but bred in the United States. Une de Mai has won nearly $1,900,000 and Fresh Yankee ended her career with $1,294,252. The two leading money-winning pacers are Albatross, retired in 1972 with earnings that totalled $1,201,470, and Rum Customer, retired with total earnings of $1,001,548.

American racing, meanwhile, produced its own roster of superhorses in the last three decades, starting with the trotting champion Greyhound in the late 1930s and including the pacers Adios, most successful money-siring stallion of any breed of all time, Good Time, Bye Bye Byrd, and Adios' sons Adios Harry, Adios Butler, and world champion Bret Hanover; and the outstanding trotters Su Mac Lad, Noble Victory, Nevele Pride, and Fresh Yankee.

Jamin of France, Tornese of Italy, and Hairos II of The Netherlands also proved true world-class competitors in international competition. The advent of the Roosevelt International Trot in 1959, the International Pace series at Yonkers Raceway in the 1960s, and the introduction of the World Driving Championship by Harness Tracks of America in 1970 all fostered international competition; and the United States Trotting Association, which administers all central record keeping of the American Standardbred, joined with counterpart Euro-

pean and Australian and New Zealand trotting groups in 1970 and 1971 to bring closer worldwide cooperation and uniformity to the sport.

Today, major tracks abound around the world. More than 60 pari-mutuel and 380 fair meetings are conducted annually in the United States; and virtually all principal cities of the North have racing plants, with New York City's Roosevelt and Yonkers raceways, Hollywood Park in Los Angeles, Sportsman's, Washington, and Maywood parks and Hawthorne Race Course in Chicago, and Liberty Bell Park in Philadelphia the largest. Paris has two great trotting centres at Vincennes and Enghein, Rome its Tor di Valle and Milan its San Siro, Stockholm its Solvalla, Vienna its Krieau, Moscow its Hippodrome; and there are fine tracks in Munich and the German Ruhr. In Australia, Harold Park in Sydney, the Royal Showgrounds in Melbourne, and Gloucester Park in Perth host major harness events; and New Zealand has excellent plants at Auckland and at Addington Raceway in Christchurch.

Herve Filion of Canada, William Haughton, and Stanley Dancer have dominated American driving championships in recent years. Filion's 605 victories and $2,473,265 in purses won by horses he drove in 1972 were world records, and he has won more than 4,000 races. Filion's 4,065 was a North American record entering 1973 and Haughton's $17,878,566 in career purses a world mark. In Europe the veteran Hans Fromming, with more than 5,000 victories, was the all-time leader. For world trotting and pacing records, see SPORTING RECORD in the *Ready Reference and Index*. (S.F.B.)

Wagering

EARLY DEVELOPMENTS

From the beginning, wagering has been an integral part of horse racing. The early rules of racing took cognizance of its gambling aspect (and one rule prohibited "spying" on horses during their training trials, in sharp contrast to the modern attitude that the form of horses is information within the public domain).

The built-in wagers represented by owners' stakes in match races necessarily were at natural odds (even money for a two-horse race, 2-to-1 for a three-horse race, etc.); but betting among spectators quickly developed, in which odds reflected prevailing opinion as to the horses' relative chances of victory. Man-to-man betting was the original form, but this required that a person who wished to wager find another person of opposite opinion but similar purse; and it was a natural step to the appearance of professionals who would accept bets in any reasonable amount from all comers.

Theory of bookmaking

The role of the bookmaker. As racing among fields of horses became popular, laying of odds became more complicated, and the bookmaker appeared on the scene. In theory, bookmaking is quite simple: the bookmaker sets his odds so that a percentage is working in his favour, an oversimplified example being a race among seven evenly matched horses in which he would offer 5-to-1 (a point shorter than natural odds) on each. Assuming equal amounts wagered on each horse, regardless of which one won the race, the bookmaker's profit would be one-seventh of the total wagered. In practice, however, such a "percentage book," in which the bookmaker has no financial interest in which horse wins or loses, is very difficult to achieve; and despite constant adjustment of the odds as bets are received, the bookmaker generally stands to win or lose depending on the result of the race. Odds quoted at the time of a wager are firm; and although the bookmaker can reduce the odds on the favourite for subsequent betting, he must pay off each wager according to the original terms. (In an extreme case, he might take the favourite off his slate and refuse further wagers on that horse or lay off all or part of the risk by betting on the favourite with other bookmakers; in either case he curtails his business.) The financial stakes of bookmakers and bettors in a race's outcome create a temptation to tamper with horses.

Entrepreneurs who preferred a guaranteed percentage to the risky business of laying odds conducted auction pools on races, in which the "odds" were established by the wagerers, so to speak. (Such pools continue to be conducted on other sports.) Each horse was "sold" at auction to the highest bidder; and after deduction of the pool seller's percentage, receipts were turned over to the buyer of the winning horse. The shortcoming of the system was that it could accommodate only one bettor (the highest bidder) per horse in each pool.

Pari-mutuel betting. In 1872, Pierre Oller, a Parisian shopkeeper (and, according to some reports, a bookmaker who had experienced frequent losses), devised a modification of the auction pool whereby betting tickets could be purchased in any quantity the wagerer desired; and after deduction of Oller's commission, the wagering receipts were distributed among holders of tickets on the winning horse in proportion to the number of tickets held by each. Oller's system, which he called "pari mutuel" (bet among ourselves) proved to be extremely popular; and, although the French government at first frowned upon it, the pari-mutuel system subsequently was declared the only legal means of wagering in France. The "takeout" specified in an 1891 regulation was 7 percent, of which 4 percent was allocated to the racing societies, 2 percent to certain charities, and 1 percent to the Minister of Agriculture for development of horse breeding. Although a tax on wagering has been imposed and the takeout has more than doubled since then, the tradition in France of providing reasonable return to the sport that produces substantial tax revenue has been preserved; and France is the envy of other countries in the economic health of its racing and breeding industry.

TOTALIZATORS

The Ekberg totalizator, a machine that mechanically records bets, was first used in New Zealand in 1880; a similar device, known as the "Australian tote," became popular in America. Some form of totalizator, now often integrated with electronic computers, is used in all pari-mutuel operations.

Persistence of bookmaking

Bookmaking dies hard. Apart from a preference for doing business with a human being rather than with a mechanical contrivance, bettors were distrustful of the early totalizators (sometimes, with good reason). The payoff odds are not known until all betting is completed; and it was dismaying to bet on a horse at 4-to-1, only to see the odds drop and the eventual payoff dwindle to 2-to-1. Dark rumours abounded of unscrupulous track operators who would insert large wagers into the totalizator system after the race was well underway and they had assured themselves that their choice had got off to a good start. Refinements of the totalizators and the increasing supervision of governmental agencies as the tax on pari-mutuel wagering became more and more significant as a revenue source have ended such complaints.

The pari-mutuel system received numerous tryouts in the U.S. during the 19th century but was not permanently established until 1908 (in Kentucky); and not until 1940 did New York become the last of the states to abolish bookmaking and make pari-mutuel wagering the only legal form. The impetus, in virtually every case, came from state governments, since pari-mutuel systems offer an exceptionally convenient method of extracting tax revenues.

In countries such as England, where both bookmaking and pari-mutuel wagering are offered, the former is by far the most popular form. Big bettors complain that they are forced to bet against themselves in the totalizator, in that a large bet depresses the odds. Small bettors, with an off-course bookmaker, can wager trivial sums that the tote does not accept; and to bettors large and small the off-course bookmaker offers the convenience of betting by telephone—and on credit. Even in some countries where bookmakers are outlawed, they continue to flourish illegally.

Betting pools. Following a custom that had applied to auction pools, in some of the early pari-mutuel systems a percentage of the money wagered to win was set aside for bettors who had backed the second (or third)

horse. This was in the nature of a consolation award rather than a successful bet, and the amount returned often was less than the amount wagered.

The modern totalizator displays approximate odds to win on each horse and the total amount of wagering on each horse in each of various betting pools. Customary pools are "win," "place," and "show." In some countries a "place" bet is paid off if the horse finishes among the first three; but in America such bets apply only to the first two finishers, and "show" betting applies to the first three finishers.

Win, place, and show entry and field bets

The pools are entirely distinct from each other and there is no relationship between the various payoffs, although the favourite in the win pool usually is also the favourite in the other two. The typical volume of wagering is in the order of win, place, and show; and payoffs are in corresponding order. There are instances, however, of the payoff for a place bet exceeding that for a win bet, and show payoffs higher than place payoffs are not at all rare. The latter occurs most frequently when more than one member of an "entry" or the mutuel "field" finishes among the first three. An entry is the coupling of two or more horses of the same ownership, or trained by the same trainer, into a single unit for betting purposes; a mutuel field is a similar consolidation of lesser regarded runners in a field that is too large for the totalizator to accommodate as individuals. For example, if there are 15 runners at a track whose totalizator is set up to handle 12 betting units, four of the horses would be lumped together as a mutuel field; and a bet on one member of the field would include a bet on the other three also.

The takeout, which varies from 12 percent to as high as 25 percent depending on locale, is divided between government and racing associations. The allocation to the racing association is used to pay purses, defray other expenses of operation, and (as the case might be) generate profit for the track operators.

In a win pool, after deduction of the takeout, the remaining money is distributed among backers of the winner only, in proportion to the amount wagered by each.

In some countries, a "place" pool, after deduction of the takeout, was simply divided into three equal parts, which were distributed among holders of place tickets on each of the first three finishers in the same manner that applied to a win pool. In such cases, the backer of a heavy favourite in a place pool could receive less than the amount of his wager. This method has lost favour to the method that applies to an American "show" pool, in which the money is distributed somewhat differently. After deduction of the takeout, the money wagered on each of the first three finishers also is deducted and set aside. What remains represents the winnings; and one-third of this sum is added to the money wagered on each horse to constitute the payoff pool for that particular horse. Pari-mutuel laws require that a successful bettor receive a minimum profit (5 percent or 10 percent) on his wager. Occasionally, such as when an exceptionally heavy favourite finishes among the first three—or two well-backed runners do so—after deduction of the takeout and setting aside of the money wagered on the first three finishers there is not enough money remaining to provide this minimum profit. In such a case, the track must make up the difference, which is known as a "minus pool." The term is rather a misnomer in that practically never does the track actually lose money on such a race—it merely has to forego some of its customary percentage and realizes less money than was expected. Minus show pools are the most common, and a minus win pool is a rarity. Tracks can protect themselves against minus pools by eliminating show or place wagering, as appropriate.

The "minus pool"

Breakage. Beyond the percentage takeout, in most pari-mutuel systems a wager is subjected to "breakage," which has been aptly described as a form of legalized larceny. On the pretext that it would be too inconvenient to include odd pennies, payoffs are rounded off to the nearest, lower, even sum. In the United States, for example, "breaks" are usually to ten cents, and the calculation of payoffs is based on the dollar, although the minimum betting denomination is $2 and other bets are in multiples of $5 (which would not entail odd pennies in the payoff). Thus, if a calculated payoff amounts to $1.89 per dollar, the break to $1.80 is applied first and then the result is doubled to arrive at $3.60 as the actual payoff on a $2 wager, resulting in a loss to the bettor of 18 cents instead of eight cents. A proper payoff on a $10 wager would be $18.90, which would require no rounding off to arrive at an even ten cents, but breakage nevertheless is applied at the $1 level and multiplied by ten, resulting in a payoff of only $18.00.

Variety bets. In addition to win, place, and show wagering, pari-mutuel systems offer a variety of other bets: doubles (selecting winners of two races), twin doubles (winners of four races), quinielas or quinellas (the first two horses to finish regardless of the order between them), exactas, perfectas, or forecasts (the first two horses in precise order), and so forth. More elaborate wagers are offered at some pari-mutuel tracks and payoffs figured according to the same considerations that govern regular wagering, although separate equipment is necessary. As is to be expected in view of the odds against success, payoffs on such wagering usually exceed those of regular wagering; and in the case of the more elaborate wagers the payoffs occasionally exceed $100,000.

Off-track betting. Off-track betting through the totalizator in Australia, New Zealand, and South Africa, for example, has been very beneficial to racing as it has increased revenue for prize money and development of racetracks. In France, the most popular form of off-track wagering is the *tierce*, in which the bettor attempts to select the first three finishers in precise order. Outlets for wagering are cafés and tobacco shops, which entail little extra expense; and the *tierce*, which is conducted on about 75 races a year, is largely responsible for the enviable economic health of racing in France.

In England, off-track betting shops (which offer wagering on other sports besides horse racing) have in general been beneficial to the shop operators but of no benefit to racing. Closure of a number of smaller racecourses has been attributed to competition from off-track betting shops.

In the United States, off-track betting made its debut in New York City in 1971. Although the announced objective was to tie the off-track betting machinery directly to the track totalizator system, it was not immediately achieved. One stumbling block was the refusal of racetracks and horse owners to cooperate with the off-track betting corporation on the ground that the share of off-track wagering allocated to them as compensation for loss of patronage at the tracks was woefully inadequate: only 1½ percent, compared to more than 7 percent of on-track wagering, was returned to the sport. As of mid-1971, modifications of the New York City system and various other off-track betting plans were being studied in a number of states.

Racing in the United States and Canada stood at a great crossroads. Depending upon how the extremely delicate and very complex matter of off-track wagering was handled, the sport could go on to even greater heights—or it might be killed or diminished beyond recognition.

Theatre racing, in which patrons could wager on televised events, had been proposed. If such a system were adopted, the possibility exists that patrons would prefer to wager on the most famous horses running in the richest races, to the exclusion of local events, and the sport would dwindle to comparatively few horses competing for enormous purses in each of a few racing centres. Whether the sport could survive without its traditional grass roots is questionable. (W.H.P.R.)

BIBLIOGRAPHY. *Stud Books* of various countries provide records of pedigrees. *Racing Calendars, Turf Registers,* or, in North America, the *American Racing Manual,* include seasonal racing records of individual horses, conditions of races, winners of important fixtures, and other statistical data. The

Thoroughbred Record (weekly), publishes as one issue each year an annual statistical review of North American racing. In addition to detailed reports and statistics concerning racing in England and Ireland, the *Bloodstock Breeders' Annual Review* offers an excellent diary, year by year, of racing throughout the world. T.H. BROWNE, *History of the English Turf, 1904–1930*, 2 vol. (1931), is a continuation of a similarly entitled series by THEODORE A. COOK (3 vol., 1901–04), authoritatively written and excellently illustrated. W.S. VOSBURGH, JOHN L. HERVEY, and ROBERT F. KELLEY, *Racing in America*, 5 vol. (1922–60), is a comprehensive record of American sport through 1959; WILLIAM H.P. ROBERTSON, *The History of Thoroughbred Racing in America* (1964), is a one-volume work. C.M. PRIOR, *History of the Racing Calendar and Stud-Book* (1926), traces the evolution of English racing. SIR CHARLES LEICESTER, *Bloodstock Breeding* (1958), summarizes various breeding theories and discusses in detail pedigrees of English Derby winners, but many of the author's observations are of universal application.

Harness racing: JOHN L. HERVEY, *The American Trotter* (1947), is the most authoritative and definitive history of the Standardbred horse and world harness racing. TOM AINSLIE, *Complete Guide to Harness Racing* (1970); and PHILIP A. PINES, *The Complete Book of Harness Racing* (1970), are excellent guides to the sport today, the former stressing racegoing and wagering and the latter an overall view of the sport. JAMES C. HARRISON *et al.*, *Care and Training of the Trotter and Pacer* (1968), covers every aspect of training, racing, and stable management. DWIGHT AKERS, *Drivers Up*, 2nd ed. (1947), is an interesting history of the sport's evolution. MARIE HILL, *Adios: The Big Daddy of Harness Racing* (1971), is a well-documented history of the most successful racehorse stallion of all time. DONALD P. EVANS, *Big Bum: The Story of Bret Hanover* (1969), reviews the career of the world champion pacer; and P.W. MOSER, *The Story of Greyhound* (1940), does the same for the trotter that held the world record for 31 years. MARGUERITE HENRY, *Born to Trot* (1950), is a good introductory book for younger readers. The UNITED STATES TROTTING ASSOCIATION, *Hoof Beats*, is the official monthly magazine of the sport and the same association's *Trotting and Pacing Guide* is a complete record book, published annually, containing full statistics of every phase of the sport.

(W.H.P.R./S.F.B.)

Horticulture

Horticulture is the branch of plant agriculture dealing with garden crops, generally fruits, vegetables, and ornamentals. The word is derived from the Latin *hortus*, garden, and *colere*, to cultivate. The English word horticulture is first found in 1678 in Edward Phillips' *The New World of English Words;* the Latin *horticultura* first appears in 1631 in Peter Lauremberg's book by that name. The word *hortus* is found in classical Latin.

The concept of garden culture as distinct from field culture dates back to medieval farming systems that used extensive areas for grains, forages, and pastures (commons); small intensive kitchen gardens; and wild lands for timber and game. Modern agriculture has maintained these traditional distinctions in the divisions of agronomy (extensively cropped grains, forages, fibre crops), horticulture (intensively cultivated garden crops for food and ornament), and forestry (forest trees and products; also wildlife).

The field of horticulture is traditionally divided into food crops (pomology and olericulture) and ornamentals (floriculture and landscape horticulture). Pomology deals with fruit and nut crops. Olericulture deals with herbaceous (nonwoody) plants, including carrot (edible root), asparagus (edible stem), lettuce (edible leaf), cauliflower (edible flower), tomato (edible fruit), and pea (edible seed). Floriculture deals with production of flowers and ornamental plants: generally, cut flowers, potted plants, and greenery. Landscape horticulture is a broad category that includes plants for the landscape including turf but particularly nursery crops such as shrubs, trees, and vines.

Horticulture also may be separated into scientific, agricultural, or artistic disciplines. These include genetics and breeding, physiology and cultural practices, soils and fertilization, economics and marketing, storage and processing, flower design and landscape architecture. Thus horticulture is an art and a science, an avocation and an industry. As an art, horticulture involves unique skills involving careful timing of ancient practices, many of which are empirically derived and perfected. It may involve an aesthetic sense of beauty and form. As an avocation, horticulture and gardening are outlets for recreation and pleasure for millions of people. Horticulture is also a huge business involved in all production phases from planting to processing. In addition, horticulture can be considered a body of technology involving many associated sciences and a scientific discipline in its own right. The science has provided methods and resources to explain the art and has become the guiding force for the improvement and refinement of horticulture.

This article is primarily concerned with the general aspects of horticultural practices, particularly those in relation to ornamental crops. For small, noncommercial gardens see GARDENING, for fruits and vegetables see FRUITS AND FRUIT FARMING and VEGETABLES AND VEGETABLE FARMING.

Horticultural practices

PROPAGATION

Propagation, the controlled perpetuation of plants, is the most basic of horticultural practices. Its two objectives are to achieve an increase in numbers and to preserve the essential characteristics of the plant. Propagation may be achieved sexually by seed or asexually by utilizing specialized vegetative structures of the plant (tubers or corms) or employing such techniques as cutting, layering, grafting, and tissue culture. (A detailed discussion of the methods of controlling sexual propagation may be found in the article PLANT BREEDING.)

Seed propagation. The most common method of propagation for self-pollinated plants is by seed. In self-pollinated plants, the sperm nuclei in pollen produced by a flower fertilize egg cells of a flower on the same plant. Propagation by seed is also used widely for many cross-pollinated plants (those whose pollen is carried from one plant to another). Seeds are usually the most inexpensive and often the only method and offer a convenient way to store plants over long periods of time. Seeds kept dry and cool normally maintain their viability from harvest to the next planting season. Some can be stored for years under suitable conditions. Seed propagation also makes it possible to start plants free of most diseases. This is especially true with respect to virus diseases, since it is almost impossible to free plants of virus infections and since most virus diseases are not seed transmitted. There are two disadvantages to seed propagation. First, genetic segregation occurs in seed from cross-pollinated plants because they are heterozygous. This means that the plant grown from seed may not exactly duplicate the characteristics of its parents and may possess undesirable characteristics. Second, a long time is required in some plants from seed to maturity. Potatoes, for example, do not breed true from seed and do not produce large tubers the first year. These disadvantages are overcome by vegetative propagation.

The practice of saving seed to plant the following year has developed into a specialized part of horticulture. Seed technology involves all of the steps necessary to assure production of seed with high viability, freedom from disease, purity, and trueness to type. These processes may include specialized growing and harvesting techniques, cleaning, and distribution.

The location of the seed-producing area varies with the crop. When the seed or the associated fruit is the commercial part of the crop, seed is usually produced within the crop-growing area. When the seed is not a usable part of the crop, as in ornamentals and many vegetable crops, seed production tends to concentrate in areas separate from crop-producing areas.

Relatively little tree and shrub seed is grown commercially; it is generally harvested from natural stands. Rootstock seed for fruit trees is often obtained as a by-product in fruit processing industries. Seed growing and plant improvement are related activities. Thus many seed-producing firms actively engage in plant-breeding programs to accomplish genetic improvement of their material.

F_1 hybrids

F_1 is the designation of the first generation resulting from crossing two different true breeding or homozygous strains. The plant so produced may exhibit better characteristics than either parent. The advantages of hybrids also include uniformity and increased vigour (heterosis or hybrid vigour). But a continuance of the same desirable characteristics cannot be obtained simply by crossing F_1 with F_1, because the offspring will exhibit the whole range of characteristics inherent in their heredity. Thus, seed of hybrids must be remade each year. Possession of the unique set of parents gives a seedsman even more effective control of a hybrid than does the patent process.

Harvesting of dry seeds is accomplished by threshing. Seeds from fleshy fruits are recovered through fermentation of the macerated (softened by soaking) pulp or directly from screening. Machines have been developed to separate and clean seed, based on size, specific gravity, or surface characteristics. Extended storage of seed requires low humidities and cool temperature.

Trade in seeds requires quality control. For example, U.S. government seed laws require detailed labelling showing germination percentage, mechanical purity, amount of seed, origin, and moisture. Seed testing is thus an important part of the seed industry.

While most vegetable seed germinate readily upon exposure to normally favourable environmental conditions, many seed plants that are vegetatively propagated fail to germinate readily because of physical or physiologically imposed dormancy. Physical dormancy is due to structural limitations to germination such as hard impervious seed coats. Under natural conditions weathering for a number of years weakens the seed coat. Such seeds may be artificially worn or weakened to render the seed coat permeable to gases and water by a process known as scarification. This is accomplished by a number of methods including abrasive action, hot water, or acid treatment. Physiologically imposed dormancy involves the presence of germination inhibitors. Germination in such seed may be accomplished by treatment to remove these inhibitors. This may involve cold stratification, storing seed at high relative humidity and low temperatures, usually slightly above freezing. Cold stratification is a prerequisite to the uniform germination of many temperate zone species such as apple, pear, and redbud.

Scarification

Vegetative propagation. Asexual or vegetative reproduction is based on the ability of plants to regenerate tissues and parts. In many plants vegetative propagation is a completely natural process; in others it is an artificial one. There are many advantages to vegetative propagation. These include the unchanged perpetuation of naturally cross-pollinated or heterozygous plants and the possibility of propagating seedless progeny. This means that a superior plant may be reproduced endlessly without variation. In addition, vegetative propagation may be easier and faster than seed propagation, because seed-dormancy problems are eliminated and the juvenile nonflowering stage of some seed-propagated plants is eliminated or reduced.

Vegetative propagation is accomplished by use of (1) apomictic seed; (2) specialized vegetative structures such as runners, bulbs, corms, rhizomes, offshoots, tubers, stems, or roots; (3) layers and cuttings; (4) grafting and budding; and (5) tissue culture.

Apomixis. Apomixis, the development of asexual seed (seed not formed via the normal sexual process), is a form of vegetative propagation for some horticultural plants including Kentucky bluegrass, mango, and citrus. Virus-free progeny may be produced in oranges from a seed that (as in many types of citrus) is formed from the nucellus, a maternal tissue.

Vegetative structures. Many plants produce specialized vegetative structures that may be used in propagation. These may be storage organs such as tubers that enable the plant to survive adverse conditions or organs adapted for natural propagation—runners or rhizomes—so that the plant may rapidly spread.

Bulbs (shortened stems with thick, fleshy leaves) are found in such plants as the onion, daffodil, and hyacinth. Bulbs commonly grow at ground level, though bulblike structures (bulbils) may form on aerial stems in some lilies or in association with flower parts, as in the onion. Buds in the axils (angle between leaf and stem) of the fleshy leaves may form miniature bulbs (bulblets) that when grown to full size are known as offsets. Corms are short fleshy underground stems without fleshy leaves. The gladiolus and crocus are propagated by corms. Corms may produce new cormels from fleshy buds. Rhizomes are horizontal, underground stems that may be compressed, as in iris, or slender, as in turf grasses. Runners are specialized aerial stems, a natural agent of increase and spread for such plants as the strawberry, strawberry geranium, and bugle weed (*Ajuga*). Tubers are fleshy enlarged portions of underground stem. The edible portion of the potato, the tuber, is also used as a means of propagation.

A number of plants form lateral shoots from the stem, which when rooted serve to propagate the plant. These are known collectively as offshoots but are often called offsets, crown divisions, ratoons, or slips.

Roots may also be structurally modified as propagative and food-storage organs. These tuberous roots, fleshy swollen structures, readily form shoots that are called adventitious because they do not form from nodes. The sweetpotato and dahlia are propagated by tuberous roots. Shoots that rise adventitiously from roots are called suckers. The red raspberry is propagated by suckers.

Layerage and cuttage. Propagation may be accomplished by methods in which plants are induced to regenerate missing parts, usually adventitious roots or shoots. When the regenerated part is attached to the plant the process is called layerage; when the regenerating portion is detached from the plant the process is called cuttage.

Layerage often occurs naturally. Drooping black raspberry stems tend to root in contact with the soil. The croton, a tropical plant, is commonly propagated by wrapping sphagnum enclosed in plastic around a stem cut to induce rooting. After rooting, the stem is detached and planted. Though simple and effective, layerage is not normally adapted to large-scale nursery practices.

Cuttage, the use of a detached plant part to regenerate a missing part or parts to form a complete plant, is one of the most important methods of propagation. Many plant parts may be used; thus cuttings can be classified as root, stem, or leaf. Stem cuttings are the most common.

The ability of stems to regenerate missing parts is variable; consequently plants may be easy or difficult to root. The physiological basis for cuttings to form roots is due to an interaction of many factors. These include transportable substances in the plant itself (plant hormones such as auxin), carbohydrates, nitrogenous substances, vitamins, and substances not yet identified. Environmental factors such as light, temperature, humidity, and oxygen are important, as are age, position, and type of stem.

Although easy-to-root plants such as willow or coleus may be propagated merely by plunging a stem in water or moist sand, the propagation of difficult-to-root species is a highly technical process. To achieve success with difficult-to-root plants special care is taken to control the environment and encourage rooting. A number of growth regulators stimulate rooting. A high degree of success has been achieved with indolebutyric acid, a synthetic auxin that is applied to the cut surface. A number of materials known as rooting cofactors have been found that interact with auxin to further stimulate rooting.

Humidity control is particularly important to prevent death of the stem from desiccation (drying out) before rooting is complete. The use of an intermittent-mist system in propagation beds has proved to be an important means of improving success in propagation by cuttings. These operate by applying water to the plant for a few seconds each minute.

Grafting. Grafting involves the joining together of plant parts by means of tissue regeneration. The part of the combination that provides the root is called the stock; the added piece is called the scion. When more than two

parts are involved, the middle piece is called the interstock. When the scion consists of a single bud the process is called budding. Grafting and budding are the most widely used of the vegetative propagation methods.

Grafting has uses in addition to propagation. The interaction of rootstocks may affect the performance of the stock through dwarfing or invigoration, and in some cases may affect quality. Further, the use of more than one component makes it possible to affect disease resistance and hardiness of the combination. Other uses include variety change (topworking) and repair (inarching, bridging, and bracing).

Grafting as a means of growth control is used extensively with fruit trees and in ornamentals such as roses and junipers. Fruit trees are normally composed of a "scion" cultivar grafted onto a rootstock. Sometimes an interstock is included between the scion and stock. The rootstock may be grown from seed (seedling rootstock) or asexually propagated (clonal rootstock). In the apple, a great many clonal rootstocks are available to give a complete range of dwarfing; rootstocks are also available to invigorate growth of the scion cultivar.

How grafting works

Stock cambium and scion cambium respond to being cut by forming masses of cells (callus tissues) that grow over the injured surfaces of the wounds. The union resulting from interlocking of the callus tissues is the basis of graftage. In dicots (*e.g.*, most trees) cambium—a layer of actively dividing cells between xylem (wood) and phloem (bast) tissues—is usually arranged in a continuous ring; in woody members, new layers of tissue are produced annually. Monocot stems (*e.g.*, lilacs, orchids) do not possess a continuous cambium layer or increase in thickness; grafting is seldom possible.

The basic technique in grafting consists in placing cambial tissues of stock and scion in intimate association, so that the resulting callus tissue produced from stock and scion interlocks to form a living continuous connection. A snug fit may be obtained through the tension of the split stock and scion or both. Tape, rubber, and nails may be used to achieve close contact. In general, grafts are only compatible between the same or closely related species. Success in grafting depends on skill in achieving a snug fit. Warm temperatures (80–85° F, 27–30° C) increase callus formation and improve "take" in grafting. Thus grafts using dormant material are often stored in a warm, moist place to stimulate callus formation.

In grafting or budding, the rootstock may be grown from seed or propagated asexually. Within a year a small amount of scion material from one plant can produce hundreds of plants. Some methods of grafting and budding are illustrated in Figure 1.

Tissue culture. Tissue-culture techniques utilizing embryos, shoot tips, and callus can be used as a method of propagation. The procedure requires aseptic techniques and special media to supply inorganic elements; sugar; vitamins; and, depending on the tissue, growth regulators and organic complexes such as coconut milk, yeast, or amino acid extract.

Embryo culture has been used to produce plants from embryos that would not normally develop within the fruit. This occurs in early ripening peaches or in some hybridization between species. Embryo culture can also be used to circumvent seed dormancy.

A shoot tip, when excised and cultured, may produce roots at the base. This technique is employed for the purpose of producing plants free of disease. Certain orchids are rapidly multiplied by this method. Cultured shoot tips form an embryo-like stage that may be sectioned indefinitely to build up large stocks rapidly. These bulblike bodies left unsectioned develop into small plantlets. A similar procedure is used with the carnation, in which the shoot tip forms a cell mass that may be subdivided.

Callus-tissue culture—a very specialized technique that involves growth of the callus, followed by procedures to induce organ differentiation—has been successful with a number of plants including carrot, asparagus, and tobacco. Used extensively in research work, callus culture has not been considered a practical method of propagation. Callus culture produces genetic variability because in some cases cells double their chromosome number. Recently, in rice and tobacco, mature plants have been obtained from callus formed from pollen. These plants have half the normal number of chromosomes, the haploid number, instead of the diploid number.

ENVIRONMENTAL CONTROL

The intensive cultivation practiced in horticulture relies on extensive control of the environment for all phases of plant life. The most basic environmental control is achieved by location and site: sunny or shady sites, proximity to bodies of water, altitude, and latitude.

Structures. Various structures are used for temperature control. Cold frames, used to start plants before the normal growing season, are low enclosed beds covered with a removable sash of glass or plastic. Radiant energy passes through the transparent top and warms the soil directly. Heat, however, as long wave radiation, is prevented from leaving the glass or plastic cover at night. Thus heat that builds up in the cold frame during the day aids in warming the soil, which releases its heat gradually at night to warm the plants. When supplemental heat is provided, the structures are called hotbeds. At first, supplemental heat was supplied by respiration through the decomposition of manure or other organic matter. Today, heat is provided by electric cables, steam, or hot-water pipes buried in the soil.

Greenhouses

Greenhouses are large hotbeds, usually steam heated. While they were formerly made of glass, plastic films are now extensively used. Modern greenhouse ranges usually have automatic temperature control. Summer temperatures may be regulated by shading or evaporative "fan and pad" cooling devices. Air-conditioning units are usually too expensive except for scientific work. Greenhouses with precise environmental controls are known as phyto-

trons. Other environmental factors are controlled through automatic watering, regulation of light and shade, addition of carbon dioxide, and fertility regulation.

Shade houses are usually walk-in structures with shading provided by lath or screening. Summer propagation is often located in shade houses to reduce excessive water loss by transpiration.

Temperature control. A number of temperature control techniques are used in the field, including hot caps, cloches, plastic tunnels, and mulches of various types. Hot caps are cones of translucent paper or plastic placed over the tops of plants in the spring. These act as miniature greenhouses. In the past small glass sashes called cloches were placed over rows to help keep them warm. Polyethylene tunnels with wire hoops are now used for the same purpose. As spring advances the tunnels are slashed to prevent excessive heat buildup. In some cases the plastic tunnels are constructed so they may be opened and closed when necessary. This technique is widely used in Israel for early production of vegetables.

Mulches, insulating substances spread over the surface of the soil, regulate soil temperature, conserve soil moisture, and control erosion and weeds. In many cases mulches are used for their pleasing effect as background for flowers and shrubs in ornamental plantings. Plastic, either clear or black, may be used. The temperature-stabilizing effect of summer mulch is due to insulation, heat absorption, and shading. The surfaces of bare, dark-coloured soils may be 30° F (16.7° C) higher than air temperature. Mulches may also be applied in the fall to temper low winter temperatures. The insulation of the mulches conserves ground heat and also stabilizes and buffers soil temperature to prevent recurring freezing and thawing that rips and injures plant roots through soil heaving. Winter mulches protect roses and strawberries in high latitudes.

The storage of perishable plant products is accomplished largely through the regulation of their temperature to retard respiration and microbial activity. Excess water loss may be prevented by controlling humidity. Facilities that utilize the temperature of the atmosphere are called common storage. The most primitive types take advantage of the reduced temperature fluctuations of the soil by using caves or unheated cellars. Above-ground structures must be insulated and ventilated. Complete temperature-regulated storages utilizing refrigeration and heating are now common for storage of horticulture products. The regulation of oxygen and carbon dioxide levels along with the regulation of temperature is known as controlled-atmosphere storage. Rooms are sealed so that gaseous exchange can be effectively controlled. Many horticultural products, such as fruit, can be kept fresh for as long as a year under these controlled conditions.

Frost control. Frost, a thin layer of ice crystals deposited on soil and plant surfaces when temperatures drop to freezing, may destroy many horticultural crops and plants. Frost is especially damaging to perennial fruit crops in the spring—because flower parts are sensitive to freezing injury—and to tender transplants. The two weather conditions that produce freezing temperatures are rapid radiational cooling at night and introduction of a cold air mass with temperatures below freezing. Radiation frost occurs when skies are clear and calm; air mass freezes occur when skies are overcast and windy.

Frost control methods involve either reduction of radiational heat loss or conservation or addition of heat. Radiational heat loss may be reduced by hot caps, cold frames, or mulches. Removing weeds that shade the soil increases the amount of heat stored during the day. Clean cultivated areas are less susceptible to frost than sodded or mulched areas. Heat may also be added from the air. Wind machines that stir up the air, for example, provide heat when temperature inversions trap cold air under a layer of warm air. These have been used extensively in citrus groves. Heat may be added directly by using heaters, usually fuelled with oil. Sprinkler irrigation can also be used for frost control. The formation of ice is accompanied by the release of large amounts of heat, which maintains plants at the freezing temperature as long as the water is being frozen. Thus continuous sprinkling during frosty nights has been used to protect strawberries from frost injury.

Frost injury to transplants may be prevented through processes that increase the plant's ability to survive the impact of unfavourable environmental stress. This is known as hardening off. Hardening off of plants prior to transplanting may be accomplished by withholding water and fertilizer, especially nitrogen. This prevents formation of succulent tissue that is very frost tender. Gradual exposure to cold is also effective for hardening. Induced cold resistance in crops such as cabbage is considerable; unhardened cabbages show injury at 28° F (−2.2° C), while hardened plants withstand temperatures as low as 22° F (−5.6° C).

Light control. Light has a tremendous effect on plant growth. It provides energy for photosynthesis, the process by which plants, with the aid of the pigment chlorophyll, synthesize carbon compounds from water and carbon dioxide. Light also influences a great number of physiological reactions in plants. At energy values lower than those required for photosynthesis, light affects such processes as dormancy, flowering, tuberization, and seed-stalk development. In many cases these processes are affected by the length of day (photoperiodicity).

The control of light in horticultural practices involves increasing energy values for photosynthesis and controlling day length. Light is controlled in part by site and location. In the tropics day length approaches 12 hours throughout the year, whereas in polar regions it varies from 0 to 24 hours. Light is also partly controlled by plant distribution and density.

Supplemental illumination in greenhouses increases photosynthesis. Cost of power, however, makes this impractical for all but crops of the highest value. Fluorescent lights are the most efficient for photosynthesis; special lights, rich in the wave lengths required, are now available.

Extension of day length through supplemental illumination and shading is common practice in the production of greenhouse flower crops, which are often induced to flower out of season. Artificial lengthening of short days, or interruption of the dark period, promotes flowering in long-day plants such as lettuce and spinach and prevents flowering of short-day plants such as chrysanthemums. Similarly, during naturally long days, shading to reduce day length prevents flowering of long-day plants and promotes flowering of short-day plants. The manipulation of day length is standard practice to control flowering of greenhouse chrysanthemums throughout the year. Tungsten lights have proven effective for extending day length because they are rich in the red end of the spectrum that affects the photoperiodic reaction. Extending the day length is an economical practice because only a low light intensity is required. The same effects can be obtained through interruption of the dark period, even with light flashes. Decreasing day length is usually accomplished by covering the plants with black shade cloth.

TRAINING AND PRUNING

Training, the orientation of the plant in space, is achieved by physical techniques that direct the shape, size, and direction of plant growth. Training may be accomplished by providing supports to which plants can be bent, twisted, or fastened. Training is often associated with pruning, the judicious removal of plant parts. Pruning, however, is performed for other purposes: for example, to adjust fruit load and to regulate size and quality. Altering form or size can improve appearance or usefulness. Trees and shrubs can be trained to a variety of shapes limited only by the imagination.

Topiary and bonsai

The training of plants to grow in unnatural shapes for ornamental purposes is called topiary. In Roman times and during the Renaissance, when topiary was in high fashion, plants were trained to unusual and fantastic shapes such as beasts, ships, and building facades. Though this type of topiary is no longer in vogue, hedges and

shrubs are still trained to geometric shapes in formal gardens.

Another extreme form of training is the Japanese art of bonsai, the creation of dwarfed potted trees by a combination of pruning (both roots and tops) and restricted nutrition. Living trees over a hundred years old and only a few feet high are grown in special containers arranged to resemble the natural landscape.

Particular spatial arrangements may increase light utilization, facilitate harvesting or disease control, or improve productivity and quality. Thus, training and pruning form an essential part of fruit growing throughout the life of the plant. Special attention is given in the formative years to obtain desired shape and structure. The key to training is the point on the main stem from which branches form. In the central-leader system of training the trunk forms a central axis with branches distributed laterally up and down and around the stem. In the open centre or vase system the main stem is terminated and growth forced through a number of branches originating close to the upper end of the trunk. An intermediate system is called the modified-leader system. In espalier systems, plants are trained to grow flat along a wire or trellis (see Figure 2). Properly executed espaliers are extremely

Pruning systems

attractive as ornamentals. Espaliers in combination with dwarfing rootstocks allow high density orchards that are very productive on a per unit area basis with the fruit close to the ground for easy harvest. Extensive pruning is required annually to maintain the system.

There are a number of physiological responses to training and pruning. Orientation of the plant may have a marked effect on growth and fruiting. Thus fruit trees planted on an inclined angle become dwarfed and flower earlier; training branches in a horizontal position produces the same effect. This effect is achieved naturally when a heavy fruit load bends a limb down. The main effects of pruning are achieved by altering the root–shoot balance. Thus an explosion of vegetative growth normally occurs after extensive shoot pruning. Severely pruned plants, especially if they are in the juvenile stage of growth, tend to remain vegetative. Similarly the slowdown of vegetative growth by root pruning encourages flowering.

The two basic pruning cuts are known as "heading back" and "thinning out." Heading back consists in cutting back the terminal portion of a branch to a bud; thinning out is the complete removal of a branch to a lateral or main trunk. Heading back, usually followed by the stimulation of lateral budbreak below the cut, produces a bushy, compact plant, suitable for a hedgerow. Thinning out, which encourages longer growth of the remaining terminals by reducing lateral branches, tends to open up the plant, producing a longer plant.

GROWTH REGULATION BY CHEMICALS

Control of plant growth through growth-regulating materials is a modern development in horticulture. These materials have resulted from basic investigations into growth and development, as well as systematic screening of materials to find those that affect differentiation and growth. This field was given great impetus by the discovery of a class of plant hormones known as auxins, which affect cell elongation.

Auxins have been correlated with inhibition and stimulation of growth as well as differentiation of organs and tissues. Such processes as cell enlargement, leaf and organ separation, budding, flowering, and fruit set and growth are influenced by auxin. In addition, auxin has been associated with the movement of plants in response to light and gravity. Auxin materials are used in horticulture for the promotion of rooting, fruit setting, fruit thinning, and fruit-drop control.

Gibberellins are a group of related, natural-occuring compounds of which only one, gibberellic acid, is commercially available. Gibberellins have many effects on plant development. The most startling is the stimulation of growth in many compact or dwarf plants. Minute applications transform bush to pole beans or dwarf to normal corn. Perhaps the most widespread horticultural use has been in grape production. The application of gibberellin is now a regular practice for the culture of the "Thompson seedless" cultivar ("Sultanina") of grapes to increase berry size. In Japan applications of gibberellic acid are used to induce seedlessness in certain grapes.

Cytokinins are a group of chemical substances that have a decisive influence on the stimulation of cell division. In tissue culture high auxin and low cytokinin give rise to root development; low auxin and high cytokinin give rise to shoot development.

Dormins have recently been established as a class of inhibitory compounds. Abscisic acid is the only naturally occurring dormin known, but similar synthetic substances have been reported.

Ethylene, a hydrocarbon compound, acts as a plant hormone to stimulate fruit ripening as well as rooting and flowering of some plants. An ethylene-releasing compound, 2-chloroethylphosphonic acid, has many horticultural applications, of which the most promising may be uniform ripening of tomato and the stimulation of latex flow in rubber.

Many compounds that inhibit growth hormones have application in horticulture. For example, a number of materials that inhibit formation of gibberellins by the plant act to dwarf plants. These include chlorinated derivatives of quaternary ammonium and phosphonium compounds. Many of these have applications in floriculture. Growth retardants such as succinic acid-2,2-dimethylhydrazide, a gibberellin supressor, have applications in horticulture from a wide array of effects that include dwarfing and fruit maturity. The growth inhibitor maleic hydrazide has been effective in preventing the sprouting of onions and potatoes.

The flowering regulating hormone (florigen) is known to

exist but as yet remains undetected. The isolation of this growth regulator will have great impact on horticulture.

SOIL MANAGEMENT

The soil must be managed for fertility (the ability to provide plant nutrients) and physical condition. Nutrients necessary for growth must be provided and released in forms readily available to the plant. Soil management is also concerned with careful and sustained land use through control of erosion. Thus conservation becomes an essential part of soil management.

Sixteen elements are essential for plant growth. Three of these, carbon, oxygen, and hydrogen, are provided through water and air; the other 13 are provided through the soil. The elements required in relatively large amounts are called major elements—nitrogen, phosphorus, potassium, calcium, magnesium, and sulfur. The minerals required in small quantities are called trace elements—iron, boron, manganese, zinc, molybdenum, copper, and chlorine.

Soil fertility, or its capacity to supply nutrients, involves the amount and availability of plant nutrients. Addition of nutrients to plants is called fertilization; the materials that supply nutrient elements are called fertilizers. Fertilizers

Fertilizers may be classified as natural organics or chemical. In the past most fertilizers were waste organic materials such as manure, crop residues, blood, or fish scraps. Many fertilizers today are chemicals synthesized from inorganic materials. Fertilizers are usually applied to the soil but may also be applied through leaves or stems. Carbon dioxide added to the air in greenhouses is also considered to be a fertilizer. Fertilizers that supply nitrogen and phosphorus and potassium, the elements that are usually the most limiting to plant growth, are referred to as "complete."

The nutrient requirement of plants can be determined by correlating plant responses with the mineral content of plant and soil through leaf or tissue analysis and soil testing. Although severe shortage of certain nutrients can be diagnosed through characteristic deficiency symptoms, in good commercial practice nutrient shortages are not permitted to become so severe.

Fertilizers may be applied in solid, liquid, or gaseous form. Some are dissolved in irrigation water or applied directly to the foliage. Nitrogen can be added to the soil as ammonia gas. Proper placement and timing are important factors in efficient fertilization practices. Timing (*e.g.*, season) may be critical. Overfertilizing is a problem that may lead to excessive salt concentrations and destruction of tender plant parts (fertilizer burn).

Soil reaction, the degree of acidity or alkalinity expressed as pH, has tremendous indirect effects on plant growth. Abnormally high or alkaline pH (above 9) or low pH (below 4) is in itself toxic to plants. Between these extremes, the effect is usually on nutrient availability. Thus, at high pH, iron deficiency often results because insoluble iron compounds form that are unavailable to plants. In addition, plants vary in their reaction to pH. Most plants thrive best in conditions close to neutral (pH 7). Plants that prefer acid soil include rhododendrons, gardenias, azaleas, camellias, cranberries, and blueberries.

Soil reaction may be modified. Soils can be made more alkaline (pH increased) by adding calcium, magnesium, sodium, or potassium. Calcium is the most efficient; it has other beneficial effects and is an essential element. Addition of calcium or compounds of calcium and magnesium to reduce acidity is called liming. Soil may be made more acid by the addition of hydrogen. This is accomplished by adding substances that produce strong acids in the soil. Addition of compounds that contain sulfur is the most efficient method. Thus fertilizers containing sulfur such as ammonia sulfate or superphosphate are used to lower pH.

In addition to the nutrient level and soil reaction, the structure of the soil plays a significant role in soil management because of its effect on water-holding capacity and aeration of the soil. Soil structure also influences root growth and soil micro-organisms, which are important in making nutrients available to plants. The physical condition of soil is largely determined by organic matter formed by decomposition of plant and animal residues. Organic matter decays when added to soil but leaves fractions that resist decomposition to form a dark, colloidal substance called humus. Humus has high adsorbent and absorptive properties for nutrients and moisture that greatly affect soil condition and fertility. Thus practices that increase or maintain soil organic matter are essential to sound horticulture. Organic matter can be applied directly by addition of natural organic fertilizers such as manures or through the plowing down of plant material such as a growing crop or grass sod (green manure). The extended use of legumes or grass sod is the best way to increase soil organic matter. The physical properties of potting soils can be controlled by direct incorporation of organic matter such as peat or through addition of inert substances such as vermiculite (expanded mica) or perlite (expanded volcanic lava).

Although soil is the most common medium for the growth of plants and thus of vital concern to horticulturists, it is not essential to plant growth. Plants can be grown quite well in nutrient solutions alone or in sand or gravel, to which nutrient solutions are added. Such soilless cultivation is known as hydroponics. Hydroponic gardens have been used to provide fresh vegetables where soil is unavailable, chiefly in coral islands. Hydroponic gardens were so used during World War II to provide military personnel with fresh vegetables. Though hydroponics is still practiced on a limited scale, in most situations soil has proven the more versatile and economic medium. Hydroponic culture is used extensively in experiments if precise nutritional control is required.

Hydroponic gardening

Water management. Water management in horticulture is concerned with the regulation and use of water in plant growth. This involves irrigation, the addition of supplemental water, and drainage, the removal of excess water. Because of the close association between water and soil, the control of moisture is an integral part of soil management.

There are a number of general methods of land irrigation. In surface irrigation water is distributed over the surface of soil. Sprinkler irrigation is application of water under pressure as simulated rain. Subirrigation is the distribution of water to soil below the surface; it provides moisture to crops by upward capillary action. A new method called trickle irrigation involves the slow release of water to each plant through small plastic tubes. This technique is adapted both to field and to greenhouse conditions.

Removal of excess water from soils may be achieved by surface or subsurface drainage. Surface drainage refers to the removal of surface water by development of the slope of the land utilizing systems of drains to carry away the surplus water. In subsurface drainage open ditches and tile fields intercept ground water and carry it off. The water enters the tiling through the joints, and drainage is achieved by gravity feed through the tiles. (See also IRRIGATION AND DRAINAGE.)

PEST CONTROL

Horticultural plants are subject to a wide variety of injuries caused by other organisms. These injuries are called diseases when caused by some infectious agent (the pathogen) living in intimate association with the plant for an extended period of time. Injuries caused by insects and animals are often classed as damage rather than disease, and in such instances the term predator rather than pathogen is used. Harmful effects of other plant species or weeds result from competition for essential growth factors such as light, nutrients, or water.

Plant pests include viruses, bacteria, fungi, higher plants, nematodes, insects, mites, birds, and rodents. The control of plant pests can be considered a discipline in itself. In Europe it is called plant protection. In the U.S. pest control is usually divided into three disciplines: plant pathology, entomology, and weed control.

There are various methods used to control plant pests. The most successful treatments are preventive rather than curative, aiming to deter injury rather than cure affected plants. Successful control often depends on the proper use of many methods. Expensive methods of pest control are only feasible with high-value products. Thus horticulture bears a disproportionate share of the cost of pest control.

Control of pests is achieved through practices that prevent harm to the plant or methods that affect the plant's ability to resist or tolerate intrusion by the pathogen. These can be classified as cultural, physical, chemical, or biological.

Cultural practices that reduce effective pest population include the elimination of diseased or infected plants or seeds (roguing), cutting out of infected plant parts (surgery), removal of plant debris that may harbor pests (sanitation), and alternating crops unacceptable to the pest (rotation). Any of a number of techniques may be employed to render the environment unfavourable to the pest, such as draining land, flooding, pH change. Safeguards against the spread of pests between geographic areas may be enforced through quarantines.

Physical methods may be used to protect the plant against intrusion or to eliminate the pest entirely. Physical barriers range from the traditional garden fence to bags that protect each fruit, a common practice in Japan. Heat treatment is used to destroy some seed-borne pathogens and is a standard soil treatment in greenhouses to eliminate soil pests such as fungi, nematodes, and weed seeds. Cultivation and tillage are standard practices for weed control.

The horticultural industry is now dependent upon chemical control of pests through pesticides, materials toxic to the pest in some stage of its life cycle. Commercial growers of practically all horticultural crops rely on complete schedules utilizing many different compounds. Pesticides are usually classed according to the organism they control: for example, bactericide, fungicide, nematicide, miticide, insecticide, rodenticide, and herbicide.

Pesticide selectivity

Selectivity of pesticides, the ability to discriminate between pests, is a relative concept. Some nonselective pesticides kill indiscriminately; most are selective to some degree. Most fungicides, for example, are not bacteriocidal. The development of highly selective herbicides makes it possible to destroy weeds from crops selectively. Selectivity may be achieved through control of dosage, timing, and method of application.

Plant pests may also be controlled through the manipulation of biological factors. This may be achieved through directing the natural competition between organisms or by incorporating natural resistance to the whole plant. The introduction of natural parasites or predators has been a successful method for the control of certain insects and weeds. Incorporation of genetic resistance is an ideal method of control. Thus breeding for disease and insect resistance is one of the chief goals of plant breeding programs. A major obstacle to this method of control is the ability of pathogens (disease-producing organisms) to mutate easily and attack heretofore resistant plants. (See also PEST CONTROL; WEED CONTROL.)

PLANT BREEDING

The isolation and production of superior types known as "cultivars" is the very keystone of horticulture. Plant breeding, the systematic improvement of plants through the application of genetic principles, has placed improvement of horticultural plants on a scientific basis. The raw material of improvement is found in the great variation that exists between cultivated plants and related wild species. The incorporation of these changes into cultivars adapted to specific geographical areas requires both a knowledge of the theoretical basis of heredity and art and skill to discover, perpetuate, and combine these small but fundamental differences in plant material.

The goal of the plant breeder is to create superior crop varieties. The cultivated variety, or cultivar, may be defined as a group of crop plants having similar but distinguishable characteristics. The term cultivar has various meanings, however, depending on the mode of reproduction of the crop. With reference to asexually propagated crops, the term cultivar means any particular clone considered of sufficient value to be graced with a name. With reference to sexually propagated crops, the concept of cultivar depends on the method of pollination. The cultivar in self-pollinated crops is basically a particular homozygous genotype, a pure line. In cross-pollinated crops the cultivar is not necessarily typified by any one plant but sometimes by a particular plant population, which at any one time is composed of genetically distinguishable individuals. (See PLANT BREEDING.)

Ornamental horticulture

Ornamental horticulture consists of floriculture and landscape horticulture, each of which is divided into the plant growing and marketing and the associated activities of flower arrangement and landscape design. The turf industry is also considered a part of ornamental horticulture.

Although flowering bulbs and flower seed represent an important component of agricultural production for the Low Countries of Europe, ornamentals are relatively insignificant in world trade. As a result world statistics on production are unavailable.

FLORICULTURE

Floriculture is the growing of cut flowers, potted plants, and associated greenery, including their subsequent arrangement. Floriculture has long been an important part of horticulture, especially in Europe and Japan, and accounts for about half of the nonfood horticultural industry in the U.S. Because cut flowers and potted plants are largely produced in plant-growing structures in temperate climates, floriculture is largely thought of as a greenhouse industry; there is, however, considerable outdoor culture of many flowers. Floriculture is a competitive and highly technical business requiring knowledge, skill, and large amounts of capital. Greenhouse floriculture is in many respects the most sophisticated part of plant agriculture.

The industry is usually very specialized with respect to its crop; the grower must provide precise environmental control and be vigilant in the constant struggle against pests and diseases. Exact scheduling is imperative since most floral crops are seasonal in demand. Because the product is perishable, transportation to market must function smoothly to avoid losses.

The floriculture industry involves the grower, who mass-produces flowers for the wholesale market, and the retail florist, who markets to the public and contributes services such as arrangement and delivery. The grower is often a family farm, but, as in all modern agriculture, the size of the growing unit is increasing. There is a movement away from urban areas of high taxes and labour costs to locations having lower tax rates and a rural labour pool and also toward more favourable climatic regions (milder temperature and more sunlight). The development of air freight has emphasized interregional and international competition. Flowers can be shipped long distances by air and arrive in fresh condition to compete with locally grown products.

The retail florist is usually separate from the grower. Typically he buys wholesale cut flowers, plants, greenery, and associated products and makes up floral arrangements. Most typically he is a designer and businessman rather than a breeder or grower.

LANDSCAPE HORTICULTURE

The industry of landscape horticulture is divided into growing, maintenance, and design. Growing of plants for landscape is called the nursery business, although a nursery refers broadly to the growing and establishment of any young plants before permanent planting. The nursery industry involves production and distribution of woody and herbaceous plants and is often expanded to include ornamental bulb crops—corms, tubers, rhizomes,

and swollen roots as well as true bulbs. Production of cuttings to be grown in greenhouses or for indoor use (foliage plants), as well as the production of bedding plants, is usually considered part of floriculture, but this distinction is fading. While most nursery crops are ornamental, the nursery business also includes fruit plants and certain perennial vegetables used in home gardens, for example, asparagus and rhubarb. Christmas tree production is also included, though the growth of other seedling trees is usually considered part of forestry.

Next to ornamental trees and shrubs, the most important nursery crops are fruit plants, followed by bulb crops. The most important single plant grown for outdoor cultivation is the rose. The type of nursery plants grown depends on location; in general (in the Northern Hemisphere) the northern areas provide deciduous and coniferous evergreens, whereas the southern nurseries provide tender broadleaf evergreens.

The nursery industry includes wholesale, retail, and mail-order operations. The typical wholesale nursery specializes in relatively few crops and supplies only retail nurseries or florists. The wholesale nursery deals largely in plant propagation, selling young "lining out" stock of woody material to the retail nursery, which cares for the plant until growth is complete. Many nurseries also execute the design of the planting in addition to furnishing the plants.

Bulb crops. The bulb crops include plants such as the tulip, hyacinth, narcissus, iris, day lily, and dahlia. Included also are nonhardy bulbs used as potted plants indoors and summer outdoor plantings such as amaryllises, anemones, various tuberous begonias, caladiums, cannas, dahlias, freesias, gladioli, tiger flowers, and others. Hardy bulbs, those left in the soil over winter, include various crocuses, snowdrops, lilies, daffodils, tulips, and many others.

Many bulb crops are of ancient Old World origin, introduced into horticulture long ago and subjected to selection and crossing through the years to yield many modern cultivars. One of the most popular is the tulip. Tulips are widely grown in gardens as botanical species but are especially prized in select forms of the garden tulip (which arose from crosses between thousands of cultivars representing several species). Garden tulips are roughly grouped as early tulips, breeder's tulips, cottage tulips, Darwin tulips, lily-flowered tulips, triumph tulips, Mendel tulips, parrot tulips, and others. The garden tulips seem to have been developed first in Turkey but were spread throughout Europe and were adopted enthusiastically by the Dutch. The Netherlands has been the centre of tulip breeding ever since the 18th century, when interest in the tulip was so intense that single bulbs of a select type were sometimes valued at thousands of dollars. The collapse of the "tulipmania" left economic scars for decades. The Netherlands remains today the chief source of tulip bulbs planted in Europe and in the U.S. The Netherlands has also specialized in the production of related bulbs in the lily family and provides hyacinths, narcissus, crocus, and others. The Dutch finance extensive promotion of their bulbs to support their market. Years of meticulous growing are required to yield a commercial tulip bulb from seed. Thorough soil preparation, high fertility, constant weeding, and careful record keeping are part of the intensive growing in The Netherlands, employing much hand labour. Bulbs sent to market meet specifications as to size and quality, which assure at least one year's bloom even if the bulb is supplied nothing more than warmth and moisture. The inflorescence (flower) is already initiated and the necessary food stored in the bulb. Under less favourable maintenance than prevails in The Netherlands, a subsequent year's bloom may be smaller and less reliable; it is not surprising that tulip-bulb merchants suggest discarding bulbs after one year and replanting with new bulbs.

Tulips

Herbaceous perennials. Garden perennials include a number of herbaceous species grown for their flowers or occasionally used as vegetative ground covers. Under favourable growing conditions the plants persist and increase year after year. The biggest drawback to perennials as compared with annuals is that they must be maintained throughout the growing season but have only a limited flowering period. Typical perennials are hollyhocks, columbines, bellflowers, chrysanthemums, delphiniums, pinks, coralbells, phlox, poppies, primroses, and speedwells.

Perennials are often produced and sold as a sideline to other nursery activities; some are sold through seedhouses. Perennial production could be undertaken on a massive scale, with attendant economies, but the market is neither large enough nor predictable enough (except for the greenhouse growing of such cut flowers as chrysanthemums and carnations) to interest most growers. In northern climates, many varieties are mulched in autumn to protect the plant from winter kill.

Shrubs. Production of ornamental shrubs is the backbone of the nursery trade in Europe and the United States. The nursery business is about equally divided among the production of (1) coniferous evergreens such as yew, juniper, spruce, and pine; (2) broad-leafed evergreens such as rhododendron, camellia, holly, and boxwood; (3) deciduous plants such as forsythia, viburnum, barberries, privets, lilacs, and flowering vines; and (4) roses, which will be discussed separately.

Fields of specialization have evolved within the ornamental shrub industry. Some firms confine activity mostly to production of "lining out" stock—seedlings and rooted cuttings for sale to growers for field plantings that must be tended several years before reaching salable size. Such firms will generally offer not only the bare root liners themselves but small plants started in plant bands or slightly larger ones in containers. They may also offer small grafted plants of expensive or rare cultivars. Lining out stock of a typical evergreen, such as the pfitzer juniper, is relatively inexpensive; it is more economical for a grower to purchase these ready to plant in the field than to undertake specialized propagation himself.

The field grower may, in turn, specialize in mass growing for the wholesale trade only. The field plantings are tended until they attain marketable size, having been shaped and sheared as necessary, provided with pest control, irrigated, culled, and so on. Because of the time required to produce a marketable crop and because of rising labour costs, this phase of the nursery industry involves economic hazards. But wholesale growing escapes the high overhead of retail marketing in urban areas, and although many growers do sell stock at the nursery, they generally avoid the expensive merchandising required of the typical urban-area garden centre. Growers are especially interested in labour-saving technology and are turning to herbicidal control of weeds and shortcut methods for transplanting (as a substitute for hand digging and burlapping).

Storage and marketing

Most shrubs are marketed "balled and burlapped" (B & B). The plants are dug with soil and wrapped with burlap or other suitable material. Recently, a trend has developed toward container-grown stock—nursery stock grown in the container in which it is sold. This allows year-round sales of plant material. Deciduous shrubs may be marketed bare root. There are obvious economies in not having to dig and wrap the plant carefully and handle added weight and soil volume. Fairly satisfactory techniques have been developed for holding bare-root ornamental shrubs in viable condition until marketed. Usually this involves digging after leaf fall in autumn and storing the plant through winter in cold cellars with regulated humidity for spring sale. Unfortunately, plants are often handled carelessly. Though the chief cause of loss during storage is desiccation, respiration also plays a part when temperatures rise. But even if the plants are properly cared for during cold storage, they often suffer from warming and drying at the sales outlet.

Roses. The production of roses is probably the most specialized of all shrub growing; the grower often deals solely in rose plants. Most are bud grafted onto rootstocks (typically *Rosa multiflora*). This is the only way

to achieve rapid and economical increase of a new selection to meet market demands. Large-scale production of roses has tended to centre in areas where long growing seasons make rapid production possible.

Because the budding operation calls for skilled hand labour and because field maintenance is expensive, few economies can be practiced in the production of roses. But techniques have been developed for the distribution of roses that do offer certain economies, such as coated paper or plastic bags instead of damp moss to retain humidity and wax coating of stems of dormant stock to inhibit desiccation.

Trees. Ornamental shade trees are usually grown and marketed in conjunction with shrubs. As part of the mid-20th-century migration to the suburbs in many countries and the construction of houses on cleared land, shade trees have become an increasingly important part of the nursery picture. As interest in shade and ornamental trees increased, creation of improved cultivars followed. There is still some activity in transplanting native trees from the woodlot, and some trees are still grown from genetically unselected seed or cuttings; but more and more trees, like roses and shrubs before them, are vegetatively propagated as named cultivars, many patented.

There are some obvious drawbacks to tree growing as an industry. The crop takes a fairly long time to reach marketable size, and trees not salable within a year or two become too large for convenient handling. The investment in a tree is high and consequently so is the price. Risks are entailed in trying to anticipate what the market will be for a crop planted today but not usable for five or six years. Yet so indispensable is an ornamental tree to attractive landscaping that this branch of horticulture continues to flourish.

The digging, handling, and transporting of trees has always been difficult. Except in the sapling stage, trees are seldom sold bare root. A good deal of experienced manpower is needed to dig a tree and wrap its root system in burlap, the traditional way of moving larger trees. Special machines with slings and hoists have been developed, and recently in the U.S. a split scoop was put into production that first digs a hole where the tree is to be planted, digs the tree so that the root ball is the exact size of the previously dug hole, and then transports the tree to the hole. Thus there is no need for wrapping or separate handling. Such a device makes it possible to move relatively large trees easily, but of course the tree must be contracted for in the field rather than selected from a nursery display.

LANDSCAPE DESIGN

The design and planning of landscapes has become a distinct profession that in many cases is only incidentally horticultural. Landscape architecture in its broadest sense is concerned with all aspects of land use for man. As a horticulturist, the landscape architect uses living plant materials along with other landscape materials—stone, mortar, wood—as elements of landscape design. Unlike the materials of the painter or sculptor, plants are not static but change seasonally and with time. The colour, form, texture, and line of plants are used as design elements in the landscape. Plant materials are also manipulated as functional materials to control erosion, as a surface material, and for enclosures to provide protection from sun and wind.

Landscape architecture originated in the design of great estates, and home landscape is still an integral part of landscape architecture. More recently, however, landscape architecture has begun to include larger developments such as urban and town planning, parks both formal and "wild," public buildings, industrial landscaping, and highway and roadside development. (See GARDEN AND LANDSCAPE DESIGN.)

TURF

The turfgrass industry produces and maintains specialized grasses and other ground covers for utility, recreation, and beautification. Grass is an ubiquitous feature of many urban and suburban facilities such as airports, cemeteries, educational institutions, golf courses, highways, residential and commercial buildings, and parks. In the U.S., annual turf maintenance expenditures exceed $4,000,000,000, of which 70 percent is spent on residential lawns.

The turfgrass industry reaches a large market throughout the affluent countries of the world. The maritime climate of the British Isles is particularly suited to beautiful turf. Although lawns are usually not the major home landscape feature, as in the U.S., public areas are even more emphasized.

The major turf species in Europe is *Poa annua*. In the U.S. the major species grown in the northern two-thirds of the country are three cool-season grass species: Kentucky bluegrass, the fine or red fescues, and bentgrass. There are a number of grass species adapted to the South: Bermuda grass, bahia grass, carpet grass, centipede grass, Zoysia grass, and St. Augustine grass.

Horticulture education and research

Scholarly works in horticulture appear continuously in scientific literature. Specific institutions devoted to horticultural research, however, go back to the beginning of the experiment-station system, the first being a private laboratory of John Bennet Lawes, with the later collaboration of Joseph Henry Gilbert, in Rothamsted, England (1834). Horticultural education and research in the U.S. was given great impetus by Morrill of the Land Grant–College Act (1862), which provided educational institutions in agricultural and mechanical arts for each state. Presently state experiment stations and the federal experiment stations of the U.S. Department of Agriculture, with its centre at Beltsville, Maryland, carry out systematic research efforts in horticulture. Although much research is carried out on horticultural food crops, there has been an increasing emphasis on ornamentals. Horticultural research is also conducted by private companies: for example, the seed industry, canning and processing firms, and finally private foundations and botanical gardens. Throughout the world there are now more than 1,000 institutes with 7,000 professional staff members conducting horticultural research.

Horticultural education is an established part of professional agricultural education worldwide. Training in horticulture up to the Ph.D. degree is offered in universities. There are relatively few schools devoted to the training of gardeners and horticultural technicians in the U.S., although a number of state universities have two-year programs in horticulture. Vocational horticultural training is more highly developed in Europe.

There are a great number of national and international societies devoted to horticulture. These include community organizations such as garden clubs, specialty organizations devoted to a particular plant or group of plants (*e.g.*, rose and orchid societies), scientific societies, and trade organizations. The first society devoted to horticulture originated in 1804 with the establishment in England of the Royal Horticultural Society. There are similar organizations in other European countries. The American Pomological Society was formed in 1848. The American Horticultural Society, established in 1945, is devoted largely to ornamentals. The American Society for Horticultural Science was established in 1903 and is now the most widely known scientific society devoted to horticulture. The International Horticultural Society for Horticultural Science, formed in 1958 with permanent headquarters in The Hague, The Netherlands, sponsors international congresses every four years. Most societies and horticultural organizations publish periodicals.

There are thousands of publications in the world devoted to some aspect of horticulture. The scientific and technical horticultural literature since 1930 is abstracted in *Horticultural Abstracts*, prepared by the Commonwealth Bureau of Horticulture and Plantation Crops, East Malling, Kent.

BIBLIOGRAPHY. J. JANICK, *Horticultural Science*, 2nd ed. (1972), an introduction to the scientific and technological as-

pects of modern horticulture; E.L. DENISEN, *Principles of Horticulture* (1958), a traditional approach to the subject; R.W. SCHERY, *Plants for Men*, 2nd ed. (1972), an economic text covering many crop plants; H.T. HARTMANN and D.E. KESTER, *Plant Propagation: Principles and Practices*, 2nd ed. (1968), the authoritative work in the field; L.R. HAWTHORN and L.H. POLLARD, *Vegetable and Flower Seed Production* (1954), on seed production technology; INTERNATIONAL SOCIETY FOR HORTICULTURAL SCIENCE, *Horticultural Research International*, 2nd ed. (1972), a world list of research stations and organizations; A. LAURIE, D.C. KIPLINGER, and K.S. NELSON, *Commercial Flower Forcing: The Fundamentals and their Practical Application to the Culture of Greenhouse Crops*, 7th ed. (1968), the standard floriculture text; A.A. HANSON and F.V. JUSKA (ed.), *Turfgrass Science* (1969), a comprehensive monograph on all aspects of the turf industry.

(J.J.)

Hospital

A hospital is an institution that is built, staffed, and equipped for the identification—diagnosis—of disease and the treatment, both medical and surgical, of the sick and the injured; for their housing during this process; and for certain other procedures, such as health examinations and the management of childbirth, that are ordinarily directed more to the preservation of health and physical well-being than to the cure of disease or of physical or mental abnormality.

Hospitals have long existed in every civilized country. In the developing countries, which contain much of the world's population, there are not enough hospitals, equipment, and trained staff, and, by the standards of the highly industrialized countries, the hospitals that are present are poorly equipped to handle the great volume of sick persons that need their care.

In many parts of the world, numbers of people fail to receive the benefits of modern medical science, do not enjoy public-health measures and hospital care, suffer through untreated illnesses, and die untimely deaths.

At the same time, in the developed countries, the hospital as an institution becomes continually more complex. Each year brings an acceleration of new medical knowledge requiring whole new hospital departments that were unknown a few years ago. The general hospital is taking on added services, some of which a few years ago were thought to be the prerogative of hospitals for persons with chronic disease. Patients are hospitalized for shorter periods in hospitals, and the cost per patient-day is rising. That general hospitals increasingly play the role of community health centres is indicated by the extraordinary increase in hospital emergency-department services and the tendency for more general hospitals to offer psychiatric, rehabilitation, and extended-care service. As hospitals become more complex and more involved treatment and surgery are undertaken, not only does the ratio of staff to patient increase but a more highly trained staff is required; during recent years a combination of medicine and engineering has produced a vast array of new instrumentation, much of which requires a hospital setting for its use. Such now relatively common procedures as open-heart surgery, for example, were unknown a few years ago.

HISTORY OF HOSPITALS

Care of the sick is a fundamental need of community life, and arrangements to deal with illness are present in all societies in some form. As it is an elemental need, care of the sick has always been closely linked with the economic and social development of people.

Hospitals in antiquity

It is known that hospitals existed in Ceylon (modern Sri Lanka) in 437 BC and were established in India somewhat earlier, in the time of Buddha. Eighteen institutions built by Aśoka, emperor of India in the 3rd century BC, are said to have had some characteristics similar to those of modern hospitals in that cleanliness was stressed, the patients were treated with kindness, and diet therapy was practiced. Temples were used as hospitals in Greek and Roman times.

The advent of Christianity gave impetus to the establishment of hospitals, which became integral parts of the church organization. From a decree of Constantine issued in AD 335, Christian hospitals developed at Rome, Constantinople, Ephesus, and other parts of the Roman Empire. The Hôtel-Dieu of Lyons was opened in 542 and the Hôtel-Dieu of Paris in 660. In these hospitals more attention was given to the well-being of the patient's soul than to curing his bodily ailments. The manner in which monks looked after their own sick became a model for the laity. The monasteries had an *infirmitorium*, a place to which their sick were taken for treatment. The monasteries possessed a pharmacy and frequently a garden with medicinal plants. In addition to caring for sick monks, the monasteries opened their doors to pilgrims and other travellers.

Religion continued to be the dominant influence in the establishment of hospitals during the Middle Ages. The growth of hospitals accelerated during the Crusades, which began at the end of the 11th century. Pestilence and disease were more potent enemies than the Saracens in defeating the crusaders. Military hospitals came into being along the travelled routes; the Knights Hospitallers of the Order of St. John in 1099 established in the Holy Land a hospital that could care for some 2,000 patients. This order has survived through the centuries as the St. John's Ambulance Corps.

While most hospitals of the Middle Ages were associated with monasteries, a few were built by cities. Three people living in the 19th century—Florence Nightingale, Louis Pasteur, and Lord Lister—had much to do with the phenomenal growth and acceptance of hospitals in modern times. Florence Nightingale organized nursing and made it a dignified profession with a high esprit de corps; nursing in modern hospitals is a direct result of her efforts. Without the work of Louis Pasteur in the development of germ theory and Lord Lister's application of it, surgery as it is now known would have been unlikely. Nineteenth-century developments in anesthesia made it possible to perform longer and more difficult operations.

Early hospitals in North America

The first hospital in North America was built in Mexico City in 1524 by Cortéz; the structure still stands. The French established a hospital in Canada in 1639 at Quebec city, the Hôtel-Dieu du Précieux Sang, which is still in operation although not at its original location. In 1644 Jeanne Mance, a French noblewoman, built a hospital of axe-hewn logs on the island of Montreal; this was the beginning of Hôtel-Dieu de St. Joseph, out of which grew the order of the Sisters of St. Joseph, now considered to be the oldest nursing group organized in America. The first hospital in the territory of the present-day United States is said to have been a hospital for soldiers on Manhattan Island, established in 1663.

The early hospitals were primarily almshouses, one of the first of which was established by William Penn in Philadelphia in 1713. The first incorporated hospital in America was the Pennsylvania Hospital, in Philadelphia, which obtained a charter from the crown in 1751.

Such hospitals had little in common with the hospital of today. The phenomenal advance in medical science in the 20th century, and its outstanding achievements in the prevention and cure of disease, the amelioration of human suffering, and the lengthening of the span of human life—all have depended in large part on the modern medical care dispensed in the general hospital.

THE MODERN HOSPITAL

Hospitals may be classified in various ways; by ownership and control; by type of service rendered; by length of stay; by size; or by facilities and organization provided. Terms in general use include the general as distinct from the special hospital; the short-stay hospital; and the long-term hospital.

Ownership, control, and financing. *Ownership and control.* In most countries outside of North America all or nearly all hospitals are governmentally owned and operated. In Great Britain, for example, except for a small number run by religious orders or serving special groups, as in the case of some Italian and Jewish hospitals and some facilities for the chronically ill, most

hospitals are within the National Health Service, and the local hospital management committee answers directly to the regional hospital board and ultimately to the Department of Health and Social Security. In the United States and Canada most hospitals are nonprofit and neither owned nor operated by governmental agencies. Many are associated with universities; others were founded by religious groups or by public-spirited individuals. Mental hospitals have been traditionally the responsibility of the state or provincial governments, while military and veterans hospitals have been provided by the federal government. In addition, there are some municipal and county general hospitals.

Financing. Almost universally, hospital construction costs are met at least in some part by governmental contributions. Operating costs are taken care of in a variety of ways. Ultimately, a large part of the expenses not covered by private endowments or gifts is met by contributions from the general funds of some unit of government or out of funds collected by insurance carriers from subscribers. In countries in which hospital insurance is not universal or complete, some of the operating costs are met by charges on uninsured or inadequately insured patients.

Carriers of hospital insurance

The carriers of the hospital insurance in a particular country may be governmental agencies, private corporations or agencies, or both. In Britain, for example, under the National Insurance Act, the government is the carrier. All persons who have reached the minimum school-leaving age and are not full-time students, beyond the age of retirement, in prison, or receivers of benefits from the insurance and who do not have less than a certain minimum income are contributors under the plan whether employed by others, self-employed, or nonemployed. Employers also contribute.

In the United States persons who are employed by others or are self-employed make compulsory contributions toward a form of national hospital insurance, Medicare, which pays a large portion of the hospital costs of persons aged 65 or over. Employers make matching payments. A majority of the persons ineligible, by reason of age, for benefits under the Medicare program are enrolled in some other form of hospital insurance. This may be Blue Cross, a group enrollment plan for employees that was sponsored by the American Hospital Association; one of the plans of approximately 900 commercial insurance companies; or one of the approximately 800 independent plans, including community and community-controlled plans and those operated by unions, employers, welfare funds, and private medical clinics.

In the United States, even with federal participation under Medicare and Medicaid (a program for persons under 65 who are unable to pay), the payment for health-care services on an insurance basis, either voluntary or governmental, is much less advanced than it is in many other parts of the world. In Europe, particularly, the financial support of services in hospitals tends to be much more collectivized. Less than 10 percent of the costs of hospital operation in Europe is covered by payments made directly by patients. Details vary somewhat from country to country: in the Union of Soviet Socialist Republics the program is based entirely on funds from a single source, while in Great Britain the funds for total hospital operation are appropriated by the Ministry of Social Security to each regional hospital board, which in turn distributes them to the local hospital groups. In Sweden some 90 percent of hospital operating costs are provided by local or provincial units of government from public revenue; the remaining 10 percent comes from payments made by insurance funds on behalf of the patient. In general, in most European countries, hospital operating costs are paid out of insurance funds; this is true in France, Germany, Italy, The Netherlands, Norway, and elsewhere.

The community general hospital

The general hospital. A community general hospital with about 200 beds has an organized medical staff, a professional nursing staff, and much expensive diagnostic equipment. In addition to the essential services of a first-class hotel, it has a pharmacy, a laboratory, departments for X-ray diagnosis and treatment and for physical therapy, probably a maternity division (ordinarily including a nursery and a delivery room), operating rooms, recovery rooms, an outpatient department, and an emergency department.

In a somewhat larger hospital one would expect to find additional facilities: dental services; a nursery for premature infants; a bank of organs for use in transplantation; a department of renal dialysis (removal of wastes from the blood by passing it through semipermeable membranes, as in the artificial kidney); equipment for inhalation therapy; an intensive-care unit; a self-care unit; a volunteer-services department; and, possibly, a home-care program. If the hospital is affiliated with a medical school, it may have facilities for closed-circuit television.

The advances made after World War II include the use of antibiotics, a vast new array of laboratory procedures, many new surgical techniques, new materials and equipment for radiation therapy, and an increased emphasis on physical therapy and rehabilitation. One trend that has developed has been the increasing use of the emergency department of the general hospital to meet medical needs that may not be critical emergencies. This is done by all classes of society and is particularly noticeable at night and during weekends.

The legally constituted governing body of the hospital, with full responsibility for the conduct and efficient management of the hospital, is usually a hospital board. The board establishes policy and, on the advice of a medical advisory board, appoints a medical staff and an administrator. It exercises control over expenditures and has the responsibility for seeing that professional standards are maintained.

The administrator is the chief executive officer, responsible to the board alone. In a large hospital there are many separate departments, each controlled by a department head. The largest department in any hospital is nursing, followed by the dietary department and housekeeping. Other departments, all important to the functioning of the hospital, include laundry, engineering, stores, purchasing, accounting, pharmacy, physical therapy, social service, pathology and X-ray, and medical records.

In many hospitals interdepartmental committees function with excellent results, and many difficulties are solved. Committees on pharmaceuticals, food service, medical records, hospital forms, laundry, and purchasing are among those that may be organized. A committee on laundry and linen, for example, might have as members the administrator or his delegate and representatives from nursing, purchasing, laundry, engineering, and the sewing room.

Organization of medical staff

The medical staff is organized into such departments as surgery, medicine, and obstetrics. The degree of departmentalization of the medical staff depends on the specialization of its members and not primarily on the size of the hospital, although there is usually some correlation between the two. The chiefs of the medical-staff departments, along with the radiologist and the pathologist, make up the medical advisory board, which usually holds monthly meetings on medical–administrative matters. The professional work of the individual staff members is reviewed by such medical-staff committees as those on medical records, medical audit, tissue (which verifies that tissue removed by a surgeon should in fact have been removed), credentials, and utilization. In a large hospital the committees may report to the medical advisory board; in a smaller hospital, to the medical staff directly, at regular staff meetings.

Specialized health- and medical-care facilities. Hospitals that specialize in one type of illness or one type of patient are common in Europe and in America, although modern opinion holds that, except in large university centres where postgraduate teaching is carried out on a large scale, the special hospital should become a department of a general hospital. Hospitals for the treatment of mental diseases and of tuberculosis are prominent examples of specialized institutions; also common

are hospitals exclusively for children; women; nervous diseases; ear, nose, and throat diseases; orthopedics; eye diseases; and cancer. Many of these hospitals are famous as centres of research and teaching.

Changing conditions or changing modes of treatment have lessened the need for some types of specialized institutions or reduced the number of such institutions that are required. This trend may be seen in tuberculosis and mental hospitals.

Tuberculosis hospitals. During the last two decades of the 19th century and the first three decades of the 20th century, much attention was given to providing tuberculosis hospitals. They were frequently situated in rural areas, where rest, relaxation, special diets, and fresh air were provided. Even if the tuberculosis was in an early stage, a stay of upward of two years was thought necessary to effect a healing of the disease; a permanent cure was not considered entirely feasible. The procedure did not change much until the discovery of antibiotics; the use of antibiotics, along with advances in chest surgery and routine X-ray programs, has changed the picture completely. Since the mid-20th century the decline in the use of tuberculosis sanatorium beds has been marked, and many of the sanatoriums in North America and Europe have been converted to other types of care. The compulsory pasteurization of milk has played a large part in eliminating bone tuberculosis, which formerly was often transmitted from cattle.

Mental hospitals. Psychiatric patients traditionally have been housed in long-stay mental hospitals, formerly called asylums. In the past few decades, however, a fundamental change has occurred, not only in the treatment of the mentally ill but also in the public attitude toward them. Most large general hospitals now have a psychiatric unit.

Changes in treatment of mental patients

The hospital stay of many persons with chronic mental disease has been shortened by modern medication and more understanding on the part of the public. Mental patients have been given an opportunity to participate in many activities, first within the hospital setting and later in the community, either with trial visits at home or with placement of selected patients in foster homes. A recent innovation has been night care for psychiatric patients, allowing the patient to work in the community during the day and return to the hospital at night for medication and other treatment.

Hospitals for women and for children. Specialized hospitals for women are common and are often staffed completely by women doctors. Many of these hospitals are privately owned. In England they are known as nursing homes (not to be confused with the North American use of the term); on the continent of Europe they are called clinics. Primarily, these hospitals are for surgical conditions, but medical and obstetrical cases are usually accepted.

There are many hospitals for children in the Union of Soviet Socialist Republics, and several cities in North America have their own specialized hospitals for children. Most hospitals accept children up to age 14, but some specify up to age 16. In cities without such hospitals the local general hospital usually provides a special ward for children.

Military hospitals. Many of the advances in medicine are the outcome of experience gained in war, and, in times of peace, military physicians and surgeons have made notable contributions in the fields of hygiene, preventive medicine, medical statistics, and hospital construction.

The largest hospital on record, the Chimorazo Hospital of Richmond, Virginia, was a military hospital of some 9,000 beds established by Confederate forces during the United States Civil War.

Advances during World War I

During World War I it was discovered that good medical care could be provided in improvised facilities, including public buildings, private homes, ships, barges, trains, and ambulances; another development was the mobile field hospital, with physicians, nurses, and supplies following the movement of troops for emergency treatment. That war also saw the mass movement of convalescent patients over long distances and by means previously considered impossible. The control of contagious diseases was much further advanced than in any previous war, and many of the new methods were later adapted to peacetime civilian practice.

One of the outstanding features of both World War II and the Korean war, as compared with earlier wars, was the much better chance a wounded soldier had of survival. This was the result not only of better medical and surgical treatment but also of much more efficient and faster evacuation of the wounded from the battle area to a sorting area, from which the more seriously injured were shipped out by plane to base hospitals several miles back. These facilities were well equipped and staffed, but the important factor was that casualties were treated soon after the wounds occurred, before infection was too far advanced.

Hospital ships, used to transport the wounded home for prolonged treatment in permanent hospitals on land, follow a long tradition; the Spanish Armada, in 1588, was accompanied by a hospital ship. Modern hospital ships are floating hospitals with equipment and medical and nursing staffs matched only by the most modern land hospitals.

Civilian hospital ship. In 1958 the organization People-to-People Health Foundation was formed to establish the first peacetime hospital ship, the "Hope." This ship, a converted naval hospital ship, set out on its maiden voyage on September 22, 1960, from California. Its purpose was to carry medical help to any country that needed and requested it. Its mission was to be threefold: to teach, to heal, and to be a pilot for what was hoped would later grow into a great fleet. The physicians who served were volunteers, while the nurses and other personnel were paid only token wages. The first voyage, which consumed a year, was to the Far East, to Indonesia, and to Vietnam.

Portable disaster hospitals

Packaged hospitals for large-scale disasters. Portable disaster hospitals have been developed, containing equipment for setting up receiving and sorting units, operating rooms, wards, a central sterile supply, a pharmacy, a general laboratory, an X-ray laboratory, and a unit for general stores. Each of the portable hospitals can be used to expand the facilities of an existing hospital or as a separate 200-bed unit in a preselected building. The equipment for a typical portable hospital of this type is contained in about 660 boxes and crates, weighs 45,000 pounds, and requires 7,500 cubic feet of storage space.

Regional planning. Sweden and the Union of Soviet Socialist Republics provide examples of advanced planning in the integration of hospital networks into coordinated health services. In both nations the government has assumed the responsibility of providing health care to all citizens. In Sweden financing is in part by compulsory health insurance.

Sweden is divided into health-service regions; each region includes several counties and has a central hospital. Each county within a region has a county hospital with up to 1,000 beds and with specialized and outpatient facilities to serve a population of about 300,000. The counties, in turn, are divided into districts, each of which has a population of about 75,000 and is served by a district hospital, which usually has 300 or more beds. Smaller communities have health centres or ambulatory service centres that are not administered as part of the hospital system.

The Soviet Union takes a somewhat different approach. In its thinly populated rural areas, general hospitals, called *uchastok* hospitals, may serve populations as small as 2,000 to 15,000 persons. These 15- to 100-bed general hospitals occupy the same premises and employ the same staff as general clinics—polyclinics—that provide general and specialized care. The hospital–clinic staff includes a general physician, a surgeon, and a dental surgeon. In larger *uchastok* centres there may also be a radiologist and a pathologist.

The hospitals next in size, the district hospitals, have 250–500 beds and usually have divisions for surgical, medical, obstetrical, and pediatric services and provide

care for infectious diseases; they may also include departments for eye, ear, nose, and throat disorders and for orthopedic surgery. Patients who cannot be treated adequately in the district hospitals are referred to the next higher level, the regional hospital, which serves a population of 1,000,000–5,000,000 people and contains up to 1,250 beds.

The republic hospital occupies the highest level in the Soviet system. Such a hospital, or complex of hospitals, serves as a referral centre and has the responsibility of undergraduate medical education. It may also be associated with one or more research institutes.

Regional planning in North America is less advanced. One regional pattern being proposed is a satellite system, centred on a metropolis and applying the principle of progressive patient care. The system would be focussed on the efficient provision of comprehensive health care to the residents of the region. Less serious cases would be handled in the outer, more accessible health facilities of the system; the more serious would be referred to the inner hospitals of the ring or to the research and teaching hospital at the core.

Metropolitan planning council

The term metropolitan planning council is used frequently to denote an advisory planning group that tries to coordinate services among member hospitals in a metropolitan area and to decide such questions as where additional beds are to be built. In North America, however, the hospitals tend not to be government operated, and it is difficult to achieve close cooperation among voluntary groups.

Extended health care and facilities. *Convalescent care.* Modern treatment of persons recovering from an illness, surgery, or injury gives attention not only to the patient's physical recovery but also to his emotional and social well-being. Many persons receive care outside the general hospital during convalescence—perhaps in (1) a convalescent hospital; (2) a nursing home, usually a smaller institution with medical attention available on call; (3) a chronic-disease hospital, providing long-care remedial treatment; or (4) the patient's own home, with the aid of services and equipment supplied by a general hospital.

Long-term hospital care. Long-term hospitals have traditionally been associated with the treatment of chronic disease requiring a limitation of activity. Among such conditions most often reported are heart disease, arthritis, rheumatism, back impairments, high blood pressure, mental and nervous disorders, and impairment of vision. The modern tendency to replace the special chronic-disease hospitals with chronic-disease units within general hospitals allows better coordination and integration of services and ensures continuity of care.

Progressive-care concept. With the advance in medical science and the ever-increasing cost of hospital operation, the progressive-care concept, a step-by-step progam for total care, is gradually gaining ground, both for outpatient and inpatient care. Progressive care can be divided into five categories: (1) intensive care; (2) intermediate care; (3) self-care; (4) long-term care; and (5) organized home-care programs. Two of the categories, self-care and home-care programs, are relatively new departures from past practice and consequently deserve special attention.

Categories of progressive care

Self-care facilities are organized into a separate unit in which ambulatory patients who require only diagnostic or convalescent care are given accommodations of the hotel type. The patients are free to wear street clothes and to go to the hospital cafeteria. It is evident that such a ward or wing of a general hospital requires much less costly equipment than the intensive- or intermediate-care units and can be staffed with far fewer nurses and aides.

Home-care programs are for selected patients who need some care but not all of the treatment facilities of a hospital. The patients are provided with a range of individualized medical, nursing, social, and rehabilitative services in their own homes, coordinated through one central agency. Patients can be considered ready for home care when: (1) diagnosis and a plan for treatment have been established; (2) inpatient hospital facilities are no longer required for proper care; (3) no more than two visits per week by physicians are required; (4) the nursing service has found that the physical environment of the home is such that the patient receives adequate care; (5) the patient is too ill to visit an outpatient clinic but does not need hospital care; (6) the family environment would have a therapeutic effect, and family members or others can be taught to provide the necessary care; and (7) the family and the patient prefer that he be cared for at home. Although home care is a means of conserving highly expensive acute-care beds and represents a significant extension of hospital service and, although most patients on home care do as well as they are expected to and some do much better, home-care programs have not been adopted on a large scale.

BIBLIOGRAPHY. The literature on hospitals is quite extensive. The best general reference book is MALCOLM T. MACEACHERN, *Hospital Organization and Management*, 3rd ed. (1969), the standard text for hospital boards, administrators, students, or anyone wishing to learn about hospitals. JOSEPH KARLTON OWEN (ed.), *Modern Concepts of Hospital Administration* (1962), has a long list of knowledgeable contributors, each of whom writes on his specialized field. For general statistical information regarding hospitals in the United States or Canada, the best source is the *Guide Issue of the A.H.A.* (published in August of each year). *Trustee* is a monthly journal (A.H.A.) for hospital governing boards but contains much information of use to the general reader with some knowledge of hospitals. A very readable history of medicine and to some extent hospitals is HOWARD W. HAGGARD, *Mystery, Magic, and Medicine* (1933; republished under the title *Devils, Drugs and Doctors*, 1937). The literature on hospitals in wartime is quite extensive. EDGAR ERSKINE HUME, *Victories of Army Medicine* (1943), sketches the United States Army Medical Department from 1775 to 1943. *Janes Fighting Ships* for 1944–45 portrays some hospital ships and gives tonnage. For the story of the hospital ship *Hope*, see WILLIAM B. WALSH, *A Ship Called Hope* (1964), *Yanqui, Come Back* (1966), and *Hope in the East* (1970). Probably the most important sources of information about hospitals may be obtained from the lending libraries of the American Hospital Association and the Canadian Hospital Association. Information on hospitals abroad may be obtained through selected publications of the World Health Organization.

(W.D.P.)

Hotel and Motel Industry

A hotel is a building or institution in which are provided lodging, meals, and other services for the travelling public. A motel, or motor hotel, generally performs the same functions in a format designed primarily for guests arriving by automobile.

Hotels have long been important elements in the economies of many countries. The enormous increase in tourism of the 20th century has caused the industry to outgrow national boundaries and become international. Growth has been especially large in certain resort areas, such as the Mediterranean and Caribbean seas. The modern industry has profited from the introduction of such new techniques as computerized reservation and credit systems and new forms of financial organization, such as the international hotel chain and the franchise motel. In the early 1970s more than 750 new hotels were planned or under construction throughout the world.

History to World War II. Inns were in existence in very ancient times to serve merchants and other travellers, though accounts of their operations are sketchy. In Roman times hostelries called *mansiones* were situated along the Roman road system, principally to accommodate travellers on government business. The commercial revival of the Middle Ages stimulated a wide development of inns and hostels. Many were operated by monasteries and other religious institutions. A famous example is the hospice in the Great St. Bernard Pass in the Swiss Alps, founded in the 10th century by St. Bernard of Montjoux (Bernard of Menthon) and still operated by the community of Augustinian monks.

Inns and hostels of the Middle Ages

In 13th-century China, Marco Polo found an extensive system of relay houses in existence to provide accommodations for travellers and way stations for the Mongol postal service.

Privately operated inns intended primarily for the use of merchants were widespread in both Islāmic and western European countries in the High Middle Ages. In many of them the innkeeper served in a semi-official capacity as part of a marketing or fair organization, safeguarding merchants' funds and acting as a broker.

The Industrial Revolution stimulated much progress in innkeeping, especially in England, whose inns became a standard for the world. Cleanliness, comfort, and good food became the hallmarks of the English inn. Meanwhile, across the Atlantic American innkeepers were setting a standard for size; by 1800 the inns of the United States were the largest in the world. The first American hotel to gain wide fame for its size was the 73-room City Hotel, described at its opening in 1794 as "an immense establishment." The American trend toward large size continued into the 20th century; hotels of 1,000 or more rooms are fairly common in the United States, while 600-room structures are rare elsewhere.

As travel for pleasure gained vogue in Europe, a new class of resort hotels was built in many countries. Along the French and Italian Riviera from Marseilles to Pisa resort hotels were constructed to serve wealthy vacationers, who frequently came for the entire summer or winter season. Luxury hotels soon made their appearance in the cities; in 1889 the Savoy Hotel in London set a new standard with its own electricity, a theatre, a private chapel, and a printing press.

Railroad hotels

The railroad had great impact on hotel development. Faster travel eliminated the need for establishments that had served the old coach routes in England, and many of them were forced out of business. On the other hand, new hotels were profitably built along rail lines. To accommodate the new travelling class, hotels were constructed as close as possible to the train station. This influence continued well into the 1930s, with the railroad companies themselves often owning hotels or leasing land for their construction.

A major development in hotel history occurred in 1908 with the opening in Buffalo, New York, of the hotel Statler (later named The Buffalo). Many innovations in services and conveniences were introduced by Ellsworth Milton Statler, the builder and operator, primarily for the convenience of the large and growing class of business travellers. From the Buffalo Statler grew the Statler Company, the first great chain operation in hotelkeeping.

World War I was followed by a period of tremendous hotel construction and growth. More new hotels were built from 1920 to 1930 than in any ten-year period before or since. Hotels increased not only in number but also in size. The Stevens Hotel (later the Conrad Hilton Hotel) in Chicago opened with 3,000 rooms and retained the title of world's largest until the late 1960s, when the Hotel Rossiya (Russia) opened in Moscow. Hotel-building declined sharply during the Depression of the 1930s and did not resume until after World War II.

Postwar developments. *The motel.* Prior to 1950, hotels were classified into the three categories of transient, residential, and resort. A fourth category—motel–motor hotel—is now necessary. It is not difficult to explain the phenomenal growth and success of this segment of the industry. The character of the hotel industry has always been directly related to the principal mode of transportation of the times. By 1950 in the United States and by the 1960s in Europe and Japan, the family automobile had become a principal mode of travel. Tourists furthermore preferred informality to the old hotel system involving formal dress, lobby parades, tipping, and parking problems. Finally, motel rooms were new, with modern furniture, wall-to-wall carpeting, and television. The swimming pool proved another popular attraction.

Although motels originated in the United States as roadside cabins, usually independently operated by a husband-and-wife team, their average size has increased to about 100 units today, and professional management has largely taken over. Though motels are still more common in the United States and Canada than elsewhere, Great Britain, Europe, the Caribbean, and Japan have all witnessed significant building in recent years.

Chain operation. Another important postwar development involves the trend to chain operation. While a number of hotel chains date from the early 1900s, the great growth period began after World War II. Although the chain-hotel operation is more predominant in the United States, the concept is becoming more common in most parts of the world. Chain operation permits increased efficiency, particularly in purchasing, personnel, promotion and sales, reservations, and financing. The four giant corporations in the hotel field in the early 1970s were Hilton Hotels Corporation; Sheraton Hotels and Motor Inns; Inter-continental Hotels; and, in the United Kingdom, Trust Houses, Ltd., later Trust Houses Forte, Ltd. Other prominent and rapidly growing chain operations are Marriott, Western International, Steigenberger, and Loew's hotels. The chain concept has become popular in the motel field as well. Holiday Inns Inc. is the single largest chain in the world, with more guest rooms than even the hotel giants.

Hotel corporations

Motel franchising

Closely allied to chain operation is the franchising concept, which has been the most rapid development in the industry since 1950. Franchising allows an individual or group of investors to go into business for themselves while enjoying most of the advantages of chain operation. The investor purchases a franchise from a major company, pays a license fee as well as some type of daily fee per room to cover advertising, and leases the sign displayed in front of the motel. The investor owns the land, the building, and the equipment. From the franchising company he receives assistance in architectural planning, in training his staff, and in developing accounting procedures, purchasing procedures, and standard operating procedures. Most important, he benefits from the referral system of the franchiser, by which guests are guided to his motel by other franchise holders through a joint reservation system. Often the investor may purchase equipment and supplies at a considerable saving from the franchise chain.

Several motel chains that pioneered the franchising concept have achieved phenomenal growth through its use. In each case, company-owned motels account for only a small portion of the total. A recent development has been the growth through the franchising concept of chains within the chains. Groups of investors form a corporation and obtain the franchise rights for a certain geographical area from the franchiser. As they build and operate the properties, they become a chain within the larger franchising chain.

The rapid growth of tourism (over 10 percent annually) exerts a strong influence on hotel operation internationally. Not surprisingly, many airlines have entered the hotel business.

Resort hotels. Resorts today fit many categories: seashore, mountain, winter, summer, year-round. Traditionally, a resort hotel provides comfortable rooms, excellent cuisine, and a location with scenic, historic, recreational, or therapeutic advantages. The majority of resorts today attempt to operate all year. The popularity of skiing and other winter sports opened a new season for northern resorts formerly restricted to summer operation.

Among the greatest growth areas have been the Mediterranean, the Caribbean, and Hawaii. Miami Beach, Florida, has 48 hotels per square mile. Jamaica, Barbados, Puerto Rico, the Virgin Islands, the Bahamas, and Trinidad and Tobago all count tourism as one of their most important industries. In Hawaii the island of Oahu has no more space available for hotels, and the outer islands are witnessing tremendous hotel growth. The Riviera and Black Sea, among the most famous of resort areas, have maintained their popularity in the face of increased competition from around the world. Spain has seen tremendous growth in its tourism, and Portugal is also becoming very popular. Resort areas in the Pacific are increasing in popularity; they are seen by many as the next great region for development in tourism.

Residential hotels. The residential hotel is essentially an apartment building offering maid service, a dining room, room meal service, and sometimes a cocktail

lounge. Residential hotels range from the luxurious, offering full suites, to the moderate, with single rooms.

The condominium

The condominium may be considered a form of residential hotel. In this concept, the apartments or suites are actually purchased by the occupant and the ownership is his. In resort areas, people often purchase condominiums as an investment. The owner may spend his vacation there and offer the condominium for rent by transients at other times, under the supervision of the condominium management. This concept is growing in popularity.

One of the most recent developments is a combination of condominiums, resort hotel, apartments, conference centre, and private homes. Many people feel that this combination is the blueprint for the resort complex of the future.

Management techniques. Today's hotel manager employs modern management techniques, to forecast and control labour and materials costs, and modern marketing methods. The electronic computer has achieved great success in hotel accounting and reservations. Research is now in progress for a completely computerized hotel operation.

The problem of employee costs versus productivity has become serious in hotel management in recent years. Since the productivity of hotel labour has remained constant or even declined, hotel architects have sought to design structures in which maximum service can be rendered with minimum personnel. Techniques for automating functions now burdened with high labour costs are being studied by hotels, manufacturers of equipment, and schools of hotel management. Automation of a service industry remains a challenge, however, with problematical results.

BIBLIOGRAPHY. For the reader who desires information on the overall nature of the hotel-motel field, description of operating departments and their functions within the enterprise, as well as the history, growth, and development of the industry, GERALD W. LATTIN, *Modern Hotel and Motel Management*, 2nd ed. (1968); and DONALD E. LUNDBERG, *Inside Innkeeping* (1956), are two excellent accounts. For information on careers in the industry and how to prepare for them, GERALD W. LATTIN, *Careers in Hotels and Restaurants* (1967), is recommended.

Technical books describing principles, practices, and theories of hotel-motel operation tend to specialize in certain function areas—*e.g.*, accounting, food and beverage, planning, sales, legal, and promotion. The most recent and very comprehensive book on accounting for the hospitality industry is CLIFFORD T. FAY, JR., RICHARD C. RHOADS, and ROBERT L. ROSENBLATT, *Managerial Accounting for the Hospitality Service Industries* (1971). Within the industry, the most widely used text on food and beverage management is JOSEPH BRODNER, HOWARD M. CARLSON, and HENRY T. MACHAL (eds.), *Profitable Food and Beverage Operation*, 4th ed. rev. (1962). All the technical procedures for performing this complex function are extremely well presented. C. DEWITT COFFMAN, *The Full House: A Hotel/Motel Promotion Primer* (1964), is by far the best book on hotel marketing, sales, and promotion. Little has been written on resort hotels, but E. ABRABEN, *Resort Hotels: Planning and Management* (1965), provides a good overview of the general procedures for planning and management. A sound technical approach to the legal problems of the industry is furnished by HENDRIK ZWARENSTEYN, *Legal Aspects of Hotel Administration* (1962). For the reader interested in a comprehensive coverage of all phases of motel operation, GEORGE O. PODD and JOHN D. LESURE, *Planning and Operating Motels and Motor Hotels* (1964), is highly recommended. HERBERT K. WITZKY, *Modern Hotel-Motel Management Methods* (1964), deals primarily with the personnel and human relations aspects of the hotel-motel business although some general management material is also covered.

A number of books have been written on the careers of famous hotelmen. Among the best are FLOYD MILLER, *Statler* (1968); CONRAD HILTON, *Be My Guest* (1957); ERNEST HENDERSON, *The World of "Mr. Sheraton"* (1962); and WHITNEY BOLTON, *The Silver Spade: The Conrad Hilton Story* (1954).

(G.W.La.)

Houseplant

Many exotic plants native to warm, frost-free parts of the world are grown indoors in portable containers or in miniature gardens, especially in colder climates. Houseplants have thus become a significant part of everyday life in economic as well as aesthetic terms and are the objects of a considerable business enterprise that supplies growing plants for interior decor.

The range of houseplants

Most houseplants are derived from plants native to the tropics and near tropics. Those that make the best indoor subjects are the species that adjust comfortably to the rather warm, dry conditions that generally prevail in indoor living spaces.

Although many plants can be grown successfully indoors, there are certain groups that, because of their attractiveness and relative ease of maintenance, are generally considered the best houseplants. These include the aroids, bromeliads, succulents (including cacti), ferns, begonias, and palms, all of which have long been favourites. Somewhat more demanding are those that are grown primarily for their flowers—the African violets, camellias, gardenias, geraniums (*Pelargonium* species), and orchids.

Historical development of the houseplant. Paintings and sculptures make clear that the practice of indoor gardening can be traced at least to the early Greeks and Romans, who grew plants in pots and perhaps brought them into their homes. The older civilizations of Egypt, India, and China also made use of potted plants but usually in outdoor situations, often in courtyards that were extensions of the house, and for centuries the Japanese have carried on the dwarfing of trees and other plants for room ornaments. But the popular art of growing houseplants did not receive much comment until the 17th century, when, in *The Garden of Eden* (printed in 1652), Sir Hugh Platt, an English agricultural authority, wrote of the possibility of cultivating plants indoors. Shortly thereafter, glasshouses (greenhouses) and conservatories, which were used during Roman times to force plants to flower, appeared in England and elsewhere to house exotic plants. In mid-19th-century England and France, books began to appear on the growing of plants in private residences, and the use of enclosed portable cases of plants (Wardian cases, or terraria) became popular. Since that time interest in houseplant cultivation has become so great that few houses in civilized countries today are without some form of plant life.

Some leading types of houseplants. There are thousands of tropical and subtropical plants that can adapt to growing indoors. Although some fancy exotic species do well only in a humid conservatory or a glass-enclosed terrarium, a great many species have been introduced that endure the adverse conditions of dry heat and low light intensity that prevail in many houses. A selection of the more widely favoured houseplants follows, under two sections: foliage plants, some of which also bear interesting flowers; and flowering plants, species kept primarily for their flowers.

Foliage plants. In the aroid family, which has provided a range of long-lived houseplants, most prominent are the philodendrons. These are handsome tropical American plants, generally climbers, with attractive leathery leaves, heart-shaped, and often cut into lobes. *Monstera deliciosa*, or *Philodendron pertusum*, the "Swiss cheese" plant, has showy, glossy, perforated leaves slashed to the margins.

Dieffenbachia, the dumb canes, in a number of attractive species, are handsome tropical foliage plants usually with variegated leaves; they tolerate neglect and thrive even in dry rooms. *Aglaonema*, the Chinese evergreens, are fleshy tropical Asian herbs of slow growth, with leathery leaves often bearing silvery or colourful patterns; they are very durable and tolerant of indoor conditions. *Scindapsus*, popularly known as pothos, or ivy-arums, are tropical climbers from the Malaysian monsoon area; their attractive variegated leaves usually are small in the juvenile stage. They do well in warm and even overheated rooms. *Spathiphyllum*, the peace lilies (not a true lily), are easy-growing, vigorous tropical herbs forming clumps; they have green foliage, and a succession of flowerlike leaves (spathes), usually white. *Anthurium* with colourful spathes, such as the flamingo flower, does best under humid conditions. *Caladium* are tropical American tuberous herbs producing fragile-look-

ing but colourful foliage; they keep surprisingly well if protected from chills and wintry drafts.

Begonias, with their often very decorative leaves, are long-time favourites among houseplants, but, with few exceptions, they require more humidity and fresh air than the modern home provides. *Begonia metallica*, with its olive-green, silver-haired foliage; *B. masoniana*, with beautiful green, puckered leaves splotched brown; and *B. serratipetala*, with small foliage spotted pink, are examples of types more resistant to dry rooms. Double-flowered varieties of *B. semperflorens*, the rose begonia, are popular plants for the windowsill.

Small foliage plants

There are many small foliage plants, often with strikingly patterned foliage, which are native to the tropical forest floor; some of them have become remarkably good houseplants. Among them are several prayer plants (*Maranta* species), which fold their attractive leaves at night; and the exquisite *Calathea makoyana*, or peacock plant, with translucent foliage marked with a feathery peacock design. *Pilea cadierei*, or aluminum plant, is easy to grow; it has fleshy leaves splashed with silver. *Codiaeum* species, or crotons, are multicoloured foliage plants that need maximum light and warmth to hold their leaves and coloration well. Although primarily thought of as bedding plants, the varicoloured coleuses, or painted nettles, can decorate a sunny window with a brilliant array of leaf patterns. *Peperomia* species form miniature rosettes or vines, with waxy foliage that are corrugated and decorated either with silver or creamy white.

Bromeliads constitute a plant family peculiar to the Western Hemisphere; they dwell on trees and rocks (as epiphytic plants) or on the forest floor (as terrestrial plants) and usually form rosettes of leathery, concave leaves, many with bizarre design or striking variegations. Their flowers may be hidden deep in the centre of the rosette, surrounded by a cup of brilliant crimson inner leaves, as in *Neoregelia* and *Nidularium*. Species of *Aechmea* and *Guzmania* form colourful spikes or heads of long-lasting leathery bracts or bright berries. *Billbergia* species are tubular in shape; their showy flower stalk, with blue flowers, is often pendant. Most forms of *Tillandsia* and *Vriesea* have spear-shaped, flattened, colourful flower spikes. The terrestrial *Cryptanthus*, the earth stars, are more or less flattened rosettes with striking leaf design, mottled, striped, or tiger-banded in silver over greens and bronzes.

Succulents. Cacti, native to the Western Hemisphere, have developed a special capacity to store water in thick, fleshy bodies. They thrive in much sun and need very little water. There are many often curious forms: the tiny button cactus, *Epithelantha;* the myriad pincushion species of *Mammillaria; Parodia*, or Tom Thumb cactus; and *Rebutia*, the pygmy cactus. The last two bloom when young and tiny. Other forms include *Gymnocalycium*, or chin cactus; *Notocactus*, or ball cactus; *Echinocactus*, known as barrel cactus; various *Opuntia* species, including bunny ears and chollas; and *Cephalocereus*, or old-man cactus, with its glistening white hair. Larger cacti include *Cereus* and its relatives, often night-blooming, and the giants of the desert, such as *Carnegiea*, the saguaro, with branching columns up to 60 feet (18 metres) in height. Cacti of tropical forests include the epiphytic *Rhipsalis* and the near-epiphytic orchid cacti, *Epiphyllum*, which blooms in many colours; both kinds are suitable for growing in baskets.

Succulents other than cacti have also contributed favourite subjects for indoor growing. Typical stem succulents are *Euphorbia*, with their often angled candelabra-like columns resembling those of cacti. Leaf succulents are represented by *Aloe*, famous since ancient times as the medicine plants; *Echeveria*, or hen and chickens; *Kalanchoe tomentosa*, the panda plant; *Crassula*, the jade plant; and *Haworthia*, which have rosettes with pearly dotted leaves. Durable pot plants include the strap-leaf snake plants, or *Sansevieria;* they are remarkable for tolerating much neglect and growing in locations in which few other plants can succeed.

Dracaena, the dragon trees, includes such good houseplant subjects as *D. marginata*, from Madagascar, which forms clusters of twisted stems topped by rosettes of narrow, leathery leaves. Other good examples are *D. deremensis* "Warneckei," with its handsome, symmetrical rosette of sword-shaped, milky-green leaves striped white; and *D. sanderiana*, the ribbon plant, a diminutive and slender, highly variegated species that can be grown in water. Similar in appearance is *Pandanus veitchii*, which has a rosette of leathery, sword-shaped leaves—glossy green and banded white—arranged in spirals.

Sub-tropical evergreens

Several subtropical evergreens can be grown in cooler locations indoors. Pre-eminent among them is the Norfolk Island pine (*Araucaria heterophylla*, or *A. excelsa*) —not a true pine—an undemanding graceful conifer with tiered branches of fresh green needles; it is long-lived even in dim corners, in any temperature above freezing. *Podocarpus*, the somber Buddhist pine, forms dense pyramids of dark-green needlelike leaves; it also prefers cooler locations.

Among the many broad-leaved woody evergreens used as houseplants are *Brassaia actinophylla*, the Queensland umbrella tree, better known as schefflera. Its spreading crowns of palmately divided, glossy green leaves, do best in a light and warm location. Another picturesque plant is *Polyscias fruticosa*, the Ming aralia, with willowy, twisting stems densely clothed toward their tops with fernlike, lacy foliage.

The so-called rubber trees of the genus *Ficus* are widely used in homes and offices. All require good light to hold their foliage well. Best known are the large-leafed *F. elastica* "Decora," but perhaps even more attractive, because of their very graceful habit, are several small-leaved kinds, such as *F. benjamina, F. retusa*, and *F. nitida.* The giant violin-like, leathery leaves of *F. lyrata*, better known as *F. pandurata*, make the plant an attractive indoor "tree." *Coccoloba*, the sea grape, is another sturdy, woody plant, somewhat resembling *Ficus*, with leathery, rounded leaves and crimson veining.

Because of their majestic beauty and distinctive decorative appeal many palms are grown indoors. Best known of the feather palms is the paradise palm (*Howeia*, or *Kentia*), a noble plant that combines natural grace with sturdiness; its thick, leathery leaves can stand much abuse. The parlour palms and bamboo palms of the genus *Chamaedorea* have dainty fronds on slender stalks; they keep well even in fairly dark places. Similar in appearance is the areca palm (*Chrysalidocarpus*) with slender yellowish stems carrying feathery fronds in dense clusters. The pygmy date (*Phoenix roebelenii*), a compact palm with gracefully arching, dark-green leaves, is an excellent houseplant if kept warm and moist.

Ferns

Ferns, which come in a wide variety of forms, provide many popular houseplants. Among the best smaller parlour ferns is the sword fern, *Nephrolepis*, with bushy rosettes of leafy fronds; the holly fern (*Cyrtomium*), which has glossy dark leathery leaves; and the leather fern (*Rumohra*), with its leathery but lacy fronds. The bird's-nest fern (*Asplenium nidus*) forms a rosette of parchment-textured, fanlike, light-green fronds. Long-lasting *Polypodium*, often known as hare's-foot ferns because of their pawlike, woolly rhizomes (rootlike structures), have feathery leaves on slender stalks. Among the attractive humid-loving ferns are the several species of dainty maidenhairs (*Adiantum*). The so-called table ferns are a varied group of manily *Pteris* and *Pellaea* species; some are frilly, others variegated; and in their younger stages they are ideal subjects for terraria, enclosed containers. *Platycerium*, or staghorn ferns, always have aroused great curiosity because of their unusual shapes. Growing as epiphytes on trees, their sterile fronds cling snugly to the bark or, in cultivation, to a wire basket or wooden block; their much divided fertile fronds resemble the antlers of deer. One of the best of the palmlike tree ferns is the Hawaiian *Cibotium*, with a stout, fibrous trunk that bears a crown of light-green fronds.

Popular fernlike plants include *Asparagus* species that have plumy fronds. Species of *Selaginella*, called sweat plants or moss ferns, are strictly warm terrarium subjects; their delicate fronds greedily soak up moisture from the atmosphere to keep from shrivelling.

Vines and trailers. Vines and trailers, weeping plants with stems too weak to support themselves, occur in most plant families. Best known are many varieties of ivy (*Hedera*). Generally, they prefer a cool location, but some small-leaved or variegated varieties do well on the windowsill. Several *Cissus* species, such as *C. rhombifolia*, the grape ivy, with metallic foliage, and the leathery *C. antarctica*, or kangaroo vine, are excellent subjects for planter boxes or room dividers. Intriguing is the slow-growing *Hoya*, or wax plant, with leathery foliage and waxy, wheelshaped blooms. By contrast, the inch plants and wandering Jew, species of *Tradescantia* and *Zebrina*, are rapid growers with watery stems and varicoloured leaves; these long-beloved houseplants are used widely in window shelves or hanging baskets. The spider plants (*Chlorophytum*, or *Anthericum*) are houseplant favourites, forming clusters of fresh green ribbonlike leaves banded white; young plantlets develop from the tip of arching stalks.

Flowering plants. Most of the flowering potted plants seen at holiday times are not easy subjects for long-term indoor cultivation. They require high light intensity, careful watering, and day–night differences in temperature that are not usually available in the home; greenhouses would offer better chances for successful cultivation. There are exceptions, however; one of the most successfully adapted houseplants is the African violet (*Saintpaulia*), with hundreds of named varieties, with blossoms from violet blue through rose to white and single- and double-flowered forms. Window bloomers, such as *Abutilon*, the parlour maples, have bell-like flowers resembling Chinese lanterns. *Impatiens*, or busy-Lizzie, are succulent herbs producing a succession of spurred flowers in gay colours. *Hibiscus*, the rose mallows, have short-lived giant blossoms in brilliant colours. Geraniums (botanically *Pelargonium*) have long been popular flowering plants in the sunny window; the foliage is often variegated or scented, and flower clusters may be in reds, pinks, and white.

A number of bulbous plants do well in lighted windows: *Hippeastrum*, better known as amaryllis; *Clivia*, the Kafir lily; *Haemanthus*, the bloodflower; *Neomarica*, the apostle plant; and *Veltheimia*, the forest lily.

Orchids present a more difficult and specialized subject for successful home cultivation, usually because of their requirements for light, controlled temperature, and sufficient humidity and ventilation. There are some kinds, however, that promise good results with ordinary care: epiphytic *Epidendrum* species, with waxy, usually fragrant, often greenish blossoms, and *Oncidium* species, or butterfly orchids, with brightly coloured, long-lasting yellow flowers marked with brown and often produced in large sprays.

Small fruit plants

Small flowering plants that produce edible fruit can be grown on a windowsill. With sufficient light and ventilation, success may be had with the Calamondin orange (*Citrus mitis*), the dwarf Chinese lemon (*C. limon* "Meyeri"), and the American-wonder lemon (*C. limon* "Ponderosa"). If space permits, the fig tree (*Ficus carica*) can be grown to yield edible fruit as can the Chinese dwarf banana (*Musa nana*) and the dwarf pomegranate (*Punica granatum nana*), the pineapple (*Ananas comosus*), and the coffee tree (*Coffea arabica*).

The needs of houseplants. This article is intended only to present basic information about houseplants; each type of plant will respond particularly well when given the special care that it needs.

The growing of houseplants can be simplified greatly by providing as close an approximation as possible to the original habitats of the various kinds. Plants that originate in the humid jungles of Malaysia or the rain forests of the Amazon, for example, generally require moist, shady conditions; others found in the semi-arid regions of Mexico or southern Africa generally respond well to dry, sunny conditions.

Light. Some of the shade-loving foliage plants (aspidistras, India-rubber plants, ivies, ferns, and some philodendrons) can subsist for months and even thrive in such darkened locations as wall pockets, niches, mantels, or alcoves. Even in these cases some bright light—not necessarily direct sunlight—during a part of the day is beneficial. Artificial light is often sufficient for some of these plants. Flowering plants, however, need much more light if they are to flower. Blooming of some kinds of plants is regulated by the duration of exposure to light, natural or artificial (see PHOTOPERIODISM).

Most houseplants do best when grown near a window. Southerly or westerly exposures are preferred for sun-loving plants, including flowering sorts (except African violets and begonias, which do better in easterly exposures) and cacti and succulents; northerly or easterly exposures are best for shade-loving plants. Many bulb plants (hyacinths, narcissuses, tulips) can be started in dim or even totally dark places, then moved into the light.

Temperature and humidity. The proper levels of these two factors, so essential to success with houseplants, are the most difficult to obtain in modern houses, especially during the winter months when most rooms are too hot and dry for the majority of houseplants. When moisture in the air is constant, a rise in temperature is accompanied by a drop in relative humidity. Temperatures as low as possible, consistent with comfort, will benefit most house plants: 60°–70° F (15°–21° C) is a good average during the day, with a drop of 5°–10° F (3°–6° C) at night. African violets, poinsettias, and most foliage plants fare best in the high part of the range; cinerarias and cyclamens respond best in the lower part. Most succulents, including cacti, prefer warm days and cool nights.

Soil. Bowls and dishes of all descriptions serve as containers for growing houseplants. Unglazed pottery with drainage holes are generally preferred to glazed containers without drainage holes because the former afford better aeration of the soil.

When, after a time, the soil mixture becomes depleted or encrusted with an accumulation of salts, or the plant becomes pot-bound (*i.e.*, the roots require more space to grow), repotting is beneficial. Decorative boxes filled with sand, gravel, or moss ensure less drying of the containers; the boxes may be filled with a soil mixture, and, allowing for necessary drainage, the plants can be grown directly in them.

Desert plants usually thrive in a gritty soil composed of clay with sand or other coarse material, whereas acid-loving plants benefit from a greater amount of leafmold and peat moss. Most houseplants generally grow well in a standard mixture composed of good garden loam, peat moss, and regular (coarse) builder's sand in equal amounts. Hydroponics, or soilless culture, in which water and minerals (and often a soil substitute such as sand) provide the support and nourishment for plants, is sometimes practiced in rooting cuttings taken from established plants; it is a common commercial method of growing many plants including vegetables.

Soilless culture

Water. Plants grown indoors in soil require regular watering, the amount depending largely upon the type of plant, the kind and size of the container, the soil mixture, and the surrounding atmosphere. The technique of watering is undoubtedly the most difficult part of indoor gardening. The soil in pots of desert plants, such as the cacti, is allowed to dry out before the next watering; that in pots of jungle plants is always kept moist but not soggy. In hot dry rooms, frequent watering and application of mist is beneficial to plants derived from moist tropical areas.

Watering by total immersion of pots is advocated when the number of plants is small. The plants can be observed for a few weeks to determine how quickly they dry out, and watering can be regulated accordingly.

Watering by immersion is not always practicable, however. A meagre supply of water applied to the surface does not penetrate deeply to the roots; watering, when done, should be thorough. Water-filled saucers placed under the pots are also beneficial but slower acting; water kept in the saucers all the time, however, may waterlog the soil and cause root rot. The microscopic root hairs, active in absorption of water and minerals, should not wither and dry; in addition, a dry ball of earth is a good

environment for mealybugs and root lice (see below *Ailments*).

Nutrients. Houseplants supplied with the necessary minerals produce the food and energy needed for healthy growth. These minerals, initially supplied in the original potting soil, are gradually depleted. Although many organic fertilizers, such as well-rotted animal manures, bone meal, and cottonseed meal, are good sources of nutriment, they are not as convenient as many commercial preparations for use indoors.

Foliar feeding, spraying nutrients on the leaves, has been practiced by florists for many years; this is one reason for the luxuriant foliage plants on display in their shops. This type of feeding, which is relatively inexpensive, can be likened to the mild feeding that tropical plants receive in their native habitats through daily rain showers. This is particularly true of all epiphytes (*e.g.*, bromeliads, certain orchids and ferns, gesneriads, and others that cling to trunks and branches of trees). Rain brings to these plants food-laden dust of the atmosphere, and the plants absorb the nutrients through their leaves. Foliar feeding is not meant to entirely replace root feeding but rather to supplement it, being applied occasionally to bolster the plants or to revive them from a dormant period.

Ailments. Houseplants are not usually troubled with fungous or bacterial diseases, probably because of the warm, dry conditions that commonly prevail in heated rooms, but they are prone to attacks by insects and mites.

Pests. Few houseplants are immune to attack by mealybugs, soft-bodied insects with a protective, cottony, white covering. Mealybugs have microscopic needlelike mouthparts that enable them to pierce plant tissues and extract sap. If the infestation is heavy, the affected plant part turns yellow and drops off. Colonies of mealybugs can be eradicated by touching them with a small brush or a cotton swab dipped in grain or rubbing alcohol. If a plant is heavy-textured like a cactus, India-rubber plant, or philodendron, a dousing of water under pressure often eliminates the bugs. Insecticides marketed in aerosol spray cans provide convenient and effective control.

Mealybug infestation

Besides the mealybugs, scale insects of both the soft and armoured variety may cause problems generally much harder to eradicate. Scale insects are characterized by a shield or scale above the body, and they become tightly attached to the plant from which they suck sap. A light-oil-emulsion insecticide is effective, especially when applied while the young insects are still present.

Plant lice, or aphids, usually appear on tender growth. About the size of a pinhead, soft-bodied, and yellow, black, or green in colour, they suck plant juices, causing stunted growth and curling of leaves. They prevent normal opening of the flowers but are easily controlled by nicotine sulfate sprays.

Thrips, small, slender blackish insects that hop when disturbed, injure plants by causing blotching and streaking of leaves; they feed by rasping the plant tissues to suck up the sap and can usually be detected by the small black dots of excrement they leave behind. For their control, a nicotine sulfate solution prepared with soap is effective, as are some of the newer commercial products.

Root lice, common in dry soil, gather about the roots, from which they suck the plant juices, causing wilting and loss of leaves. They can be eliminated by washing the roots under running water and then replanting in fresh soil. Organic pesticides are also effective; they are applied either directly to the soil and watered in immediately or dissolved in water used to water the plants. This treatment also eliminates worms, ants, and other pests that may be living in the soil.

Red spider, a mite, is another troublesome pest. Ornamental plants suffer from them greatly, especially if they are kept in a warm, dry atmosphere. These tiny mites spin fine strands of silk, particularly on the underside of the leaves, where they are not easily detected until the infestation is severe. Their damage causes a speckled condition on leaves, which eventually drop off. A daily syringing with water helps to eliminate these pests; chemical substances called miticides also aid in their control.

Lack of vigour. Plants are often disfigured by a drying or browning of portions of the leaves. This may result from a food deficiency; from the presence of artificial gas or coal gas; from sudden exposure to brilliant sunlight or cold drafts; from improper application of fertilizer or insecticide; or from high room temperatures, very low humidity, and either an excess or deficiency of water.

All houseplants require sunlight in some degree, otherwise they cannot manufacture food to grow. When a plant shows no signs of growing or the growth becomes spindly from too subdued light conditions, gradual exposure to more light may revive it. Artificial lighting of the proper quality and intensity can be substituted for natural light.

It is common for all plants to enter a period of rest or dormancy, the season and length of which vary with the species. Many foliage plants, notably ferns and palms, produce fewer new leaves during winter; cacti and succulents are often quiescent in early autumn; and some flowering plants after blooming appear on the verge of death. During such dormant periods, houseplants require much less water, warmth, and attention.

BIBLIOGRAPHY. General popular books dealing with houseplants include A.B. GRAF, *Exotic Plant Manual*, 2nd ed. (1972), with 4,200 photographs; ARNO and IREN NEHRLING, *An Easy Guide to House Plants* (1958); MONTAGUE FREE, *All About House Plants* (1946); and EIGIL KIAER, *The Complete Guide to Indoor Plants* (1958). Three more complete referential sourcebooks are A.B. GRAF, *Exotica 3* (1970), a monumental pictorial encyclopaedia (12,000 photographs), with a key to plant care in five languages and an extensive bibliography; ROYAL HORTICULTURAL SOCIETY, *Dictionary of Gardening*, 4 vol. (1951; suppl. 1956, 2nd ed. 1969), an extensive work on all aspects of gardening, with much information on houseplants; and F. ENCKE (ed.), *Pareys Blumengaertnerei*, 2nd ed., 2 vol. (1958–61), one of the best works on cultivated plants, in German, well illustrated and thorough.

(A.B.Gr.)

Hsia Kuei

One of China's greatest masters of landscape painting, Hsia Kuei (Xia Gui in Pin-yin romanization) was influential in developing during the period of the late Sung dynasty (1126–1279) a style of painting characterized by lyric expressiveness, subtle mood, and a quality of nature mysticism. Neatly placed headlands, evenly fading mists, soaring peaks, broad spaces, and tiny people presented a landscape picture that was definite as well as poetic and suggestive—an effect achieved by combining quick powerful brushstrokes with telling areas of ink wash.

Hsia Kuei's birth and death dates are unknown. According to most Chinese sources, he served in the Imperial Academy (Yü hua-yüan) under the emperor Ning Tsung (reigned 1195–1224), eventually attaining the rank of *tai-chao*, or "painter in attendance," and being awarded the highest honour a court painter could receive, the Golden Belt. The earliest source of information on him, however, a collection of painters' biographies compiled in 1298 by Chuang Su and titled *Hua-chi pu-i*, states that he was active in the academy under the reign of the emperor Li Tsung (reigned 1225–64). Perhaps his service in the Academy overlapped these two reigns and can provisionally be dated around 1200–40.

He was born in or near the city of Hangchow in Chekiang Province, then the capital of China, to which the Imperial Court had been moved in the early 12th century when the north of China was invaded by the Chin (Jurchen) Tatars. Because of this move, the latter half of the Sung dynasty is known as the Southern Sung period (1126–1279). During this period, the centre of painting, and the concentration of major artists, was in the Imperial Painting Academy. Accordingly, the leading masters of the 12th and first half of the 13th centuries, with a few exceptions, were the court painters of Hangchow. Most famous among them are Hsia Kuei and his contemporary Ma Yüan, whose school of painting came to be known as the Ma-Hsia school.

Influence of Li T'ang

No information exists on Hsia Kuei's early artistic training or the identity of his teacher, but most sources agree that he followed the stylistic tradition of an earlier landscapist in the academy, Li T'ang. Li T'ang's career extended from the late 11th century until sometime after 1138, when the court resettled in Hangchow; he had followed it there on its southward exodus and rejoined the academy when peace allowed its resumption of activity, living long enough after that to set the new direction that its painting took in the Southern Sung period. Li T'ang transformed the monumental, imposing landscape type of the 11th century into a new image of nature, seen closer up, less awesome, allowing easier response by the viewer. Where early Sung landscape paintings had been carefully constructed microcosms, complex in design and full of detail, with small figures, buildings, and so forth, scattered throughout the scene, Li T'ang tended to simplify his compositions and limit his materials, achieving thereby a more sharply focussed and immediate effect. He thus, with his followers, created the new mode of landscape sometimes called the lyric style. His ideas were developed and exploited by academy landscapists later in the 12th century, practically all of whom were to some degree his followers.

Hsia Kuei was no exception. The painting that is stylistically earliest among his signed, reliable works—a fan-shaped album leaf in the National Palace Museum, Taipei, representing two men in a house in a valley gazing out at a waterfall—follows fairly closely the models of earlier 12th-century academy masters who imitated Li T'ang but brings the scene even closer than they had, further limiting the range of view and focussing interest on the two figures. The drawing is more conventional than in Hsia Kuei's later works, although a few features of style that anticipate these are to be seen.

Album leaves

The favourite form of the Southern Sung academy painters was the album leaf, which sometimes took the round or oblate shape that indicates it was originally mounted on a flat fan but more often was square, or nearly square, in shape. Most of Hsia Kuei's surviving works are album leaves. Two preserved in Japan—a signed landscape in the famous collective album called *Hikkoen* ("Garden Plowed by the Brush") and another, unsigned, in the Tokyo National Museum—along with a signed, fan-shaped leaf in the Boston Museum of Fine Arts representing a sailing boat on a river during a storm, with houses and windswept trees on the shore—are widely accepted as genuine productions of his hand. All are painted on silk, the two in Japan in ink monochrome, the Boston leaf with a few touches of light colour. All follow the same simple but effective scheme: the composition is diagonally divided, upper left to lower right, with the landmass in the lower segment and the upper occupied only by distant hills (in the Hikkoen picture, even these are missing). In each, a central group of leafy trees projects into the empty area, and a house is seen below, partly hidden. In both the leaves in Japan, a figure of a farmer returning homeward enters across a bridge in one lower corner; in the Boston leaf, a sailing boat at left serves the same function as a secondary focal point. All are exquisitely calculated, perfectly balanced, conveying with great precision a scene glimpsed through haze, sharply focussed at a few points but obscured at others. In all, the void plays as positive a role as the solid masses.

Hand scrolls

Hsia Kuei was also a master at composing the hand scroll, or horizontal scroll, which one viewed by unrolling from one end to the other, rerolling the portion already viewed as one moved. The effect was that of gazing at a continuous panorama, as in an imaginary journey through the scenery of nature. The finest example of that form is his great "Pure and Remote View of Streams and Mountains" in the National Palace Museum, Taipei. Originally signed, it is now missing a final section that bore the signature. A colophon by a later writer, dated 1378, ascribes it to Hsia Kuei. The remaining portion is about 27 feet long. Executed on paper, in rich ink tones ranging from the deepest blacks to subtle, seemingly evanescent, washes of pale gray, it is probably the most brilliant performance in the ink-monochrome technique in the whole of Chinese painting. Strong tonal contrasts are used to give powerful bulk to the rocks by distinguishing their sunlit and shadowed faces. Broad, broken strokes of ink render their rough-textured surfaces. This technique is derived from Li T'ang's "small ax-cut" texture strokes, so-called because they suggest a surface hewn with an ax; the broader form, seen in works by Ma Yüan and Hsia Kuei, are called large ax-cut strokes.

These and other features of the drawing agree closely with descriptions of Hsia Kuei's style by Chinese writers. They speak of his use of a "split brush" (*i.e.*, the brush tip divided so as to make two or more strokes at once) in painting tree foliage, and of his freehand drawing of architecture, bridges, and so forth, "without employing a ruler." They say that he liked to use a brush with a worn tip, the purpose of this presumably being to avoid the over-refined, "slick" drawing of other Southern Sung academy artists. They speak also of his working with great facility and spontaneity, so that the painting was "finished suddenly, in a strange and mysterious way."

By courtesy of the National Palace Museum, Taipei, Taiwan, Republic of China

Detail, length 68.58 cm, "Pure and Remote View of Streams and Mountains," hand scroll in ink and paper by Hsia Kuei, early 13th century (Southern Sung). In the National Palace Museum, Taipei, Taiwan.

The composition of the "Pure and Remote View" offers dramatic juxtapositions of near and far, solid and void. Distant parts of the picture are painted in dimmer ink, a basic device for achieving a sense of space in Chinese landscape that is known as atmospheric perspective. The whole impression is of a spacious, mist-hung, peaceful terrain, seen toward twilight. The standard characterization of Ma-Hsia landscape as "romantic" seems well justified in this, the supreme surviving work of the school.

Several others of Hsia Kuei's hand scroll compositions survive in original or copy. The "Twelve Views from a Thatched Hut" exists in several versions, of which the best by far, preserving, however, only four of the views, is in the William Rockhill Nelson Gallery of Art in Kansas City. Another fine composition is preserved in a copy in the Shanghai Museum, which originally bore an inscription and the date 1204. A famous and often-recorded work of Hsia Kuei, his "Ten Thousand Miles of the Yangtze River," now survives only in a copy that is probably of the 16th century, in the National Palace Museum, Taipei.

Hanging scrolls

Hanging scroll compositions based on Hsia Kuei's paintings are less common. The "Landscape: A Fisherman's Abode After the Rain" in the Boston Museum of Fine Arts is ascribed to him and is in his style. A painting of "A Misty Gorge" in the Freer Gallery of Art is in his style and of his period. It reportedly once bore his signature, which was lost in remounting. Several paintings in Japanese collections may be copies of his works; the most famous and often-reproduced is the "Rain Storm" formerly in the Kawasaki Collection, once regarded as a major work of the master but now recognized to be a copy.

For a time after his death, Hsia Kuei may have suffered the same low esteem as other Southern Sung academy painters in the eyes of proponents of the new literati, or scholar-amateur, school of painting, for whom professionalism was equated with empty technique and academicism. Chuang Su wrote in 1298 (*Hua-chi pu-i*):

> He painted landscapes and figures, all very vulgar and debased. In the late Sung period, when the way the world had fallen into decline, and people's minds were restless and upset, Hsia Kuei won a name for himself by pursuing excess. But of real substance there is none.

Hsia Wen-yen, in *T'u-hui pao-chien* (1365), wrote of him in more positive terms:

> His works have an exciting (stimulating) quality. His ink tones give the effect of colours; his brushwork is mature and controlled; the ink washes are applied rich and wet, a remarkable achievement. His snow scenes are completely based on those of [the 11th-century landscapist] Fan K'uan. Of all the Academy masters of landscape after Li T'ang, none was his equal.

Tung Ch'i-ch'ang (1555–1636), great artist-critic of the late Ming period, who was generally scornful of the entire professional-academy tradition, exempted Hsia Kuei somewhat from his sweeping condemnation.

> Hsia Kuei followed Li T'ang but added the element of *simplicity* to his style. What he did was like what clay-workers call "reduced modeling." In his conceptions and intent, he is quite devoid of the "shortcuts" of imitativeness. With some forms hidden, some sunk [into mist], he has the "ink-plays" of the two Mi's at his brush-tip.

The last sentence, obscure as it may sound, is especially significant. "Ink-plays" was a term used by the scholar-amateur artists for their unassuming, noncommercial pictures. Two of them who were particularly fond of so designating their paintings were Mi Fei, also known as Mi Fu (1051–1107), and his son Mi Yu-jen (1086–1165), both highly respected by Tung Ch'i-ch'ang and other literati critics for their spontaneity and inspired, intuitive mode of painting. To relate Hsia Kuei to them was to credit him with the same qualities, in which academy artists were generally held to be deficient. While it is difficult to see much clear resemblance between paintings by or after the two Mi's and those of Hsia Kuei, Tung Ch'i-ch'ang's observation is not an empty one: in his use of subtle ink washes to render atmosphere, in his hiding of transitions in mist and reduction of fine-drawn detail, Hsia Kuei does appear to have learned something from Mi Yu-jen. Such affinities set him apart from his co-workers in the academy, including Ma Yüan, whose sleeker and more elegant style, used for carefully constructed, often mannered compositions, seems quite incompatible with the literati painters' ideals.

Ma Yüan's style proved relatively easy to imitate, and hundreds of later painters did so. The style of Hsia Kuei, on the other hand, produced its brilliant effects only in the hands of a master; direct attempts at imitation by lesser painters of later times are on the whole pallid and uninteresting. Nevertheless, his influence was considerable. One painter in the Yüan period (1279–1368), Sun Chün-tse, did creditable pictures in a mixed Ma-Hsia manner, and some artists of the Che school under the Ming dynasty, in the 15th and 16th centuries, played entertaining variations on the style, while robbing it of most of its depth, both pictorial and expressive. Through these Ming epigones and their flatter, more decorative landscapes, the Ma-Hsia school was transplanted in Japan, where it served as the basis for most of the ink-monochrome landscapes of the Muromachi period (1338–1573). Two of the major works of the Japanese painter Sesshū (1420–1506), both hand scrolls, appear to be modelled on paintings by Hsia Kuei. As late as the early 17th century in China, a few painters were still producing landscapes avowedly "in the manner of Hsia Kuei." But the direction that painting took in the Ch'ing dynasty (1644–1911) did not allow such tonal subtleties or such concern with space and distance, and Hsia Kuei's style was scarcely reflected in paintings of that period, nor was the artist himself mentioned in its literature. It is only in modern times that he has come to be recognized as one of the leading masters of Chinese landscape painting and one of the great interpreters of nature in world art.

Influence on Japanese painting

MAJOR WORKS

Some examples of Hsia Kuei's style and work (dating from the 13th century or considered to be faithful copies); "Pure and Remote View of Streams and Mountains" (National Palace Museum, Taipei, Taiwan; other versions and variations of this work may be found in the Asano Collection, Odawara, Japan; the Metropolitan Museum of Art, New York; and in the Freer Gallery of Art, Washington, D.C.; "Rain Storm" (formerly Kawasaki Collection, Kōbe, Japan); "Twelve Views from a Thatched Hut" (William Rockhill Nelson Gallery of Art, Kansas City, Mo.; a copy is held in the Moore Collection of Yale University Art Gallery, New Haven, Conn.); "Hikko-en," album, 2 leaves attributed to Hsia Kuei (Nakamura Collection, Tokyo); "Ten Thousand Miles of the Yangtze River," attributed to Hsia Kuei (National Palace Museum, Taipei, Taiwan); "Landscape with Two Men Gazing at a Waterfall," fan-shaped painting (National Palace Museum, Taipei, Taiwan); "River Landscape with a Windswept Tree" (Museum of Fine Arts, Boston); "River View with a Boat at Anchor" (Tokyo National Museum; a copy in the Iwasaki Collection, Tokyo).

BIBLIOGRAPHY. One of the best English language sources of information on Hsia Kuei is the article on him by S.E. LEE in the *Encyclopaedia of World Art*, vol. 7, col. 650–654 (1963). See also OSVALD SIREN, *Chinese Painting: Leading Masters and Principles*, vol. 2, pp. 119–124 (1956); LAURENCE SICKMAN and ALEXANDER SOPER, *The Art and Architecture of China*, pp. 129–137 (1956); JAMES CAHILL, *Chinese Painting*, pp. 79–87 (1960), and *Chinese Painting, XI-XIV Centuries*, pp. 14–15, 34–35 (1960).

Hsi Chiang (River)

The Hsi Chiang (Xi Jiang in Pin-yin romanization), the major river of southern China, flows generally eastward for 1,216 miles (1,957 kilometres) from the Yunnan highlands to the South China Sea and drains, along with the Pei Chiang (*chiang*, "river") and the Tung Chiang, a basin 173,000 square miles (448,000 square kilometres) in extent. It is shorter than the other important Chinese rivers—the Yangtze, the Huang Ho (Yellow River), and the Sungari, but it delivers an enormous quantity of water, and its rate of flow is second only to that of the Yangtze.

Ports such as Canton, Hong Kong, and Macau are located in the delta region, one of the heavily populated

areas of China. The delta's fertile soil is intensively cultivated, and as many as three rice crops a year can be produced. The river's name, applied only to its lower course, means West River (*i.e.*, flowing from the west). The Hsi Chiang is also an important commercial waterway, navigable as far inland as Wuchow—170 miles upstream from Canton—and beyond (see CANTON; HONG KONG; MACAU).

The river basin. The Hsi Chiang itself drains an area of about 127,000 square miles of southern China and North Vietnam. It shares a delta with the Pei Chiang and the Tung Chiang. Over half of the basin is mountainous and lies between 9,900 and 1,650 feet above sea level; more than 40 percent of the rest of the basin is occupied by hills between 330 and 1,650 feet high. The lowlands of the delta account for less than 5 percent of the total drainage area. Most of the mountains and hills are composed of limestone, and the river has cut a cavernous valley through them. The riverbed is broken by rapids and gorges, and its walls are often high and steep; the landscape is of the type known as karst, in which the limestone rocks are honeycombed with tunnels and openings, so that much of the drainage runs underground, and deep sinks or swallow holes abound.

The Nan-p'an Chiang

The river course. The main headstream is generally considered to be the Nan-p'an Chiang (South Pan River), rising in the Yunnan–Kweichow plateau region at an altitude of about 6,900 feet but dropping a total of 5,900 feet in the first 530 miles of its course, which flows in a southeasterly direction through Yunnan Province. It then forms part of the border between Kweichow Province and the Kwangsi Chuang Autonomous Region for a distance of about 535 miles. Southeast of the town of Ts'e-heng, the river receives the Pei-p'an Chiang (North Pan River) and is then known as the Hung-shui Ho, or Red River. This section of the river flows for about 400 miles through a narrow valley with high, mountainous banks dropping down about 850 feet. Its bed—between 165 and 1,000 feet wide—is broken by rocky rapids that are less than three feet deep and difficult to navigate. For the first 75 miles of its course the Hung-shui continues to form part of the Kweichow–Kwangsi border, flowing in an easterly direction until just before it reaches the town of Chiu-t'ien-o, where it makes a great bend to the south and flows through Kwangsi. At Kungchuan it turns northward and then resumes its easterly direction.

At Shih-lung the river receives the Liu Chiang, its most important left-bank tributary, and is then called the Ch'ien Chiang. This shortest section of the river is no more than 75 miles in length, the river dropping about 50 feet in this distance. The channel grows dramatically, occasionally achieving depths of 280 feet. For almost half its length, the Ch'ien Chiang flows through the narrow, rock-strewn Tat'eng Gorge between the cities of Wu-hsüan and Kuei-p'ing, at the end of which it receives its most important right-bank tributary, the Yü Chiang, and is then known as the Hsün Chiang. This section flows for about 120 miles in an easterly direction, dropping a further 55 feet and receiving the Jung Chiang on the right bank at T'eng-hsien, and the Kuei Chiang on the left bank at Wuchow (Ts'ang-wu) on the Kwangtung Province border. The widest point of the Hsün Chiang is 1,120 feet, at Lungtangsha (gorge), while its maximum depth reaches almost 200 feet.

Below Wuchow, where it enters Kwangtung Province, the river is known as the Hsi Chiang. Its valley consists of a series of winding gorges and wide hollows. The Sanjung and Lingyang gorges narrow to widths of 230 to 260 feet and are about 250 feet deep. Throughout its 130-mile length the Hsi Chiang drops only about 30 feet, flowing to the east until it joins with the Pei Chiang at San-shui. It then turns south through the vast Chu Chiang, or Canton, Delta before emptying into the South China Sea west of Macau.

Rivers that form the delta

The delta. The delta is formed by three main rivers —the Hsi Chiang, the Pei Chiang (North River), and the Tung Chiang (East River). At San-shui, the Hsi Chiang and Pei Chiang are joined by a short channel and then divide. The larger branch, the Hsi Chiang, bends to the south and forms the western border of the delta, while a lesser branch, the Fo-shan Chih-liu, flows eastward into the delta itself. The Tung Chiang flows from the east and enters the delta's main channel, the Chu Chiang (Pearl River), which begins just above Canton. Canton lies west of the point where the Tung Chiang flows into the main channel; Hong Kong stands to the east and Macau to the west of the entrance to the Chu Chiang estuary, which is about 18 miles wide.

Covering an area of about 1,500 square miles in southeastern Kwangtung Province, the delta is a complex network of river branches and channels, divided by islands of alluvial soil and by hills that were once coastal islands. The fertile islands are only slightly above sea level and are protected from the sea by a system of flood dikes.

Climate. Because of its great size and its varied terrain, the Hsi Chiang Basin experiences a wide climatic range. In general, temperatures and rainfall increase from west to east. In the west at K'un-ming, in Yunnan Province, the annual temperature averages 62° F (17° C); the annual precipitation of 41 inches falls mainly during the months of July and August. At Canton, in the east, the annual average temperature is 73° F (23° C), and the rainfall is 64 inches, most of it falling in May and June. Far to the north of the basin, at Kuei-lin, in Kwangsi Chuang Autonomous Region, the yearly average temperature is 62° F (17° C), and rainfall averages 74 inches a year, falling mostly in May and June.

Vegetation. Forests cover much of the mountainous region of the basin, especially in the north and west, the stretch along the border of Kweichow Province being the most heavily forested. The more important trees are the pine, the fir, the camphor, the tung, and bamboo. In the eastern part of the basin, in the low places of the maritime zone and in the valleys, the vegetation is mostly cultivated, and includes rice, peanuts (groundnuts), sugarcane, hemp, tobacco, and fruit.

Animal life. The river contains an abundance of freshwater fish. The waters of the Chu Chiang Delta are well utilized as fishponds. Monkeys, bears, and tapir frequent the mountainous regions to the west.

Human ecology. Throughout the mountainous part of its course, the river has but little relationship to the peoples who live in its vicinity. Most settlement occurs in small valleys or in plains between mountains, known as *patse*. The villages are isolated, compact agricultural units. River towns become more frequent in the hilly part of the Kwangsi region, where the river is an artery of commerce; towns include Kungchuan, Ch'ien-chiang, Lai-pin, Kuei-p'ing, T'eng-hsien, and Wuchow.

The Chu Chiang Delta is one of the most densely populated regions of China. It supports about 10,000,000 people and contains the cities of Canton, Fo-shan, Hsin-hui, and Chiang-men. The entire region is intensively cultivated. Rice is the most important crop, but in the cooler, drier climate of the west wheat, corn, sorghum, beans, and potatoes are also grown. An intricate irrigation system includes over 1,200 miles of flood dikes. The waters are also used as fishponds. The delta's many channels are vital to Canton's international commerce, as well as to trade with the interior.

Agricultural products

Hydrology. The river basin is nourished mainly by rainfall, and its water levels and volume vary according to the relative abundance of precipitation. The rate of flow more than doubles in the summer season. Most of the large flow results from the summer monsoon rains, when torrential floods may occur and frequently do cause catastrophic damage. The water is at its lowest during the winter dry period.

Fluctuations in the water level during the year may vary by as much as 80 feet at Wuchow; in the lower course and the delta variations in the level are less. Especially dangerous are the delta floods that are caused by the combined flooding of the Hsi Chiang, the Pei Chiang, and high tides. In the river basin, there were 29 floods in the 17th century, 26 in the 18th, 36 in the 19th, and 24 in the first half of the 20th century.

Navigation. The river is important for its use as a transportation artery. The basin contains over 9,000

miles of water routes, of which more than 6,800 miles are in use. Steamships can sail along more than one-third of the total length of the waterways, while Chinese junks and small craft ply all the navigable waters. Navigation is hampered by low water on many tributaries and by rapids on some sections of the river. In several places, as on the Yü Chiang, river craft are pulled over the rapids with hand-worked windlasses. During low-water periods, transportation ceases on some rivers, including the Tung Chiang and the Pei Chiang.

The water routes do not form an integrated system. Canton, the largest city in the basin, does not have direct access to either the Hsi Chiang or the Pei Chiang. The channels that connect the city to the water routes of the basin are winding and mud filled and are navigable only by shallow-draft boats. Because most of the river branches of the delta are shallow, oceangoing vessels cannot reach Canton, but must dock at Huang-pu-chiang (Whampoa), ten miles downstream.

Hydroelectric potential

Prospects for the future. The river basin has a large hydroelectric potential. Of the estimated potential supply of 28,500,000 kilowatts, about 25,000,000 can be generated by the Hsi Chiang itself. By the early 1970s, however, this resource was little developed. A series of major hydroelectric projects are planned at Sanjung, Tat'eng, Feilan, and Lungtang gorges, which will not only supply electricity but will also regulate the river's flow and provide protection from ruinous floods.

(A.A.So.)

Hsüan-tsang

In the 7th century AD Hsüan-tsang (Pin-yin romanization Xüan-zang), one of the most famous Buddhist monks in Chinese history, made a perilous journey from China to India and back, bringing home with him not only the sacred books of Buddhism but also invaluable geographical knowledge concerning the countries through which he passed on his journey. He is honoured by Buddhists in East Asia for his courage in undertaking the journey, for the volume and diversity of his translations of Buddhist texts into Chinese from Sanskrit, and for his founding in China of the Buddhist Ideation Only school, which stressed that the world is but a representation of the mind. Hsüan-tsang is further noted for his achievement as the transmitter of a great religious tradition from India to China and thence to Japan.

He was born in 602 in Ch'en-liu (modern K'ai-feng, in Honan Province), the youngest of four sons in a family in which there had been scholars for generations. He received a classical Confucian education in his youth, but under the influence of an older brother he became interested in the Buddhist scriptures and was soon converted to Buddhism. With his brother he travelled to Ch'ang-an and then to Ssu-ch'uan (modern Szechwan) to escape the turmoil that had resulted from the dynastic change from the Sui (581–618) to the T'ang dynasty (618–907). While in Ssu-ch'uan, Hsüan-tsang began studying Buddhist philosophy but was soon troubled by numerous discrepancies and contradictions in the texts. Not finding any solution from his Chinese masters, he decided to go to India to study at the fountainhead of Buddhism.

Journey to India

The biography of Hsüen-tsang by Hui-li and Yen-tsung, two Chinese monks, has preserved a detailed description of him as he set out all alone for India in 629. He was tall and handsome like a figure in a painting.

> His colouring was delicate, his eyes brilliant. His bearing was grave and majestic, and his features seemed to radiate charm and brightness. . . . His voice was pure and penetrating in quality and his words were brilliant in their nobility, elegance, and harmony, so that his hearers never grew weary of listening to him.

Later in India, his handsome features were the cause of his being seized by a group of river pirates, who were followers of the Hindu goddess Durgā and wanted to present him as a sacrifice to her. His protestations that he was only a devout pilgrim searching for the truth of Buddhism fell on deaf ears, whereupon he went into a deep meditation to prepare for his death. While he was absorbed in meditation, a violent storm arose that buffeted the boat. The pirates were so terrified that they freed the holy monk and asked for forgiveness and repentance.

Hsüan-tsang's journey took him across the frightful deserts of Central Asia and the towering, snowcapped mountains of northwest India before he arrived in the holy land of Buddhism, in 633. His journey across Central Asia was almost interrupted in Turfan in present-day Sinkiang Province, where the King was so impressed by Hsüan-tsang and his learning that he wanted to keep the Chinese monk there in his court as his spiritual preceptor. But Hsüan-tsang threatened a hunger strike, which weakened the King's will to detain him. The King proved to be the pilgrim's greatest benefactor, for he provided the Chinese traveller with letters of introduction to various ruling princes along the way, thus facilitating his travel to the very gates of India.

In India, Hsüan-tsang visited all the sacred sites connected with the life of the Buddha, and he journeyed along the east and west coasts of the subcontinent. The major portion of his time, however, was spent at Nālandā to perfect his knowledge of Sanskrit, Buddhist philosophy, and Indian thought.

Though Hsüan-tsang was attracted by the land of India and by Buddhist thought and was a man of universal interests, he remained true to his Chinese heritage. He spoke as a Chinese endowed with Confucian moderation and practical common sense when he severely criticized the ascetic excesses of the Hindu holy men, who wore garments soiled with dirt, ate decayed food, and moved around the land naked and filthy, with skin broken and feet horny and cracked. When he expressed his desire to return to China after his sojourn in Nālandā, his fellow Indian monks tried to dissuade him from leaving, saying that China was the land of the barbarians, because the Buddha had not been born there. This aroused Hsüan-tsang to a spirited defense of China, stating that in his native land the laws were universally observed, the ruling princes were virtuous, the subjects loyal, fathers affectionate, and sons obedient. He also pointed to the advances achieved by the Chinese in astronomy, music, and engineering.

While he was in India, the fame of Hsüan-tsang became so great that he was honoured and respected even by the powerful King Harṣa, ruler of North India. When Harṣa heard that the famous Chinese pilgrim had arrived near his camp, he hurried in person to the place where the pilgrim was staying so that he might pay his respects. Harṣa then convened a grand religious assembly presided over by Hsüan-tsang, on which occasion the latter successfully dispelled the reputed ignorance of the Theravāda (Way of the Elders) Buddhists and shattered the pride of the Brahmins (Hindu priestly caste). When Hsüan-tsang prepared to return to China, Harṣa loaded him with gifts and provided him with escorts.

Return to China

Hsüan-tsang returned to Ch'ang-an, the T'ang capital, in 645, after an absence of 16 years. His return contrasted markedly with his departure from China; he had had to leave by stealth and to travel only by night for fear of detection by the imperial guards stationed at the western passes of China to guard its borders. Now, however, he was accorded a tumultuous welcome at the capital, and, within a short time after his arrival, he was received in audience by the Emperor, who questioned him in detail about the climate, products, peoples, and manners of the countries he had visited. The T'ang legions had carried the might of the dynasty clear across Central Asia, and the Emperor thus was interested in the countries and peoples of that region. So impressed was he with what he heard from the Buddhist monk that he offered him a ministerial post. Hsüan-tsang, however, preferred to serve his religion, so he respectfully declined the imperial offer.

Hsüan-tsang spent the remainder of his life translating the Buddhist scriptures, numbering 657 items packed in 520 cases, that he brought back from India. He was able to translate only a small portion of this huge volume, about 73 items in 1,330 chapters. His main interest was centred on the teachings of the Ideation Only school, and in his massive work, *Ch'eng-wei-shih-lun* ("Treatise

on the Establishment of the Doctrine of Consciousness Only"), he summarized the teachings of the Indian masters of this tradition. Together with his chief disciple, K'uei-chi, he founded the Wei-shih school (Ideation Only school) in China. While Hsüan-tsang and K'uei-chi lived, the school achieved some degree of eminence and popularity, but its subtle and abstruse philosophy was alien to the Chinese tradition, and with the passing of the masters the school declined. Before this happened, however, a Japanese monk named Dōshō arrived in China in 653 to study under Hsüan-tsang, and, after he had completed his study, he returned to Japan to introduce the doctrines of the Ideation Only school in that country. During the 7th and 8th centuries, this school, called Hossō by the Japanese, became the most influential of all the Buddhist schools in Japan.

In addition to his translations, Hsüan-tsang composed a *Ta-T'ang Hsi-yü-chi* ("Records of the Western Regions of the Great T'ang Dynasty"), which preserved his account of the various countries passed through during his journey. The data this work contains has proved to be most useful for historians and archaeologists working in Central Asiatic and Indian history.

Hsüan-tsang died in 664. Out of veneration for this intrepid and devout Buddhist monk and pilgrim, the T'ang Emperor cancelled all audiences for three days.

BIBLIOGRAPHY. The works of SAMUEL BEAL, *The Life of Hiuen-tsiang*, new ed. (1911); and STANISLAS JULIEN, *Histoire de la vie de Hiouen-Thsang et de ses voyages dans l'Inde* (1853), are translations of a biography of Hsüan-tsang, compiled by two Chinese monks, HUI-LI and YEN-TSUNG. Beal's translation, however, covered only five of the ten chapters in the original Chinese; Julien's version is a complete translation. ARTHUR WALEY, *The Real Tripitaka*, pp. 11–130 (1952), is a popular version of the biography written in a lively and interesting style. It is not as complete as the account found in RENE GROUSSET, *Sur les Traces du Bouddha* (1929; Eng. trans., *In the Footsteps of the Buddha*, 1932), which relied mainly on Julien's translation as its source, and which discusses the life of the Chinese pilgrim against the background of T'ang history and Buddhist philosophy.

(K.K.S.C.)

Hsün-tzu

Hsün-tzu (in Pin-yin romanization Xun-zu) was one of the three great Confucian philosophers of the Classical period in China. He elaborated and systematized the work undertaken by Confucius and Mencius, giving a cohesiveness, comprehensiveness, and direction to Confucian thought that was all the more compelling for the rigour with which he set it forth; and the strength he thereby gave to that philosophy has been largely responsible for its continuance as a living tradition for over 2,000 years. Author of the book that bears his name, Hsün-tzu did not confine his philosophical energies to ethics and politics; he also made original contributions to philosophy in such divergent fields as semantics, aesthetics, education, logic, and the psychology of perception. He was also a distinguished Classical scholar with a rich knowledge of archaic Chinese myths, legends, ceremonies, and folklore. Many of his intellectual achievements came to be obscured as later Confucians focussed on the misanthropic view attributed to him—perhaps erroneously—that human nature is basically ugly or evil, and, beginning about the 12th century AD, his writings fell into a period of disfavour and neglect from which they are only now re-emerging.

Conjectural character of Hsün-tzu's life story

Personal life and official career. Hsün-tzu shares with many other influential figures of antiquity a hazy personal background and history; virtually nothing is known of his ancestry or of his personal life. Even his precise surname is disputable, with Sun occurring more regularly in early records than Hsün. The two characters that represent these names are written differently but are thought to have been pronounced the same in archaic Chinese. His given name was probably K'uang, his honorary cognomen *ch'ing*, a title for an official or nobleman. According to some sources he may actually have been descended from minor nobility, but his patrimony was without economic consequence, for no record shows him to have been a man of means. Like most other Chinese scholar-philosophers, he is generally accorded the honorific title *tzu*, and hence he has come down to posterity simply as Hsün-tzu—Master (or Philosopher) Hsün.

He was born in the ancient state of Chao, most of which lay in what is now Shansi Province. The several dates given for his birth span almost a half century, from an early estimate of 340 BC to a late one of 298 BC. The latter date is probably nearer the mark, but by any calculation his life falls squarely in the Warring States period (481–221), a period of almost unremitting political intrigue and internecine warfare.

Thus, he lived in a milieu of great change and instability, the antithesis of the harmonious and well-ordered traditional society he came to advocate as the philosophical ideal. Hsün-tzu was no hater of change, for the detailed descriptions of the just society found in his writings reflect a sophisticated appreciation of the manifold advantages in areas such as trade, social mobility, and technology that were accompanying the breakdown of the feudal order. At the same time, he could see that these societal transformations were also bringing to the Chinese the demise of their ancient socio-religious institutions, and he believed that the ritual practices (*li*) linked with those institutions were too important to be lost during secularization. For him, those ritual practices were important to the society because they were a culturally binding force for a people whose existence depended on cooperative economic efforts, and further, those ritual practices were important to the individual because they provided an aesthetic and spiritual dimension to the lives of the practitioners. By his fundamental insistence on the necessity of cultural continuity for both the physical and psychological well-being of his fellows, Hsün-tzu placed himself squarely in the ranks of Confucian philosophers.

Stress on value of ritual practices

Like many other intellectuals of the time, he first came to public attention in Chi-hsia, a famous centre of learning in the state of Ch'i, whose rulers traditionally provided subventions for scholars. That Hsün-tzu was already a mature thinker when he arrived there is suggested by the record of his having thrice officiated at a special court ceremony, an honour generally reserved for scholars of distinction. From his own writings it is clear that he visited the authoritarian state of Ch'in briefly—perhaps in 264—but the only date in his entire life on which all accounts agree is 255, when he was given the position of magistrate in the city of Lan-ling in the state of Ch'u. Unlike Confucius and Mencius, both of whom travelled extensively from state to state seeking a morally conscious ruler who would employ them and implement their ideas, Hsün-tzu chose a more modest official life. Except for one brief period, he continued as a magistrate until the death of his political patron, in 237. After leaving office he remained in Lan-ling until he died a few years later (*c.* 230).

Teaching and writing. Hsün-tzu is remembered for his teaching and his writing, not for his official or personal life. As a teacher, he had the distinction of being the tutor to not one but two of the most politically influential men in ancient China: Han-fei-tzu and Li Ssu. But the former became a Legalist philosopher opposed to the principles of his mentor, and the latter censured the Confucians and their writings when he became prime minister of China (*c.* 219 BC). Thus, both men earned the enmity of later Confucian historians, and the approbrium they have consistently received through the centuries has also affected the evaluation of their teacher. Ironically, his most famous students brought Hsün-tzu more reproof than renown.

Doctrine of man's evil nature

His writings were no less the recipient of moral disapproval than his teaching, owing in large measure to the oft-quoted essay "Man's Nature is Evil." Because Mencius believed that human beings were innately disposed toward moral behaviour, Hsün-tzu was perceived, as the author of this essay, to be attacking his illustrious predecessor. The Neo-Confucians of the Sung dynasty (AD 960–1279) adjudicated the controversy in favour of Mencius, who was canonized as the second Sage of Confucianism, while Hsün-tzu was declared heterodox. Some

contemporary scholarship suggests that the passages containing this doctrine are later interpolations into Hsün-tzu's text. Authentic or not, the doctrine has probably received more attention historically than it deserves, because it does not appear to be essential to the development of Hsün-tzu's overall philosophical position.

Whatever the final verdict on the significance of the "Man's Nature is Evil" passages, however, textual corruption is the exception and not the rule for Hsün-tzu's writings; unlike most other Chinese works of the same period his book managed to escape the forger's pen, and most of the material in the 32 essays that comprise the *Hsün-tzu* is considered to have come from his own hand. These essays are a milestone in the development of Chinese philosophy, because the anecdotal and epigrammatic style which had characterized earlier philosophical literature—*i.e.*, the *Analects*, *Tao-te Ching*, *Mencius*, *Chuang-tzu*—no longer sufficed to convey fully and persuasively the complex philosophical disputes of Hsün-tzu's day. He lived when the "hundred schools" of thought were competing for adherents in the Chinese marketplace of ideas, and, in order to meet the objections of his opponents and advance the Confucian position, he introduced a more rigorous style of writing that emphasized topical development, sustained reasoning, detail, and clarity.

Social and ethical stress

Hsün-tzu's primary concern was with social philosophy and ethics, as evidenced by the content of his essays: 18 of the 32 fall solely within these areas, and the remainder fall partly so; even the technical, linguistically oriented "Rectification of Names" is liberally sprinkled with comments about the adverse social consequences attending the abuse and misuse of language.

Among his other famous essays, "A Discussion of Music" became the classic work on the subject in China. Here, too, social issues are under consideration as Hsün-tzu discusses the importance of music as a vehicle for expressing human emotions without generating interpersonal conflict. Almost equally celebrated is "A Discussion of Heaven," in which he attacks superstitious and supernatural beliefs, and again the focus is social: one of the main themes of the work is that unusual natural phenomena (eclipses, etc.) are no less natural for their irregularity—hence are not evil omens—and therefore men should not be concerned at their occurrence; rather should men be concerned about what lies within their power to alter, namely hunger and sickness, which are portents of famine, disease, and death.

In the essay "A Discussion of Ritual" (*li*), Hsün-tzu elaborates the concept central to his entire philosophy. The *li* constituted the "Way" of Confucianism as interpreted by Hsün-tzu, being the ritualized norms governing the mores, manners, and morals of the people. Originally the behavioral expressions of early supernatural beliefs, the historical *li* were being abandoned by an increasingly agnostic intelligentsia during the Warring States period, and Hsün-tzu—an avowed atheist—provided an ethical and aesthetic philosophical basis for these ritual practices as their religious foundation was weakening.

The *li* are the basic stuff out of which Hsün-tzu builds his ideal society, and the scholar-officials who are to govern that society have as their primary function the preservation and transmission of these ritual practices. Like all early Confucians, Hsün-tzu was opposed to hereditary privilege, advocating literacy and moral worth as the determinants of leadership positions, rather than birth or wealth; and these determinants were to have as their foundation a demonstrated knowledge of the high cultural tradition—the *li*. No less significant politically than socially, the *li* were to be employed by scholars to ensure that everyone was in a place; and officials were to employ the *li* to ensure that there was a place for everyone.

Stature and influence. Hsün-tzu's model society was never put into practice, and, like Confucius and Mencius before him, he probably died believing himself to have been a failure. Yet the rationalism, religious skepticism, concern for man in society, historical and cultural sensitivity, and fondness for ancient lore and customs that pervade his writings also pervaded Chinese intellectual life for over two millennia. No one dealt with these issues more thoroughly than Hsün-tzu, and his passionate defense of the Confucian moral vision contributed substantively to lessening the distance between the philosophical ideal and the historical reality. He has been correctly described as the molder of ancient Confucianism. Traditional China, with its extensive lands and huge population, came to be largely a Confucian state—making Hsün-tzu one of the most influential philosophers the world has ever known.

BIBLIOGRAPHY. There is no complete translation of the *Hsün-tzu*. Competent partial works are HOMER H. DUBS, *The Works of Hsüntze* (1928); and BURTON WATSON, *Hsün Tzu: Basic Writings* (1963). The most detailed exposition of Hsün-tzu's philosophy is HOMER H. DUBS, *Hsüntze: Moulder of Ancient Confucianism* (1927). FUNG YU-LAN in *A History of Chinese Philosophy*, 2nd ed., 2 vol. (Eng. trans. 1952–53), presents the standard analysis and evaluation of Hsün-tzu's views against their Chinese background. Two recent works that de-emphasize the significance of natural human evilness in Hsün-tzu's philosophy are DONALD MUNRO, *The Concept of Man in Early China* (1969); and HENRY ROSEMONT, JR., "State and Society in the *Hsün Tzu*," in *Monumenta Serica* (1971).

(He.Ro.)

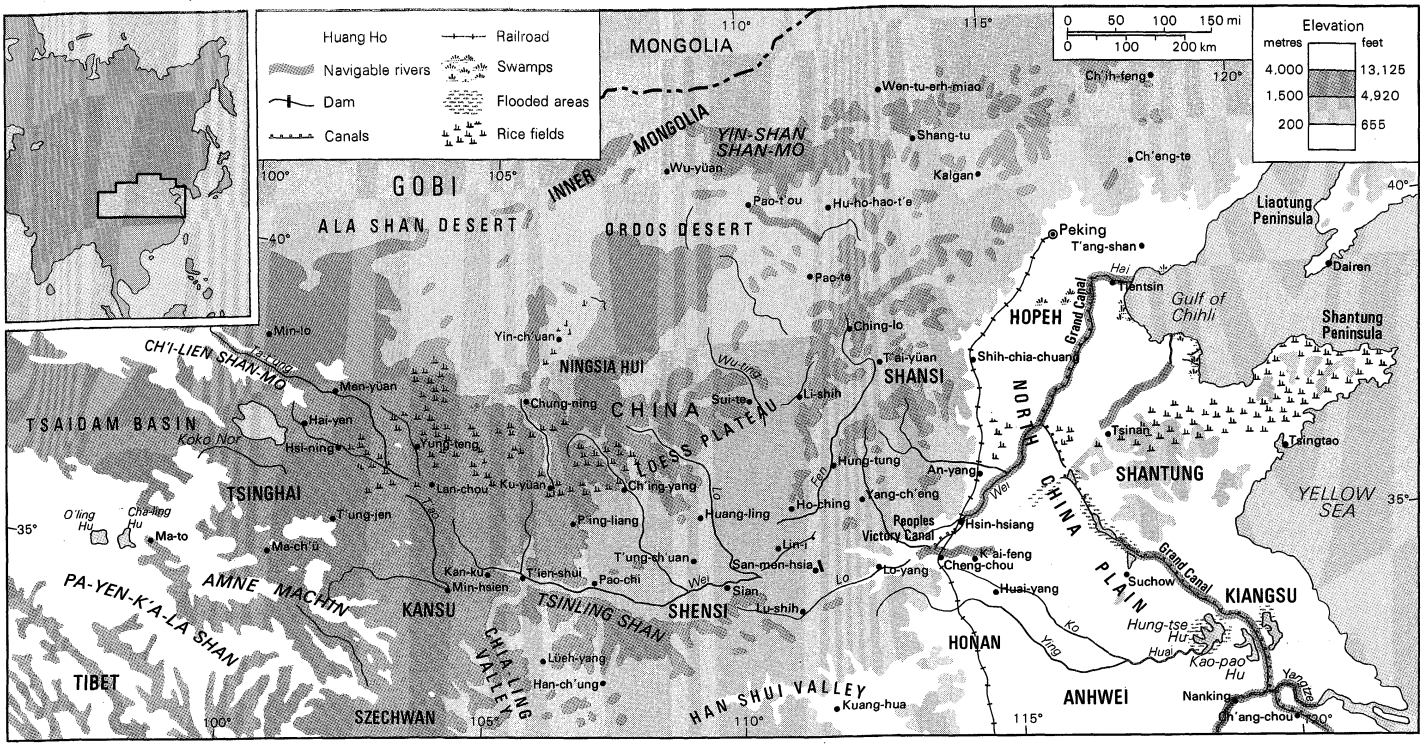
Huang Ho (River)

The Huang Ho (Huang He in Pin-yin romanization) or Yellow River, one of the most northerly and second longest of China's rivers, flows from the eastern highlands of the Tibetan Autonomous Region 3,011 miles (4,845 kilometres) to the Yellow Sea. It passes through the provinces of Tsinghai and Kansu, the autonomous regions of Ningsia Hui and Inner Mongolia, and then into the provinces of Shensi, Shansi, Honan, and Shantung as a shifting, turbulent, muddy stream that often overflows its banks and sends floodwaters across the North China Plain. For this it has been called "China's Sorrow" and "The Ungovernable." The name Huang (Yellow) comes from the fine, loess soil that it brings down with it. More than 110,000,000 people live in the basin of the Huang Ho, which flows past the cities of Lan-chou, Pao-t'ou, Sian, T'ai-yüan, Lo-yang, Cheng-chou, K'ai-feng, and Tsinan. It drains an area of 288,000 square miles (745,000 square kilometres).

Chinese civilization arose in the lower valley of the Huang Ho, which is mentioned in ancient Chinese writings of the 3rd millennium BC. During the reign of one Yao, runs the record, catastrophic flooding occurred on both the Huang Ho and Yangtze River, inundating all of the North China Plain. Regular records have been kept since the 6th century BC of major floods and also of changes in the river's course. Water levels have been studied since 1736. The first European to explore the upper reaches of the Huang Ho was a Russian traveller, Nikolay Przhevalsky, in 1879 and 1884. Since the 1950s the river has been studied intensively by Soviet scientists as well as by the Chinese.

The basin. The Huang Ho is divided into two distinct parts: the mountainous upper basin and the plains section, which is subdivided into the middle and lower basins. The broad highlands of the mountainous part rise 1,000 to 1,300 feet (300 to 400 metres) above the river and its tributaries. The highlands are built upon crystalline rocks, sometimes visible as eroded outcroppings on the surface. On the plateau these rock systems are covered with thick layers of friable deposits, mainly loess. The loess strata have thicknesses of 160 to 200 feet and in some places as much as 500 feet, extending eastward from the highlands of Tibet all the way to the North China Plain. Through this loose loam the river has cut deep valleys, carrying away with it huge quantities of silt; the easily eroded loess soil accounts for the instability of the river bed.

Downstream the Huang Ho Basin becomes fan shaped as it broadens out across the North China Plain, which is broken only by the low Shantung Hills. The plain consists of fine silt brought down by the river, over sand and gravel deposited when the sea receded in the geological past. Along the river are occasional areas of sand dunes 15 to 30 feet in height. The plain, which contains a number of old beds of the river, is China's rice granary.



The Huang Ho Basin and its drainage network.

The upper basin. The Huang Ho originates at an altitude of about 15,000 feet in the Pa-yen-k'a-la Shan (Pa-yen-k'a-la Mountains), in the eastern Tibetan Highlands. In its upper reaches the river crosses two large lakes, Cha-ling Hu and O-ling Hu. These are shallow lakes covering an area of about 40 square miles, rich in fish and frozen in winter. The Huang Ho in this region flows generally from west to east. It enters deep gorges winding its way along the southern slopes of the Amne Machin, somewhat above the city of Lan-chou. With many rapids, its fall exceeds ten feet per mile. Populated areas are few. Past the gorges it leaves the Tibetan Highlands and flows northward across the Ordos Desert, in northern China, having flowed about 726 miles from its source. The basin upstream from that point covers an area of about 48,000 square miles, consisting chiefly of inaccessible, highly mountainous terrain with a cold climate. The few inhabitants engage in cattle breeding.

Lakes Cha-ling Hu and O-ling Hu

The middle basin. The middle part of the Huang Ho consists of a great northward loop through the Ordos Desert and then a southward course through a long trench forming the border between Shensi and Shansi provinces to the city of Cheng-chou, a distance of more than 1,800 miles. Most of the middle basin is cut through the Loess Plateau at altitudes ranging between 3,000 and 7,000 feet. The plateau contains terraced slopes as well as alluvial plains and a scattering of peaks sometimes exceeding 1,500 feet in height. Within its large loop, the Huang Ho drains an area of about 23,000 square miles. The river at first flows in a northeasterly direction for about 550 miles among bare loess hills; it has many rapids, and in a number of places it narrows. It then turns eastward and flows for another 500 miles through alluvial plains; in this stretch it has many branches, and its fall is less than four inches per mile. If it continued eastward it would flow to Peking, but instead it turns sharply to the south and flows for about 445 miles through narrow gorges with steep slopes several hundred feet in height. The river's width usually does not exceed 150–200 feet in this section. The Huang Ho gradually widens and then turns sharply to the east for another 300 miles. Here it flows through inaccessible gorges between the eastern peaks of the Tsinling Shan. The average fall in this stretch is about 14 inches per mile and increasingly rapid in the last 100 miles before the river enters the North China Plain.

This middle basin of the river, between the Tibetan Highlands and the North China Plain, contains the two longest tributaries: the 537-mile Wei Ho of Shensi Province and the 430-mile Fen Ho of Shansi Province.

The two longest tributaries

The lower basin. The lower part of the Huang Ho is about 435 miles long with an average fall of about three inches per mile. This is an area of great floods because the river bed in many places lies above the surrounding land. In the section above the city of K'ai-feng, the low-water level is between six and ten feet above the surrounding countryside; the mid-water level is between 19 and 23 feet; and the high-water level sometimes as much as 33 feet above that of the land. From K'ai-feng to the Grand Canal (Yün Ho), the riverbanks rarely exceed three to six feet in height. Marshes are common. Below the Grand Canal the height of the banks increases to 13–16 feet and in some places to 25. Several centuries ago the Chinese built dikes along the river, which in places are broad enough to accommodate villages.

The delta of the Huang Ho begins approximately 160 miles from its mouth, spreading out over an area of about 950 square miles. Built up by silt brought down by the river, the delta is swampy and covered with reeds. A sand bar at the mouth impedes navigation by boats drawing more than four feet of water at low tide; at high tide the depth on the bar is eight or nine feet.

Hydrography. *Changes in course.* In the past 4,000 years several radical changes have occurred in the Huang Ho's course; at different times the river has entered the Yellow Sea at points varying by as much as 500 miles. From 2278 BC to 602 BC, when it occupied its northernmost course, it flowed through the city of Tientsin and entered the nearby Gulf of Chihli (Po Hai). From 602 BC to AD 70, both the river and its mouth shifted to the south of the Shantung Peninsula. From AD 70 to 1048 the Huang Ho again shifted north, taking up a course much along its present bed.

From 1048 to 1194 changes in the course of the river occurred farther inland, where the river enters the North China Plain. In 1194 the river occupied its southernmost course, the mouth having shifted to the southern edge of the delta. In that year, as a result of the rupturing of the protecting dikes, a second arm of the Huang Ho was created in the southern part of the Shantung Peninsula. From 1289 to 1324 the river took over the bed of the Ko Ho and a large part of the Huai Ho, later returning to its old bed. It was stable for more than 500 years until 1854,

when it again began to move farther to the north of the Shantung Peninsula, where it now is located.

Upstream alterations in course

In the upper and middle sections of the Huang Ho, alterations of the riverbed are comparatively slight; concave banks have been washed away, and the alluvial deposits have formed radiating convex banks, or arms, some of which are under cultivation. Numerous outcroppings of rock on the bottom of the river also cause changes in the bed. In the downstream areas, however, where the riverbed is higher than the surrounding land, changes in the bed sometimes lead to a sudden rupturing of the dikes and the flooding of extensive areas. This flooding, which occurs during periods of high water, covers the surrounding territory with huge amounts of silt.

History of floods. Breaks in the dikes have occurred throughout history. Between 960 and 1048 there were 38 breaks, and 29 from 1048 to 1194. In later years such breaches were less frequent as a result of systematic construction. The slackening of these efforts during the Taiping Rebellion led to a significant change in the course of the river in 1852–54.

In 1887 the Huang Ho burst the dikes near the city of K'ai-feng and began to flow into the Huai Ho, but engineering efforts succeeded in returning it to its former location in 1889. The flood of 1887 covered 30,000 square miles, completely burying many villages under silt. In 1889 another flooding injured nearly 1,000,000 persons and destroyed 1,500 villages. The next major flood, in 1921, wiped out hundreds of populated places, mainly near the mouth of the delta. In the flood of 1933 more than 3,000 populated places were submerged, 3,600,000 people injured, and 18,000 killed. Other floods occurred in 1938 and 1949.

The delta of the Huang Ho is one of the most active in the world. In 1870–1970 it pushed outward into the sea an average of more than 12 miles. Some outlying parts have been expanding even more rapidly: one area grew 6 miles during the period 1949–51, and another grew more than 15 miles in 1949–52.

Flowage and siltation. The Huang Ho carries an average annual volume of about 11.6 cubic miles (48.2 cubic kilometres) of water down to the sea—as much as 16.8 cubic miles in high-volume years and as little as 4.8 to 6.0 in low-volume years. There are also seasonal variations in its volume. More than half of the annual precipitation falls during the rainy season, July to October. The average annual precipitation for the entire basin is about 18½ inches, but its distribution is very uneven. In some years the bulk of the river volume comes from its tributaries. In the upriver areas the main source is snowfall in the mountains, with the high-water level (33 feet) occurring in the spring. The highest water levels in the middle and lower parts of the river (10 to 23 feet) occur in July and August. The maximum flow of water near Lan-chou is 7,000–8,000 cubic yards per second; near Lung-men, 13,000; and in the lower parts of the river, 47,000 (as recorded in 1943).

The Huang Ho is the world's muddiest river. It carries along about 57 pounds of silt per cubic yard of water, as compared with two pounds for the Nile, seven for the Amu Darya, and 17 for the Colorado. Floodwaters may contain up to 1,200 pounds of silt per cubic yard of water (70 percent by volume). The river carries down to the sea about 1,520,000,000 tons of silt a year, partly because much of the basin is composed of loess, which is loose and easily moved. Other factors are the steepness of the slopes, the rapidity of the current, and a lack of forested areas and reservoirs to check erosion and allow the silt to settle out. The irrigation system in the plain is not enough to slow the river current.

The Huang Ho freezes over in parts of its middle section for several months a year. On the great plain near K'ai-feng there are 15 to 20 ice-bound days a year but none at all farther downstream. Ice blockage is broken up with the help of bombs dropped from airplanes or sometimes artillery shelling.

Canals and dams

River development. The 4,000-year-old irrigation system of the Huang Ho, augmented by recently constructed irrigation and navigation canals, brings water to about 10,000 square miles of land. The Grand Canal, cutting across the lower river, runs for more than 1,100 miles from Peking in the north to Hangchow in the south. The People's Victory Canal, completed in 1953, runs for 30 miles parallel to the Peking–Hankow railroad and links the Huang Ho north of Cheng-chou with the Wei Ho at Hsin-hsiang. It raises the level of the Wei Ho, improving navigation between Hsin-hsiang and Tientsin and also providing a network of irrigation channels between Hsin-hsiang and the Huang Ho.

The government has plans for the development of "China's Sorrow" into a productive watercourse. A 1,000,000-kilowatt power station and dam has been built at San-men-hsia (Three-Gate Gorge) on the Honan-Shansi border, 130 miles west of Chengchou; the reservoir is 120 miles long. Before the construction of the reservoir, navigation by boat was restricted to a stretch of 100 miles or so on the lower reaches of the river. Current plans envisage the construction of new dams and reservoirs, the exploitation of its hydroelectric potential (estimated at 30,000,000 kilowatts), and extension of the navigable length of the river and its tributaries. (I.V.P.)

Hudson, Henry

Henry Hudson, an English navigator and explorer, made four historic voyages in the early 17th century, seeking a short route from Europe to Asia by way of the Arctic Ocean. The Hudson River, in what is now the eastern United States, and Hudson Strait and Hudson Bay, in what is now Canada, are all named for him. In 1607 and again in 1608, he attempted to discover a Northeast Passage to China. In the 1607 voyage he explored the coasts of the Svalbard (Spitsbergen) archipelago, to the north of Norway, to about latitude 80° N and rediscovered Jan Mayen Island to the east of Greenland (originally believed to have been discovered in the 15th century). His accounts of immense numbers of whales and walrus at Svalbard led the English and Dutch to establish a whaling industry there. On his third voyage in 1609, sailing for the Dutch, he laid the basis for that nation's claims to the Delaware and Hudson rivers in what is now the eastern United States. On his final voyage, from 1610 to 1611, he established an English claim to Hudson Bay that was later expanded to cover much of Canada. He is thought to have died in 1611.

The first and second voyages. Of Hudson's early life, nothing is known. Several Hudsons were associated with his sponsors, the Muscovy Company of London, a generation before his own time. A 1585 voyage by the English navigator John Davis, who sailed to the Arctic to make the first attempt to find a Northwest Passage from Europe to Asia, was planned in the home of a Thomas Hudson in Limehouse, now in the docks area of London's East End. Henry Hudson may have been present on that occasion and consequently developed a lifelong interest in Arctic exploration. It is certain that he was well informed about Arctic geography and that his competence as a navigator was such that two wealthy companies chose him to conduct hazardous explorations.

The search for the Northeast Passage

In the spring of 1607, sailing for the Muscovy Company, Hudson, his son John, and ten companions set forth "for to discover a Passage by the North Pole to Japan and China." Believing that he would find an ice-free sea around the North Pole, Hudson struck out northward. On reaching the edge of the polar ice pack, he followed it east until he reached Svalbard. From there he extended explorations made earlier by the 16th-century Dutch navigator Willem Barents, who had also sought a Northeast Passage to Asia.

A year later, the Muscovy Company again sent Hudson to seek a Northeast Passage, this time between Svalbard and the islands of Novaya Zemlya, which lie to the east of the Barents Sea. Finding his way again blocked by ice fields, he returned to England.

The third and fourth voyages. Shortly after his return, Hudson was lured to Amsterdam to undertake a third northeast voyage under contract to the Dutch East India Company. While there, he heard reports of two possible channels to the Pacific across North America. One of these, said to be in about latitude 62° N, was described in the logbooks of a voyage made in 1602 by an English explorer, Captain George Weymouth. The other, said to be in the vicinity of about latitude 40° N, was newly reported from Virginia by the English soldier, explorer, and colonist Capt. John Smith. Although his interest in a Northwest Passage had been aroused, Hudson agreed to return directly to Holland if his northeast voyage should prove unsuccessful.

Hudson sailed from Holland in the "Half Moon" on April 6, 1609. When head winds and storms forced him to abandon his northeast voyage, he ignored his agreement and proposed to the crew that they should instead seek the Northwest Passage. Given their choice between returning home or continuing, the crew elected to follow up Smith's suggestion and seek the Northwest Passage around 40° N. While cruising along the Atlantic seaboard, Hudson put into the majestic river that was discovered by the Florentine navigator Giovanni da Verrazano in 1524 but that was thenceforth to be known as the Hudson. After ascending it for about 150 miles (240 kilometres) to the vicinity of what is now Albany, New York, Hudson concluded that the river did not lead to the Pacific.

On his way to Holland, Hudson docked at Dartmouth, England. The English government then ordered him and the English members of his crew to desist from further explorations for other nations. His log and papers were sent to Holland, where his discoveries were soon made known.

Hudson now made ready a voyage to America to follow up Weymouth's suggestion. Weymouth had described an inlet (now Hudson Strait) where a "furious overfall" of water rushed out with every ebb tide. This phenomenon suggested that a great body of water lay beyond the strait. Hudson was confident that it was the Pacific Ocean. The British East India Company contributed £300 toward his voyage, and the Muscovy Company presumably furnished a like amount; Hudson's private sponsors included five noblemen and 13 merchants.

The voyage to Hudson Bay

Sailing from London on April 17, 1610, in the 55-ton vessel "Discovery," Hudson stopped briefly in Iceland, then proceeded to the "furious overfall." Passing through it and entering Hudson Bay, he then followed the east coast southward, rather than striking boldly westward. Finding himself in James Bay at the southernmost extremity of Hudson Bay and with no outlet to the Pacific to be found, Hudson cruised aimlessly until winter overtook him.

In the close confinement of an Arctic winter, quarrels arose. Hudson angered one of his crew, Henry Green, by first giving him a gray gown and then, when Green displeased him, taking it back and giving it to another. Some of his crew suspected that Hudson was secretly hoarding food for his favourites, and tempers flared when Hudson ordered the crew's own sea chests searched for extra victuals. Robert Juet, the mate, had been demoted, and he conspired with Green and others to mutiny. Once the homeward voyage had begun, the mutineers seized Hudson, his son, and seven others, casting them adrift in Hudson Bay in a small open boat on June 22, 1611. Although the "Discovery" sailed home to England, neither of the ringleaders returned with her, having been killed, together with several others, in a fight with Eskimos. No more was ever heard of Hudson and his small party, although in 1631 to 1632 another explorer found the ruins of a shelter, possibly erected by the castaways.

As a commander, Hudson was more headstrong than courageous. He violated his agreement with the Dutch and failed to suppress the 1611 mutiny. He played favourites and let morale suffer. In James Bay he appeared irresolute.

Yet Hudson undertook four dangerous voyages, brought his crew through an Arctic winter, and preserved his vessels amid the dangers of ice and unknown shores. He was a competent navigator who materially extended the explorations of Verrazano, Davis, and Barents. His contribution to geographical knowledge was great, while his discoveries formed the basis for the Dutch colonization of the Hudson River and for English claims to much of Canada.

ASHER (ed.), *Henry Hudson the Navigator* (1860, reprinted 1963), provides the surviving journals of Hudson's four voyages, supplementary materials, and an important critical introduction. SAMUEL PURCHAS, *Purchas his Pilgrimes* (1625, reprinted 1906), gives the journals. LLEWELYN POWYS, *Henry Hudson* (1928), is a good popular biography. R.A. SKELTON, *Explorers' Maps* (1958, reprinted 1970), reproduces pertinent charts.

(Jo.E.C.)

Hudson Bay

Roughly oval-shaped, Hudson Bay is one of the major fringing continental seas of the Arctic Ocean, covering 316,000 square miles (819,000 square kilometres)—an area larger than that of France and Italy combined—in the Canadian depression of northeast North America. The northern exit to the bay bifurcates: on either side of the long, narrow Baffin Island, Hudson Strait, curving away to the southeast, provides a narrow link with the Atlantic Ocean; and Foxe Basin and the narrow straits of the Canadian Arctic Archipelago provide a link with the Arctic Basin to the north. The bay is named after Henry Hudson, who, in 1610, on board the aptly named "Discovery," was seeking a Northwest Passage to Asia.

Exploration and scientific study

The east coast of Hudson Bay proper was mapped two years later; the south coast was traced in 1631; and the explorer Luke Foxe lent his name to Foxe Channel in the same year. The west coast was not mapped until the early 1820s, and the first investigations in depth of the area were made by Canadians during 1929–31, followed by hydrographic researches in 1948. During the 1954–62 period, six research cruises took place; but following observations on ice conditions in 1955 and 1956, air reconnaissance became more frequent. (For related information see NORTH AMERICA; CANADA; ARCTIC ISLANDS; NORTHWEST TERRITORIES. For historical aspects, see CANADA, HISTORY OF; NORTHWEST PASSAGE.)

Physical characteristics. Hudson Bay has a shallow and quite smooth floor, averaging 330 feet (100 metres) in depth, with a maximum around 900 feet. The coast, situated in a region of permanently frozen earth layers, or permafrost, is a marsh-ridden lowland fed by lake waters and turbulent rivers. In the east and northeast the shores are high and sheer, but elsewhere they are low. Coniferous woods border the southerly James Bay, the shallowest part, but most of the shore is covered with dwarf birch, willow, aspen, and bushes, growing among moss, lichen, and grass.

The eastern coast is bordered, at a distance of some 200 miles, with a set of islands and has cliffs formed of geologically ancient (over 570,000,000 years old) crystalline and sedimentary rocks. The only other islands are a small cluster at the bay exit. Bottom deposits are derived from the earth rather than from the shells of minute organisms, as in the case of the ooze of some of the coastal islands. The bottom deposits are washed in from the nearby coasts or dropped from encrustations below the "dirty ice" of Foxe Basin.

Hudson Bay has a severe continental climate. January temperatures average −20° F (−29° C), while July temperatures are only 47° F (8.3° C). Annual averages are 9.3° F (−12.6° C), but extremes have plunged to −60° F or reached 80° F in the summer. Spring is mild and cloudy, whereas summer is clear, though the bay itself is often coated with fog. Autumn starts cool, with frequent fogs, clearing later; early winter is very cold, clear, and calm, but this pattern is interrupted, after December, by strong winds and snowstorms. The thaw sets in in late April. Annual precipitation totals 12 to 20 inches (300 to 500 millimetres), all but a third of it coming in summer. Only 60 days are without frost.

Hudson Bay is filled by the numerous peripheral rivers and also by currents from Foxe Basin in the north, cre-

ating a counterclockwise general movement. Outflow occurs along the eastern Hudson Strait coast, rounding Chidley Cape (the northernmost tip of the Quebec–Newfoundland border), and passing into the Labrador Current. Flow is highest in July.

Hudson Bay has much ice, mostly local, though there is some influx of pack ice from Foxe Basin. Southern and central areas have solid, floating ice fields only during February and March; but a shore ice belt appears earlier. Freezing begins in October, and floating ice persists here and there into the following summer. Salinity increases with depth: below 80 feet it is 31 parts per thousand (‰); the layer above registers 23‰; and the upper six feet registers only 2‰ when the current is strong and ice is melting. Water temperatures can be as low as 29° F (−1.8° C) at depth in August, although surface temperatures may reach 49° F in September. Tides are important, with currents in the bay responding to the fierce tidal flow off the Labrador coast. The tidal amplitude and the associated current movements cause much mixing of waters in the region.

Biological characteristics. Hudson Bay contains a great quantity of dissolved nutrient salts, since unicellular algae, especially microscopic types, grow fast in the well-heated and illuminated upper layers. Small, shrimplike crustaceans occupy the open waters and form a food source for mollusks, sea urchins, starfish, and worms, together with many other invertebrates living on the bottom.

Variety of sea life

Fish include numerous polar plaice, cod, halibut, salmon migrating to the lakes and rivers to spawn, and also freshwater species. Seals, feeding on fish and invertebrates, inhabit the areas around openings in the ice: they include ringed, bearded, and Greenland varieties. Walrus, dolphins, and killer whales live in the northern sector, and the polar bears come down from the north to hunt seals among the ice. About 200 species of birds gather on the coasts and islands; they include ducks, gulls, eiders, loons, snow geese, swans, sandpipers, snow owls, and crows. There are also such herbivorous mammals as caribou, musk oxen, and rodents, as well as fur-bearing animals.

Human exploitation. Fishing, and hunting for sea mammals or furs, are the main local occupations. Indians inhabit the southern region between Eskimo Point (about halfway along the west coast) to Fort-George (on the eastern coast of James Bay, the embayment thrusting inland from the southeast corner of Hudson Bay); Eskimos live in the north. Population density is very low. For conservation purposes, the Canadian government has designated the whole Hudson Bay Basin a "mare clausum" (closed sea).

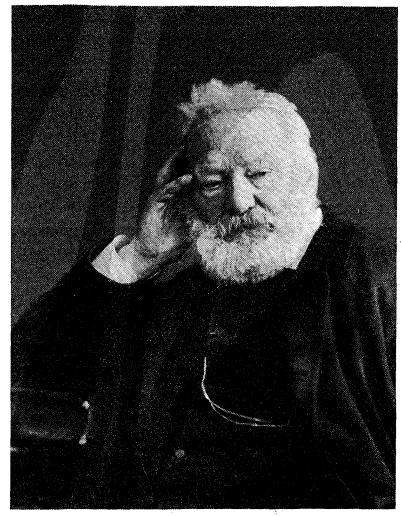
Hugo, Victor

A poet, novelist, dramatist, critic, and polemicist of vast creative energies, Victor Hugo first gained fame as the champion of the Romantic movement against the classicism and temperate good sense of a long-entrenched public literature in France. Popular during his lifetime as the author of such novels as *Les Misérables*, *Notre-Dame de Paris*, and *Toilers of the Sea*, he is critically important today chiefly for his poetry.

Early years (1802–30). Born at Besançon on February 26, 1802, Victor was the third son of Joseph-Léopold-Sigisbert Hugo, a major and, later, general in Napoleon's army. The paternal family consisted of farmers and artisans; the maternal, seamen and lawyers. Victor claimed that he came of "a stock both Breton and Lorrain," but it was Paris, where he went to live with his mother when he was two, that he called the birthplace of his soul.



Hugo, photograph by Nadar (Gaspard-Félix Tournachon).
Archives Photographiques

Hugo's childhood was coloured by his father's constant travelling with the imperial army and by the disagreements that soon alienated his parents from one another. His mother's royalism, a development perhaps subsequent to marriage, and his father's loyalty to successive governments—the Convention, the Empire, the Restoration—reflected their deeper incompatibility. It was a chaotic time for Victor, continually uprooted from Paris to set out for Elba or Naples or Madrid, yet always returning to Paris, usually with his mother alone. Such an existence at least fed his mind on contemporary history, if it did not provide a settled upbringing. Nevertheless, his intellectual education did achieve a solid basis, especially in Latin literature, and his private reading, though without order, was omnivorous. A few clear images from this period stayed in his mind: of Spain, especially, and of the garden of the Feuillantines in the Latin Quarter—a paradise, long since disappeared, that seemed to hold all the poetry of childhood. The fall of the empire gave him, from 1815 to 1818, a time of uninterrupted study at the Pension Cordier and the Lycée Louis-le-Grand, after which he matriculated at the law faculty at Paris, where his studies seem to have been purposeless and irregular. Memories of his life as a poor student later inspired the figure of Marius in his novel *Les Misérables*.

Indeed, from 1816, at least, he had conceived ambitions other than the law; he was already filling notebooks with verses that he later called "nonsense I perpetrated before my birth": translations—particularly from Virgil—two tragedies, a play, elegies. Encouraged by his mother and excited by the dazzling example of François-René de Chateaubriand, the author, diplomatist, and statesman, he founded a review, the *Conservateur Littéraire* (1819–21), in which his own articles on the poets Alphonse de Lamartine and André de Chénier stand out. His mother died in 1821, and a year later Victor married a childhood friend, Adèle Foucher, to whom he wrote some charming love letters, the *Lettres à la fiancée*, which were published posthumously. They had five children, four of whom survived: Léopold (died 1823), Léopoldine (1824–43), Charles (1826–71), François-Victor (1828–73) and Adèle (1830–1915). In the same year as his marriage, he published his first book of poems, *Odes et poésies diverses*, which earned him a pension from Louis XVIII. Behind Hugo's concern for classical form and his political inspiration, it is possible to recognize a personal voice and his own particular vein of fantasy. Fantasy had become fashionable, and Hugo developed his gift for it in his first published novel, *Han d'Islande* (1823), which in 1825 appeared in an English translation with illustrations by the caricaturist George Cruikshank. Charles Nodier, a journalist and himself author of novels of fantasy, was enthusiastic about the novel and drew Hugo into the group of friends, all devotees of Romanticism,

Early works

who met regularly at the Bibliothèque de L'Arsenal, where he was curator. Hugo continued to frequent this literary circle, called the Cénacle, though he sometimes professed indifference to the theoretical distinctions it debated. He shared also in launching a new review of moderate tendencies, the *Muse Française* (1823–24), to which he contributed essays on the Roman Catholic apologist Félicité-Robert de Lamennais and the poets Alfred de Vigny, Lord Byron, and Walter Scott. In 1824 he published a new collection, *Nouvelles Odes*, and followed it two years later with an exotic romance, *Bug-Jargal*, developed from a short story written in 1819. In 1826 he also published *Odes et ballades*, an enlarged edition of his previously printed verse, the latest of these poems being brilliant variations on the fashionable Romantic modes of mirth and terror. The youthful vigour of these poems was also characteristic of another collection, *Les Orientales*, which appealed to the Romantic taste for Oriental local colour and to sympathy for the Greek War of Independence and was an instant success. Hugo here displayed such technical mastery that some critics, Sainte-Beuve among them, regarded the book as nothing more than "a splendid throne raised to the honour of pure art"—a judgment in which the modern reader can share. Yet it can also be remarked that the poet, skillfully employing a great variety of metres in his verse and using ardent and brilliant imagery, was gradually shedding the legitimist royalism of his youth. It may be noted, too, that "Le Feu du Ciel," a visionary poem, forecast those he was to write 25 years later. The fusion of the contemporary with the apocalyptic is a particular mark of Hugo's genius.

The preface to *Cromwell*

Hugo emerged as a true Romantic, however, with the publication in 1827 of his verse drama *Cromwell* and a once-famous preface. The subject, with its near-contemporary overtones, was that of a national leader risen from the people who sought to be crowned king; but the play's reputation rested largely on the long, elaborate preface, in which Hugo proposed a doctrine of Romanticism that for all its intellectual moderation was extremely provocative. He demanded a verse drama in which the contradictions of human existence—good and evil, beauty and ugliness, tears and laughter—would be resolved by the inclusion of both tragic and comic elements in a single play. Such a type of drama, which abandoned the formal rules of classical tragedy for the freedom and truth to be found in Shakespeare, would provide a vantage point from which to view history and men. *Cromwell* itself, though immensely long and almost impossible to stage, was written in verse of great force and originality.

Success (1830–51). The defense of freedom and the cult of an idealized Napoleon in such poems as the ode "À la Colonne" and "Lui" brought Hugo into touch with the liberal group of writers on the newspaper *Le Globe*, and his move toward liberalism was strengthened by Charles X's restrictions on the liberty of the press as well as by the censor's prohibiting the stage performance of his play *Marion de Lorme* (1829), the story of a courtesan purified by love, in which the character of Louis XIII was portrayed unfavourably. He immediately retorted with *Hernani*, the first performance of which, on February 25, 1830, gained victory for the young Romantics over the traditional Classicists in a literary battle that became known as the "battle of *Hernani*." In this play he extolled the Romantic hero already sketched in the character of Didier in *Marion de Lorme:* the noble outlaw at war with society, dedicated to a passionate love and driven on by inexorable fate. The actual impact of the play owed less to the plot than to the sound and beat of the verse, softened only in the elegiac passages spoken by Hernani and Doña Sol. The triumph of *Hernani* was due to the student audience, for it was an homage from a youth to youth.

Hugo had derived his early renown from his plays; he gained wider fame in 1831 with his historical novel *The Hunchback of Notre-Dame*, an evocation of medieval life under the reign of Louis XI. The novel condemned a society that, in the persons of Frollo the archdeacon and Phoebus the soldier, heaped misery on the hunchback Quasimodo and the gypsy Esmeralda. The theme touched the public consciousness more deeply than had that of his previous novel, *Le Dernier Jour d'un condamné* (1829), the story of a condemned man's last day, in which Hugo launched a humanitarian protest against the death penalty. He later renewed this theme in *Claude Gueux* (1834). While *Notre-Dame* was being written, Louis-Philippe, a constitutional king, had been brought to power by the students and the liberal bourgeois in the three days of the July Revolution. Hugo composed a poem in their honour—*Dicté après juillet 1830;* it was a forerunner of much political verse.

Four books of poems came from Hugo in the period of the July monarchy: *Les Feuilles d'automne* (1831), intimate and personal in inspiration; *Les Chants du crépuscule* (1835), overtly political; *Les Voix intérieures* (1837), at once personal and philosophical in tone; *Les Rayons et les ombres* (1840), in which the poet, renewing these different themes, indulged his gift for colour and picturesque detail. Hugo was not content merely to express personal emotions; he wanted to be the "sonorous echo" of his time and thus to fulfill the poet's function as he saw it. Political and philosophical problems were integrated with the religious and social disquiet of the period; one poem evoked the misery of the workers, another praised the efficacy of prayer. He addressed many poems to the glory of Napoleon, though he shared with his contemporaries the reversion to republican ideals. Independent of party and church, he restated the problems of his century and the great human questions always asked by man, and he spoke with a warmhearted eloquence and reasonableness that moved men's souls. Such was his influence that he even gained an admirer at court: the young Duchess of Orléans, whose protection he enjoyed after 1837.

Dramatic works

So intense was Hugo's creative activity during these years that, having at last achieved a stage production of *Marion de Lorme* in 1831, he continued to pour out plays. There were two motives for this: first, he needed a platform for his political and social ideas, and, second, he wished to write parts for a young and beautiful actress, Juliette Drouet, with whom he had begun a liaison in 1833. Juliette had little talent and, perhaps persuaded by her lover, soon renounced the stage in order to devote herself exclusively to him, becoming the discreet and faithful companion she was to remain until her death in 1883. The first of these plays was another verse drama, *Le Roi s'amuse* (1832), set in Renaissance France and depicting the frivolous love affairs of Francis I while antithetically revealing the noble character of his court jester. This, like *Marion de Lorme*, was at first banned but was used by Giuseppe Verdi as the libretto of his opera *Rigoletto*. Three prose plays followed: *Lucrèce Borgia* and *Marie Tudor* in 1833 and *Angelo, tyran de Padoue* in 1835. *Ruy Blas*, a play in verse, appeared in 1838. The hero, Ruy Blas, becomes prime minister of Spain, wins the love of the queen, and institutes various social reforms. But there is more to this play than its romantic theme of a lowborn poet's passionate love of a queen; the whole piece is filled with the democratic faith and the ideals of reform for which the hero is the author's spokesman. The historical and geographical diversity of the plays is striking and was emphasized by Hugo himself when he came to classify his works on a basis of epochs and countries. Germany, he realized, was absent, and he filled the gap by writing *Le Rhin* in 1842, a book of travel composed of letters written during a series of journeys in the Rhine valley (1839–40), and *Les Burgraves* the following year. An attempt to portray greatness and decadence in German medieval history, *Les Burgraves* emerged as an epic melodrama and a vivid theatrical extravaganza that was hissed off the stage. The failure of *Les Burgraves* interrupted Hugo's career as a dramatist; exile and preoccupation with other tasks discouraged him from writing for the stage, though from time to time he composed the plays, giving rein to his fantasy, that make up the posthumous volume *Théâtre en liberté*, published in 1886.

Hugo's literary achievement was recognized in 1841 by his election, after three unsuccessful attempts, to the Académie Française and by his nomination in 1845 to the Chamber of Peers. From this time he almost ceased to publish, partly because of the demands of society and political life but also as a result of personal loss: his daughter Léopoldine, recently married, was accidentally drowned with her husband in September 1843. He was travelling with Juliette Drouet when it happened and learned the news from a paper. His intense grief found some mitigation in poems that later appeared in *Les Contemplations*, a volume that he divided into "Autrefois" and "Aujourd'hui," the moment of his daughter's death being the mark between yesterday and today. He found relief above all in working on a new novel, which became *Les Misérables*, published in 1862 after work on it had been set aside for a time and then resumed. Other distractions were a liaison with the wife of an artist, Léonie Biard, herself a writer, and, because of his close friendship with Louis-Philippe and his daughter-in-law, the Duchess of Orléans, an assiduous attendance at court festivities. It seemed as if he wished to forget his personal sorrows and the menace of social unrest, but in fact his writings both in verse and prose reflect his troubled mind, and it was in his grief that his genius matured.

Hugo's political intuition was confirmed when the revolution of February 1848 was seen to be less political than social in its aims, as compared with that of 1830. Hugo's plan to form a regency under the Duchess of Orléans was unsuccessful, and he entered the political arena of the Second Republic, first as a deputy for Paris in the Constituent Assembly and later in the Legislative Assembly, where he upheld his ideals of education for all and the well-being of the people. Such aspirations and his loyalty to the name of Bonaparte led him to support the candidature of Prince Louis-Napoléon for the presidency in 1848. The more the President evolved toward an authoritarianism of the right, however, the more Hugo moved toward the assembly's left. When in December 1851 a coup d'etat took place, which eventually resulted in the Second Empire under Napoleon III, Hugo made one attempt at resistance and then fled to Brussels.

Political life

Exile (1851–70). His exile was to last until the return of liberty and the reconstitution of the republic on September 4, 1870. Enforced at the beginning, exile later became a voluntary gesture and, after the amnesty of 1859, an act of pride. He remained in Brussels for a year until, foreseeing expulsion, he took refuge on British territory. He first established himself on Jersey, where he remained from 1852 to 1855. When he was expelled from there he moved to the neighbouring island of Guernsey.

Satire and historical works

Immersed in politics as he was, he devoted the first writings of his exile to satire and recent history: *Napoléon le Petit* (1852), an indictment of the "little Napoleon" (Napoleon III) as opposed to the "great" (Napoleon I), and *Histoire d'un crime*, a day-by-day account of Louis Bonaparte's coup as seen by a dissentient witness. His return to poetry was an explosion of wrath: *Les Châtiments* (1853). This collection of poems unleashed his anger against the new emperor as well as, on a technical level, it freed him from his remaining classical prejudices and enabled him to achieve the full mastery of his poetic powers. During this exile of nearly 20 years he produced the most extensive part of all his writings and the most original. It was accomplished in virtual solitude—his only companion, except for his family and the ever-faithful Juliette, was the restless sea. *Les Châtiments* ranks among the most powerful satirical poems in the French language. The ironic section titles parody the claims of the new leader in his attempt to justify the coup—"Society is saved," "Order is Re-established," etc. On the other hand, Bonaparte is presented as a thief and a killer. All Hugo's future verse profited from this release of his imagination: the tone of this collection of poems is sometimes lyrical as in "Stella," sometimes epic as in "L'Expiation," sometimes moving as in "Souvenir de la nuit du 4," most often virulent as in "Nox" and such poems in which Hugo heaps outrage on the ruler of France in an impassioned rhetoric. The inspiration behind *Les Châtiments*, with its undertone of national and personal frustration, was borne out by a poetic breath that was to be sustained and developed in all his subsequent work, however flawed by repetition and blemishes that inevitably go with it.

Despite the satisfaction he derived from his political poetry, Hugo wearied of its limitations and, turning back to the unpublished poems of 1840–50, set to work on a volume of "pure poetry," *Les Contemplations* (1856). In the meantime, however, he had become obsessed with the preternatural, or the *surréel*, as he called it: table turning, dreams, knockings, and other such phenomena were recorded in the private notebooks. *Les Contemplations* contains the purest of his poetry—the most moving because the memory of his dead daughter is at the centre of the book, the most disquieting, also, because it transmits the haunted world of a thinker. In poems such as "Pleurs dans la nuit" and "La Bouche d'ombre," he reveals a tormented mind that struggles between doubt and faith in its lonely search for meaning and significance.

The apocalyptic approach to reality dominated the poet's inspiration; it was the source of those epic or metaphysical poems for which there has been growing admiration among modern readers: *La Fin de Satan* and *Dieu*—poems of vast scope, the first a tapestry of resplendent visions, the second tense with urgent debate, both of them confrontations of the problem of evil. Written between 1854 and 1860, they were not published until after his death because his publisher preferred the little epics based on history and legend, the "Petites Épopées" of *La Légende des siècles* (1859). These, which for Hugo himself formed a single poem with the metaphysical epics, are the summit of his art; they display all his spiritual power without sacrificing his exuberant capacity to tell a story. Hugo's personal mythology of the human struggle between good and evil lies behind each of the legends: Eve's motherhood is exalted in "Le Sacre de la femme"; mankind liberating itself from all religions in order to attain divine truth is the theme of "Le Satyre"; and "Plein Ciel" proclaims, through utopian prediction of men's conquest of the air, the poet's conviction of indefinite progress toward the final unity of science with moral awareness. Hugo was a prophet of the modern world at a moment when his century was foundering in religious disbelief.

Yet he was prudent enough not to overtax his readers' comprehension. After the publication of three long books of poetry, he turned to prose and took up his abandoned novel, *Les Misérables*. Its extraordinary success with readers of every type when it was published in 1862 brought him instant popularity in his own country, and its speedy translation into many languages won him fame abroad. The plot, that of a detective story, is as well the epic of the people of Paris. Its author claimed it as a "religious" work; and indeed by means of its characters, sometimes a little larger than life yet always vital and engaging, and by its re-creation of the swarming Parisian underworld, the main theme of man's ceaseless combat with evil clearly emerges while the whole gives a faithful picture of the ebb and flow of life. Hugo relives his youth in this vast novel, and the ordinary reader can still be moved by its author's search for justice; even the more critical can admire the novel's complex structure, in spite of lengthy digressions in the narrative.

Success of *Les Misérables*

When the translation of Shakespeare's works by his son François-Victor was nearing its end, Hugo wrote a preface. It became an essay, *William Shakespeare*, published for Shakespeare's tercentenary (1864), in which he elaborated his theory of the poetic imagination as divided between light and darkness, joy and grief. The experience of the great dramatist, he believed, confirmed his own. In this essay, Hugo developed a hierarchy of human genius—Job, St. Paul, Dante, Cervantes, Shakespeare—that went beyond the customary classifications, and there is little doubt that he saw himself in these ranks. Two novels also showed this tendency toward the grandiose: *Les Travailleurs de la mer* (1866), dedicated to the island of Guernsey and its sailors, the "toilers" of

the sea; and *L'Homme qui rit* (1869), a curious baroque novel about the English people's fight against feudalism in the 17th century, which takes its title, "the man who laughs," from the perpetual grin of its disfigured hero. His last novel, *Quatrevingt-treize*, planned at the same period but finally written in Guernsey in 1873, centred around the tumultuous year 1793 in France and portrayed human justice and charity against the background of the French Revolution. These were not the only works of his exile; on his return to France he left behind many manuscripts that were to be published later.

Return to Paris

Last years (1870–85). The defeat of France in the Franco-German War and the proclamation of the Third Republic brought Hugo, faithful to his vow, back to Paris. He agreed to play his part in public affairs as a deputy in the National Assembly (1871) but resigned the following month. Though he still fought for his old ideals, he no longer possessed the same energies. The trials of recent years had aged him, and there were more to come: in 1863 his daughter Adèle had eloped to America, and nine years later she returned to France insane; in 1868 he had lost his wife, a profound sadness to him after their many years together; in 1871 his son Charles died and in 1873, François-Victor. Increasingly detached from life around him, the poet of *L'Année terrible*, in which he recounted the siege of Paris during the "terrible year" of 1870, had become a national hero. He went on with his task, his gaze fixed on the horizons closing in. He had his grandchildren, Georges and Jeanne, for whom he wrote genial verse on the art of being a grandfather, *L'Art d'être grand-père* (1877). In March 1871, outraged by the terms of the peace treaty after the siege, insurrectionists seized power in Paris and established a council called the Commune, which was not suppressed until the end of May. The episode of the commune, which met with Hugo's disapproval, found him once more at Brussels, and he was again expelled for giving shelter to the defeated rebels. After a temporary refuge in Luxembourg he returned to Paris, where he was elected senator. During 1872–73 he was in Guernsey for the writing of *Quatrevingt-treize* and the preparation of his remaining works for publication. In 1878 he was stricken by cerebral congestion, but he lived on for some years in the Avenue d'Eylau, renamed Avenue Victor-Hugo on his 80th birthday. Two years after the death of Juliette, his faithful companion, he died on May 22, 1885. He was given a national funeral, lay in state under the Arc de Triomphe, and was buried in the Panthéon, having been taken there in a pauper's hearse as he had wished.

Reputation. Hugo's enormous output is unique in French literature; it is said that he used to write each morning 100 lines of verse or 20 pages of prose. "The most powerful mind of the romantic movement," as he was described in 1830, laureate and peer of France in 1845, he went on to assume the role of an outlawed sage who, with the easy consciousness of authority, put down his insights and prophetic visions in great prose and verse, becoming at last the genial grandfather of popular literary portraiture and the national poet who gave his name to a street in every town in France.

This instinctive recognition of Hugo as a great poet at the time of his death was followed by a period of critical neglect. A few of his poems were remembered and *Les Misérables* continued to be widely read; his poetic art was prized by the few; only the generosity of his ideas and the warmth of their expression still moved the public mind. What the novelist François Mauriac has called "the heroism of banality" made him a poet of the common man, because he knew how to write with simplicity and power of common joys and sorrows. There was another side to this people's poet—what Paul Claudel called his "panic contemplation" of the universe, the numinous fear that penetrates the sombre poems of the 6th book of *Les Contemplations*, *La Fin de Satan*, and *Dieu*. He knew, as the poet Charles Baudelaire wrote of him, how to evoke the ambience of mystery. His knowledge of the resources of French verse and his technical virtuosity in metre and rhyme, moreover, rescued French poetry from the sterility of the 18th century. The poets who succeeded him—Baudelaire, Rimbaud, Claudel, Apollinaire—are indebted to his vast poetic experience.

André Gide, when asked whom he considered the greatest French poet, replied "Victor Hugo, alas," explaining that if it was a regrettable fact at least it was fact. The time has come to replace this ambiguous verdict by that of another poet, Léon-Paul Fargue: "Victor Hugo, un poète d'avenir," which might be translated as "a poet who has time on his side." Poet of the real and the surreal, Hugo must be accepted whole.

MAJOR WORKS

POETRY: *Odes et poésies diverses* (1822); *Nouvelles Odes* (1824); *Odes et ballades* (1826, enlarged 1828 to include earlier poems and collections); *Les Orientales* (1829); *Les Feuilles d' automne* (1831); *Les Chants du crépuscule* (1835); *Les Voix intérieures* (1837); *Les Rayons et les ombres* (1840); *Les Châtiments* (1853); *Les Contemplations* (1856); *La Légende des siècles* (3 series: 1859, 1877, 1883); *Les Chansons des rues et des bois* (1865); *L'Année terrible* (1872); *L'Art d'être grand-père* (1877); *Les Quatre Vents de l'esprit* (1881). Posthumously published poems and collections include the unfinished *La Fin de Satan* (1886, written 1854–60) and *Dieu* (1891, written 1855); *Toute la lyre* (1888, 2 series; 1893, 1 series); *Les Années funestes, 1852–1870* (1898).

NOVELS: *Han d'Islande* (1823); *Bug-Jargal* (1826); *Le Dernier Jour d'un condamné* (1829); *Notre-Dame de Paris* (1831); *Claude Gueux* (1834); *Les Misérables* (1862); *Les Travailleurs de la mer* (1866); *L'Homme qui rit* (1869); *Quatrevingt-treize* (1874).

DRAMA (POETIC): *Cromwell* (1827); *Marion de Lorme* (written 1829); *Hernani* (1830); *Le Roi s'amuse* (1832); *Ruy Blas* (1838); *Les Burgraves* (1843). (PROSE): *Amy Robsart* (1828, from Sir Walter Scott's novel *Kenilworth* of 1821); *Lucrèce Borgia* (1833); *Marie Tudor* (1833); *Angelo, tyran de Padoue* (1835). *Théâtre en liberté* (posthumously 1886, collects plays written 1854 onward).

PROSE (CRITICAL): The preface to *Cromwell* (1827); *Littérature et philosophie mêlées* (1834); *William Shakespeare* (1864). (POLITICAL): *Napoléon le petit* (1852); Histoire *d'un crime* (1877, written 1852); *Actes et paroles*, 4 series: 1, *Avant l'exil*, 1841–51; 2, *Pendant l'exil*, 1852–70; 3 and 4, *Depuis l'exil*, 1870–85 (collection of articles, essays, etc., from papers and periodicals). (DESCRIPTIVE): *Le Rhin* (1842); *Alpes et Pyrenées* (posthumously 1890); *La France et la Belgique* (posthumously 1894). The posthumous *Choses vues*, 2 vol. (1887–99), contains descriptive pieces, notes, and observations.

TRANSLATIONS: An edition of the *Works of Victor Hugo*, 10 vol., was published in 1907. Many translations from Hugo's poems were made during the 19th century, none satisfactory. Selected *Poems*, ed. by Alfred T. Baker, appeared in 1934; *Selected Prose and Verse*, ed. by W.G. Hartog, in 1927. In 1899 a work entitled *The Novels of Victor Hugo: Complete and Unabridged* was published, and there have since been many adequate translations of individual novels, especially of *Les Misérables* and *Notre-Dame de Paris* (including a 1956 version of the latter by Lowell Blair, under the book's usual English title of *The Hunchback of Notre Dame*). *The Dramas of Victor Hugo*, 4 vol., trans. by I.G. Burnham, was published in 1895–96. In 1964 *Choses vues* was translated as *Things Seen*, by David Kimber.

DRAWINGS: The main collection is in the Musée Victor-Hugo, Paris. It consists of some 350 drawings in many media. They range from the naturalistic representations of buildings and places of his early period, through a more visionary group dating from 1848–50 (among them "La Vue de Paris," "Les Trois Arbres," and "Le Burg à la Croix") to the anticipations of Surrealism of the period *c.* 1853–*c.* 1871. Many drawings of this period are in albums, or on the pages of the manuscripts of Hugo's writings, in the Bibliothèque Nationale, Paris.

BIBLIOGRAPHY. E.M. GRANT, *Victor Hugo: A Select and Critical Bibliography* (1967); and *The Career of Victor Hugo* (1945), a good all-around study in English; J.B. BARRERE, *Hugo, l'homme et l'oeuvre*, 7th ed. (1969), a standard one-volume study for the student and scholar; and *La Fantaisie de V. Hugo*, 3 vol. (1949–60), a thorough exploration of Hugo's imagination in its happy mood; ANDRE MAUROIS, *Olympio ou la vie de V. Hugo* (1954; Eng. trans., *Victor Hugo*, 1956), the best biography for the layman, better in its first half; PIERRE ALBOUY, *La Création mythologique chez Victor Hugo* (1964), a thorough study of Hugo's epic and myths; JEAN GAUDON, *Le Temps de la contemplation . . ., 1845–1856* (1969), a brilliant study of Hugo's imagination in its darker shades.

(J.-B.Ba.)

Human Behaviour, Development of

The essential phenomena of human development are enlargement and change. Bone, muscle, and fat become larger and heavier but retain the same basic structure throughout life. In contrast, psychological processes (including observable behaviours) undergo major changes during the first dozen or so years of life. Delineation of these changes deserves close attention for a number of reasons. First, knowledge of how a structure develops aids in understanding how that structure functions in its mature state. For example, the sociological principles that describe how contemporary cities function throughout the world are different from the principles describing how those cities grew to their current size and form.

Similarly, an understanding of the psychological functions of an adult is facilitated if one knows how the adult developed. Second, the organization of motives, beliefs, anxieties, skills, defenses, and cognitive functions varies with age. Attempts to teach a child a new skill should acknowledge the organization of his abilities at that time. Finally, appreciation of developmental change can serve the practical need to predict the quality of a child's adult behaviour and to anticipate possible personality disturbance from knowledge of a child's life experiences. Many developmental theorists assume that what is learned in childhood directs future behaviour and provides a thread of continuity in human development. It is also assumed that there are especially sensitive periods in development and that experiences during these periods are most likely to predispose the individual to develop particular ways of acting as an adult.

Sensitive periods

The notion of sensitive periods implies that specific psychological processes are changing rapidly during particular phases of development and that environmental changes that intrude during a sensitive period are likely to alter the course of the behaviour or structure undergoing development at that time. The term sensitive period refers to those times when an event has its most dramatic influence on a specific psychological process. Examples of sensitive-period phenomena in human development are not as frequent as they are in the development of other animals. One example comes from the child's physical growth. The first three years of life roughly constitute the period of most rapid growth in stature; this is also the time when quality of diet exerts a maximal effect on eventual adult height. There is a coincidence of the phase during which stature is developing most rapidly and the time when stature is most vulnerable to environmental deficiency. Many psychologists regard the first few years of life as a sensitive period for the establishment of a trusting attachment to adults.

Contrasting conceptions of development

AREAS OF CONTROVERSY

The child as active or passive

Basic philosophical differences regarding the fundamental nature of children and their growth are found among psychologists. One dimension of controversy involves the degree to which a child is viewed as active or passive in response to his setting. In the English empiricist tradition (of which 17th-century philosopher John Locke is called the father) the child is seen as a passive product of environmental forces, his behaviour being molded by empirical, sensory experience. According to the continental tradition (of which the 18th-century moralist Jean-Jacques Rousseau was an exemplar) a child is regarded as actively manipulating and engaging his environment, trying to mold it to his skills, and attempting to understand it in terms of his current information. The psychological doctrines called behaviourism and psychoanalysis include views that regard the child as passive; while in the theories of Swiss psychologist Jean Piaget children are considered as active.

A second controversy pivots on the degree of continuity to be expected in psychological development. Does a child's behaviour progress continually, by gradual accretions, without sudden dramatic shifts? Or is the course of developmental progress steplike and segmented into stages? The term stage in psychological theory has no explanatory value but implies that the psychological function or behaviour is different during different stages. Most stage theories assume that each child must pass through successive stages in a fixed order. Some psychoanalytic theories, for example, indicate a fixed sequence of focal points for psychosexual developments, beginning with what is called the oral stage and progressing through anal, phallic, and genital stages. Piaget's theory states that each child passes from a sensorimotor stage (of relatively primitive coordination of perception and action) through a concrete operational stage in thinking to a final stage of formal operations (characterized by abstract thinking).

Most stage theories in psychology are descriptive rather than explanatory, for they lack an explicit set of rules that indicate the mechanisms by which a child progresses from one stage to the next. Behaviourism, one approach that does not make use of such stage concepts, is concerned with processes that produce changes in behaviour.

Idealized goals versus open-ended development

Another controversy turns on whether development proceeds toward an idealized goal, in contrast to being an open-ended program, much like biological evolution, with no special terminal state defining the goal of growth. Sigmund Freud and Piaget may be understood in such ideal terms, Freud suggesting that, at psychological maturity, the adult would have invested his libidinal energy (the energy of the sex drive) in a love object so that his anxiety over sexuality would be minimal. Piaget wrote that a capacity for logical reasoning is the goal of development; this suggests that when an adolescent can test hypotheses and solve problems in a systematic manner, he has reached the final stage of formal operations. Behaviourism and what is called modern cognitive theory, by contrast, do not conceptualize development as proceeding in a specific direction. A child is understood to acquire beliefs and responses, but no specific end point is defined as being fundamentally more mature or desirable than another; and no developmental goals are perceived as being independent of the culture in which the child is growing.

Most psychologists at least implicitly take a theoretical position on each of these dimensions. The discussion to follow is dominated by the view that each child is active rather than passive, that there are stages in development, but that there is no idealized goal independent of environmental needs and pressures.

In retrospect, theories of human development seem to have been neither logically rigorous nor to have attempted to account for both intellectual and motivational phenomena. Historically, major personality theories approaching the motivational development of the child have included psychoanalytic theory and social learning theory. Influential theorists of intellectual development have been Piaget and Heinz Werner.

PERSONALITY THEORIES

Psychoanalytic stages

There are critical differences between the conceptions of psychoanalytic and social learning theories with respect to the emergence of individual differences in children. Psychoanalytic theory, as first offered by Freud, assumes that the child passes through a series of stages hopefully culminating in an idealized adult state characterized by low anxiety, capacity for sexual satisfaction, effective defenses against stress, and an ability to love and work. It is a major tenet of psychoanalytic theory that the source of energy (that underlies such basic drives as sex) changes as development proceeds.

Thus, during the first postnatal year, excitation is held to focus on the mouth; infants indeed apparently obtain gratification through a reduction of excitation in the oral regions. Expectably, in psychoanalytic theory, this period is called the oral stage of development. During the second year the source of excitation is said to shift to the anal area, and new objects and behaviours are believed to bring gratification as the child enters this so-called anal stage. During the pre-school years, the source of excitation is expected to shift to the genitals, but not yet

in a fully heterosexual sense. Freud called this the phallic period of development. During the final and so-called genital stage of development, gratification is said to be sought in a love relationship with another.

A second important Freudian principle states that although id impulses are constantly directed toward gratification of the major drives of the organism, ego and superego functions act to set limits on this process. In Freud's language, as the child grows the reality principle gradually begins to control the pleasure principle; the child learns that the environment does not always permit immediate gratification. Development is primarily concerned with the emergence of so-called ego functions, those that are held to be responsible for the acquisition of behaviours, beliefs, and controls that channel the discharge of fundamental drives through thinking and via defense mechanisms.

Social learning theory

Social learning theory takes a more relativistic and arbitrary stance with respect to idealized notions of adult maturity. Social learning theory is concerned with identifying those mechanisms that can be offered to explain differences in behaviour, motives, and values among children. Its major principles stress the effects of external reward and punishment (administered by parents, teachers, and peers) on the child's tendency to adopt the behaviours and values of others. Also, this theory differs from psychoanalysis with respect to primary focus. Psychoanalytic theory is concerned with inferred internal processes surrounding motives, fears, and defenses, and only secondarily with behaviour. Social learning theory primarily is directed to the overt actions of the child, and less to inner mechanisms. As a result, while the principles and concepts of the theories differ, they often may be complementary rather than contradictory.

THEORIES OF INTELLECTUAL DEVELOPMENT

Piaget and Werner both postulated ideal states of intellectual development toward which the child is supposed to be progressing. Piaget's theory is the more detailed and rests on the fundamental notion that the child develops through stages until he arrives at a stage of thinking that resembles that of an adult from one of the western cultures. The five stages given by Piaget (and characterized below) are: (1) the sensorimotor stage from birth to 18 months; (2) the intuitive stage of primitive reasoning from 18 months to 3 years; (3) the preoperational stage from 3 to 7 years; (4) the concrete-operational stage from 7 to 12 years; and (5) the stage of formal operations that characterizes the adolescent and adult.

Piaget's stages

Most research and theoretical concerns have been focused on the last three of Piaget's stages. Prior to the concrete-operational stage the child seems unable to reason about several important classes of problems, even though he may have adequate language function. These problems include those that require the ability to represent a series of actions conceptually. Only when he becomes a concrete-operational child can he think representationally of a route he might take to a friend's house. The concrete-operational child shows what is called the ability to conserve; he states that liquids and solids do not change their amount or quantity merely because their external shape changes. In addition, concrete-operational children understand relational words such as darker, bigger, and larger, and cease to think about them in absolute terms. Such a child is able to reason simultaneously about the whole and about part of the whole. If a five-year-old child is shown eight yellow candies and four brown candies and is asked, "Are there more yellow candies or more candies?," he is likely to say, "More yellow candies," evidence that he cannot reason about a part and a whole simultaneously. But a child at Piaget's stage of concrete operations answers this question correctly. He also can organize objects along a quantified dimension; this is called serialization.

Piaget characterized the stage of formal operations, beginning at about age 12, as revealing the adolescent's ability to think about hypothetical problems that are not necessarily in accord with his experience. He shows willingness to think about possibilities. The adolescent is said to generate a number of possible solution hypotheses to a particular problem. Consider the following: A man was found in the back seat of a car that had hit a telephone pole. What happened? A child who conformed to Piaget's stage of concrete operations might think up one reasonable answer that satisfied him and state it. The older child typically would generate more than one of the possible ways this event might have happened, and then select the one that seemed the most logical. The adolescent's thinking tends to be self-consciously deductive and resembles that of a scientist. Piaget's stage of formal operations (typical of adolescents and adults) is basically an orientation toward problem solving, reflecting a tendency to isolate the elements of the problem and systematically to explore possible solution hypotheses, regardless of how they match what is called reality. Formal thinking is rational and systematic. Finally, the adolescent often broods about his own thinking and is self-conscious about his introspections.

Werner's theory

Werner's theory, which has had considerably less influence than that of Piaget, is that development proceeds from a state of relatively global, undifferentiated ability to a state of increasing articulation, differentiation, and integration. Although this idea makes intuitive sense, recent research indicates that the young infant is more differentiated than Werner would have led us to expect. Differentiation refers to a differentiation of functions. Initially all parts of the organism, according to Werner, operate in a similar way and only gradually does each assume different functions. Werner wrote that the child's thinking becomes more discrete, more analytic, and more flexible as he matures. Werner suggested that the same objective solution to a problem can be brought about by different functions: this is in contrast to Piaget, who posited only one principle of solution to certain problems. Werner emphasized how the child generates hypotheses and remains flexible; Piaget stressed the gradual attainment of a single hypothesis. Finally, Werner tended to be more concerned with language than was Piaget, and assigned language a more vital part in the child's subjective life.

Development before and at birth

INFLUENCE OF THE PRENATAL ENVIRONMENT

Periods of the ovum, embryo, and fetus

Development during the roughly 40 weeks prior to normal human birth is divisible into three phases. The first, which may be called the period of the ovum, lasts from fertilization until the time the fertilized egg is implanted in the wall of the uterus, a process that typically takes 10 to 14 days. A second phase, lasting from the second to the eighth week after conception, is called the period of the embryo, and is characterized by differentiation of the major organs that normally are present in the newborn. The last phase, from the eighth week to delivery, called the period of the fetus, is characterized by dramatic growth in the size of the organism.

Prenatal development is extremely rapid; by the 18th day the embryo already has taken some shape and has established a longitudinal axis. By the ninth week the embryo is about an inch long; face, mouth, eyes, and ears have begun to take on a well-defined form; arms, legs, hands, feet, and even fingers and toes have appeared. The sex organs, along with muscle and cartilage, have begun to form. The internal organs have a definite shape and assume some primitive function. The period of the fetus (from about the second month until birth) is characterized by increased growth of the organism and by gradual assumption of physical functions. At 32 weeks the normal fetus is capable of breathing, sucking, and swallowing, and by 36 weeks can show a response to light and sound waves.

Since prenatal environment is not the same for all fetuses, such variations can lead to differences in development. Factors related to these variations include the age of the mother, maternal diet, drugs, radiation, and disease. Even maternal emotional states may influence the infant: for example, extreme maternal anx-

iety during pregnancy seems to increase the chances of difficult labour and delivery.

THE BIRTH PROCESS

Hypoxia and prematurity

Major problems surrounding birth include hypoxia (partial lack of oxygen) and prematurity. Hypoxia in a newborn is most likely to injure nerve cells of the brain stem. Damage to these cells can produce such motor defects as those shown in paralysis of limbs, in tremor of face or fingers, or in an inability to use vocal muscles. The term cerebral palsy refers to a variety of motor defects associated with damage to the brain cells, usually as a result of oxygen deficiency during the birth process. Hypoxic infants commonly are unusually irritable during the first weeks of life and show more muscular tension and rigidity than do normal infants.

Prematurity also influences the child's development during the early years of postnatal life. According to one criterion, an infant born prior to 37 weeks of gestation is classified as premature. Since it is difficult to obtain information on the exact date of conception, physicians use the child's birth weight as an index. An infant with a birth weight under five and a half pounds is likely to be regarded as premature; with a birth weight under four pounds he is apt to be classified as severely premature. Worldwide data on the incidence of prematurity vary from 6 percent to 10 percent from country to country. About 7.6 percent of hospital births in the United States are categorized as premature. This figure is higher in underdeveloped countries. Premature infants remain relatively small in height and light in weight until they are about five years of age, and generally earn comparatively low scores on tests of cognitive and motor development during the first five years. However, after the child enters school, these differences tend to disappear. In the United States, most health problems associated with pregnancy and delivery are roughly four times more frequent among families with low incomes than among middle-class families.

The infant

Infancy may be defined as covering the first 18 months of life; alternatively, a child may be called an infant until he begins to speak meaningful language and is able to understand complex communications from adults. A universally accepted definition is not available. Statistical data to follow are based on body growth data provided by the World Health Organization. Average values, of course, vary from country to country and from one ethnic group to another.

BODY GROWTH

Full-term male babies tend to be slightly larger than females in all body dimensions, averaging about 20 inches tall and about 7½ pounds in weight. Body length increases by more than a third, and weight almost triples in the first year, so that by the age of 12 months the typical baby is about 28 inches high and weighs about 20 pounds. The infant's body proportions change rapidly, particularly during the second half of the first year. The total length of the head of a three-month fetus is about half the length of his body. At birth the head length is about one-quarter the body length and at adulthood only one-tenth. Bones of the body originate from soft tissue, which gradually hardens (becomes calcified or ossified). Most infant bones are incompletely ossified and, being relatively soft and pliable, are particularly susceptible to deformity. Tiny beginnings of teeth are present in the fetus at ten weeks and calcification has begun by the fifth prenatal month. The first tooth, generally the lower front, commonly erupts when the infant is about seven months of age; by one year the child has about six teeth. The newborn has all the muscles he will ever have, but they are small in relation to his size.

ENDOWMENT AT BIRTH

A newborn human being is a remarkably capable organism. From the moment he begins to breathe, he normally behaves as if he can see, hear, smell, and is sensitive to touch, painful stimulation, and changes in position. Perhaps taste is not yet functioning during the first day after birth. The newborn has a variety of reflexes, some of which serve his very survival and many of which are complex. An infant only two hours old typically will follow a moving light with his eyes, will show dilation and constriction of his pupils as darkness changes to light, will suck almost anything (*e.g.*, a finger) inserted into his mouth, and will turn his head in the same direction as the side on which his cheek or the corner of his mouth is touched. The newborn baby can cry, turn away, vomit, lift his chin from a front position, and grasp an object placed in his palm. The outer layers of the brain (cerebral cortex) tend to be incompletely functional in the newborn and only gradually assume a fuller role in the infant's behaviour during the first weeks of postnatal life. As the cortex gains function, it begins to inhibit the lower brain centres that mediate early reflexes (see Table).

Sensorimotor functions

MILESTONES DURING THE FIRST YEAR

The period of the newborn covers the first five to seven days during which the infant normally is recovering from the stresses of delivery. During the succeeding eight weeks, the child typically becomes markedly more attentive to his surroundings, and his vocalizations increase dramatically. Between eight and ten weeks after birth he apparently begins to appreciate visual depth, for he will look longer and smile more frequently at a three-dimensional face than at one shown in two dimensions. He also will seem to begin to lose interest in repetitions of the same event and to show frequent smiles to human faces. At about seven months of age the child may display signs of anxiety in response to unexpected events, especially when he is confronted by an unfamiliar adult. Between 12 and 18 months of age he commonly will show signs of walking and increased mobility, together with some understanding of language.

Visual development

The normal infant seems able to see light and colour at birth and shows signs of respectably good visual acuity. His pupils dilate and constrict to changes in brightness, he will efficiently follow a moving light with his eyes, and he shows some degree of visual accommodation (the ability to focus on near and far objects). By the age of six months his visual acuity appears comparable to that of normal adults. Evidence of duration of sustained attention in the young infant seems at first to depend on the degree of movement and contrast in the visual stimulus. Thus, stimuli with relatively sharp black and white contours and those that move will tend to elicit the most prolonged signs of attention. At about three months of age the child seems to attend most readily to stimuli that are moderately discrepant from those to which he has been accustomed. Attention appears to be attracted least when there is either a relatively small or a comparatively large discrepancy between an event and what one might infer the infant's expectation to be. During the latter part of the first year the child commonly behaves as if he has begun to think of ways in which different experiences may be classified. An unusual or discrepant event seems to provoke the child to activate hypotheses about its classification. The richer the set of hypotheses the child appears to have available to him, the longer and more sustained his attention seems to be. To summarize: the duration of the infant's visual attention is related to contrast and movement, discrepancy, and richness of his store of hypotheses for classifying sensory experiences.

Auditory perception

Normally capable of hearing at birth, a newborn is sensitive to the location of the sound source as well as to differences in the frequency of the sound wave. Low-frequency waves tend to increase motor behaviour if the child is normally alert, and to inhibit distress if the child is crying. High-frequency auditory stimuli tend to freeze motor behaviour or to elicit what seems to be a dramatic alerting reaction. Sound stimuli of a few seconds' duration have a minimal effect, while those that last 5 to 15 seconds are most apt to maximally affect the infant's

Reflexes of the Newborn

effective stimulus	reflex
Tap upper lips sharply	lips protrude
Tap bridge of nose	eyes close tightly
Bright light suddenly shown to eyes	closure of eyelids
Clap hands about 18 inches from infant's head	closure of eyelids
Touch cornea with light piece of cotton	eyes close
With baby held on back turn face slowly to right side	jaw and right arm on side of face extend out; the left arm flexes
Extend forearms at elbow	arms flex briskly
Put fingers into infant's hand and press his palms	infant's fingers flex and enclose finger
Press thumbs against the ball of infant's feet	toes flex
Scratch sole of foot starting from toes towards the heels	big toe bends upward and small toes spread
Prick soles of feet with pin	infant's knee and foot flex
Tickle area at corner of mouth	head turns toward side of stimulation
Put index finger into mouth	sucks
Hold infant in air, stomach down	infant attempts to lift head and extends legs

activity level. Newborns also are likely to become quieter when auditory stimulation is rhythmic, and intermittent patterns have a more quieting effect than does a steady sound. Contrast, discrepancy, and richness of hypotheses also seem likely to modify attention in the auditory mode.

The newborn infant can make some discrimination among odours. The typical two-week-old shows positive sucking responses to sweet substances and makes negative responses to bitter stimuli. Highly sensitive to changes in spatial position of the body, the newborn baby who is jarred or who falls from a sitting position will make energetic postural adjustments.

Many motor responses are maturational and develop with no special training. Given the opportunity to use limbs and body, every normal child will begin to creep, stand, walk, sit up, and grab objects. Most babies are able to sit for a minute or so with support at three months of age, and by eight months can sit without support. Most begin creeping at about 40 weeks and are crawling adequately by 50 weeks of age. The typical infant is standing and walking by 64 weeks of age. Maturational changes in the neuromuscular systems largely seem to determine the time at which the child will sit, stand, and walk.

Vocalization and speech

Babbling and vocal sounds are almost universal during the infancy period in normal children, and no relationship has been established between the amount of babbling during the first six months and the amount or quality of speech when the child is two years old. Vocalization in the young infant often accompanies motor activity and usually occurs when the child appears to be excited by something he sees or hears. During the second half of the first year the child often will grow quiet while apparently listening with interest and may begin to show signs of excitement by babbling when the sound ends.

Use of meaningful words differs from simple babbling in that speech primarily helps obtain goals, rather than simply reflecting excitement. The first of two basic sounds includes all those related to crying; this is present at birth. A second category, described as cooing, emerges at about eight weeks, and includes sounds that eventually become part of meaningful speech. Environmental experiences ordinarily do not begin to influence vocalization seriously before two months of age, and differences in vocalization related to social class do not emerge until about 18 to 24 months of age. During the first two months of postnatal life the vocalizations of deaf children born to deaf-mute parents are indistinguishable from those of infants born to normal parents. Environmental effects on the variety and frequency of the infant's sounds become more evident after roughly eight weeks of age. The typical child utters his first meaningful word at about one year and his first short sentences between 18 and 27 months.

Piaget stated that an infant has a set of so-called internal schemes that control his external coordinations. He identified the first phase of mental development as the sensorimotor stage; this, in turn, was held to differentiate into six subphases covering the first year and a half of life. The first four of these are said to be achieved during the first year; during the first (reported to last one month) innate reflexes become more efficient. Piaget labeled the second subphase as primary circular reactions, characterized by simple acts that are repeated for their own sake; *e.g.*, sucking, opening and closing the fists, and fingering a blanket. He attributed no intent on conscious purpose to this activity. The last four of these six initial subphases are interpreted as being more intentional. During the third (called secondary circular reactions), said to last from the fourth to sixth months, the child is described as repeating responses that produce interesting effects; for example, he may kick his legs to produce a swinging motion in a toy. In the fourth subphase (lasting from the seventh to the tenth months and called coordination of secondary reactions) the child is expected to begin to solve simple problems, building on actions he has mastered previously. Thus, he may knock down a pillow to obtain a toy hidden behind it. During the fifth (tertiary circular reactions, 11th to 18th months) he is described as carrying on trial-and-error experimentation. At this time he may change his responses toward the same object or try out new responses to obtain the same goal.

Piaget's views of infant development

The final stage of infancy, held to be achieved by the age of 18 months, is characterized as involving the invention of new ways to solve problems. By now the child is said to have developed a primitive form of representation, defined as a kind of imagery that is used to solve problems. According to Piaget, the child gradually learns during the first year that an object exists permanently, even though it is not always in view. Prior to six months of age he is not expected to behave as if objects that are out of sight continue to exist. For example, he may grab for objects he can see, but probably will not reach for objects outside his immediate visual field. However, from about nine months on he will be expected to reach for objects hidden from view if he has watched them being hidden. During the first half of the second year he even may search for objects that he has not watched being hidden, indicating an inference about their location. In the final stage he is described as searching for objects that he has not actually seen being hidden. Show such a child a toy placed in a box, put both under a cover, then remove the box and its contents and the child will search under the cover as though he inferred the location of the toy.

Social learning in the first year

The infant is born showing very few specific emotional or motivational responses to other people. But his experiences with adults during the first year presumably lay the foundation for his relationship with and later behaviour toward them. From the moment the baby is born he exhibits responses. Some are spontaneous, others are reactions to what seem to be his needs for nourishment, alleviation of pain, and warmth. The infant spontaneously scans the environment, vocalizes, sucks, smiles, cries, and thrashes. During the third and fourth month he is apt to begin to cling to objects, manipulating his own fingers, toys, and parts of his mother or nurse. Human infants, like those of other species, have many unlearned, built-in reactions that they direct at whatever interacts with them. As a result, the infant under typical conditions becomes attached to the biological mother. Each vertebrate species is provided with a special set of responses that offspring can exhibit at birth (or hatching) or very soon afterwards. Each makes these responses to the first appropriate object that the environment supplies. The objects that elicit these responses are likely to become objects of attachment for the young mammal or bird. The mother is usually the most effective stimulus for these reactions. In addition, the mother commonly provides food, alleviates discomfort, and is a source of pleasant stimulation.

In humans, important consequences of these early ex-

periences of attachment to and contentment with the mother or nurse include a generalization of responses from her to other people, and an articulated imaginary representation of her face, form, and voice. It is inferred from the infant's smile in response to a human face that the child has developed a subjective representation (or schema) of the person who takes care of him. Most four-month-old infants smile at a motionless representation of a human face. Neither movement nor voice is necessary, although facial movement and voice increase the probability that the smile will occur.

Relation between attachment and anxiety

Increasing familiarity with a specific adult seems to increase the chance that the infant will become afraid when he encounters a less familiar face. This is called stranger anxiety and even may be elicited by the father's face at the appropriate point in the infant's development. A common source of concern among fathers who have grown accustomed to smiles from the infant, this abrupt change should be welcomed and understood. It indicates that the child has developed sufficiently to distinguish one face from another.

The emergence of stranger anxiety at about seven months indicates that by this age most infants have developed a good representation of the mother's face. The infant is alerted by the relatively strange person but is too immature to do much more than cry. Five months later he usually is able to ask who the stranger is, run to his mother, or run away. Or he will have been exposed to strangers so often that he will have learned not to cry.

Another kind of infant distress called separation anxiety is elicited when the mother leaves the infant. The more closely attached the infant is to her the more likely he is to cry upon her departure. When the mother leaves such a child in an unusual or discrepant location, he is alerted and cries. As he develops he experiences more frequent separations from his mother in unusual locations and gradually seems to acquire the ability to interpret her actions, or to reassure himself of her return, and his signs of anxiety diminish. Children who do not have a particular adult devoted to their care often do not become attached to one adult, are less likely to show separation and stranger anxiety, and are less socially responsive—less likely to smile, vocalize, laugh, or approach adults. Similar behaviour has been observed in monkeys reared in isolation and in children raised in relatively impersonal institutional surroundings.

Intellectual development during the preschool and early school years

Intelligence is a murky word that resists easy definition. Many psychologists define the term as the quality of the subjective processes activated when one tries to solve a problem, to attain a desired goal, or to make sense of his experience. The development of adaptive thinking or behaviour is said to require a set of so-called intellectual units and a set of routines by which they are organized. Units or elements of thinking include what commonly are called schemata, images, symbols, concepts, and rules; these may be called cognitive units. The routines include perceiving, remembering, generating hypotheses, evaluating, and deducing; these often are called cognitive processes. To the extent that cognitive units are processed appropriately, one may be said to be thinking intelligently.

Among the many philosophical attitudes toward thinking, one view assumes that there is within each person a kind of psychological executive that continually monitors the cognitive processes, much as an architect supervises the construction of a house. An alternative view is that monitoring is a function of the units and processes themselves, analogous to the behaviour of chemicals in a beaker. The chemical units called hydrochloric acid and sodium hydroxide interact, facilitated by the process of ionization, yielding the products salt and water. No external executive or separate force watches over the beaker to guarantee the proper reaction. The reaction is understood to be inherent in the nature of the chemicals. North American psychologists generally have been friendly to the view that regards thinking as a more or less mechanistic activity. European theorists such as Piaget hold that higher-order "mental structures" organize and keep thinking adaptive, coordinated, and efficient. This view has strong intuitive appeal; although a ten-year-old child retains considerable information, he quickly selects the correct facts and applies the precise routine when asked how a bird and a fly are alike.

Units in thinking

Those who posit such cognitive units as schemata, images, symbols, concepts, and rules hasten to add that such units are not to be viewed as physical things with size or shape. Instead, they are regarded as properties or activities of the thinker, in much the same way as temperature is considered to be a property of molecules in motion. Each cognitive unit provides the child with the ability to make sense of experience, to remember past events, and to generate solutions to problems.

Schemata, probably the earliest of these to develop, are defined as abstract representations of specific events. These representations are not photographic copies or visual images but are more like schematic blueprints that emphasize the arrangement of a set of salient elements. The salient elements supply the schema with distinctiveness and differentiate it from those of similar events.

Images are reconstructions from schemata that preserve the spatial and temporal detail of the event.

Symbols represent the next level of abstraction from experience and are arbitrary names for things and qualities. Common examples of symbols are the names for letters, numbers, or objects. While a schema or image represents a specific experience, such as a sight or a sound, and preserves the relations in that experience, a symbol is an arbitrary representation of an event. The child who can name as the letter *A* a specific arrangement of three lines, and can point to *A* when asked, is said to possess the symbol for *A*. Children beyond six years of age commonly have schemata, images, and symbols for letters of the alphabet. Symbols are used in the development of other cognitive units called concepts.

A concept may be thought of as a special kind of symbol that represents a set of attributes common to a group of symbols or images. The concept defines a common attribute or meaning from a diverse array of experiences, while a symbol stands for a particular class of events. Consider a drawing of a cross. An eight-month-old is apt to represent this object as a schema or image. The three-year-old names it a cross and thereby represents it as a symbol. An adolescent may regard it as a cross of Christianity, thinks of it in relation to religion and the church, and therefore represents it as a concept. A concept is a person's way of extracting common traits from a variety of experiences. For additional discussion and other definitions see CONCEPT FORMATION.

A rule may be understood to state a relation among or between the dimensions of two or more concepts. A rule implies that the presence of one dimension is correlated with the presence of another. Consider the rule that candy is sweet. This states a relation between two concepts (candy and sweet) and describes the dimensions they share. A second meaning may be assigned to the notion of rule. A rule may be understood to state a routine or function imposed on a set of concepts to produce a new concept. Multiplication is a rule imposed on concepts called numbers to yield a new concept.

Informal rules refer to imperfect relations involving two or more dimensions. The statement that candy is sweet is an informal rule, for occasionally one finds sour candy. Most of a child's beliefs are informal rules; *e.g.*, snakes are dangerous, water is cool, men are tall.

What are designated as formal rules state relations that are asserted always to be true and specifiable. The rules of mathematics and physics are familiar examples. The formal rule $6 \times 11 = 66$ states a fixed relation between the concepts 6 and 11.

COGNITIVE PROCESSES

Cognitive processes include two very general types: undirected and directed. Undirected thinking refers to free

association, dreaming, or reverie, and includes the apparently free flow of thinking of which one is aware as he walks home or stares out the window. Directed thinking refers to activities that proceed when one tries to solve a problem that has been given to him or that he has set for himself. A normal preschool child seems to know that there may be a solution to a problem and apparently realizes when he has reached an answer. Problem-solving processes typically involve the sequence: perceiving, remembering, generating concepts, evaluating, deducing, and (under some circumstances) reporting the answer to someone.

Consider the general changes that normally occur from 3 through 12 years of age. The richness of the child's supply of symbols, concepts, and rules increases; and his tendency to rely on images in problem solving decreases. The child shows growing concern with whether his concepts and rules agree with those of other children; he may appear more apprehensive about making mistakes and his memory function may show dramatic improvement.

Perceiving

Perceiving refers to the process by which an individual selects, organizes, and initially interprets sensory impressions. To perceive is to extract information from the environment. These perceptual interpretations change with experience. As a child develops there is evidence of greater precision in recognizing similarities and differences; the child makes more differentiations among stimuli in his environment. Acquisition of language helps the child to learn by distinguishing specific features of new events. When the child gives objects distinctive names, it is easier for him to perceive them as separate and different from each other. Once he learns the words red and pink he is more likely to notice differences among objects of these two colours than if he had learned neither word or only one of them. Each event is defined by its salient elements: eyes are salient for a face; legs help define an animal; a break in the continuity of a line is a salient element for defining a letter of the alphabet.

In contrast to older children, a young child is apt to exhibit difficulty in attending to more than one event at a time. If he seems to try to listen or watch many things at once, he often appears to become confused. An adult is likely to divide his attention among competing stimuli with better efficiency. For example, adults can attend alternately to two conversations with greater efficiency than can children, who are less familiar with word sequences and who have a harder time making sensible constructions from partial sentences (see also ATTENTION).

Language

A remarkable development during the second year is the typical child's enormous progress in acquiring language. During this period he begins to relate many symbols with objects and to use words meaningfully. He understands verbal signals better and his speech becomes more complex. Available data indicate that a typical one-year-old understands only three words. By 15 months the average is 19 words and by 21 months, 118 words. At two years of age, this comprehension vocabulary contains an average of 272 words. Children in the 1970s tend to have larger vocabularies than did their counterparts of the 1940s, and they use longer clauses and sentences. In the U.S., three-year-olds in 1930 used about 3.4 words per sentence; about 25 years later children of the same age averaged 4.0 words. It is thought possible that the widespread use of radio and television, a drop in migration from other countries and in the proportion of bilingual children, and the availability of nursery schools contributed to the change.

Early forms of grammar

Ordinary verbal language has a vocabulary and grammatical rules for arranging words into meaningful sentences. Even a very young child may have a kind of grammar, although these rules for arranging words are very basic or elementary. The first words spoken at the end of the first year generally are simple labels for persons, objects, or simple actions; *e.g.*, milk, go, mommy. A child also begins to make requests or to describe the environment: "Want out," "Daddy away." Single words may stand for entire sentences. Thus, the word shoe may mean, "Take off my shoe." Eat may signify, "Can I eat now?"

At about 20 months most children begin putting a few words together to make simple statements that are abbreviated versions of adult sentences. The sentence, "That's the ball" becomes "that ball"; the sentence, "Where is the ball?" becomes "where ball?" So-called function words (as, and, at, the, his) are almost completely absent at this stage. The young child seems to have his own special, simplified set of grammatical rules for forming sentences. It consists of two classes of words: pivot words and variable words. A series of sentences might be comprised of the verb see followed by a variety of words, to produce "see hat," "see sock," "see horsey," "see boy." The pivot word is see and the noun objects are the variable words. The variable class is large and open, and consists of almost all of the child's vocabulary, except for some of the pivots. After using these pivot-variable constructions for about a half-year most children begin to utter two-word sentences in which the variable word occupies both utterance positions. Examples would be "man car," for "The man is in the car"; "car bridge," for "The car is under the bridge." These are not pivotal constructions but illustrate primitive sentence forms in which both components can be expanded.

It is not yet clear how the child acquires grammar so early and how he comes to be able to generate so many new sentences he has never heard before. His grammar does not seem to be acquired by direct training, for parents do not consistently reward grammatically correct sentences nor do they punish incorrect usage each time. His speech does not appear to be the result of direct imitation alone for he creates new, grammatically correct sentences that he does not seem to have encountered before.

Memory functions

Memory involves both the storage of traces of past experience and the retrieval of that stored information at a later time.

It is useful to distinguish between what are called short-term and long-term memory processes. Short-term memory may be defined as referring to traces available for a maximum of 30 seconds immediately after stimulation, but typically for a much shorter period. Unless such factors as heightened attention or repetition serve to transfer information from short-term traces to long-term storage, the ability to remember a specific experience may be lost forever.

One usually judges how much a child can remember by asking him to recall what he saw or heard, or by asking him to recognize selected stimuli. When he is asked to recall an event he is required to retrieve the necessary information and is given no hints. When he is asked to recognize an event he is presented with an array of information from which he is to select only that which seems familiar. Children and adults tend to perform much better when they have to recognize than when they have to recall. This difference is most dramatic in young children. Thus, a young child may only recall 3 of 50 pictures he has seen, but typically can recognize almost all of them. The young child's ability to recall is less efficient than that of the adolescent, perhaps because he has a less adequate set of cognitive units to label incoming information.

Images, symbols, and concepts seem to function metaphorically as the glue of thinking; simply naming an event tends to increase the length of time over which it is remembered. The very act of naming requires increased attention to the event and tends to facilitate rehearsal. A young child is less likely to have learned to use the trick of rehearsal. He is not likely to repeat events to himself spontaneously in an effort to aid in their storage. Remembering is a most elusive yet a most central process in thinking, and is easily disturbed when one is anxious, distracted, or fatigued.

The process of explaining

Perceiving and remembering typically are the first two processes in a problem-solving sequence. Next, one com-

monly generates possible solutions to the problem. Important steps in the effort to explain include: searching the available set of concepts and rules for precursors of an event that is not immediately understood; and checking each precursor for consistency with presently established rules or causal beliefs about the object or event. If the explanation that results contradicts an old rule, it is likely to be rejected. Finally, if the explanation is judged to match experience and does not seem to contradict old rules, it is apt to be accepted.

Critical factors in generating acceptable solution hypotheses include a set of available cognitive units appropriate to the event and the absence of a firmly held rule that contradicts the new hypothesis. Some children fail in this effort by simply being unable to think of new explanations; some encounter strongly held rules that contradict the new explanation; others seem never to feel sure their hypotheses are correct. An important change, usually observed to occur between 7 and 11 years of age, is an increasing ability to generate possible explanations of hypothetical events that violate conclusions drawn from the child's experience.

An obstacle to the adaptive use of concepts and rules by young children is their tendency to regard a concept as absolute rather than relative. When a four-year-old first learns the concept dark, he is likely to regard it as descriptive of an absolute class of colours (namely, black and other dark hues). The phrase dark yellow may make no sense to him if dark does not yet mean relative darkness. It often is difficult to teach a five-year-old to grasp both the absolute and relative aspects of a number; this involves persuading him that a concept can have more than one meaning.

Children seem to vary in the degree to which they pause to evaluate the quality of their thinking and the accuracy of their hypotheses and conclusions. Some children behave as if they accept and report the first hypothesis they produce, acting upon it with only the barest consideration of its accuracy. Others seemingly devote a long period of time to considering their ideas, and evidently censor many of their hypotheses. This dimension of difference can be seen as early as two years of age. As children mature they are likely to devote longer and longer periods of time to considering the validity of their thinking. It may be inferred that they have become increasingly afraid of making mistakes.

Deductive thinking

The complementary processes of generating hypotheses and of deductive thinking have been called the essence of problem solving. To deduce is to apply a rule to solve a problem, and a most important limiting factor in the quality of deductive activity is the child's store of rules, which increases with age. Of major theoretical interest is the question that centres on whether there are basic changes in the use of rules over the first dozen years. According to one view, the child merely learns more rules each day, storing them for future use; but it also is asserted that there is no rule too difficult for a child of any age to acquire. An alternative assumption is that some rules are too complex for young children to understand and apply. This viewpoint (vocally advocated by Piaget) assumes that there are stages in the development of reasoning.

MOTIVATIONAL DEVELOPMENT

Most children evidently think about goals they would like to attain. These ideational activities are called motivational, and the evidence is that they undergo regular changes with development.

The concept of a motive may be distinguished from that of a biological drive. A drive is definable as a state of deprivation or discomfort associated with an imbalance in the physiology of an organism. Hunger, thirst, cold, and pain are common biological drives. Each drive involves the activation of certain structures in the central nervous system, often with internal sensory experiences that are unpleasant.

As distinguished from drives, motivational activities include wishing, striving, hoping; they represent what the individual desires to experience or to possess. Such activities are cognitive and have no necessary relation to overt action. A child may have wished for many years to be able to fly but may not have taken observable steps toward attaining that goal. Motivational states can be potential or active, much as the energy of movement has a potential and a kinetic state. Most of the time a child is not aware of being motivated toward a given goal; at these times the motivational state is potential. The motivational state becomes active when some arousing event, called an incentive, stimulates the child.

Children differ in the ease with which an incentive can evoke such striving or wishing. Some are easily provoked to hope that their mothers will hug them; others rarely respond this way. Some react to being slightly frustrated by becoming motivated in a hostile manner; others require more substantial disappointment before they show hostility. The easier it is for a particular incentive to elicit a motivational response, the stronger that response tendency is said to be. Such tendencies seem to form a hierarchy; that is, at any given stage of development some incentives are more potent than others and tend to dominate the child's ideational activities. At two years of age the child's interest in a close relationship with the parent tends to dominate most other motivational preoccupations, while at 15 years of age this normally is much weaker as the adolescent strives for a satisfying heterosexual relationship (see also MOTIVATION).

Efforts toward gratification

Since subjective activities have no necessary link to overt action, factors that prompt a child overtly to attempt to gratify himself should be understood. The child first must have learned responses that are effectively gratifying. A six-year-old who strongly desires to control his older brother may not have learned how to effect this control and, therefore, will not show signs of this motivational tendency in his everyday behaviour. The child also should expect that his overt action will be successful in obtaining the goal. A five-year-old who has lived in one foster home after another, none of which responded to his requests for affection and help, is likely to stop displaying such signals and become sullen and withdrawn. The less the child expects to be gratified the less likely he will be to direct his behaviour toward attaining the goal involved.

Feelings of anxiety over displaying the goal-related behaviour also modify the link between motivational function and direct action. Many inner strivings in a two-year-old are likely to lead to behaviour aimed at gratification, ostensibly because such a young child has not learned to delay or inhibit these attempts. A normal seven-year-old, by contrast, has learned that he must delay satisfying many of his desires and may inhibit certain actions because he feels guilty or fears parental rejection.

A final factor in goal-directed behaviour is the immediate situation in which the child becomes aroused. A child who feels strong hostility toward his mother is less likely to reveal these feelings when he is sitting in a classroom than he would be if he were at home. In general, any member of the social environment reacts to and classifies each child primarily on the basis of his observable actions, rather than on his inferred motives; it is through his overt behaviour that others initially come to know him. People generally care more about whether a child hits other children than they do about his hostile thinking. More concern is shown about his observable sexual behaviour than about the quality of his sexual fantasies.

Efforts to reduce uncertainty

A basic motivational characteristic of all but the earliest phases of human development normally is the desire to keep feelings of uncertainty at a minimum. Particular classes of events have the common effect of making one seriously uncertain about the future. The feeling of uncertainty may begin when one encounters an unfamiliar situation or person, when he doubts the consequences of an action, or is unsure about being loved or rejected, about passing or failing a test, or about being fired or promoted. Thus, a child may become anxious when he is in an unfamiliar situation or when he is uncertain about the likelihood of various events and is not sure what response

to make or as yet has no response appropriate to the unfamiliar situation.

Feelings of anxiety are most likely to occur when a person does not know how to behave in an uncertain situation. Since the sources of uncertainty change as the child develops, the dominant aspects in the motivational hierarchy will change. During the first postnatal year, uncertainty about the mother's presence and a need for signs of her approval are dominant; thus, the child is said to have a strong motive for parental presence and affection. During the second year uncertainty about parental punishment becomes salient and the child is motivated to avoid parental disapproval. During the preschool years the child is apt to be uncertain about his competence and sex role. When he enters school, the major uncertainties centre on mastering school subjects and on gaining the acceptance of the other children (his peers). A primary source of uncertainty in early adolescence is the tendency to doubt one's ability to maintain a satisfactory heterosexual relationship; hence, sexual motives become dominant.

Important changes in salient motives during the first 15 years are related to changes in major sources of uncertainty. Uncertainty may prompt a person to wish for another to intervene and to reduce the unpleasant feeling of anxiety by offering affection, reassurance, advice, or money; such a person is said to have the motive for affiliation. Anxiety does not always lead to the motive for affiliation, and each can occur separately. Thus, some children may wish to be alone when anxious rather than to seek out others.

Anger and hostility

Some classes of incentive have the effect of thwarting or of threatening the child's attempts to attain desired goals. In a general sense, these conditions frustrate the child and he normally becomes emotionally (affectively) aroused; in this case the affective reaction is called anger. Other events may threaten the beliefs or values of the child and indicate that his standards are incorrect or morally reprehensible. This experience also may lead to the emotional arousal called anger. Anger has to be differentiated from the motivational state of hostility. To be hostile is to wish to inflict pain, distress, or anxiety on another person or on a substitute for (surrogate of) that person. The person to whom the hostility is directed is inferred to be the one the child identifies as the thwarting agent or the one who threatens the child's standards. Although anger and hostility often seem to occur together, they can occur separately. A five-year-old who cannot open a screen door to enter a house may become angry and may stamp his feet, but may not experience hostile wishes toward anyone at that moment.

The situations that are likely to arouse anger change as the child develops. During the first two years of life, restriction of the child's tendency to explore the environment is a major factor in eliciting signs of anger. The child is apt to become angry at the parents' efforts to force him to go to bed, to stay within fenced areas, and to keep away from attractive but fragile objects. During the preschool years, when the child is apt to be given more freedom, deprivation and postponement of specific goals typically elicit signs of anger. During the school years, when even more freedom may be granted to the child, he usually seems angered by events that threaten his standards regarding sex role, passivity, autonomy, or his acceptance by others. These values may be threatened when someone implies that the child has an undesirable set of characteristics, or when he encounters a salient person who holds values different from those he holds.

Although it usually is assumed that all aggressive behaviour is derived from hostility, this does not seem to be the case. Some behaviours that manifestly hurt people are not in the service of anger or hostility. Aggression, therefore, is defined as an action that inflicts pain, anxiety, or distress on another, and is in the service of a hostile motive or of the emotion of anger. The advantage of this definition is that it allows us to reject actions that unintentionally hurt others, and to include acts that, on the surface, appear to be culturally valued but that intentionally cause distress to another person.

Sexual motives

Most children are motivated to see and explore their own genitals and to manipulate them for pleasant sensations. The child who wants to view and explore the genitals of others may do so to satisfy a general curiosity about discrepant events. Discrepancy in physical appearance between the child's own anatomy and that of the opposite sex seems to elicit a strong motive to understand the difference. Thus, the young child's sexual motives appear, in part, to be tied to pleasant sensations derived from genital manipulation and, in part, from an effort to understand differences in sexual anatomy. They are not yet associated with the romantic interactions that adults label sexual love. As the child approaches adolescence the nature of the motive apparently changes, as does the nature of his behaviour.

Effectance motivation

Effectance motivation may be defined as a desire to master a new skill or to perfect an old one. A major basis for the effectance motive during the first three postnatal years seems to be the child's desire to match his actions and their products to an internal standard (or schema). As early as four months of age the infant is likely to smile when he studies a face that almost matches the schema he has acquired for a face. The dynamic process of matching to a schema is a pleasant experience. Similarly, the two-year-old who builds a tower may smile as the tower gradually becomes taller. The child appears to have an internal representation for the tower he wishes to build and, as his product comes closer to matching that idea, he behaves as if he experiences pleasure. The effectance motive also stems from what seems to be a desire to predict and control events. When a one-year-old discovers that hitting the keys of a toy xylophone produces varied sounds, he is likely to repeat this action many times. When he appears to be able to predict the outcome of his behaviour every time, he is apt to become bored.

The involvement generated by a challenging task seems to entail uncertainty of prediction. The challenge of many school-age games tends to be maximized when the child seems unsure of what will happen. The more varied and unpredictable the outcome, the more likely the child will be to perceive a particular game as interesting. Another possible basis for effectance motivation involves a desire for self-definition. According to this interpretation, the child wishes to know his attributes and needs to believe that he is competent in at least one skill. A particular skill is understood to have salience for the child if it is distinctive and is not possessed by everyone.

In sum, the preschool and early school years are witness to the growth of several motivational and behavioural systems. By the time the child is ready for school he normally is motivated toward affiliation, genital stimulation, instrumental help, affection, effectance, and hostility. Several factors determine whether any of these motivational tendencies will lead to observable attempts at gratification. The child's possession of behaviours that can gratify a motive, the degree of his anxiety associated with gratification, and his expectancy of gratification all influence his goal-directed behaviour. Finally, a behaviour that to the observer seems intended to gratify a specific motive may be aimed at gratifying a quite different motive. It is difficult to make absolute statements about the meaning of particular goal-oriented behaviours or to predict what behaviour will result from an inferred motive. Each child apparently possesses his private code, and more must be learned about the way he thinks if the aims of his actions are to be interpreted correctly.

MORAL DEVELOPMENT

One's morality embraces his beliefs about the appropriateness or goodness of what he does, thinks, or feels. These beliefs reflect what are called standards. The middle childhood years, from ages 5 to 11, represent a sensitive period during which moral standards typically develop at a rapid rate. According to Piaget, from the ages of 5 to 12 the child's concepts of right and wrong pass

from rigid and inflexible notions learned from his parents to a sense of equity and moral judgment that takes into account the specific situation in which a presumed moral violation has occurred. Five-year-olds commonly view lying as bad, regardless of the situation or the circumstances; with age, the child tends to become more flexible and to consider exceptions to this strict rule. His judgments become less absolute or authoritarian, and depend more on the needs and desires of members of the group within which he functions. He becomes a moral relativist in contrast to being a moral realist.

The U.S. psychologist Lawrence Kohlberg hypothesized that the child's development of moral standards passes through developmental stages grouped into three moral levels. At the early level the child is characterized as being guided by an orientation toward punishment and obedience; standards are held to be based strictly on what will avoid punishment or bring pleasure. At the intermediate level, the child is said to view moral standards as a way of maintaining the approval of others; the child is portrayed as accepting the precepts of authority. Moral standards at this level are held to rest on a positive evaluation of authority, rather than on fear of punishment. At the third level Kohlberg describes the child as viewing moral principles as obligations to others and to his individual conscience. Thus, the bases for justifying moral standards are understood to pass from avoidance of punishment, to avoidance of adult disapproval, to avoidance of self-recrimination. This progression is described as being accompanied by a progression from fear of being hurt, to anxiety over rejection, to guilt and self-derogation.

Defenses against feelings of guilt

Violations of moral standards often can produce symptoms of psychological distress. In Western culture, violation of standards surrounding hostility, aggression, dependence, sexuality, or incompetence are most likely to produce signs of anxiety and guilt. As a result, a child often erects defenses against the sources of anxiety or guilt.

Repression, which Freud called the most basic defense, is said to keep the person from being aware of ideas that make him anxious. In denial (another defense mechanism), the child insists that a situation that makes him feel anxious is not true, to the point that he believes in the accuracy of his denial. In the mechanism called projection, unacceptable feelings or impulses are acknowledged but the child attributes them to other sources. In projecting, he ascribes his own undesirable impulses or actions to other persons. The child may place the blame for injury suffered by a child he was chasing by saying, "He made me chase him. If he didn't make me chase him, I wouldn't have bumped into him." In what is called displacement, the child directs his actions toward a substitute target. The child who wishes to hit his father may displace this response to a younger sibling (brother or sister) or to a pet cat. In exhibiting signs of the Freudian mechanism of rationalization, the child offers a socially acceptable reason for his unacceptable behaviour, attitudes, or thinking. In behavioural withdrawal, a defense mechanism frequently employed by preschool children, the child simply avoids threatening situations or people.

Evidence of anxiety and fear

The importance of feelings of anxiety in the lives of school-age children is attested by the observation that almost a third of children's drawings (in response to the request that they draw the most important event in their lives), illustrate fear- or anxiety-provoking experiences. Although many childhood fears are related to direct experience with dangerous events (*e.g.*, a speeding car), or are a result of parental warnings (*e.g.*, to stay away from fire), many symbolic fears are also noted. Young children are only moderately fearful of immediate and possible dangers such as being hit by a car, but seem intensely afraid of remote or highly improbable events such as runaway lions or ghosts. When children are very anxious, they are prone to develop phobias, obsessions, compulsions, or such psychophysiological symptoms as asthma or ulcerative colitis (an intestinal disorder). Some children with initially intractable asthma experience rapid relief as soon as they are taken from their mothers to live in residential treatment centres (see PSYCHIATRIC TREATMENT, CONCEPTS OF; PSYCHONEUROSES).

THE ROLE OF THE FAMILY

Effect of parents

A child is influenced by a vast array of stimuli, including his parents, siblings, peers, teachers, and the public media. Parents and siblings (brothers and sisters) tend to have their major effect during the child's first six years; peers (fellow children) and teachers usually are most influential during the child's preadolescent period; the public media (*e.g.*, television) tend to prevail during the person's early adolescence. Parents can mold the behaviour of a child through reward, punishment, instruction, and by serving as models for the child. If he values parental acceptance and praise, these adult responses can be used to establish and maintain selected behaviour in the child. Punishment (whether it be spanking, threat of rejection, or deprivation) also produces changes in behaviour. The child's feelings of anxiety generated by anticipated punishment lead him to inhibit undesired responses and to substitute more acceptable acts. Parents also influence behaviour through instruction and by serving as models, facilitating imitation and identification.

Important dimensions of parental behaviour include what are called affection-hostility and control-permissiveness. The affectionate parent is described as accepting, approving, and understanding. The hostile parent is characterized as excessively punitive, critical, and as holding a negative view of the child. The dimension of control-permissiveness is defined by the degree to which the parent restricts the child and enforces demands on the child's sexuality, hostility, manners, neatness, orderliness, care of household goods, obedience, and so on. A child may be living with parents who are: affectionate and permissive; affectionate and controlling; hostile and permissive; or hostile and controlling. Some psychologists state that each of these classes of parent tends to produce a different kind of personality in the child. The affectionate-permissive parent is said to make the child friendly, dominant, and possessed of high self-esteem. The affectionate-controlling parent is held to favour the development of a more dependent, less friendly, less creative, more hostile child. The hostile-controlling parent is said to produce a child with strong tendencies toward feelings of guilt and one who is disposed to shyness and social withdrawal. It is stated that the hostile-permissive parent is apt to have an aggressive child who has poor control over his behaviour.

Effect of siblings

The psychological influence of siblings is likely to be felt most keenly by a child who is between three and nine years of age. Rivalry with a younger brother or sister represents a major threat to the firstborn's relationship to the mother. The secondborn child, on the other hand, is apt to perceive the older sibling as omnipotent, competent, and entitled to special privileges. Critical factors associated with being a firstborn child include the child's tendency to orient to his parents for values and to identify with parental models; he commonly exhibits anxiety over the loss of parental affection when a sibling arrives. He also tends to think of himself in a privileged role, because parents are apt to accord firstborn children special advantages. Firstborn children generally hold more standards that conform most closely to those values that parents promote than do later-born children. The firstborn child is more likely to identify with adult authority figures outside the home and is more apt to trust adults.

The later-born child tends to have a greater sense of inadequacy when he compares himself with his older sibling, especially if their age difference is less than four years and when both are of the same sex. However, the later-born child does not tend to excuse his relative incompetence as the result of being younger than his sibling. He commonly seems to assume that he should be as talented as his older brother or sister. A disadvantage in the role of the firstborn child is that he tends to experience more anxiety over loss of parental affection; he also may become more dependent in time of stress. The first-

born child is especially vulnerable to guilt over his hostility toward the second-born sibling, probably because he is not readily able to justify his resentment to the younger child.

Adolescence

PHYSICAL CHANGES IN ADOLESCENCE

Puberty refers to the first stage of adolescence during which the reproductive system matures. The bodily changes at this time result, in part, from increased amounts of gonadotropic hormone released by the pituitary gland. This hormone stimulates the sex glands (gonads: testes or ovaries) to produce sex hormones and induces the growth of mature sperm or ova. This typically is accompanied by a growth spurt, an accelerated rate of increase in height and weight. In boys, the growth spurt may begin as early as 10 years of age or as late as 13½, but usually begins at 13 years of age, with a peak between 13½ and 14 years. In girls, the growth spurt may begin as early as 8 years of age or as late as 11½, but usually begins at about age 11, two years before the boy, and reaches a peak at 11½ to 12 years of age. The impression that girls mature earlier stems primarily from the observation that girls tend to attain adult height and weight about two years earlier than do boys. Almost every part of the body undergoes some change during adolescence and many tissues increase in size. The heart beats faster and the reproductive organs increase in size. Bones grow in size, changing proportion and shape. At the same time cartilage begins to calcify, and the bones become harder, denser, and more brittle (see BONE).

The average age at which girls in temperate climates begin to menstruate (reach menarche) is about 13 years; about 97 percent of these girls reach menarche between 11 and 15 years of age. In warmer lands menstruation tends to begin earlier, and in colder countries, later. Sexual maturity in boys tends to be reached between 13 and 14 years of age, if the male's development of pigmented pubic hair is considered equivalent to the menarche in girls (see MENSTRUATION).

Major developmental tasks facing the adolescent include the establishment of personal independence, sexual adjustment, peer relations, and preparation for a vocation. Establishing independence from parents is not a simple matter. In the face of cultural pressures for independence from peers, parents, and teachers, the child tends to strive toward an adult state of independence. However, the child commonly is not assigned a clear functional role in many Western societies. Since parents sometimes put pressure on him to remain passive and obedient, the child often is placed in conflict.

Many societies have seen a significant increase during recent years in the expression of sexual interests and related behaviour during adolescence, and these activities continue to be considerably greater among boys than among girls. Recent changes in British, European, and North American cultures indicate more openness and candor about sexual motives and behaviour than were observable in the 1950s. Thus, 52 percent of one sample of males attending school said that sexual intercourse was acceptable for a male before marriage if he was engaged; a lower proportion of the females in the sample gave a similar answer for their own sex. Within a group composed of 20 percent of the males, each said that sexual intercourse was acceptable to him before marriage, even if he did not have any particular affectionate feelings toward his partner, while only 10 percent of the females seemed to accept such values for themselves (see SEXUAL BEHAVIOUR).

THE INFLUENCE OF PEERS

Relationships with peers serve many important functions, providing an opportunity to learn how to interact with others, how to control social behaviour, and promoting the development of relevant skills and interests. The peer group also may act as a therapeutic agent; *e.g.*, if it helps the adolescent understand and allay his feelings of anxiety over conflicts. The peer group can promote discussion of sexuality, may give license for aggressive play, and permit the adolescent to vent hostility. The child is likely to feel safe with his peers in discussing and expressing officially prohibited actions and ways of thinking. Friends sometimes function as mutual psychotherapists and may help to buffer feelings of conflict.

The peer group also can be influential when it communicates its evaluation of the child, positive or negative, by giving or withholding group acceptance. The child tends to trust his own group's evaluation more than he does that of adults; he is likely to feel that adults either are overly accepting of his undesirable qualities or at other times are overcritical. The adolescent is apt to require evaluation by peers since he ordinarily lacks absolute standards to help him judge how bright, handsome, wise, or likable he is. The adolescent is prone to use his immediate peer group as the reference for the qualities he wishes to assess in himself. His evaluation is partially dependent on the size of the reference group, and on how he perceives its quality relative to the larger community in which he lives. The larger the peer group, the less likely the adolescent is to decide that he is exceptionally talented or capable of leadership.

The peer group provides role-playing models with which he may identify. He is likely to respect those peers who command positions of power. The young adolescent tends to adopt the leader's values, imitating his behaviour in the hope of eventually commanding the same powers and competencies. Moreover, peers teach the child a role to play in the group. Unlike the family, the adolescent peer group composed of members of the same sex has no obvious differentiation by age and sex. Instead, differentiation in the group rests on assigning different roles to various members. Essential roles include those of the leader, the leader's advisor, and the scapegoat. Other roles may be those of the intellectual, the clown, the rebel, the athlete, or the ladies' man. Adolescents cast in these roles commonly take them seriously and each tends to behave in accordance with how he perceives the role given to him. Apparently the child adopts the behaviour appropriate to his role in an effort to gain acceptance and distinction for playing the role properly.

Antisocial behaviour

An adolescent who drops out of the school enterprise is most likely to come from an emotionally troubled, socially isolated, lower-class home that typically is located in a segregated ethnic or economic urban ghetto. He is likely to have friends of whom his parents do not approve, who share his aversion to academic activities, and who already have dropped out of school or who soon will drop out themselves. He usually has had academic difficulty (especially in reading) for many years, even though he may be of average or higher intelligence. He is likely to have been held back to repeat one or more grades and to have begun to feel frustrated. Troubled by feelings of inadequacy, anger toward authority, and lacking a clear sense of his own identity, he tends to be a creature of the moment; impulsive and low in frustration tolerance.

Often these children become juvenile delinquents; in typical Western societies boys are about four times more likely to commit offenses than are girls. The most frequent delinquent acts recorded for boys involve such aggressive behaviours as burglary, malicious mischief, larceny, and automobile theft. For girls, the commonest offenses include running away from home and promiscuous sexual behaviour. The incidence of cases of juvenile delinquency in the U.S. has increased substantially since 1948; estimates in the 1970s suggest that at least 12 percent of all children (this includes 22 percent of all boys) turn up in juvenile-court records before the end of their adolescence. While delinquents often are found in lower-class neighbourhoods, specific relationships also have been reported that link personality, intelligence, and delinquency among children from more privileged homes.

SUMMARY

The major theme of this discussion has been that the components of human psychological development (in-

cluding motives, moral standards, expectancies, emotions, sources of anxiety, cognitive structures, and actions) are reorganized as development proceeds. This discussion has been largely descriptive since developmental psychology lacks a tight net of interlocking theoretical propositions that reliably permit satisfying explanations. Developmental psychologists still are unable to achieve agreement in explaining how a child passes from one presumed developmental stage to another or how environmental experiences facilitate or obstruct this passage. However, a few related conclusions seem appropriate at this time: psychological organization changes as the child grows; also, the exact relationship of a child's overt behaviour to his subjective state is always to be regarded as uncertain. The major task of developmental psychology is to map the child's observable behaviour on the internal, dynamic processes that are inferred as adapting him to his environment and as helping him make sense of his experiences.

(J.K.)

Human Behaviour, Innate Factors in

Many people believe that, although most bodily characteristics are inherited, psychological or behavioural traits are not. Nevertheless, one's hereditary endowment (genotype) indeed predisposes him to become bright or dull, or to be prone to show specific personality traits fully as much as to be tall or short, or to have dark or light hair. The biochemical and physiological processes that are involved in linking the potentials of genotype to the actualization called the phenotype are complex in all such cases.

Properties of behaviour

Behaviour is somewhat more difficult to study genetically than are such traits as eye colour. Since most psychological characteristics are continuous (*i.e.*, each such trait varies by degrees), more complex extensions of the simple methods of classical genetics must be used in their investigation. Further, behaviour is fluid or environment sensitive in that its phenotypic values may fluctuate widely under environmental influence. Thus one's exposure to a learning task tends to change his performance. Likewise the environment in which a child is reared may markedly affect his measured intelligence and personality.

Since behaviour is complex, even its special definitions tend to be imprecise. Most psychologists, for example, consider intelligence to be a loose term that covers many distinctive kinds of ability. These difficulties are not unique to the study of behaviour. Many bodily traits are also continuous, environment sensitive, and complex; height and weight are examples.

NATURE AND NURTURE

Phenotypic characteristics result from the interaction of nature (genotype) and nurture (environment). A main goal of geneticists is to establish the degree to which each genetic or environmental component contributes to phenotypic variation.

The term genetic commonly is used interchangeably with such words as innate, inherited, or heritable. Likewise, environmental corresponds to acquired. The designation congenital refers merely to a trait or syndrome that is present at birth, for whatever reason: genetic, prenatal, paranatal, or whatever. However, these equivalences are loose; thus, to say that a trait is genetically based is to indicate that its expression in the individual depends on genes. The heritability of a trait, on the other hand, technically refers to the degree to which the expression of that character in a sample of individuals is controlled by genotype. Heritability concerns populations rather than individuals, and heritability estimates for a trait may vary widely from one population to another.

The proposition that characteristics acquired through exposure to environment can be transmitted to succeeding generations was proposed by Jean Lamarck (1744–1829). Widely debated in the 19th century, championed even by Charles Darwin, forms of Lamarckism continued (despite contradictory evidence) to be espoused, notably in the U.S.S.R. where so-called Michurin-Lysenko genetics once had official government approval. Reports offered in support of this position strained the credulity of most non-Soviet geneticists. Thus, a report of the transformation (by environmental treatment) of one species of wheat (*Triticum durum*) into another (*Triticum vulgare*) was compared by U.S. geneticist Theodosius Dobzhansky to having a domestic cat give birth to a lion.

To the extent that behaviour is genetically based, it should follow the same kind of rules that apply to bodily traits. Consequently, such changes as those induced in temperament or intelligence through learning are not expected to be incorporated in the chromosomes to be passed on to offspring. Indeed, most studies to test the inheritance of acquired behavioural traits in laboratory animals have given negative results. The few that seemed to support the Lamarckian view either had obvious flaws or could not be verified by other investigators.

Chromosomes and mental retardation

This is not to say that environmental factors cannot change the genotype. Thus, actual chromosomal aberrations may arise during embryological development; mongolism (Down's syndrome) is such a case. The origin of this form of retardation in intelligence remained a mystery until 1959, when it was reported that a sample of mongoloids showed a complement of 47 chromosomes rather than the usual 46, the extra one belonging to a chromosome group labelled number 21. These groups normally contain two chromosomes, and in this anomaly (designated as trisomy 21) there are three. The probability is that half of the children of female mongoloids will also show the syndrome. Assuming that trisomy arises environmentally, then this acquired character is genetically transmitted; similarly, heritable changes may be induced by environmental radiation (*e.g.*, X-rays) through chromosomal mutation. (See also BIRTH DEFECTS AND CONGENITAL DISORDERS.)

Likewise, when fruit-fly (*Drosophila*) pupae are exposed to severe heat, about half of them develop defective wing structure (absence of cross-veins). Further treatment and breeding of the abnormal insects eventually produces descendants that show the defect even without the heat treatment. A character that originally appears only under environmental manipulation now emerges spontaneously. This does not, however, give clear support to the simple notion that all acquired characters can be inherited. Presumably a line of *Drosophila* has been bred from ancestors whose threshold for the expression of a genetically based character is extremely low, the tendency to express the trait clearly existing in the original genotypes.

GENETICALLY MEDIATED INDIVIDUAL DIFFERENCES

Bodily characteristics. The pattern of human inheritance for some bodily characteristics is not as simple as was once supposed. Eye colour, for example, long has been thought to depend on a dominant gene B· (for brown), and a recessive gene b (for blue), so that BB and Bb produce brown, and only bb yields blue. (Genes that have such alternative forms as B and b are called alleles.) While this model often applies, sometimes two blue-eyed parents may provide genetic material that produces a brown-eyed child; apparently small, ordinarily undetectable brown spots in the iris of the eye were present in the parents. Blond hair seems to be recessive to brown and black, and red hair apparently depends on a different pair of recessive genes. There are so many intermediate variants, that the presence of other modifying (epistatic) genes must be considered.

Genes and eye colour

The inheritance of skin pigmentation probably also depends on a number of gene pairs. This continuous (quantitative) trait can be measured with special methods (*e.g.*, spectrophotometry) or by matching skin hue against a standard scale. Work using these techniques indicates at least five allelic gene pairs to be involved, largely producing intermediate degrees of pigmentation.

Human bodily form showed significant heritable components: stature; height-weight proportionality; some fat, bone, and muscle indexes; physique (somatotype); and bodily signs of bisexuality (masculinity-femininity).

Studies in biochemical genetics have generated information about a number of specific diseases; for example, so-called hemoglobinopathies and inborn errors of metabolism. A notable hemoglobin disorder is sickle cell anemia, called the prototype of the molecular diseases. Involving a tendency of red blood cells to assume an abnormal sickle shape, its clinical manifestations include anemia, jaundice, and obstruction of blood vessels. These symptoms have been found to reflect the substitution of an amino acid (valine) for a glutamic acid in a complex amino-acid chain found in the hemoglobin molecule. Sickle cell anemia is an example of what is called a balanced polymorphism. Transmitted as a dominant by a single pair of alleles (SS), this double-dominant, killing disorder should tend to die out, being subject to strong negative selection; but the recessive condition (ss) is especially susceptible to malaria. Hence ss is subject to negative selection, and the genotype Ss has an advantage in resisting malaria. (Indeed, the sickling trait is largely confined to parts of Africa where malaria is a major disease.) Thus, both genes are maintained in the population, an example of balanced polymorphism.

Inborn errors of metabolism

It has been suggested that a continuing high frequency of psychiatric disturbance, in spite of strong negative selection, may also represent a case of balanced polymorphism.

More than a hundred inborn errors of metabolism have been identified. Common examples include phenylketonuria, tyrosinosis, galactosemia, albinism, and alkaptonuria. Besides the physiological abnormalities produced by the enzyme defects involved, such behavioural changes as retardation in intelligence may also result. Phenylketonuria (PKU), for example, in which an amino acid (phenylalanine) found in some protein foods is improperly metabolized and accumulates in the body, may result in IQ (Intelligence Quotient) levels of 20 or less. In some (but not all) PKU sufferers, more intelligent behaviour appears when a diet low in phenylalanine is instituted. (Perhaps the degree of responsiveness to such treatment is itself genetically controlled.) PKU generally is thought to depend on a pair of recessive genes, and heterozygotes (people who carry just one of the pair) are detectable through a phenylalanine tolerance test. When they ingest enough phenylalanine, they show about twice the normal level of this amino acid in their blood.

Hemophilia, a disorder in which blood fails to clot normally, is carried by a recessive gene that is sex-linked (located on a sex chromosome). Diabetes mellitus, a deficiency of insulin, does not seem to fit such a simple genetic model; it shows different degrees of severity and exhibits variable age of onset. There may, however, be a complex of syndromes involved; perhaps a juvenile variant and an adult form of diabetes.

Genetic transmission of epilepsy also is incompletely understood, although there is clear evidence for a strong heritable component. For example, abnormal brain-wave patterns frequently are observed among close relatives of epileptics, being especially pronounced in mothers of those who show abnormal electrical activity associated with specific parts of the brain (focal psychomotor discharge). Evidence based on one family pedigree suggests that at least one form of catalepsy (in which bodily motion is arrested during seizures) may be inherited, possibly through the action of a single dominant gene.

Psychological characteristics. *Sensory functions.* From a genetic point of view, one of the better understood sensory functions is the tendency of different people to experience a chemical called phenylthiocarbamide (PTC) as bitter or as tasteless. The substance is one of a number of compounds containing the carbamide group. In most populations, taste thresholds (*e.g.*, for hydrochloric acid) are distributed according to chance (*i.e.*, normally). This is not the case, however, for PTC, the proportion of nontasters ranging from about 20 percent among Africans to about 35 percent in Europeans. Pedigree data suggest that PTC "taste-blindness" depends on one pair of recessive alleles, although other studies have not always given support to this simple notion. The ability to taste PTC as bitter appears to be highly specific, in that the substance can be recognized by a "taster" only when it is dissolved in his own saliva. The trait is neither related to overall taste acuity nor to the general ability to taste noncarbamides (*e.g.*, quinine sulfate) as bitter. Since the carbamides exist only as man-made synthetics, it is difficult to guess what adaptive function the taster gene might serve in human evolution. Suspicion of its association with diabetes has not been confirmed. Taste thresholds for PTC and for such compounds as quinine, however, seem to be related to food preferences, smoking, performance on intelligence tests, and proneness to peptic ulcers; age and sex were found not to be directly implicated.

Taste and smell

Little work has been done on the genetics of differences in the sense of smell (olfactory function). Scattered pedigree reports may implicate hereditary factors in selective inability to detect particular odours (specific anosmia).

Deafness can have both hereditary and environmental bases; the origins of congenital deafness (present at birth) or deafness appearing early in childhood may be assigned as shown in Table 1. These figures are based on data from large populations in several countries.

Normal auditory function also depends heavily on genotype. There is evidence of heritability for loudness discrimination, rhythm, and auditory acuity; tone deafness in human populations probably depends on a single chromosomal locus. This is not to say that these abilities may not be improved with practice, however.

Genetic factors are important in many forms of blindness and in defective ability to converge the eyes or to focus (accommodate) for near and far objects. Some common forms of colour blindness are clearly hereditary. Most varieties of red-green blindness usually are regarded as classic examples of sex-linked transmission, but the genetic situation probably is more complex. Thus there appear to be at least four distinct phenotypes (protanopia,

Vision

Table 1: The Causes of Early Childhood and Congenital Deafness

cause	percent
Assignable disease of trauma	25
Multiple autosomal recessive loci at complete penetrance	40
Autosomal dominant loci with an average of 85% penetrance	15
Nonsegregating factors (either unrecognized diseases or effects of polygenes)	19
Sex-linked or sex-influenced loci	<2

Source: K.S. Brown and C.S. Chung.

protanomaly, deuteranopia, and deuteranomaly) distinguishable by noting how a subject matches a yellow with mixtures of red and green. Pedigree data suggest that protanopia and protanomaly are mediated by sets of multiple allelic genes (independent of those producing deuteranopia and deuteranomaly), each set producing a specific chemical defect as in the inborn errors of metabolism.

Personality and intelligence often are said to be reflected by performance on selected visual tasks. Whatever the validity of such statements, many sets of data (from twins and other family members) suggest that heritable components mediate susceptibility to selected visual illusions, eidetic imagery ("photographic" memory), spatial orientation and afterimage characteristics, and differences in ability to detect flicker in a source of light (flicker-fusion frequency). Since most studies have involved small samples of people and have done little to control for prior experience, they call for cautious interpretation.

Sensorimotor functions and special abilities

There is a paucity of data bearing on genetic factors in motor skill. Twin and family studies suggest some heritability for such abilities as tapping speed, athletic performance, motor-reaction time, card sorting, hand steadiness, mirror-image drawing, and manual dexterity. In some cases, however, results have varied considerably between initial and final performance. Many other kinds of performance tend to change with training, and it should not be assumed that heritability estimates will show a constant value over practice trials. Such estimates also tend to be higher when based on the performance of the right hand (preferred by most people) and could simply reflect superior, more reliable performance.

Based on studies of the behaviour of twins, it has been reported that outstanding athletic ability (as in Olympic competition) strongly depends on heredity.

Musical ability shows a strong tendency to run in families. The pedigree of composer Johann Sebastian Bach shows many relatives with substantial musical talent and represents a notable, but not unique illustration.

Data gathered at the Juilliard School of Music in New York City show a clear degree of musical talent in 50–75 percent of the parents of opera singers, instrumental virtuosos, and music students. It would appear that significant musical ability emerges very early in life; in general, such aptitudes improve steadily among the gifted, even without practice, and in a variety of environmental settings. Such data point to maturation in the gradual unfolding of genotype as a major factor.

Many other studies implicate heredity in musical ability, whether measured as a global score or by means of different subtests. For example, musical quotients based on tests of musical intelligence have shown identical (monozygotic: MZ) twins to be much more alike than are fraternal (dizygotic: DZ) twins.

Genetic models put forward to account for the transmission of musical talent include: single-gene action with incomplete dominance; a single or a few recessive genes; several major genes with multiple alleles. None of these theories seemed to account completely for the data available in the 1970s.

Intelligence. In the 19th century, Sir Francis Galton analyzed a large number of pedigrees of distinguished statesmen, scientists, military commanders, literary men, artists, divines, and other groups. He concluded that high intelligence (as manifested in such activities) strongly depends on heredity; his later work with twins pointed to the same conclusion. Although noting that his method failed to control for them, Galton accorded environmental influences little importance. Subsequent studies strongly tend to endorse Galton's conclusion that intelligence runs in families. Except in such extreme cases as infantile malnutrition, environment indeed seems to play a minor role; for example, adopted children resemble their biological parents in measured intelligence more than they do their foster parents. This tendency increases with the age of the child and applies even for widely disparate socioeconomic environments. Also, children living in such homogeneous environments as orphanages show as great a range in intelligence as that found among comparable children living in their own homes, each home representing a different environment.

Heritability of intelligence

Up to about puberty, raw scores on intelligence tests tend to increase regularly with age (as does any biologically rooted character), and are largely independent of all but the most pronounced deviations in environment. For example, monozygotic twins reared apart (though less alike than those reared together) still tend to be more similar in intelligence than are dizygotic twins raised in the same home. This has been found to hold no matter how early in life such twins are separated. Within wide limits, long exposure to a common environment does not seem to make people more similar in intelligence. Scores of studies clearly emphasize the role of heredity in intelligence among human beings and other animals.

Concerning the extent of genetic determination in human intelligence, most investigations have yielded heritability estimates between 70–80 percent. Since such values are relative to the population studied and to the method of estimation, some disagreement should be expected. It seems most unlikely, however, that genotype contributes less than 50 percent of the variability and it is conceivable that the figure is closer to 80 percent.

Major, independent studies concur in showing that specific aspects of intelligent behaviour (verbal ability, spatial intelligence, and word fluency) have strong genetic dependence. In one especially sophisticated study, numerical ability also was found to be significantly heritable.

Thus both general intelligence (*e.g.*, IQ) and its specific component abilities seem to be heritable, some of the latter being more dependent on genotype than are others. The precise genetic mode for the transmission of intelligence was incompletely understood in the 1970s. Some theorists favoured the notion of multiple genes; one suggested a major gene pair (Nn), dominant for normal intelligence (IQ range 90–110), with five additional minor pairs of genes acting as modifiers that could push IQ up or down in the absence of the dominant gene N. A mathematically advanced attempt to fit a genetic model to sets of twin and family IQ data suggested that about a hundred chromosomal loci were involved, and indicated dominance for higher intelligence; it yielded no evidence for interaction between genotype and environment.

Retardation

Cases of severely low intelligence tend to involve gross neurological, biochemical, or chromosomal impairment; single dominant or recessive genes generally are implicated. When there is only mild retardation with few or no physical defects, the individual may be regarded simply as representing the low end of the IQ range.

At least a quarter of the known inborn errors of metabolism have been found to produce severe defects in intelligence. Some examples are Tay-Sachs disease (idiocy associated with blindness), Gaucher's disease (anemia of the spleen), Wilson's disease (a defect in copper metabolism), galactosemia (a disturbance in sugar metabolism), and phenylketonuria (PKU). The majority of phenylketonurics shows IQs below 50, although their group average is about 50. Adaptive and language functions are most adversely affected, while motor and personal-social skills show the least retardation. A marked deficit in attention span has been demonstrated among PKU children. All or most of these aberrations can be alleviated in at least some PKU groups that are maintained on a low-phenylalanine diet.

A major breakthrough in understanding the etiology of many gross forms of retardation was the identification of chromosomal anomalies. Mongolism (Down's syndrome) has been noted above as being associated with autosomal trisomy. Risk increases from less than 1:1,500 for mothers under 30 years of age to 1:60 for mothers age 45 and over.

In another type of chromosome abnormality part of one of the short arms in the 4–5 chromosome group is missing. The syndrome thus produced has been called *cri du chat* because an affected infant's vocalization may be compared to the mewing of a cat. Well-known aber-

Cri du chat, Turner's and Klinefelter's syndromes

rations involving the sex chromosomes include Turner's syndrome (gonadal dysgenesis), associated with absence of one of the X chromosomes among females; and Klinefelter's syndrome (seminal duct dysgenesis) in which males have two or more X chromosomes. Most of these conditions produce subnormal intelligence and other psychological changes. In this connection, there may be a relation between the presence of surplus chromosomes and antisocial behaviour. Men who show extra Y chromosomes have been reported to be unusually tall and aggressive; but it is likely that any connection between this chromosome anomaly and criminal behaviour is very indirect.

Thus it has been suggested that any chromosomal aberration produces a variety of physiological symptoms, including cerebral changes akin to minimal brain damage. This, in turn, may result in changes in personality that dispose to many forms of abnormal behaviour. A link has been suggested between chromosomal anomalies and some of the major psychoses (*e.g.*, schizophrenia), but available evidence has failed to support the hypothesis.

Attitudes and beliefs. Although family tendencies to hold specific beliefs and attitudes have been demonstrated, it seems most unlikely that these could be under genetic control. Inherited personality dispositions (*e.g.*, aggressiveness) might, however, predispose an individual to, for example, authoritarian attitudes. Indeed, a study of MZ and DZ twins demonstrated significant hereditary contributions to scores on several scales of vocational interest (*e.g.*, those for physicist, mathematician, osteopath, dentist). Any connection between genetic makeup and such vocational interests is, however, apt to be rather remote. It often is argued that MZ twin pairs share more similar environments than do DZ twins (a general criticism of the twin method).

Personality. Studies on the heritability of basic personality characteristics (largely among twins) have yielded variable results. Inconsistencies appear among reports regarding tests of dominance, psychoneurotic tendency, and need for achievement. A number of studies suggest sex differences in heritability estimates for personality traits, however. And there is some consensus that the dimension of introversion-extroversion is strongly heritable; perhaps to the same extent as intelligence. One analysis of twin data showed a heritability of 67 percent for this trait. It was concluded that the introvert genotype is more modifiable by environmental factors than is that for the extrovert. This seems to converge with the notion that introverts are more readily trainable through conditioning than are extroverts. Other dimensions that show evidence of heritability (perhaps of evolutionary significance) are aggression, anxiety, attention to detail, social attachment, activity, and emotionality. Individual differences in some of these appear early in life; infants, for example, tend to be reliably indentifiable as "cuddlers" and "noncuddlers." It has been suggested that cuddlers may become extroverts as adults, and that noncuddlers are prone to become introverts.

Psychiatric disorders

While many gross deviations such as metabolic errors or chromosomal abnormalities are inherited, the evidence is less clear for so-called psychiatric disorders. The psychotic disturbance called schizophrenia has received most attention and Table 2 summarizes genetic studies from several European countries and the U.S. While there is general support for schizophrenic inheritance, the average values in the table show little of the variation typically found. Different reports of rates at which pairs of MZ twins both are affected (concordance rates) range from as low as zero to higher than 80 percent. In one study, schizophrenic symptoms were found in five of 47 foster-home children of schizophrenic mothers; no symptoms were observed among a matched group of similarly reared children of normal mothers. Few authorities discount environmental influences in schizophrenia.

Likely factors contributing to such variability include sex differences (female twins being more concordant), severity and chronicity of the disturbance, age, criteria for identifying DZ and MZ twins and for diagnosing schizophrenia itself, and gene frequency and incidence (or penetrance) in particular populations. Some theorize the action of one or a few pairs of major recessive genes; others favour a dominant mode of transmission; a few hold that a model based on the cumulative effects of a number of genes (a so-called polygenic, threshold model) most suitably accommodates the data. If the diagnostic label schizophrenia covers more than one disorder, all of these mechanisms may be operating.

Table 2: Studies on the Incidence of Schizophrenics in Relatives of Varying Degree of Kinship

relationship to schizophrenic	expectation of schizophrenia (percent)	number of investigators	number of countries
Unrelated (gen. pop.)	0.86	19	6
Parents	5.07	14	8
Siblings	8.53	12	7
Children	12.31	6	2
Uncles and aunts	2.01	4	4
Nephews and nieces	2.24	5	4
First cousins	2.91	4	4
Twin pairs	**Both twins affected**		
DZ OS	5.6	6	5
DZ SS	12.0	9	7
MZ	57.7	10	8

Population levels of schizophrenia hold at about one percent in spite of apparently strong selection against it. Schizophrenics are relatively unlikely to marry, have fewer children than the average, and these have a comparatively high rate of early mortality. It has been suggested that negative selection of any schizophrenic genotype may be compensated by a positive selection for carriers (as in sickle cell anemia). Indeed, unaffected sisters of schizophrenic females tend to have more children than average; and unaffected offspring of schizophrenic mothers included more conspicuously successful adults than were observed among a control group.

Among other forms of psychological disorder, significant contributions of genotype have been claimed for manic-depressive psychosis, involutional depression, senile psychosis, homosexuality, alcoholism, childhood schizophrenia and autism, hysteria, obsessional and anxiety neuroses, psychopathy, cyclothymia, schizoid personality, bedwetting (enuresis), and reading difficulties (dyslexia). Few of the studies adequately controlled for environment by using separated twins, and the data often do not permit specific genetic hypotheses. In the case of manic-depressive psychosis, several investigators agreed that a dominant gene (or genes) is involved but differed about whether it is sex-linked or not. Dominant inheritance also has been suggested for enuresis and for anxiety neurosis; a polygenic model has been offered for hysteria. It has been hypothesized that genotype does not so much predispose to neurotic breakdown as it does to determine the form the disorder will take if it does occur.

While considerable evidence points to genetic factors in normal and abnormal personality, exact modes of transmission are poorly understood; environmental influences should be considered in themselves and as interacting with particular genotypes.

GENETICALLY MEDIATED GROUP DIFFERENCES

Passionate opinions are held on whether human groups in relative cultural, economic, or geographic isolation differ genetically. The explosive political implications have led some to argue that the problem should not even be examined by scientists. Most authorities suggest, however, that emotional attitudes and conflict are generated more by ignorance than by empirical evidence.

Early attempts at classifying human groups stressed such variations as skin colour, facial features, or bodily measurements. Later classifications emphasized geographic isolation and criteria of gene frequencies for traits; for example, local genetic groups (microraces) in Wales as defined by blood groups.

Efforts to identify so-called racial groups

People with some common feature (*e.g.*, dark skin) may not differ from other groups in gene frequencies for other traits and may not be geographically isolated, and the same geographic region may have genetically isolated populations. Combinations of these variables can identify groups for specific research purposes. Thus, groups distinguished on the basis of skin colour and geographic location (*e.g.*, U.S. white, Charleston Negro, U.S. non-Charleston Negro, and West African Negro) also can be compared genetically. Estimates of gene flow (exchange of genes through interbreeding) can be depicted in terms of a combination of bodily traits, blood-group factors, and so-called biological distances. Such a multivariate scheme tends to avoid the oversimplification of cruder systems of classification. Since multivariate classification had not been used widely up to the 1970s, the bulk of earlier information about alleged racial differences in behaviour seemed primitive at best. Nevertheless, for genetically distinct groups between which there is little or no gene flow, inherited differences should be anticipated both for adaptive and nonadaptive forms of behaviour.

Most available data concern broad comparisons among rather ill-defined groups, particularly of European and African origin. Intergroup differences have been claimed for such psychological functions as reaction time, visual and auditory acuity, colour-blindness, pain sensitivity, and discrimination of tone, weight, touch, taste, and smell; however, problems of design and control make these findings somewhat ambiguous. Differences in complex traits also have appeared (*e.g.*, susceptibility to visual illusions, and performance on tests of intelligence and personality) and for these the problems of interpretation are even more formidable. Average intelligence test scores clearly have been higher among so-called whites than among populations identified as black, tending to divert attention from millions of superior blacks and inferior whites. Since test performance is related strongly to expenditure for schools, it is controversial whether genotypes or environmental factors contribute most to such differences. Until environmental variation can be controlled more fully even such simplistic abstractions as group averages will be difficult to interpret.

Even greater caution needs to be applied to score differences on personality tests for such crudely defined so-called racial groups. Their significance is badly clouded by such variables as language skill, motivation, test-taking attitudes, and rapport with the tester.

Traits related to social class

The possibility of genetic bases for similarly reliable differences among socioeconomic groups has been considered. Social constraints indeed may tend to isolate such groups biologically, each potentially constituting a kind of microrace. If environmental factors alone were operating, those reared in impoverished settings invariably would tend to develop low ability, and, if a rich environment or special education were provided, could rise to a high socioeconomic level. Yet genetic factors seem to modify this view; for example, the IQ's of children within any social class tend to show regression (to approach the average IQ of all classes combined). Thus, many individuals are born into environments geared to occupations above or below their abilities. A British psychologist, Sir Cyril Burt, has estimated from empirical data that about 45 percent of adults are "incorrectly" placed in society. He suggested that a substantial proportion of the population would need to move from one class to another if any distribution of ability across occupational strata were to be preserved. On the other hand, selective mating on the basis of class-related traits (*e.g.*, IQ, educational background) should tend to reduce variability and to diminish "incorrect" placement within social classes. In any case, the evidence fails to show that people who hold socioeconomic power constitute a genetically elite class.

STATISTICAL CONSIDERATIONS

The main goals in studying the genetics of human behavioural traits are (1) to assess the relative influence of hereditary as compared with environmental contributions to the variance of the traits; (2) to assess the importance both of correlations and interactions among these components; (3) to identify the particular genetic mechanisms involved in the transmission of the traits. Basically, all methods used assume that the phenotypic differences among individuals (that is, the observed trait variance) may be partitioned into genetic, environmental, and interactional components as follows:

(1) $V_P = V_G + V_E + V_I$

in which

V_P = phenotypic or observed variance of a trait;
V_G = genetic contribution to that variance;
V_E = environmental contribution to that variance;
V_I = contribution of interaction between genetic and environmental factors.

Contributions to phenotypic variance

V_I represents a component of variance that will occur when different genotypes respond differently to the same environmental treatment. For example, a genetically "bright" child may gain more from enriched rearing conditions than a genetically "dull" child. It is important to note that this source of variance is difficult to estimate in ordinary human populations, since, more often than not, there is already present a correlation between genotype and environment. This reflects evidence that "brighter" children tend to be more favoured than dull children in respect to environmental treatment. The terms V_G and V_E can, under special circumstances, be broken down further. Thus V_G may be partitioned into additive and nonadditive or dominance components. Likewise, V_E may be divided into as many components as can be observationally identified. One study on heritability of human birth weight can serve as an example. The data are shown as Table 3.

Table 3: Genetic and Environmental Components of Variation in Human Birth Weight

component of variation	percent of total
Genetic	
Additive	15
Nonadditive	1
Sex	2
Total genotype	18
Environmental	
Maternal genotype	20
Maternal environment, general	18
Maternal environment, immediate	6
Age of mother	1
Parity	7
Intangible	30
Total environmental	82

Generally, heritability is estimated as the ratio of additive genetic to total phenotypic variance. But, since in much work with human beings this component cannot be separated readily, the ratio of total genetic to total phenotypic variance is used. This is sometimes called degree of genetic determination rather than heritability.

Basically, all methods used to study the genetics of human data are based on a comparison of similarity among relatives of varying degrees of kinship as well as similarity among relatives as against nonrelatives. Methods commonly used to make these comparisons include the classical approach through correlations involving relatives, particularly monozygotic (MZ, or identical) and dizygotic (DZ, or fraternal) twin pairs. Heritability estimates may be calculated from correlations between parents, half-brothers, half-sisters, and full siblings. Some information regarding mode of inheritance is yielded by comparing correlations among siblings with those between parents and their children. When dominant genes are present sibling correlations are higher than are those between parents and children. Likewise, twin data provide a number of indexes of heritability (H or HR) in the broad sense. Some examples are:

(2) $$H = \frac{r_{MZ} - r_{DZ}}{1 - r_{DZ}}$$

and

(3) $$HR = \frac{2(r_{MZ} - r_{DZ})}{r_{MZ}}$$

in which r_{MZ} and r_{DZ} are correlations for identical and fraternal twin pairs, respectively.
A variant of these is given by:

(4) $$E = \frac{r_{MZT} - r_{MZA}}{1 - r_{MZA}}$$

where E is environmental influence, and r_{MZT}, r_{MZA} are correlations for identical twin pairs reared together and apart, respectively.

These formulas and alternative forms of them also can be expressed in terms of variances rather than with correlations. Further, if the investigator is interested merely in establishing that hereditary factors have a statistically significant effect, (rather than attempting an estimate of their magnitude) MZ and DZ variances can be compared by means through which a probability value may be ascertained (*e.g.*, the so-called F ratio).

Multiple abstract variance analysis

Another approach, known as multiple abstract variance analysis (MAVA), leads to the estimation of so-called nature-nurture ratios both within and between families and to estimations of correlations between genetic and environmental influences as found within families and within whole cultures. Basically, MAVA starts with sets of observed variances that are then expressed in terms of abstract or hypothetical variances and covariances. For example, the variance between identical twins reared apart represent the variance due to environment, much as does E in equation (4). Likewise, the variance between siblings reared together is expressed as:

(5) $$\sigma^2_{ST} = \sigma^2_{wg} + \sigma^2_{we} + 2r_{wg \cdot we}\sigma_{wg}\sigma_{we}$$

in which

σ^2_{ST} = variance of siblings reared together
σ^2_{wg} = variance component due to genetic differences within the family
σ^2_{we} = variance component due to environmental influences within the family
$2r_{wg \cdot we}\sigma_{wg}\sigma_{we}$ = twice the covariance between genetic and environmental components within the family.

A great many other empirical variance estimates can be obtained that can likewise be equated to a number of abstract variances, some of which will be common to several equations. In addition, some of the unknowns (particularly, covariance terms) can be dropped if they seem not to correspond to empirical situations. The result is a possible solution for the abstract variances separately in terms of the empirical variances to which they have been equated. Applications of this method to data on human intelligence and personality have indicated strong hereditary determination for intelligence and for 2 out of 11 personality factors (schizothymia and impulsivity). This promising MAVA approach, however, takes no explicit account of interactions between genetic and environmental influences. Also the number of abstract variances that can be put into an equation are so numerous as to make analysis unwieldy. For example, it may be elected to specify that the kinds of treatment accorded to identical twins, fraternal twins, and siblings are a priori distinct. Again, a special term representing degree of assortative mating in the population could be introduced. The question of which of these terms can be logically dropped or included is thorny. Nor does MAVA generate conclusions regarding the mode of genetic transmission of a trait, nor does it indicate hypotheses concerning its evolutionary history.

Another approach used to study human behavioural data is the biometrical genetic analysis initiated by British statistician Sir Ronald A. Fisher (1890–1962). Application of the method to twin and family data has permitted the remarkably sophisticated conclusions that IQ shows high heritability, about 70 to 80 percent being attributable to genetic factors; that it is transmitted polygenically (about 100 genes); that superior IQ has a high level of dominance; and that the gene action involved suggests that IQ has undergone much natural selection in human evolution.

All of these methods have been developed for use with continuous traits only. With discrete traits (*e.g.*, metabolic defects), applications of the so-called Hardy-Weinberg rule may be made; that is, gene frequencies are estimated for the trait and then predictions are generated concerning incidence of the trait in offspring from parents of various genotypes. This method has been successfully used with phenylketonuria, Huntington's chorea (a hereditary disorder of the nervous system), and many other syndromes. An attempted application of the method to twin and family schizophrenia data, however, yielded indefinite results.

BIBLIOGRAPHY. J.L. FULLER and W.R. THOMPSON, *Behavior Genetics* (1960), a comprehensive text that covers basic methods and surveys human and laboratory animal studies of the genetics of sensory and response systems, intelligence, temperament, and psychiatric disturbance; D.C. GLASS (ed.), *Genetics* (1967), contains a variety of approaches to behaviour genetics, and particularly interesting chapters relating genetics and the social sciences; J. HIRSCH (ed.), *Behavior-genetic Analysis* (1967), a relatively technical treatment of the subject; M. MANOSEVITZ, G. LINDZEY, and D.D. THIESSEN (eds.), *Behavioral Genetics: Method and Research* (1969), includes reviews on most aspects of behaviour genetics in humans and other animals; D. ROSENTHAL and S.S. KETY, *The Transmission of Schizophrenia* (1968), an account of data on the heritability of the disorder; S.G. VANDENBERG (ed.), *Methods and Goals in Human Behaviour Genetics* (1965), a survey that takes up a number of the major statistical problems as well as the methodology in dealing with the genetic analysis of human intelligence and personality.

Human Culture

Culture may be defined as behaviour peculiar to *Homo sapiens*, together with material objects used as an integral part of this behaviour; specifically, culture consists of language, ideas, beliefs, customs, codes, institutions, tools, techniques, works of art, rituals, ceremonies, and so on. The existence and use of culture depends upon an ability possessed by man alone. This ability has been called variously the capacity for rational or abstract thought, but a good case has been made for rational behaviour among subhuman animals, and the meaning of abstract is not sufficiently explicit or precise. Thus the term symbolling has been proposed as a more suitable name for man's unique mental ability—symbolling consisting of assigning to things and events certain meanings that cannot be grasped with the senses alone. Articulate speech—language—provides a good example. The meaning of the word dog is not inherent in the sounds themselves; it is assigned, freely and arbitrarily, to the sounds by human beings. Holy water, "biting one's thumb" at someone (*Romeo and Juliet*, Act I, scene 1), or fetishes are other examples. Symbolling is a kind of behaviour objectively definable (symbolling should not be confused with symbolizing, which has an entirely different meaning).

Culture and "symbolling"

This article is divided into the following sections:

The concept of culture

VARIOUS DEFINITIONS OF CULTURE

What has been termed the classic definition of culture was provided by the 19th-century English anthropologist Edward Burnett Tylor in the first paragraph of his *Primitive Culture* (1871):

> Culture . . . is that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities and habits acquired by man as a member of society.

In *Anthropology* (1881) Tylor made it clear that culture, so defined, is possessed by man alone. This conception of culture served anthropologists well for some 50 years. With the increasing maturity of anthropological science, further reflections upon the nature of their subject matter and concepts led to a multiplication and diversification of definitions of culture. In *Culture: A Critical Review of Concepts and Definitions* (1952), U.S. anthropologists A.L. Kroeber and Clyde Kluckhohn cited 164 definitions of culture—ranging from "learned behaviour" to "ideas in the mind," "a logical construct," "a statistical fiction," "a psychic defense mechanism," and so on. The definition—or the conception—of culture that is preferred by Kroeber and Kluckhohn and also by a great many other anthropologists in recent years is that culture is an abstraction or, more specifically, "an abstraction from behaviour."

These conceptions have defects or shortcomings. The existence of behavioral traditions—that is, patterns of behaviour transmitted by social rather than by biological hereditary means—has definitely been established for nonhuman animals. "Ideas in the mind" become significant in society only as expressed in language, acts, and objects. "A logical construct" or "a statistical fiction" is not specific enough to be useful. The conception of culture as an abstraction led, first, to a questioning of the reality of culture (inasmuch as abstractions were regarded as imperceptible) and, secondly, to a denial of its existence: thus, the subject matter of nonbiological anthropology, "culture," was defined out of existence; and without real, objective things and events in the external world there can be no science.

Kroeber and Kluckhohn were led to their conclusion that culture is an abstraction by reasoning that if culture is behaviour it, ipso facto, becomes the subject matter of psychology; therefore, they concluded that culture "is an abstraction from concrete behavior but is not itself behavior." But what, one might ask, is an abstraction of a marriage ceremony or a pottery bowl, to use Kroeber and Kluckhohn's examples? This question poses difficulties that were not adequately met by these authors. A solution was perhaps provided by Leslie A. White in an essay, "The Concept of Culture" (1959). The issue is not really whether culture is real or an abstraction, he reasoned; the issue is the context of the scientific interpretation.

Importance of the context

When things and events are considered in the context of their relation to the human organism, they constitute behaviour; when they are considered not in terms of their relation to the human organism but in their relationship to one another, they become culture by definition. The mother-in-law taboo is a complex of concepts, attitudes, and acts. When one considers them in their relationship to the human organism—that is, as things that the organism does—they become behaviour by definition. When, however, one considers the mother-in-law taboo in its relationship to the place of residence of a newly married couple, to the customary division of labour between the sexes, to their respective roles in the society's mode of subsistence and offense and defense, and these in turn to the technology of the society, the mother-in-law taboo becomes, again by definition, culture. This distinction is precisely the one that students of words have made for many years. When words are considered in their relationship to the human organism—that is, as acts—they become behaviour. But when they are considered in terms of their relationship to one another—producing lexicon, grammar, syntax, and so forth—they become language, the subject matter not of psychology but of the science of linguistics. Culture, therefore, is the name given to a class of things and events dependent upon symbolling that are considered in a kind of extrahuman context.

Universalist approaches to culture and the human mind. Culture, as noted above, is due to an ability possessed by man alone. The question of whether the difference between the mind of man and that of the lower animals is one of kind or of degree has been debated for many years, and even today reputable scientists can be found on both sides of this issue. But no one who holds the view that the difference is one of degree has adduced any evidence to show that nonhuman animals are capable, to any degree whatever, of a kind of behaviour that all human beings exhibit. This kind of behaviour may be illustrated by the following examples: remembering the sabbath to keep it holy, classifying one's relatives and distinguishing one class from another (such as uncles from cousins), defining and prohibiting incest, and so on. There is no reason or evidence that will lead one to believe that any animal other than man can have or be brought to any appreciation or comprehension whatever of such meanings and acts. There is, as Tylor argued long ago, a "mental gulf that divides the lowest savage from the highest ape" (*Anthropology*).

In line with the foregoing distinction, human behaviour is to be defined as behaviour consisting of, or dependent upon, symbolling rather than upon anything else that *Homo sapiens* does; coughing, yawning, stretching, and the like are not human.

Next to nothing is yet known about the neuroanatomy of symbolling. Man is characterized by a very large brain, considered both absolutely and relatively, and it is reasonable—and even obligatory—to believe that the central nervous system, especially the forebrain, is the locus of the ability to symbol. But how it does this and with what specific mechanisms remain to be discovered. One is thus led to the conclusion that at some point in the evolution of primates, a threshold was reached in some line, or lines, when the ability to symbol was realized and made explicit in overt behaviour. There is no intermediate stage, logical or neurological, between symbolling and nonsymbolling; an individual or a species is capable of symbolling or he or it is not. The life of Helen Keller makes this clear: when, through the aid of her teacher, Anne Sullivan, Helen was enabled to escape from the isolation to which her blindness and deafness had consigned her and to effect contact with the world of human meanings and values, the transformation was instantaneous.

Evolution of "minding." But even if almost nothing is known about the neuroanatomy of symbolling, a great deal is known about the evolution of mind (or "minding," if mind is considered as a process rather than a thing), in which one finds symbolling as the characteristic of a particular stage of development. The evolution of minding can be traced in the following sequence of stages. First is the simple reflexive stage, in which behaviour is determined by the intrinsic properties of both the organism and the thing reacted to—for example, the contraction of the pupil of the eye under increased stimulation by light. Second is the conditioned reflex stage, in which the response is elicited not by properties intrinsic in the stimulus but by meanings that the stimulus has acquired for the responding organism through experience—for example, Pavlov's dog's salivary glands responding to the sound of a bell. Third is the instrumental stage, as exemplified by a chimpanzee knocking down a banana with a stick. Here the response is determined by the intrinsic properties of the things involved (banana, stick, chimpanzee's neurosensory–muscular system); but a new element has been introduced into behaviour, namely,

the exercise of control by the reacting organism over things in the external world. And, finally, there is the symbol stage, in which the configuration of behaviour involves nonintrinsic meanings, as has already been suggested.

Evolution toward increased security and expanse of life

These four stages exhibit a characteristic of the evolution of all living things: a movement in the direction of making life more secure and enduring. In the first stage the organism distinguishes between the beneficial, the injurious, and the neutral, but it must come into direct contact with the object or event in question to do so. In the second stage the organism may react at a distance, as it were—that is, through an intermediate stimulus. The conditioned reflex brings signs into the life process; one thing or event may serve as an indication of something else—food, danger, and so forth. And, since anything can serve as a sign of anything else (a green triangle can mean food, sex, or an electric shock to the laboratory rat), the reactions of the organism are emancipated from the limitations that stage one imposes upon living things, namely, the intrinsic properties of things. The possibility of obtaining life-sustaining things and of avoiding life-destroying things is thus much enhanced, and the security and continuity of life are correspondingly increased. But in stage two the organism still plays a subordinate role to the external world; it does not and cannot determine the significance of the intermediary stimulus: the bark of a distant dog to the rabbit or the sound of the bell to Pavlov's dog. This meaning is determined by things and events in the external world (or in the laboratory by the experimenter). In stages one and two, therefore, the organism is at the mercy of the external world in this respect.

In the third stage the element of control over environment is introduced. The ape who obtains food by means of a stick (tool) is not subordinate to his situation. He does not merely undergo a situation; he dominates it. His behaviour is not determined by the juxtaposition of things and events; on the contrary, the juxtaposition is determined by the ape. He is confronted with alternatives, and he makes choices. The configuration of behaviour in stage three is constructed within the dynamic organism of the ape and then imposed upon the external world.

The evolution of minding is a cumulative process; the achievements of each stage are carried on into the succeeding one or ones. The fourth stage reintroduces the factor of nonintrinsic meanings to the advances made in stages two and three. Stage four is the stage of symbolling, of articulate speech. Thus one observes two aspects of the evolution of minding, both of which contribute to the security and survivability of life: the emancipation of behaviour from limitations imposed upon it by the external world, on the one hand, and increased control over the environment, on the other. To be sure, neither emancipation nor control becomes complete, but quantitative increase is significant.

Evolution of culture. The direction of biological evolution toward greater expansion and security of life can be seen from another point of view: the advance from instinctive behaviour (*i.e.*, responses determined by intrinsic properties of the organism) to learned and freely variable behaviour, patterns of which may be acquired and transmitted from one individual and generation to another, and finally to a system of things and events, the essence of which is meanings that cannot be comprehended by the senses alone. This system is, of course, culture, and the species is the human species. Culture is a man-made environment, brought into existence by the ability to symbol.

Once established, culture has a life of its own, so to speak; that is, it is a continuum of things and events in a cause and effect relationship; it flows down through time from one generation to another. Since its inception 1,000,000 or more years ago, this culture—with its language, beliefs, tools, codes, and so on—has had an existence external to each individual born into it. The function of this external, man-made environment is to make life secure and enduring for the society of human beings living within the cultural system. Thus, culture may be seen as the most recent, the most highly developed means of promoting the security and continuity of life, in a series that began with the simple reflex.

Absence of culture in primate societies

Society preceded culture; society, conceived as the interaction of living beings, is coextensive with life itself. Man's immediate prehuman ancestors had societies, but they did not have culture. Recent studies of monkeys and apes have greatly enlarged scientific knowledge of their social life—and, by inference, the scientific conception of the earliest human societies. Data derived from paleontological sources and from accumulating studies of living, nonhuman primates are now fairly abundant, and hypotheses derived from these are numerous and varied in detail. A fair summary of them may be made as follows: The growth of the primate brain was stimulated by life in the trees, specifically, by eye–hand coordinations involved in swinging from limb to limb and by manipulating food with the hands (as among the insectivorous lemurs). Descent to the ground, as a consequence of deforestation or increase in body size (which would tend to restrict arboreal locomotion and increase the difficulty of obtaining enough food to supply increased need), and the assumption of erect posture were other significant steps in biological evolution and the eventual emergence of culture. Some theories reject the arboreal stage in man's evolutionary past, but this does not seriously affect the overall conception of his development.

The Australopithecines of Africa, extinct manlike higher primates about which reliable knowledge is very considerably today, exemplify the stage of erect posture in primate evolution. Erect posture freed the arms and hands from their earlier function of locomotion and made possible an extensive and versatile use of tools. Again, the eye–hand–object coordinations involved in tool using stimulated the growth of the brain, especially the forebrain. It is not possible to determine on the basis of paleontological evidence the precise point at which the ability to symbol (specifically, articulate speech) was realized, as expressed in overt behaviour. It is believed by some that man's prehuman ancestors used tools habitually and that habit became custom through the transmission of tool using from one generation to another long before articulate speech came into being. In fact, some theorists hold, the customary use of tools became a powerful stimulus in the development of a brain that was capable of symbolling or articulate speech.

Immediate effects of symbolling

The introjection of symbolling into primate social life was revolutionary. Everything was transformed, everything acquired new meaning; the symbol added a new dimension to primate—now human—existence. An axe was no longer merely a tool with which to chop; it could become a symbol of authority. Mating became marriage, and all social relationships between parents and children, between brothers and sisters became moral obligations, duties, rights, and privileges. The world of nature, from the stones beside the path to the stars in their courses, became alive and conscious spirits. "And all that I beheld respired with inward meaning" (Wordsworth). The anthropoid had at last become a man.

Relativist approaches to sociocultural systems. Thus far in this article, culture has been considered in general, as the possession of all mankind. Now it is appropriate to turn to particular cultures, or sociocultural systems. Human beings, like other animal species, live in societies, and each society possesses culture. It has long been customary for ethnologists to speak of Seneca culture, Eskimo culture, North American Plains culture, and so on—that is, the culture of a particular society (Seneca) or an indefinite number of societies (Eskimo) or the cultures found in or characteristic of a topographic area (the North American Plains). There is no objection to this usage as a convenient means of reference: "Seneca culture" is the culture that the Seneca tribe possesses at a particular time. Similarly, Eskimo culture refers to a class of cultures, and Plains culture refers to a type of culture. What is needed is a term that defines culture precisely in its particular manifestations for the purpose of scientific study, and for this the term sociocultural

system has been proposed. It is defined as the culture possessed by a distinguishable and autonomous group (society) of human beings, such as a tribe or a modern nation. Cultural elements may pass freely from one system to another (cultural diffusion), but the boundary provided by the distinction between one system and another (Seneca, Cayuga; United States, Japan) makes it possible to study the system at any given time or over a period of time.

Every human society, therefore, has its own sociocultural system: a particular and unique expression of human culture as a whole. Every sociocultural system possesses the components of human culture as a whole—namely, technological, sociological, and ideological. But sociocultural systems vary widely in their structure and organization. These variations are attributable to differences among physical habitats and the resources that they offer or withhold for human use; to the range of possibilities inherent in various areas of activity, such as language or the manufacture and use of tools; and to degree of development. The biological factor of man may, for purposes of analysis and comparison of sociocultural systems, be considered as a constant. Although the equality or inequality of races, or physical types, of mankind has not been established by science, all evidence and reason lead to the conclusion that whatever differences of native endowment may exist, they are insignificant as compared with the overriding influence of the external tradition that is culture.

CULTURE AND PERSONALITY

The powerful influence of culture

Since the infant of the human species enters the world cultureless, his behaviour—his attitudes, values, ideals, and beliefs, as well as his overt motor activity—is powerfully influenced by the culture that surrounds him on all sides. It is almost impossible to exaggerate the power and influence of culture upon the human animal. It is powerful enough to hold the sex urge in check and achieve premarital chastity and even voluntary vows of celibacy for life. It can cause a person to die of hunger, though nourishment is available, because some foods are branded unclean by the culture. And it can cause a person to disembowel or shoot himself to wipe out a stain of dishonour. Culture is stronger than life and stronger than death. Among subhuman animals, death is merely the cessation of the vital processes of metabolism, respiration, and so on. In the human species, however, death is also a concept; only man knows death. But culture triumphs over death and offers man eternal life. Thus, culture may deny satisfactions on the one hand while it fulfills desires on the other.

The predominant emphasis, perhaps, in studies of culture and personality has been the inquiry into the process by which the individual personality is formed as it develops under the influence of its cultural milieu. But the individual biological organism is, itself, a significant determinant in the development of personality. The mature personality is, therefore, a function of both biological and cultural factors, and it is virtually impossible to distinguish these factors from each other and to evaluate the magnitude of each in particular cases. If the cultural factor were a constant, personality would vary with the variations of the neurosensory–glandular–muscular structure of the individual. But there are no tests that can indicate, for example, precisely how much of the taxicab driver's ability to make change is due to innate endowment and how much to cultural experience. Therefore, the student of culture and personality is driven to work with "modal personalities," that is, the personality of the typical Crow Indian or the typical Frenchman insofar as this can be determined. But it is of interest, theoretically at least, to note that even if both factors, the biological and the cultural, were constant—which they never are in actuality—variations of personality would still be possible. Within the confines of these two constants, individuals might undergo a number of profound experiences in different chronological permutations. For example, two young women might have the same experiences of (1) having a baby, (2) graduating from college, and (3) getting married. But the effect of sequence (1), (2), (3) upon personality development would be quite different than that of sequence (2), (3), (1).

CULTURAL COMPARISONS

Ethnocentrism in primitive and modern cultures

Ethnocentrism. Ethnocentrism is the name given to a tendency to interpret or evaluate other cultures in terms of one's own. This tendency has been, perhaps, more prevalent in modern nations than among preliterate tribes. The citizens of a large nation, especially in the past, have been less likely to observe people in another nation or culture than were members of small tribes who were well acquainted with the ways of their culturally diverse neighbours. Thus, the American tourist could report that Londoners drive "on the wrong side of the street" or an Englishman might find some customs on the continent "queer" or "boorish," merely because they were different. Members of a Pueblo tribe in the American Southwest, on the other hand, might be well acquainted with cultural differences not only among other Pueblos but also in non-Pueblo tribes such as the Navajo and Apache.

Ethnocentrism became prominent among many Europeans after the discovery of the Americas, the islands of the Pacific, and the Far East. Even anthropologists might characterize all preliterate peoples as being without religion (as did Sir John Lubbock) or as having a "prelogical mentality" (as did Lucien Lévy-Bruhl), merely because their ways of thinking did not correspond with those of the culture of western Europe. Thus, inhabitants of non-Western cultures, particularly those lacking the art of writing, were widely described as being immoral, illogical, queer, or just perverse ("Ye Beastly Devices of ye Heathen").

Cultural relativism. Increased knowledge led to or facilitated a deeper understanding and, with it, a finer appreciation of cultures quite different from one's own. When it was understood that universal needs could be served with culturally diverse means, that worship might assume a variety of forms, that morality consists in conforming to ethical rules of conduct rather than inhering in the rules themselves, a new view emerged that each culture should be understood and appreciated in terms of itself. What is moral in one culture might be immoral or ethically neutral in another. For example, it was not immoral to kill a baby girl at birth or an aged grandparent who was nonproductive when it was impossible to obtain enough food for all; or wife lending among the Eskimo might be practiced as a gesture of hospitality, a way of cementing a friendship and promoting mutual aid in a harsh and dangerous environment, and thus acquire the status of a high moral value.

The view that elements of a culture are to be understood and judged in terms of their relationship to the culture as a whole—a doctrine known as cultural relativism—led to the conclusion that the cultures themselves could not be evaluated or graded as higher and lower, superior or inferior. If it was unwarranted to say that patriliny (descent through the male line) was superior or inferior to matriliny (descent through the female line), if it was unjustified or meaningless to say that monogamy was better or worse than polygamy, then it was equally unsound or meaningless to say that one culture was higher or superior to another. A large number of anthropologists subscribed to this view; they argued that such judgments were subjective and therefore unscientific.

The question of subjective judgments

It is, of course, true that some values are imponderable and some criteria are subjective. Are people in modern Western culture happier than the Aborigines of Australia? Is it better to be a child than an adult, alive than dead? These certainly are not questions for science. But to say that the culture of the ancient Mayas was not superior to or more highly developed than the crude and simple culture of the Tasmanians or to say that the culture of England in 1966 was not higher than England's culture in 1066 is to fly in the face of science as well as of common sense.

Evaluative grading. Cultures have ponderable values as well as imponderable, and they can be measured with

objective, meaningful yardsticks. A culture is a means to an end: the security and continuity of life. Some kinds of culture are better means of making life secure than others. Agriculture is a better means of providing food than hunting and gathering. The productivity of human labour has been increased by machinery and by the utilization of the energy of nonhuman animals, water and wind power, and fossil fuels. Some cultures have more effective means of coping with disease than others, and this superiority is expressed mathematically in death rates. And there are many other ways in which meaningful differences can be measured and evaluations made. Thus, the proposition that cultures have ponderable values that can be measured meaningfully by objective yardsticks and arranged in a series of stages, higher and lower, is substantiated. But, it should be noted, this is not equivalent to saying that man is happier or that the dignity of the individual (an imponderable) is greater in an industrialized or agriculturized sociocultural system than in one supported by human labour alone and sustained wholly by wild foods.

Actually, however, there is no necessary conflict between the doctrine of cultural relativism and the thesis that cultures can be objectively graded in a scientific manner. It is one thing to reject the statement that monogamy is better than polygamy and quite another to deny that one kind of sociocultural system contains a better means of providing food or combatting disease than another.

CULTURAL ADAPTATION AND CHANGE

Ecological or environmental change. Every sociocultural system exists in a natural habitat, and, of course, this environment exerts an influence upon the cultural system. The cultures of some Eskimo groups present remarkable instances of adaptation to environmental conditions: tailored fur clothing, snow goggles, boats and harpoons for hunting sea mammals, and, in some instances, hemispherical snow houses, or igloos. Some sedentary, horticultural tribes of the upper Missouri River went out into the Great Plains and became nomadic hunters after the introduction of the horse. The culture of the Navajos underwent profound change after they acquired herds of sheep and a market for their rugs was developed. The older theories of simple environmentalism, some of which maintained that even styles of myths and tales were determined by topography, climate, flora, and other factors, are no longer in vogue. The present view is that the environment permits, at times encourages, and also prohibits the acquisition or use of certain cultural traits but otherwise does not determine culture change. The Fuegians living at the southern tip of South America, as viewed by Charles Darwin on his voyage on the "Beagle," lived in a very cold, harsh environment but were virtually without both clothing and dwellings.

Diffusion. "Culture is contagious," as a prominent anthropologist once remarked, meaning that customs, beliefs, tools, techniques, folktales, ornaments, and so on, may diffuse from one people or region to another. To be sure, a culture trait must offer some advantage, some utility or pleasure, to be sought and accepted by a people. (Some anthropologists have assumed that basic features of social structure, such as clan organization, may diffuse, but a sounder view holds that these features involving the organic structure of the society must be developed within societies themselves.) The degree of isolation of a sociocultural system—brought about by physical barriers such as deserts, mountain ranges, and bodies of water—has, of course, an important bearing upon the ease or difficulty of diffusion. Within the limits of desirability on the one hand and the possibility of communication on the other, diffusion of culture has taken place everywhere and in all times. Archaeological evidence shows that amber from the Baltic region diffused to the Mediterranean coast; and, conversely, early coins from the Near East found their way to northern Europe. In aboriginal North America, copper objects from northern Michigan have been found in mounds in Georgia; macaw feathers from Central America turn up in archaeological sites in northern Arizona. Some Indian tribes in northwestern regions of the United States had possessed horses, originally brought into the Southwest by Spanish explorers, years before they had ever even seen white men. The wide dispersion of tobacco, maize, coffee, the sweet potato, and many other traits are conspicuous examples of cultural diffusion.

Evidence of diffusion in the ancient past

Acculturation. Diffusion may take place between tribes or nations that are approximately equal in political and military power and of equivalent stages of cultural development, such as the spread of the sun dance among the Plains tribes of North America. But in other instances, it takes place between sociocultural systems differing widely in this respect. Conspicuous examples of this have been instances of conquest and colonization of various regions by the nations of modern Europe. In these cases it is often said that the culture of the more highly developed nation is "imposed" upon the lesser developed peoples and cultures, and there is, of course, much truth in this; the acquisition of foreign culture by the subject people is called acculturation and is manifested by the indigenous populations of Latin America and other regions. But even in cases of conquest, traits from the conquered peoples may diffuse to those of the more advanced cultures; examples might include, in addition to the cultivated plants cited above, words ("coyote"), musical themes, games, and art motifs.

One of the major problems of ethnology during the latter half of the 19th and the early decades of the 20th centuries was the question "How are cultural similarities in noncontiguous regions to be explained?" Did the concepts of pyramid building, mummification, and sun worship originate independently in ancient Egypt and in the Andean highlands and in Yucatán or did these traits originate in Egypt and diffuse from there to the Americas, as some anthropologists have believed? Some schools of ethnological theory have held to one view; some, to another. The 19th-century classical evolutionists (Edward Burnett Taylor, Lewis H. Morgan, and others) held that the mind of man is so constituted or endowed that he will develop cultures everywhere along the same lines (see also CIVILIZATION AND CULTURAL EVOLUTION). "Diffusionists"—those, such as Fritz Graebner and Elliot Smith, who offered grand theories about the diffusion of traits all over the world—maintained that man was inherently uninventive and that culture, once created, tended to spread everywhere. Each school tended to insist that its view was the correct one and to hold it unless definite proof of the contrary could be adduced. The tendency nowadays is not to side categorically with one school as against another but to decide each case on its own merits. The consensus with regard to pyramids is that they were developed independently in Egypt and the Americas because they differ markedly in structure and function: the Egyptian pyramids were built of stone blocks and contained tombs within their interiors. The American pyramids were constructed of earth, then faced with stone, and they served as the bases of temples. The verdict with regard to the bow and arrow is that it was invented only once and subsequently diffused to all regions where it has been found. The probable antiquity of the origin of fire making, however, and the various ways of generating it—by percussion, friction, compression (fire pistons)—indicate multiple origins.

Evolution. Evolution of culture—that is, the development of forms through time—has taken place. No amount of diffusion of picture writing could of itself, for instance, produce the alphabetic system of writing; as Tylor demonstrated so well, the art of writing has developed through a series of stages: picture writing, hieroglyphic writing, and alphabetic writing. In the realm of social organization there was a development from territorial groups composed of families to segmented societies (clans and larger groupings). Sociocultural evolution, like biological evolution, exhibits a progressive differentiation of structure and specialization of function.

A misunderstanding has arisen with regard to the relationship between evolution and diffusion. It has been argued, for example, that the theory of cultural evolution

Relationship between diffusion and evolution

was unsound because some peoples skipped a stage in a supposedly determined sequence; for example, some African tribes, as a consequence of diffusion, went from the Stone Age to the Iron Age without an intermediate age of copper and bronze. But the classical evolutionists did not maintain that peoples, or societies, had to pass through a fixed series of stages in the course of development, but that tools, techniques, institutions—in short, *culture*—had to pass through the stages. The sequence of stages of writing did not mean that a society could not acquire the alphabet without working its way through hieroglyphic writing; it was obvious that many peoples did skip directly to the alphabet.

Approaches to the study of culture

VIEWING CULTURE IN TERMS OF PATTERNS AND CONFIGURATIONS

Cultural traits. The concept of culture embraces the culture of mankind as a whole. An understanding of human culture is facilitated, however, by analyzing "the complex whole" into component parts or categories. In somewhat the same sense that the atom has been regarded as the unit of matter, the cell as the unit of life, so the culture trait is generally regarded as the unit of culture. A trait may be an object (knife), a way of doing something (weaving), a belief (in spirits), or an attitude (the so-called horror of incest). But, within the category of culture, each trait is related to other traits. A distinguishable and relatively self-contained cluster of traits is conventionally called a culture complex. The association of traits in a complex may be of a functional and mechanical nature, such as horse, saddle, bridle, quirt, and the like, or it may lie in conceptional or emotional associations, such as the acts and attitudes involved in seclusion in a menstrual hut or retrieving a heart that has been stolen by witches.

Cultural areas. The relationship between an actual culture and its habitat is always an intimate one, and therefore one finds a more or less close correlation between kind of habitat and type of culture. This results in the concept of culture area. This conception goes back at least as far as the early 19th century, but it was first brought into prominence by the U.S. anthropologist Clark Wissler in *The American Indian* (1917) and *Man and Culture* (1923). He divided the Indian cultures (as they were in the latter half of the 19th century) into geographical cultural regions: the Caribou area of northern Canada; the Northwest coast, characterized by use of salmon and cedar; the Great Plains, where tribes hunted the bison with the horse; the Pueblo area of the Southwest; and so on. Others later distinguished culture areas in other continents.

Cultural types. Appreciation of the relationship between culture and topographic area suggests the concept of culture type, such as hunting and gathering or a special way of hunting, such as use of the horse in bison hunting in the Plains or the hunting of sea mammals among the Eskimo; pastoral cultures centred upon sheep, cattle, reindeer, etc.; horticulture (with digging stick and hoe) and agriculture (with ox-drawn plow). Less common are trading cultures such as are found in Melanesia or specialized production of some object for trade, such as pottery, bronze axes, or salt, as was the case in Luzon.

Culture configurations and patterns

Configuration and pattern, especially the latter, are concepts closely related to culture area and culture type. All of them have one thing in common; they view culture not in terms of its individual components, or traits, but as meaningful organizations of traits: areas, occupations, configurations (art, mathematics, physics), or patterns (in which psychological factors are the bases of organization). Clark Wissler's "universal culture pattern" was a recognition of the fact that all particular and actual cultures possess the same general categories: language, art, social organization, religion, technology, and so on.

VIEWING CULTURE IN TERMS OF INSTITUTIONAL STRUCTURE AND FUNCTIONS

Social organization. A sociocultural system presents itself under two aspects: structure and function. As culture evolves, sociocultural systems (like biological systems) become more differentiated structurally and more specialized functionally, proceeding from the simple to the complex. Systems on the lowest stage of development have only two significant kinds of parts: the local territorial group and the family. There is a corresponding minimum of specialization, limited, with but few exceptions, to division of function, or labour, along sex lines and to division between children and adults. The exceptions are headmen and shamans; they are special organs, so to speak, in the body politic. The headman is a mechanism of social integration, direction, and control, expressing, however, the consensus of the band. The shaman, though a self-appointed priest or magician, is also an instrument of society; he may be regarded as the first specialist in the history of human society.

"Classes" and "segments"

All human societies are divided into classes and segments. Class is defined as one of an indefinite number of groupings each of which differs in composition from the other or others, such as men and women; married, widowed, and divorced; children and adults. Segment is defined as one of an indefinite number of groupings all of which are alike in structure and function: families, lineages, clans, and so on. On more advanced levels of development there are occupational classes, such as farmers, pastoralists, artisans, metalworkers, and scribes, and territorial segments, such as wards, barrios, counties, and states.

Segmentation is a cultural process essential to the evolution of culture; it is a means of increasing the size of a society or a grouping within a sociocultural system (such as an army) and therefore of increasing its power to make life secure, without suffering a corresponding loss of effectiveness through diminished solidarity; segmentation is a means of maintaining solidarity at the same time that it enlarges the social grouping. A tribe could not increase in size beyond a certain point without resorting to segmentation: the formation of lineages, clans, and the like. The word clannish points to one of the functions of segments in general: the fostering of solidarity. Tribes become segments in confederacies; and above the tribal level, the evolution of civil society employs barrios, demes, counties, and states in its process of segmentation. In present-day society, the army and the church offer illuminating examples of increased size and sustained solidarity proceeding hand in hand.

Economic systems. Division of labour along occupational lines is rare, although not wholly lacking, in preliterate societies—despite a widespread notion that one member of a tribe specializes in making arrows, which he exchanges for moccasins made by another specialist. Occupational groupings were virtually lacking in all cultural systems of aboriginal North America, for example. Guilds of metalworkers are found in some African tribes and specialists in canoe making and tattooing existed in Polynesia. But it is not until the transition from preliterate society, based upon ties of kinship, to civil society, based upon property relations and territorial distinctions (the state), that division of labour along occupational lines becomes extensive. On this level there are found many kinds of specialists: metalworkers, scribes, astrologers, soldiers, dancers, musicians, alchemists, prostitutes, eunuchs, and so forth.

Distribution and exchange of goods

Production of goods is everywhere followed by distribution and exchange. Among the Kurnai of Australia, for example, game was divided and distributed as follows: the hunter who killed a wallaby, for example, kept the head; his father received the ribs on the right side, his mother the ribs on the left side, plus the backbone, and so on; the various parts of the animal went to various classes of relatives in accordance with fixed, traditional rules.

Distribution along kinship lines constitutes a system of circulation and exchange within the tribe as a whole, for everyone is a relative of everyone else. It takes the form of bestowing gifts to relatives on all sorts of occasions—such as birth, initiation, marriage, death. In some cases there is an exchange of goods on the spot, but more often A gives something to B who gives A a gift at a later date.

All this takes place in the network of rights and obligations among kindred; one has both an obligation to give and a right to receive on certain occasions and in certain contexts. The whole process is one of mutual aid and cooperation.

The consequence of this form of distribution and exchange is that the recipient receives kinds of things that he already has; each household has the same kinds of foods, utensils, ornaments, and other things that every other household has. Why, then, it might be asked, does this form of exchange take place? Two reasons may be distinguished. First, this kind of exchange fortifies ties of kinship and mutual aid—as neighbourhood exchange among households in modern American culture initiates friendships that in times of need constitute mutual aid. Second, this system of circulation of goods is in effect a system of social security: a household in need, due to illness or accident, receives help from the community ("No household can starve as long as others have corn," as the Iroquois put it). Here we have an economic system subordinated to the welfare of the society as a whole.

Exchange or circulation of goods and services (a basket is the material form of "a service," that is, human labour) must, of course, take place in sociocultural systems where division of labour finds expression in specialization: the ironworker must obtain food; the horticulturalist needs an iron hoe.

Exchange of goods between sociocultural systems is universal and takes place on the lowest levels of cultural development. In some instances it is the only form of nonhostile communication: in the so-called silent trade the actual exchange takes place in a neutral zone without the presence of the participating parties. Archeological evidence shows that intergroup exchange occurred in remote times and over great distances, as already noted above in the discussion of diffusion.

An interesting form of the circulation of goods—usually referred to as redistribution—occurs among more highly developed tribes. The head of the sociopolitical system, that is, the chief or priest-chief, imposes levies upon all households, thus acquiring a large amount of goods—food, utensils, art objects, and so on—which he then redistributes to the households of the tribe. This may take the form and occasion of ceremonies and feasts or distribution may be made in cases of need. This widespread and interesting form of redistribution serves the same ends as those served by distribution as a function of the kinship system, namely, fostering solidarity and social security—an equitable distribution that tends to iron out inequalities among households.

Ownership and use

Some economic concepts in modern Western culture do not correspond closely with conceptions and customs in many preliterate societies. Ownership is a case in point. Complete possession of and exclusive right to use something in an economic context, such as land, a dwelling, or a boat, is rare, if not wholly lacking, in preliterate societies (although one might have exclusive rights to a dream, spell, or charm). In general, one has merely the right to use or occupy a tract of land or a house; when its use has terminated, anyone can take it over. In some societies it might be said that a boat "belonged" to the men who made it or even to the individual who initiated its construction. But anyone else in the community would have the right to use it when the "owners" (the men who made it) were not using it. It is right to use, rather than exclusive and absolute possession, that is significant; there is no such thing as absentee ownership in primitive society.

A band or tribe "holds" the land it occupies; here again, it is tenure rather than ownership that is significant; the land "belongs" to Nature, or Mother Earth; people merely hold and use it. There is usually an intimate relationship between the people and "their" land. Navajo Indians fell on their knees and kissed the earth when they were returned to their former territory after forcible detention in an alien land. Land is defended against outsiders, except when they are accepted as guests, but the significant thing is not that the outsiders do not own the land but that they pose a threat to those who occupy it.

In some tribes there is a distinct conception that the land held "belongs" to the tribe, the chief of which allots plots or tracts to individuals or households for their use. But when use terminates, the land reverts to the tribal domain.

During the latter part of the 19th century there was considerable discussion of "primitive communism." This doctrine came to be interpreted as meaning that private property, private right to hold or use, was nonexistent in primitive society. It was extended also to communism in wives and children in some tribes; this was interpreted to be a vestige of a former stage of "primordial promiscuity." Many ethnologists, however, launched a vigorous attack upon "the doctrine of primitive communism." Some of the conceptions of earlier anthropologists—such as group marriage—were shown to be unwarranted in the light of later research.

Today, with these polemics well in the past, the situation with regard to property rights in tribal societies may be summarized as follows. Tenure and use, rather than ownership in fee simple, were the significant concepts and practices. Private, or personal, possession of goods and use of land were recognized. But possession and right were qualified by the rights and obligations of kinship: one had an obligation both to give and to receive within the body of kindred, according to specific rules. In a de facto sense, things belonged to the body of kindred; rights of possession and use were regulated by customs of kinship. In some cultures a borrower was not obliged to return an object borrowed, on the theory that if one could afford to lend something he relinquished his right to its possession. The mode of life in preliterate society, based upon kinship and functioning in accordance with the principles of cooperation and mutual aid, did indeed justify the adjective communal; it was the noun communism that was resented—if not feared—because of its Marxist connotation.

One of the most important, as well as characteristic, features of the economic life of preliterate societies, as contrasted with modern civilizations, is this: no individual and no class or group in tribal society was denied access to the resources of nature; all were free to exploit them. This is, of course, in sharp contrast to civil society in which private ownership by some, or a class, is the means of excluding others—slaves, serfs, a proletariat—from the exploitation and enjoyment of the resources of nature. It is this freedom of access, the freedom to exploit and to enjoy the resources of nature, that has given primitive society its characteristics of freedom and equality. And, being based upon kinship ties, it had fraternity, as well (see also ECONOMIC SYSTEMS, PRIMITIVE).

Education. In the human species, individuals are equipped with fewer instincts than is the case in many nonhuman species. And, as already noted, they are born cultureless. Therefore an infant *Homo sapiens* must learn a very great deal, acquire a vast number of conditioned reflexes and habit patterns in order to live effectively, not only in society but in a particular kind of sociocultural system, be it Tibetan, Eskimo, or French. This process, taken as a whole, is called socialization (occasionally, enculturation)—the making of a social being out of one that was at birth wholly individualistic, egoistic.

Socialization or enculturation

Education in its broadest sense may properly be regarded as the process by which the culture of a sociocultural system is impressed or imposed upon the plastic, receptive infant. It is this process that makes continuity of culture possible. Education, formal and informal, is the specific means of socialization. By informal education is meant the way a child learns to adapt his behaviour to that of others, to be like others, to become a member of a group. By formal education is meant the intentional and more or less systematic effort to affect the behaviour of others by transmitting elements of culture to them, be it knowledge or belief, patterns of behaviour, or ideals and values. These attempts may be overt or covert. The teacher may make his purpose apparent, even emphatic, to the learner. But much education is effected in an unobstrusive way, without teacher or learner being

aware that culture is being transmitted. Thus, in myths and tales, certain characters are presented as heroes or villains; certain traits are extolled, others are deplored or denounced. The impressionable child acquires ideals and values, an image of the good or the bad.

The growing child is immersed in the fountain of informal education constantly; the formal education tends to be periodic. Many sociocultural systems distinguish rather sharply a series of stages in the education and development of full-fledged men and women. First there is infancy, during which perhaps the most profound and enduring influences of a person's life are brought to bear. Weaning ushers in a new stage, that of childhood, during which boys and girls become distinguished from each other. Puberty rites translate children into men and women. These vary enormously in emphasis and content. Sometimes they include whipping, isolation, scarification, or circumcision. Very often the ritual is accompanied by explicit instruction in the mythology and lore of the tribe and in ethical codes. Such rituals as confirmation and Bar Mitzwa in modern Western culture belong to the category of puberty rites.

With marriage come instruction and admonition, appropriate to the occasion, from elder relatives and, in more advanced cultures, from priests.

In some sociocultural systems men may become members of associations or sodalities: men's clubs, warrior societies, secret societies of magic or medicine. In some cases it is said that in passing through initiation rites a person is "born again." Women may belong to sodalities, also, and in some instances they may become members of secret, magical societies along with men.

Religion and belief. Man's oldest philosophy is animism, the doctrine that everything is alive and possesses mental faculties like those possessed by man: desire, will, purpose, anger, love, and the like. This philosophy results from man's projection of his own self, his psyche, into other things and beings, inanimate and living, without being aware of this projection. "To the Omaha," wrote anthropologist Alice Fletcher,

> nothing is without life: . . . He projects his own consciousness upon all things and ascribes to them experiences and characteristics with which he is familiar; . . . akin to his own conscious being ("Wakonda," in F.W. Hodge [ed.], *Handbook of American Indians North of Mexico*).

Development of religion

"A belief in spirits is," according to Edward Burnett Tylor, the great pioneer of English anthropology, "the minimum definition of religion." Preceding this stage, according to some students, is a belief in impersonal, supernatural power, or mana (manitou, orenda, etc.). In any case, these two elements of religion are virtually worldwide and undoubtedly represent a very early stage in the development of religion. In some cultures spirits are virtually innumerable, but, in the course of time, the more important spirits become gods. Thus, there has been a tendency toward monotheism in the evolution of religion. The German Roman Catholic priest and anthropologist Father Wilhelm Schmidt argued not only that some primitive peoples believe in a Supreme Being but that monotheism was characteristic of the earliest and simplest cultures. Schmidt's thesis, however, has been severely criticized by other ethnologists. Also, as Tylor pointed out many years ago, the Supreme Being of some very primitive peoples is not, in fact and effect, a god but rather a philosophic explanatory device that accounted for the existence and structure of the world; after his work was completed he had no other significance; he was not worshipped and played no part in the daily lives of the people.

In the past there was much discussion—and debate—about the difference between magic and religion. Both were deemed expressions of a belief in the supernatural. Some argued that religion was social (moral) whereas magic was antisocial (immoral). Another distinction was that magic was the use of supernatural power divorced from a spiritual being. The distinction between religion and magic was so beset with exceptions as to render most definitions of these terms logically imperfect. Another difficulty was the tacit assumption that different entities, religion and magic, exist per se, and therefore that "correct" definitions of them must exist also (Adam called the animal a horse because it was a horse). Much confusion and debate would have been obviated if it had been recognized (as it generally is now) that there is no such thing as a "correct" definition—all definitions are man-made and arbitrary—and that the problem is not what is religion or magic but what beliefs, events, and experiences does one wish to designate with the words religion and magic (see also MAGIC; RELIGION, SOCIAL ASPECTS OF; RELIGION, STUDY OF).

Custom and law. Sociocultural systems, like other kinds of systems, must have means of self-regulation and control in order to persist and function. In human society these means are numerous and varied. The kinship organization specifies reciprocal and correlative rights, duties, and obligations of one class of relatives to another. Codes of ethics govern the relationship of the individual to the well-being of society as a whole. Codes of etiquette regulate class structure by requiring individuals to conform to their respective classes. Custom is a general term that embraces all these mechanisms of regulation and control and even more. Custom is the name given to uniformities in sociocultural systems. Uniformities are important because they make anticipation and prediction possible; without them, orderly conduct of social life would not be possible. Custom, therefore, is a means of social regulation and control, of effecting compliance with itself in order to render effective conduct of social life possible.

Ethics, etiquette, law, and other norms

As in the case of religion and magic, much effort and debate have been spent in attempts to achieve a clean-cut distinction between custom and law. There is little or no difficulty when one is concerned with the extremes of the spectrum of social control. The way that a Hopi Indian holds his corn-husk cigarette in his hand is a matter of custom rather than law, as most ethnologists would probably agree. At the other extreme, a state edict prohibiting the manufacture and sale of alcoholic beverages is a law, not a custom. But in other situations, the distinction is far from clear and disagreement with regard to definitions arises. For example, in marriage the obligation to wed someone within a specified group or class (endogamy) or outside a group or class (exogamy) has been called both law and custom. Probably the most useful distinction between custom and law is the following. If an infraction of a social rule or deviation from a norm is punished merely by expressions of social disapproval, gossip, ridicule, or ostracism, the rule is called custom. If, however, infractions or violations are punished by an agency, designated by society and empowered to act on its behalf, then the rule is called a law. But even here there is difficulty. The same kind of offense may be punished by custom in one society, by law in another: for example, adultery, incest, miscegenation, black magic.

It is the ethnologist, rather than the historian, who is disturbed by instances of ambiguity with regard to custom and law; in preliterate societies the distinction between the two is not always clear. But in civil societies—that is, states brought into being by the agricultural revolution and their more recent successors—the distinction is usually sharper and more apparent, though instances of sumptuary laws that prohibit the wearing of silk or that limit the length of a garment merge law and custom or reinforce the latter by the former.

One need not be unduly disturbed by the difficulty of making sharp distinctions among sociocultural phenomena and of formulating definitions. The phenomena of culture, like those of the external world in general, are what they are, and if man-made concepts and words do not correspond closely with them, one may regret the lack of fit. But it is better to do this than to distort real phenomena by trying to force them into artificial concepts and definitions.

BIBLIOGRAPHY. For a general account of man and culture, see RALPH L. BEALS and HARRY HOIJER, *An Introduction to Anthropology*, 3rd ed. (1965); ELMAN R. SERVICE, *Primitive Social Organization: An Evolutionary Perspective* (1962); and SOL TAX (ed.), *Horizons of Anthropology* (1964). EDWARD

BURNETT TYLOR, *Anthropology* (1881; abr. ed., 1960), is still valuable. The question of whether man is unique psychologically or "just a more highly developed primate" is discussed by LESLIE A. WHITE, "The Symbol: The Origin and Basis of Human Behavior," in *The Science of Culture*, 2nd ed., pp. 22–39 (1969); and by ERNST CASSIRER, *An Essay on Man: An Introduction to a Philosophy of Human Culture* (1944 and 1956). A compilation and critical review of the numerous conceptions of culture are provided by A.L. KROEBER and CLYDE KLUCKHOHN, *Culture: A Critical Review of Concepts and Definitions* (1952). A conception of culture based on the material reviewed by Kroeber and Kluckhohn is found in LESLIE A. WHITE, "The Concept of Culture," *Am. Anthrop.*, 61:227–251 (1959).

(L.A.W.)

Human Cultures, Primitive and Non-Urban

So great are the variations in ways of life, past and present, that comparisons among them are difficult. Any simple classification of human societies and cultures can only be viewed as arbitrary. From a modern urban point of view, nevertheless, there is the obvious distinction between the primitive and the civilized: between *simple* and *complex* societies; between *tiny* and *huge* social agglomerations; between *scattered* and *dense* populations; and, above all, between *prestate* societies and societies that have developed *states*. In general, civilization involves the rise of legal institutions and the acquisition of a legal monopoly of force by a government. Those developments made possible the cities and empires of classical times and the growth of dense populations. Thus "civilized" is nearly synonymous with "urban."

The varieties of non-urban, or primitive, societies may be further classified. One way is by the methods they use to get food. Those who hunt and gather behave quite differently, as societies, from herdsmen and mounted predator-warriors, the *pastoralists*, who in turn live quite differently from the various kinds of *agriculturalists*. These distinctions are not sharp, for of course there are societies that combine foraging with some agriculture; others, some agriculture and some herding; and, in a few cases, a class of herders may live in the same society with a class or caste of agriculturalists. A whole continuum of societies may be constructed, ranging from tiny, simple bands of hunter-gatherers in poor environments to large, dense populations of irrigation agriculturalists —that is, from the entirely nomadic to the fully sedentary. The degree to which societies approach the sedentary deserves prominence in any classification, since sedentary ways are accompanied by so many other cultural traits and institutions.

Primitive societies

NOMADIC SOCIETIES

Throughout 99 percent of the time *Homo sapiens* has been on earth, or until about 8,000 years ago, all peoples were foragers of wild food. There were great differences among them; some specialized in hunting big game, fishing, and shellfish gathering, while others were almost completely dependent on the gathering of wild plants. Broadly speaking, however, they probably shared many features of social and political organization, as well as of religions and other ideologies (in form though not in specific content). The hunting-gathering societies declined with the growth of agricultural societies, which either drove them from their territories or assimilated or converted them.

The later rise of the nation-states, especially after the Industrial Revolution in Europe, resulted in the near extermination of hunting-gathering societies. Today, the remaining ones are confined to desert, mountain, jungle, or Arctic wastelands. Some have been studied and described by anthropologists; the central and northern Australians, the Bushmen of the Kalahari in southern Africa, the Pygmies of the central African forests, the Pygmies of the Andaman Islands in the Indian Ocean, the Ona and Yahgan Indians of southern South America, the "Digger" Indians of Nevada, the Indians of the northern Canadian forests, and the Canadian, Alaskan, and Greenland Eskimos.

All of these peoples inhabit areas representing almost every extreme in climate and environment, but they have one thing in common: their marginality to, or relative isolation from, modern economic systems. Their techniques and forms of food getting vary greatly. The Eskimos, for example, are entirely dependent on hunting and fishing; the African Bushmen, the Australian aborigines, and the Nevada Indians are chiefly dependent on the gathering of seeds, nuts, and tubers.

The significance of nomadism to the student of primitive cultures may be suggested by a comparison of the Ona and Yahgan of Tierra del Fuego. The Ona inhabit the interior forests and depend heavily on hunting guanaco (a small New World camel). The Yahgan are canoe-using fishermen and shellfish gatherers. Yet, despite their utterly different ecological adaptation, the two Indian societies share a common culture that is so similar that anthropologists conventionally lump them together with the neighbouring Chono and Alakaluf of Chile as a "Fuegian culture area." They are all nomadic, though the Ona are "foot Indians" and the others are "canoe Indians"; they are all relatively sparsely scattered over the landscape, poor in material culture, and with similar social, political, ceremonial, and ideological customs and institutions.

Common characteristics of nomadic societies

All of the nomads so far mentioned share important general characteristics. The first and most obvious is that their nomadism severely restricts the amount of their "baggage," or material culture. Bows and arrows (except in Australia, where the unique boomerang is used instead) and perhaps a simple spear javelin, or in some areas throwing sticks or clubs, are the usual hunting and fighting weapons. In warmer zones shelter is a simple lean-to or small beehive hut of sticks, twigs, and leaves. In Arctic zones there are the caribou-skin tent and the famous Eskimo igloo—or, in more permanent or revisited places, the stone hut.

Camps are small and impermanent. The nuclear family likes to camp near related families when possible, and usually this forms the patrilineally extended family—a group of brothers with their own nuclear families and perhaps a few dependent elders. But the size of the camp depends on the season: in times of easily gathered plant food, large groups may come together for ceremonies such as puberty rites. At other times, the constituent families may scatter widely because food and water are scarce. Patrilineally related men and their families, scattered or not, commonly regard themselves as a group with rights over a particular territory and may be distinguished from neighbours on a territorial basis as well. Marriages are often arranged among territorial groups so that contiguous groups tend to be related, or at least certain members of different groups will be related. But this is the only organizing principle that extends beyond the territorial band. Each band may be thought of as part of a larger society comprised of distant as well as close relatives—a "tribe" in one of the original meanings of the word.

The social organization looks as though it had been built up from within, so to speak. Family-like statuses and roles, alliances by marriage, and systems of "social distance" based on family relationships are the bones and connective tissues of the society. These are all ingredients of the family itself, however extended or metaphorically construed; it is as though these societies were simply the result of the growth of individual families. But this is only appearance; such societies also grow by accretion. But inasmuch as alliances and the compounding of different groups normally are brought about by arranged marriages, the familistic appearance of the whole is therefore maintained.

Almost all status positions rest upon the same criteria of age, sex, and kinship distance. The only achieved status is that of the magical curer, the "shaman." Again, with the exception of the shaman, the only division of labour in these societies is on the basis of age and sex—

just as in the individual nuclear family unit. Among adults, the hunting of big game is confined to men, whereas the gathering of vegetable foods or small animals, birds' eggs, and so on are women's tasks. This division of labour seems obviously related to men's propensity and relative ability to range far from camp, women being too burdened with the problems of motherhood to track animals wherever they may lead. But the separation of tasks is usually more rigid and confining than the physical and circumstantial differences between men and women dictate, since these would vary among individuals and from society to society—and for that matter, from day to day. Domestic tasks are strictly defined as female and are undertaken only by women even when they seem exceptionally taxing, as attest the following remarks by Lewis Garrard, who travelled with a Cheyenne Indian camp in 1846:

> After a ride of two hours, we stopped, and the chiefs, fastening their horses, collected in circles, to smoke the pipe and talk, letting their squaws unpack the animals, pitch the lodges, build fires, arrange the robes, and when all was ready, these 'lords of creation' dispersed to their several homes, to wait until their patient and enduring spouses prepared some food. I was provoked, nay, angry, to see the lazy, overgrown men, do nothing to help their wives; and, when the young women pulled off their bracelets and finery, to chop wood, the cup of my wrath was full to overflowing, and, in a fit of honest indignation, I pronounced them ungallant, and indeed savage in the true sense of the word (*Wah-To-Yah and the Taos Trail;* University of Oklahoma Press, Norman, Oklahoma, 1966).

Status within the family is based on age, sex, relationships by blood, or marriageability. Males are regarded as superior to women in most activities; the elders are respected as repositories of both secular and spiritual wisdom; and people, such as cousins who may be of the same genealogical distance, are frequently divided into "marriageable" and "nonmarriageable" groups, with consequent differences in their interpersonal behaviour. But in all other respects hunting-gathering societies are profoundly egalitarian, especially in intergroup relations.

Outside the family there is no system of coercive authority. Some persons may, by their wisdom, physical ability, and so on, rise to positions of leadership in some particular endeavour, such as a raiding party or a hunt. But these are temporary and variable positions, not posts or offices within a hierarchical structure. Social order is maintained by emphasizing correctness in conduct—etiquette—and ritual and ceremony. Ceremonies bring together the scattered members of the society to celebrate birth, puberty, marriage, and death. Such ceremonies have the effect of minimizing social dangers (or the perception of them) and also of adjusting persons to each other under controlled emotional conditions. (It may very well be true that "the family that prays together, stays together.")

The passage rites at birth, marriage, and death are universal in human society, though puberty celebrations are less common in the modern world, except for such survivals as the Jewish Bar Mitzwa. In most hunting-gathering societies, however, male puberty rituals take up more social time and engage more people than do the other three ritual occasions. They may last as long as a month, food supplies permitting. Almost universally puberty rites include a period of instruction in adult responsibilities, rituals dramatizing the removal of boys from the mothers' care and signallizing the changed social relations between boys and girls of the same generation, and physical ordeals, including scarification or some other mark that will permanently demonstrate the successful passage to manhood.

The Plains Indians

The mounted buffalo hunters of the North American Great Plains, common in popular literature and cowboy movies, constituted a type of nomadic hunting society. But they represented a brief and very special development: an interaction and amalgamation of elements of Indian culture to Spanish horses and the training of them, as well as to metal and guns. The Indians, once mounted, could follow, surround, and kill tremendous numbers of buffalo, where previously the Indians had found the buffalo herds nearly impregnable. So productive was mounted buffalo hunting that tribes of diverse languages and customs were quickly drawn into the Great Plains from all directions. A distinctive, picturesque culture arose among them, reaching its peak about 1800. But from 1850 through the 1870s the tide of white settlers virtually wiped out the buffalo. By that time most of the Indians had been defeated in battle and confined to reservations.

Equestrian Indians can be regarded as a special form of nomadic hunters rather than as a form of pastoralists. Pastoral culture is dominated by the requirements of domesticated livestock and by the relation of herds to pasture. The Plains Indians' nomadism, however, was determined by the habits of the wild buffalo herds. The natural cycle of the buffalo was to concentrate in huge herds in summer and disperse into smaller groups in winter and spring. The Indians accordingly travelled in small camps of a few related families in winter and formed huge encampments in summer and fall for tribal ceremonies and organized cooperative hunts. The summer camps sometimes numbered several thousand people.

The continual intrusion of new groups into the Plains —first Indians, then whites—and the introduction of new weapons constantly altered the balance of power and kept the region in a state of belligerent turmoil. Equestrian bow-and-arrow Indians were superior militarily to those on foot; Indians with guns, of course, were superior to bow-and-arrow Indians; but Indians with both guns and horses—as happened in the Central Plains first—were vastly superior to the others. But the supply of horses and guns and especially ammunition continued to fluctuate wildly as access to sources varied greatly from place to place and time to time.

Nomadism places limitations on property and material technology, and the Plains Indians consequently manufactured no pottery, cloth, or basketry, although leatherwork and beadwork were highly developed. On the other hand, being equestrian, they could carry far more goods than nomadic hunters on foot. Perhaps the most notable thing they carried was the large conical tent (tepee) of decorated buffalo hide.

Socio-political organization was informal, probably because of the fluidity of the population. On the other hand, some tribal cohesion and systems of alliance were required because of the constant raiding. Consequently a large number of pan-tribal associations arose, especially military societies and male age-graded societies.

Religion among the Plains Indians reflected the varying sources of the original religions of the prehorse tribes. Some elements, however, became widespread in the Plains. The folk-hero of a great many myths was the trickster Old-Man-Coyote. There was a widespread concept of Manitou, the pervasive spirit. Most notable was the nearly universal importance attached to the sun—but without the notion of sun as a supreme deity. Ordeals and self-torture and mass ritual self-torture were common Plains religious practices. The Indian tortured himself and fasted in order to suffer hallucinations that would reveal a personal guardian spirit for his protection in the hunt and in battle.

As in other nomadic hunting-gathering societies, principal ceremonies were related to the life cycle, with special prominence given to male puberty rites to instill bravery, endurance, and hunting and raiding skills.

SETTLED HUNTING AND FOOD-GATHERING SOCIETIES

Outstanding examples of the settled hunters and gatherers were the peoples of the North Pacific Coast of North America, roughly from Oregon to southern Alaska. The resources of the sea and inlets and rivers were in astonishing variety, and some, like the salmon during their runs, were so easy to catch that the word "harvesting" seems more appropriate than "fishing" for this activity. In central and northern California there were numerous sedentary Indian groups, such as the Pomo, Wintun, and Yurok. Their basic food was the acorn, which was

ground and stored as flour. Many of the streams had salmon, and the Indians also gathered roots and berries and hunted wild fowl and deer. Other sedentary hunter-gatherer societies are rare and scattered. The most prominent of these are in southwestern New Guinea, as represented by the Asmat. These groups rely on the sago palm, whose starchy pith is easily reduced to flour. Fish, wild birds, and semidomesticated pigs supplement the basic sago.

The effect of food on population and culture

The basic foods of these sedentary peoples had one common characteristic: they were reliable, and they could be stored, much as can the products of agriculture. Salmon were smoke-dried and stored in wooden boxes by the Northwest Coast Indians, and acorn flour obviously could be stored just as can grain flour. Sago flour can also be stored, but it has no season; a palm can be cut at any time the food is required. So abundant and reliable are these resources that such peoples are said to practice a "natural agriculture."

Sedentary life makes possible many improvements in material culture. Houses become larger and more elaborate and are improved over time. The Asmat of New Guinea and the Northwest Coast Indians make huge houses of planks, and are among the best wood-carvers of the primitive world.

Permanent villages and a consistent abundance of food make possible high population densities. The California tribes are estimated to have reached 11 or 12 persons per square mile, as did those of the Northwest Coast. The Asmat of New Guinea have villages ranging up to 2,000 people, which is from 10 to 20 times the size of the average hunting-gathering settlement. Usually such large villages remain politically independent. Intermarriages occur, of course, and some local cohesion is achieved by secret societies and other clublike associations. But such integration is only incidental.

The Northwest Coast Indians

The Northwest Coast Indians elaborated a hierarchical form of organization, or chiefdom. They are the only hunter-gatherers to have done so. Chiefs or nobles occupied positions of high status, inherited in a single descent line by primogeniture. Secondary lines of descent, collateral to the above, were of lesser status. Finally, there were the commoners.

Along with chiefly status went the socio-economic institution of redistribution. Surplus products of family production were passed on to the chief, who in turn gave a large feast (or "potlatch"), during which he distributed gifts to those who needed them. This process of redistribution had the economic function of encouraging specialization and division of labour. The potlatch in late times on the Northwest Coast became famous for its competitiveness. A chief of a lineage or longhouse, for example, would amass as much food and material goods as he could in order to lay on a feast and give presents lavishly in hopes that the guest lineage would be unable to reciprocate on the same scale. Thus one lineage, house, or perhaps village might "defeat" the others.

The Northwest Coast Indian type of chiefdom is primarily social and economic. It can be called political only to the extent that a certain amount of personal authority for decision making may reside in a high social status. This authority can serve a purpose, however. The egalitarian nature of hunting-gathering bands tends toward anarchy, which becomes perilous in populous societies. Quarrels can turn into feuds for lack of a higher authority to settle them.

HORTICULTURAL SOCIETIES

Primitive agriculture is called horticulture by anthropologists rather than farming because it is carried on like simple gardening, supplementary to hunting and gathering. It differs from farming also in its relatively more primitive technology. It is typically practiced in forests, where the loose soil is easily broken up with a simple stick, rather than on grassy plains with heavy sod. Nor do horticulturalists use fertilizer intensively, or crop rotation, terracing, or irrigation. Horticulture is therefore much less productive than agriculture. The villages are small—some no larger than many hunting-gathering settlements—and the overall population density is low compared with farming regions.

Forest horticulturists use fallowing techniques variously called "slash-and-burn," "shifting cultivation," and "swidden cultivation" (a northern English term now widely used by anthropologists). After about two years of cropping a plot is left fallow for some years and allowed to revert to secondary forest or bush. Before resuming cultivation the bush may be cut, left to dry, and then burned. The ashes bestow some fertilization, but the foremost benefit of this procedure is that the plot will be relatively weed free at first.

Since the fallowing periods of the plots are much longer than the planted periods, the swidden horticulturalists must gradually encroach on more distant land. Sometimes this results in semisedentary villages when the newly arable plots finally are so distant that a few horticulturalists must start to build huts near the newer fields, to be joined later by others. Such a land-hungry system, in a region of competing populations, greatly increases the chances of conflict. Population dispersal thus becomes a grave threat in horticultural regions. Land for expansion inevitably must be found at the expense of neighbours or by shortening the fallowing periods—which eventually results in lower production.

Many forest tribes—typical are the horticulturalists of the South American tropical forest—constantly maintain a military posture. Large-scale warfare is not usual (because of the lack of political leadership) but raids, cannibalism, torturing of captives, and other forms of belligerence are.

Horticulturalists have more material goods than most hunter-gatherers, though not more than such societies as the Indians of the Northwest Coast. This suggests that the accumulation of domestic goods is related not so much to the higher productivity of the horticulturalists as to their greater stability of settlement.

The most highly developed of aboriginal slash-and-burn horticulturalists were undoubtedly the Maya of Guatemala and Yucatán, who had a chiefdom or primitive state. But this was most exceptional, for almost all other primitive horticulturalists did not go beyond simple tribes with egalitarian and nearly autonomous communities. Any regional confederation was likely to be only on the basis of intermarriage and clanship. Sometimes an ephemeral sort of near-chiefdom arises, founded on the capabilities of a charismatic leader. In Melanesia, where a well-established form of personal politics thrives, the leader is called Big-Man or Centre-Man.

The Big-Man of Melanesia

The Big-Man in Melanesia is big because he has a following. He begins with his own family and near relatives and friends, who provide goods that he, on behalf of his group, gives away to other groups at a feast on some ceremonial occasion. He and his faction are feasted reciprocally by others at other times. His ability to redistribute on an increasingly lavish scale to larger groups expands his following. He thus amasses what the anthropologist Bronisław Malinowski, in reporting on the Trobriand Islanders, called a "fund of power." With the public esteem gained in this economic contest, the Big-Man is sought out for giving advice, adjudicating quarrels, planning ceremonies, admonishing and conciliating. But this is influence, not the true authority that inheres in a status or office in an established hierarchy. A really big Big-Man may succeed in integrating a region of several villages, but when he loses to a rival or dies, the unity of the region dissolves until some other unusually influential man unites it again.

In many respects the religion of horticultural peoples resembles that of hunting-gathering peoples. Shamans, life-crisis ceremonies—especially puberty rites—totemism (ceremonies for plant or animal species believed to be ancestral to particular human groups like clans or lineages), and the worship of animistic spirits are common in the religion of many kinds of primitive societies. The egalitarian society does not usually practice ancestor worship, as does the hierarchical society. Among horticultural peoples with chiefdoms, the chief's ancestors, in

time, become gods. The most remote ancestors, the founders of the chiefly lineage, are the most important gods; more recent ancestors and those of related but collateral lines have a lesser status. The result is a hierarchy of gods resembling the political hierarchy on earth. Furthermore, the chiefdoms tend to be theocracies, with the hierarchy of priests closely and functionally related to the political hierarchy.

HERDING SOCIETIES

Herding societies are in many respects the direct opposite of forest horticulturalists. They are usually the most nomadic of primitive societies, they occupy arid grasslands rather than rain forests, they have a nearly total commitment to their animals, and their socio-political system is nearly always that of a true hierarchical chiefdom rather than of egalitarian villages and tribal segments.

The military advantages of herders

A society largely committed to herding has military advantages that a settled agricultural society does not have. If military power is important to survival, it will increase the commitment to the herding specialization, mainly because of the advantage conferred by mobility. This increased commitment, however, will result in the gradual loss of certain previously acquired material developments such as weaving, metalworking, pottery, substantial housing and furniture, and, of course, variety in the diet. Wealth is a burden in such societies. Successful nomadic pastoralists normally have some kind of symbiotic relationship to a settled society in order to acquire goods they cannot produce themselves. The symbiosis may be through peaceful trade. But often the military advantage of the pastoralists has led to raiding rather than exchange.

The best known and purest pastoral nomads are found in the enormous arid belt from Morocco to Manchuria, passing through North Africa, Arabia, Iran, Turkistan, Tibet, and Mongolia. They include peoples as diverse as the Arabized North Africans and the Mongol hordes. Other less specialized and successful pastoralists include the Siberian reindeer herders, cattle herders of the grasslands of north-central Africa, and the Hottentot and Herero of southern Africa.

Classic, full pastoralism with its powerful equestrian warriors seems to have developed around 1500 to 1000 BC in inner Asia. This relatively late full-scale pastoralist specialization may have resulted from population pressure. Horticulture mixed with domestication of animals seems to have predominated until even the least cultivable zones were filled. When warfare became endemic in such zones, many groups were forced to become fully nomadic in the arid grasslands. They might have been the losers, pushed out of their homelands, only to discover later the military power that accrued to the pastoral way of life. Thus the victims became victors.

The full pastoralism of inner Asia requires the care of animals—including varying combinations of horses, cattle, camels, sheep, and goats—kept in ecological balance with grazing conditions over an enormous area. In some regions, however, the people may depend on a single animal species. In Arabia it is the camel (although most tribes in Arabia or North Africa also keep horses), and in east-central Africa some peoples specialize exclusively in cattle. Among these there is sometimes found a complete symbiosis between a tribe of herders and an adjacent tribe of horticulturalists to the point that they resemble a single society composed of two specialized castes, the herders occupying the superior position.

There are many part-time herding societies, and many that have merely borrowed herding techniques. The reindeer breeders of the Siberian tundra have learned to apply to reindeer some of the methods of the horsemen farther south, but hunting remains their main subsistencial activity. In the Argentine pampas, Indians learned to domesticate and ride the Spanish horse, which they used to hunt the rhea bird and the wild herds of Spanish cattle. The Navaho and other Indians of the American Southwest have exploited the sheep brought in originally by Spaniards, but mostly as a source of wool for blanket and rug weaving. Llamas and alpacas were domesticated in the South American Andes, but no independent pastoral society ever emerged there.

Fully committed pastoralists manifest a considerable degree of cultural uniformity. In economics, social organization, political order, and even in religion, their livelihood with its functional requirements has ironed out what must have been considerable cultural differentiation among such disparate peoples as Mongols, Arabs, and African Negroes.

Cyclical routes of the pastoralists

The wanderings imposed on pastoralists by the necessities of forage and water tend to be cyclical and to follow long-established routes. The cycles are usually seasonal: to the lowlands in winter, to highlands in summer in temperate zones, to more arid areas in the wet season, to more watered regions in the dry season, and so on. Frequently the seasonal moves are accompanied by cultural and organizational changes. For example, a large group may draw together to pass through hostile territory and disperse later when in their own land; frequently the lush (normally wet) season brings the pastoralists together for ceremonies, trade, and fun, while the dry season requires dispersion and arduous work (as in digging deep wells to water the animals). Anthropologists call such established cyclical movements "transhumance orbits."

Since pastoralists live in so many different environments, and since even the same society varies from season to season and in response to wider spaced drought cycles, it is reasonable to expect great variations in population density. These factors, of course, affect political organization. Nomadic pastoralism lends itself to wide fluctuations in the size of political units, political cohesion, and degree of centralization.

The elementary unit of organization is the patrilineally extended family, frequently an elder patriarch and his sons and their families. In addition, if some degree of primogeniture (*i.e.*, the eldest son inheriting most of the decision-making power for the group) prevails, and if it is extended to include other groups in terms of putative birth order and patrilineal descent, the basis of the pastoral social organization is established. This social structure has been called the "conical clan" (for its hierarchical shape). It is a characteristic social organization of chiefdoms everywhere. Its capacity for waxing and waning, fusion and fission, has obvious advantages, especially when a brief makeshift political ordering of a very large horde is militarily necessary. But the large organizations cannot maintain themselves for very long, since they easily split into their parts.

It has been noted that herders are likely to raid settled villages. But herders frequently raid each other as well. Livestock is wealth and can be exchanged for other forms of wealth—including wives. Stock raiding, like most forms of aggression, has two facets: one seems to be to replenish one's wealth at a stranger's expense; the other is to warn strangers against encroachment. But a raid frequently leads to retaliation and then to counterretaliation, until such raiding societies gradually become hereditary enemies.

The militarism of herding societies has played a major role in history. As wealthy agricultural civilizations developed in the Fertile Crescent of the ancient Near East, in the Indus River Valley, and at the middle bend of the Yellow River in China, they became easy prey for nomads. Indeed, it is likely that urbanization was stimulated for defensive reasons because of the dangers posed by nomads. These dangers may also have stimulated the formation of legal and governmental institutions in sedentary societies threatened by the pastoral raiders.

Trend to ancestor worship

To the extent that pastoral nomadic societies achieve wealth and success in herding and in war, they tend to solidify and extend their chiefdom structure. They also add to their religious organization a hierarchical principle together with the content known as ancestor worship. Much of the mythology by which a primitive people ex-

plains itself and its customs comes in this way to have an ingredient familiar to readers of the Old Testament—the lengthy story of who begat whom and in what order.

Increased dependence on herds, particularly dependence on one particular species, such as cattle, horses, or camels, is reflected in much of the ideological and ritual content of religion. Sometimes the significance of herding leads not only to the glorification of herds and herding but even to a religious taboo against planting. Some Mongols, so quintessentially pastoral, believe that plowing and planting defile the earth spirit. Among the Nuer, as among other African cattle herders, horticulture may be practiced in time of need, but it is considered degrading toil whereas herding is a very prideful occupation. The ethnologist of the Nuer, E.E. Evans-Pritchard, wrote:

> They are always talking about their beasts. I used sometimes to despair that I never discussed anything with the young men but livestock and girls, and even the subject of girls led inevitably to that of cattle . . . . (From E.E. Evans-Pritchard, *The Nuer;* Oxford University Press, London, 1940.)

Peasantry

The one remaining category of non-urban society is the peasant. Peasants are not nomadic but sedentary (thus distinguishable from both hunting-gathering societies and pastoralists); they are not horticultural tribal societies but more intensively and fully agricultural; and neither are they urban, like populations who lived in the centres of the classic civilizations. Except for a few other characteristics, however, writers on peasantry have not agreed on a precise definition. Everyone notes that peasant communities tend to be small, and most also agree that they tend to be tradition bound and resistant to change, also, that they are "part-societies" or "part-cultures" in relation to some larger civilization, colony, urban centre, state, or elite class.

PEASANT COMMUNITIES

The best way to proceed, then, is to consider, however briefly, all the kinds of societies that have been conventionally called peasant in their full historical, geographical, and cultural diversity. One way to decide the question of peasant society's structural relationship to a larger society is to review a wide variety of examples.

The first agricultural revolution

By about 4000 BC in Mesopotamia and about 1000 BC in Middle America some agricultural villages had begun to become cities. This was part of the evolution of intensive agriculturalists that was to lead gradually to the empires of classical civilization. One major significance of the classical empire was that it could protect, and thus politically incorporate, at least in some areas, scattered villages of simple cultivators; it could tax them (exact tribute in some form), even conscript them, and, thus, make a census of them. The invention of writing may well have gotten its start in such record keeping. At least, it was developed greatly in urban centres.

Outlying agricultural villages could not have survived without internal pacification (in the law-and-order sense) and without some kind of frontier militia. The rulers of the urban centre would soon find that the price of the protection they extended to the peasants could easily be increased to the point of virtual expropriation. As a result, the peasants were reduced to the barest subsistence level. But even without exploitation, the peasant acquires a lowly status. Dependence often creates servility in manner, rural isolation tends to make the peasant ignorant and no match for the sophisticated urbanite, and poverty keeps him dependent generation after generation. It is not simply that the peasant is somehow "exploited" (a difficult point to determine in most cases) but that his village is normally small, poor, ignorant, and generally backward compared with the urban centre or feudal manor. Horticultural tribes, of course, live in even smaller villages and are poorer and more ignorant, but they in some sense possess a complete culture, while a peasant villager has only a part-culture. What seems to be universal is the peasant's low status, with its concomitant ascription of poverty and ignorance, in contrast to other parts of the same culture.

Peasants distinguished from farmers

The pre-industrial urban centre with its statelike protection and intervention in the lives of peasants made it possible to extend agricultural domains, usually as peasant holdings, into pastoral or other "wild" territory. An enormous part of the world's population became peasants as primitive peoples and nomads were dominated and displaced or transformed. Today, with the rise of modern science and industry, peasants are being rapidly displaced in all of the so-called developing or modernizing parts of the world.

To understand what peasants are it is helpful to contrast them with what they are not—farmers in an industrialized world. The modern farmer, operating on a cost-accounting basis, has little in common with the peasant family or villager. Industrialization increased the need for agricultural produce, which stimulated production for the market. The application of science—with such aids as artificial fertilizers, pesticides, farm machinery, and hybrid grains—enabled large-scale production with relatively little labour.

Peasants could not simply turn into farmers because they lacked the capital. Some became hired workers in the fields. But most migrated to the cities or overseas to the Americas. In some parts of Great Britain, central France, and the Low Countries, however, peasant villages have managed to survive by maintaining a low standard of living and long working hours, and often by developing some special handicraft for sale as folk art.

Along with the rise of commercialism and industrialization in modern times, certain changes of a political nature have affected the rural areas. Strong national states have replaced old feudalistic dependencies, many nations have even expropriated the holdings of large absentee landowners, and civil rights and legal protection have been extended to peasants. Everyone has become, to some degree, a citizen of a modern state. Yet peasants are still handicapped by their relative isolation and poverty, and they tend to be the last group (other than primitives) to become full participants in modern national cultures.

The distribution of peasant societies

Western Europe (including Great Britain) can be treated as an entity, since its feudal epoch, rise of national states, and finally its full and earliest participation in the commercial and industrial revolutions sets it apart as a region of distinctive similarities among its diverse parts and certain important dissimilarities from other large world regions.

The industrialization of eastern Europe and western Asia occurred later than that of western Europe, and its effect on the demography of peasant villages was much less. The Soviet Union's collectivization of agriculture in the late 1920s had the greatest influence on the lives of the peasants in that region (and in the Soviet bloc of eastern Europe after World War II). The ancient classical peasantry of Russia and adjacent regions thus merits a separate classification.

Japan is unique among modern nations in the character of its peasantry and the changes from its original feudal-like system to rapid industrialization and transformation of its traditional countryside. Certainly Japan cannot be simply lumped with China and perhaps some smaller entities as "the Far East."

Similarly, China is China. China was a "sea of peasants" over such an enormous span of time that the peasants' was more than a "part-culture" in the ancient Chinese civilization. The peasants themselves became distinctive and "classic."

Southeast Asia, especially Indonesia, qualifies as a separate peasant region not only because of its ancient cultural distinctiveness but also because of its epochs of Islāmic and European colonialism, which set it off from Japan, especially, and from China.

India experienced various foreign invasions and finally British colonialism, itself an administration of a distinctive sort. Next to China, India has the largest peasantry and the most problems in modernizing its agriculture.

The complexity resulting from Hindu, Islāmic, and British policies has resulted in a mosaic of local practices in land tenure, and the residue of the caste system causes special difficulty in modernizing most rural villages.

Latin America, together with the Caribbean islands, is the only region in the Western Hemisphere to contain sizable numbers of peasants. There are no peasants in the United States or Canada, except, perhaps, for a few widely scattered villages of French Canadians, Appalachian mountaineers, southern sharecroppers (rapidly disappearing because of mechanization), and perhaps Pueblo and Navaho Indians. These all seem like peasants in their poverty, the backwardness of their isolated village life, and their dependent status; but these groups are not numerous and are disappearing rapidly, and it has been argued that their members should not be considered peasants at all.

Latin America's distinctiveness in this respect stems from two historical factors. (1) The Spanish and Portuguese colonized the area so long ago that the inhabitants have had time to develop a stable, though complex, amalgam of Iberian and Indian culture. (2) During the pre-Columbian epoch in Middle America, in parts of the circum-Caribbean region, and in the Andean highlands, the aboriginal Indians achieved a form of state-empire with a stratified society of the same general order that existed in early classical civilizations of the Old World. Thus a class of native peasants was already in existence in several large regions when the Spaniards arrived. In other areas —Amazonia and Argentina, for example—quite different developments resulted from the nonpeasant Indian societies there: tribal horticulturalists in Amazonia and nomadic hunters in Argentina, neither of which became dependent on the new colonial regimes.

In Africa, scattered peasant communities occur in the upland areas of the Mediterranean shore, but they are closely related in origin to Arabic culture and European colonialism and are not numerous. Sub-Saharan Africa, despite the colonialism of many of its areas, is distinctively African. Nevertheless, there is wide disagreement on how to classify its rural inhabitants, who, for the most part, make up the basic citizenry of its new nations and are not so much members of a dependent part-culture.

TYPES OF PEASANT SOCIETIES

The community of self-serving households. Though peasants are usually thought of as living in small, close-knit communities huddled against outside danger, they sometimes are so well-protected in mountainous or insular isolation that they feel secure enough to live more independently. In such circumstances, they dwell in scattered households in close proximity to the land they cultivate. They require a market centre of some sort where they may exchange goods and services. The Irish countryman, the isolated *fermier* of the French Massif Central, the Scottish crofter, the Paraguayan *campesino,* and the Brazilian *caboclo* are examples of such independent peasants. Occasionally the same people will be found living in close communities and also in scattered, more self-sufficient households. In the state of Michoacán in Mexico, for example, some of the tightest and closest knit communities to be found anywhere on earth ring Lake Pátzcuaro, in immediate proximity to the large modern market town and tourist centre of Pátzcuaro. These are the fishing-, agricultural-, and handicraft-specialist villages of the Tarascan Indians. But many more thousands of Tarascans also live scattered in the adjacent mountains, making only infrequent visits to the market centres.

The village with internal specialization and exchange. In certain times and places peasant villages have developed considerable self-sufficiency by creating part-time specialists and even full-time professional occupations. Such a development, however, presupposes an intensive agriculture in support of a fairly large population, in order that the specialists may be kept fully occupied. The best examples of this kind of village are found in India, in the European medieval manor, and in some Latin American haciendas.

Hindu villages

The most distinctive, as well as the most clear-cut, specialization occurs in Hindu India, where a typical village may contain as many as 2,500 people. The professional specialties are pottery manufacturing, stoneworking, barbering, trading, weaving, laundering, and herding. All of these occupations are carried on by separate castes, to which should be added the "twice-born" caste, the Brahman, or wise-man priest, though this is more of a status than an occupation.

The specialized services of the various castes often are rendered without any immediate payment or return service. The occupational castes all have an obligation to provide their services. The full-time peasant agriculturalist, for example, expects a new plow or hoe from the carpenter, a pot from the potter, haircuts from the barber, and so on. After the semi-annual harvest, the peasant distributes appropriate shares of produce to those who have served him.

The caste system of occupations largely determines the status of individuals, but there are ways to attain higher status by acquiring wealth or political office. A wealthy landowner of low caste will continue to observe all the traditional attitudes of deference to those of higher caste; yet his opinion may be important and his power considerable in other than direct interpersonal dealings. And, of course, high and low status may be earned within a given caste depending on individual skill and personality.

Land ownership and tenure patterns are variable and complex. There are large owners who hire labour by wage or by shares. The majority are family-owners and workers of small plots, but large numbers of agricultural workers are landless, working only for others. Many families own some land and at the same time work other plots by shares or for wages. The usual peasant holding is worked jointly by a father and his sons. When the father dies, the land, stock, and implements are distributed equally among the sons. This practice is the major cause of the small size of the individual peasant holdings.

Many Indian peasant villages are exogamous (marrying outside), which results in ties among several villages as a consequence of giving and receiving wives. In such cases, every person participates in a social network outside his village to a greater extent than he associates with persons of other castes within his own village. These regional relationships are the means by which a common culture is diffused over a wide area. Hindu peasant villages are less alike the farther they are from each other, yet vast areas of rural India are remarkably homogeneous in culture.

The medieval manor

The European feudal estate also tended toward economic self-sufficiency in its local specialized occupations but was unlike the Hindu peasant village in several respects. For one thing, there were no castes. The aristocrats considered both their own and the peasant class to be permanent, God-given arrangments of hereditary status. Thus, to the extent that membership was in fact static, these classes were like Hindu castes (which have frequently been defined as "frozen classes"). But the other occupational classes of medieval times were not so castelike, although a tendency existed for son to succeed father. The occupational guilds resembled, to a certain extent, the wide geographical relationships of the Hindu castes. At the time of greatest stability in the European system, the social and political differences from Hindu practice were perhaps largely those of degree.

Other differences were enormous. India, no one needs to be told, is overcrowded. Medieval Europe, between the 11th and 15th centuries, was almost a wasteland by comparison. In fact, the existence of vast tracts of forest lands gave urgency to the problem of law and order; large groups of outlaws and predators could easily hide out. The essentials of the feudal system were master-client relationships: between kings and nobility, and between the nobility. The superior individual gave protection to his clients, who in turn provided crops or services (especially labour and military duty).

The institution most typical of medieval society was the local *seigneurie,* which may be defined as an estate com-

prising a group of people subjected to a single master. The land in such a system was of two kinds. One was the large home-farm, cultivated under the immediate direction of the *seigneur* or his supervisors. The other part of the *seigneurie* consisted of various small to middle-sized holdings whose tenants occupied and cultivated them freely under the *seigneur's* protection in return for helping him in the cultivation of his demesne.

There were essentially three kinds of labourers: (1) the tenure holders, who owed regular services to the demesne; (2) wage labourers, normally paid in kind, unless they were imported labour to help out at some crisis like the grape harvest; and (3) workers housed and provisioned by the demesne. These workers are called "prebendal" in English (French *provendiers*) because they were provisioned and housed at the master's expense. The only difference between a prebendal worker and a slave was the freedom of the prebendal worker to leave if he was dissatisfied.

The tenure holder, or peasant, owed the *seigneur* two basic obligations, rent and services. Rents were highly variable, but services were usually still the greater burden. The basic services were agricultural labour on the demesne land, military duty, and craft work. Agricultural labour, for example, might be calculated as three man-days a week per tenure holding. Since a family on a holding might be quite large, the three days could be divided among several men. Military duty would be highly variable because it would be a simple response to emergency —ordinarily an "all-hands" response.

Craft work was divided among peasants who had some skill passed on from father to son, especially metalworking. Spinning and weaving, wine making, carpentry, and sometimes milling and baking were duties divided among certain, but not all, peasant families. Probably most craftsmen worked at these tasks only part of the time in addition to the basic form of work.

The crafted products did not pass from peasant to peasant or between different specialists but were usually paid to the *seigneur* who reassigned them to others. This kind of indirect passage of goods from producer to centre and thence to ultimate consumer is the essence of the redistributional system described earlier as characteristic of chiefdoms. It is a way by which a power-holder can muster goods and serve his people at the same time. In political as well as economic structure, the resemblance of the *seigneurie* to a primitive chiefdom is remarkable.

The *seigneur* was thus not simply a landowner or an exploiter of labour. He was a leader of men whose political-military status was highly direct and personal. He had command over his tenants, and the system would not have worked unless his subjects generally believed in and accepted him. His protective function gave rise to the seignorial court, which was the recognized place for a hearing of pleas and complaints. All in all, the seigneur served his people in many necessary ways, and they served him in others.

Naturally the asymmetrical power relationship between seigneur and peasant sometimes resulted in attempts by seigneurs to multiply the services or benefits due them. On the other hand, the peasants, if numerous enough, often found ways to resist. But the power of the seigneurs presumably lay originally in their ability to allow or prevent the occupation by peasants of land under their military power. Similarly, peasants at certain early and insecure epochs might want the security of hereditary tenure; at other more secure and prosperous times, they might want freedom to leave.

By the 12th and 13th centuries in France every tenant was either free or a serf. The norm among free tenants was to be bound to the *seigneur* only because of their occupation of the land. If the tenant left, all obligations both ways were broken. On the other hand the serf was not free to leave the land. Otherwise mutual dues and obligations were the same.

The hacienda

Another form of agricultural self-sufficiency is exemplified by the hacienda. In the early colonial period of Latin America the hacienda combined the Iberian and American Indian systems of land use. Pre-Columbian Indians in large areas of Latin America (from Chile north through the Andes, and in Middle America) were densely settled on communal village holdings under the suzerainty of absentee aristocratic Indians. Other areas of Latin America were inhabited by more primitive tribes of slash-and-burn horticulturalists and nomadic hunter-gatherers. During colonial times in the areas of densely settled Indian population, the leading Spaniards were granted political control over designated villages. They were allowed to tax the Indian families and in return were supposed to protect them and educate them in the Catholic faith. Sometimes Spaniards were rewarded by the crown with enormous tracts of land, *latifundios,* usually in areas of lesser population where large-scale herding would be the primary economic resource. Indian labour was also exploited in gold and silver mining and in workshops (*obrajes*).

The economy based on the exploitation of unskilled Indian labour was eventually disrupted by disease. Indians had no immunity to several commonplace European afflictions such as smallpox, typhoid fever, measles, and malaria. Numerous disastrous epidemics occurred, and by about 1600 both Spain and its richest New World possessions were in rapid economic decline.

Meanwhile, a new form of rural estate came into being as the economy of town and city, workshops, mines, and commerce was depressed. A large, privately owned estate could withstand monetary and commercial crises by becoming increasingly self-sufficient. The estate was manned by impoverished Indian workers who needed security and protection. The workers were usually paid in kind, enough for bare subsistence and given credit (against the promise of future labour) for the purchase of other necessities. This debt peonage was the foundation of a permanent labour supply, resembling the serfdom of medieval Europe.

The hacienda had a permanent group of peons settled on its lands, allowed to farm small plots for themselves. There were also house servants, some of whom might reside in the master's home. Other Indians might be residents of neighbouring villages but dependent on the hacienda for protection and often for grazing rights on fallowed rangeland claimed by the hacienda. A hacienda with numerous dependent villages on its periphery could muster a large labour force when needed and not employ it when not needed. The permanent debt peons, however, were more closely bound up in the everyday life of the hacienda. Like the European serf, the peon in difficult times probably welcomed the security of such an arrangement.

The hacienda probably was never completely self-sufficient, but it could take care of its own people in many ways. Large haciendas, some with thousands of peons, could afford numerous specialists, such as metalworkers and leatherworkers, weavers, bakers, masons, carpenters, and sometimes even a resident priest. There might also be a jail and a whipping post. And just as in European seignorial law, the master adjudicated disputes and meted out punishment. The economy of the specialized crafts resembled the European redistributional system in so far as the planning, commissioning, and delivery of all benefits were centralized under the hacienda master and his agents.

Although debt bondage no longer exists in Latin America, the tenant worker on the remaining large haciendas in some of the Andean areas seems as closely bound to the soil as peasants ever were. The Chilean tenant is legally free to move as he pleases, but he cannot, in fact, usually do so. He works his ancestral land, which he understands belongs to the hacienda, whose owner he has been conditioned all his life to regard as his master and protector. Were the worker and his family to leave, the other haciendas would not accept him. And since there is no vacant fertile land, as in Paraguay and parts of Brazil and Argentina, he could not become a squatter. Most peasants fear the city, which is already filled with the unemployed younger sons of peasants.

In Mexico, it was not until well into the 20th century that the hacienda system began to yield to modernism and more liberal laws, and the hacienda became increasingly commercialized. But earlier the peasant could not improve his position, legally or economically. By the end of the Díaz regime in 1910, the concentration of ownership of land in the hands of a few *hacendados* was greater than in any other Latin American country. But the payment for agricultural labour had not risen appreciably since 1792. Over the same period the price of maize had increased 179 percent and that of beans 565 percent.

The closed regional market system. A kind of regional self-sufficiency may be seen among peasants in the Middle American highlands and the Andes, in parts of Indonesia, and in West Africa. These are nearly self-sufficient regions embracing peasant hamlets and villages that trade with each other, usually on a periodic market day or fair. These villages are typically cohesive and tend to be self-governing through ritual and religion. The relations of peasants with the outside world are usually mediated by the community (or its officials), except in the peasant market, where frequently some kind of middleman or representative of a store sells items not produced in the region itself.

The highland Indians of Mexico and Guatemala

The highland Indian communities, especially in Mexico and Guatemala, are quintessentially of this type. The inhabitants of the region are Indians (although there is a heavy overlap of Old Spanish custom, dress, and a folkish variant of Spanish Catholicism). They all speak the same Indian regional dialect. They occupy such a distinctly inferior and helpless relationship to the outer society that intermediaries of some sort are needed, and as a consequence of the felt inferiority they act toward outsiders in an extremely withdrawn manner. This withdrawal trait of the Indian peasantry has been appropriately labelled the "*encogido* syndrome," meaning a nearly utter lack of self-confidence.

The Indian communities which have legal ejidos (communal holdings) as well as small family properties, are not usually subject to outside landowners. Thus the *encogido* syndrome derives not from any inferior position of the peasantry to a resident owner (as in the hacienda system) but from the simple fact of ethnic stratification. These Indians feel themselves in an inferior position to everyone else in the whole outside world, that is, inferior to everybody except others designated as Indians. And they are usually also inferior in visible ways: extremely poor, uneducated, and ignorant of the manners and customs of the nation's urban citizenry. They have responded by withdrawing into their own community, which only serves to continue or to exacerbate the inferior condition, since much of it is caused simply by economic and social isolation from the main currents of national life.

'Within the community of Indians extreme egalitarianism prevails. Prestige is won only in community service, which means giving more than receiving—very much like the general reciprocity of primitive society. Giving takes the form of subsidizing one of the traditional fiestas of the community, an obligation that may be expensive in food, liquor, candles, and fireworks. Families work for years to get up the capital to sponsor a magnificent festival, at which they not only spend their savings but go into considerable debt. Lavishness in money and labour equals love (of the community); the poverty of an individual family may be accompanied by the highest prestige. This bears a resemblance to the Big-Man system of Melanesia, where prestige is also linked with lavish giving.

The economic egalitarianism of the village does not rule the periodic regional market. There the family, or its agent, tries to maximize its gains. Outsiders who see more of the marketing behaviour than of the more pervasive social economy within the individual villages are often misled by the ferocious haggling and cheating. Many regional markets are held in a smallish city of the national, non-Indian sort. The economically important market is the one in which the Indians exchange their own products with each other, yet it may be overshadowed by the market in which Indian handicrafts are sold to outsiders. Town stores may display their own wares in stalls at the market, and the carrier-middlemen may have brought materials from a considerable distance to sell where such items are rare and will bring a better price. And the same middleman (often simply the owner of a pickup truck) may buy materials or handicrafts that are abundant at one market for sale in another. In Mexico the weekly Tarascan market in Pátzcuaro, or the Otomí at Ixmiquilpan, or in Guatemala the Mayan markets at Chichicastenango or Panajachel, are large and complex, incorporating all of the above elements.

In these highland Indian communities the emphasis is on self-sufficiency, at least for the regional economy, instead of on the personal dependency and exploitation that characterize the hacienda and seignorial communities. The Indian peasant commune is of interest because the tradition-bound folk culture, so dominated by the sacred, so unindividualized, and so homogeneous, contrasts strikingly with modern urban societies.

Close-knit peasant communities do change, of course; but it is their resistance to change that commands attention in modern times, when virtually all other institutions are committed to rapid change. Because the peasant community is a rigid structure, the individuals who want change and have the means or capacity to carry it out simply leave the village to find their place in some mixed community. In some peasant communities this is not possible. Thus in densely settled central Java opportunities for the surplus peasant population to adapt to other modes of life were few. As population increased, putting stress on the traditional network of communal villages, the community tried to fit more people into the traditional system. The social patterns grew more elaborate but remained traditional; cooperative labour and tenancy institutions became more intricate but otherwise did not change. Just as in the Latin American Indian commune, egalitarianism continued on a basis of what has been called shared poverty.

In West Africa peasant society is based on full-time intensive agriculture, with a considerable amount of craft specialization and a large amount of trade carried on in great markets. In ancient times the more populated areas were organized as chiefdoms and primitive states, which exacted a tribute or tax from the agriculturalists in exchange for their protection and regulation. Intensive cultivators produce mainly for their own consumption, but with a frequent surplus or specialized handicraft to trade in the market. In modern times, they may produce surpluses to trade with a middleman representing an exporter. African villagers traditionally have been politically dependent on some hierarchical chieftains or patrimonial retainers. But they do not, like peasants elsewhere, feel themselves to be different from or inferior to any other class or culture. Nor are they so regarded by the urbanites with whom they come in contact.

General characteristics of peasant societies

One characteristic of peasant economy is that the production unit is normally the family. But this does not mean that families are all the same size. Mainly, technical and economic requirements tend to govern the size of the family, which ranges from large three-generational extended families down to the nuclear unit of one set of parents and their unmarried children. Inheritance patterns tend to reflect the requirements of the agricultural operation. Whether the land is split equally among the heirs or passed on as a single unit (commonly through the eldest son) will depend on whether farming requires large holdings or whether a small, intensively farmed area is sufficient. In some historical instances, the ecological determinant of the size of holdings has been contravened by ideology or law. For example, the Code Napoléon required that agricultural holdings be inherited equally, with the result that when the fragments of land were obviously becoming too small the French peasants responded with one of the most drastic reductions in the birth rate in all of recorded demographic history.

Some villages, notably among Latin American Indians,

are quite communalized. Individual families work plots of land, but it is the community as a whole that makes the important decisions. Other peasant societies with more independent households find numerous occasions for cooperation and labour exchanges among families. One widespread means of establishing a network of reciprocal obligations and trust within a peasant community is through ritualized ties of fictive kinship, such as the godparent-hood common throughout most of peasant Europe and Latin America (in Spanish it is coparenthood—*compadrazgo*). Other forms of fictive kinship are the familiar blood brotherhood of Balkan Europe, the *mit* of Nepal, and the *oyabun-kobun* of rural Japan.

THE POLITICAL ROLE OF THE PEASANTRY

Peasants have sometimes exploded with pent-up mass violence. Such revolts occurred in late medieval times in western Europe, feudal Japan, and in the 19th century in tsarist Russia and Manchu China, to cite only the more well-known ones. Peasants in modern times have also fought valiantly and stubbornly in China, Algeria, Cuba, Mexico, Vietnam, and elsewhere. These latter movements were not all as independent and spontaneous as the earlier ones, however; they were part of non-peasant, national political movements, with leadership, ideology, and revolutionary objectives far from the peasants' immediate aims or comprehension.

Marx and Engels considered the peasantry to be a passive if not reactionary force in revolutionary situations. Marx thought of peasant life as "rural idiocy," which he contrasted with the revolutionary education undergone by the urban proletariat. He believed that the continued growth of capitalism would destroy the peasantry and increase the numbers of wage labourers. Revolutionary tactics should therefore allow the peasantry to continue its inevitable decline and demise.

Revolts aimed at restoring past

Marx may have been influenced by the history of the peasant revolts of 1524–25 in Germany, which his colleague Engels wrote about in *The Peasant War in Germany*. The revolts were caused by a sharp deterioration in both the economic and legal position of the peasants. The commercial revolution of the late 15th century had impoverished the landholding nobles, who in turn expropriated more and more of the peasants' produce. At about the same time, the introduction of Roman law sped the decline of the peasants into serfdom. The brutal repression of the peasants after their uprising prolonged serfdom in many parts of Germany until the French Revolution. The significance of the peasant rising to Marxists and other theorists of revolution, however, was that it represented an attempt to restore deteriorating conditions to their earlier state, not to make any basic change in the structure of society.

In tsarist Russia, from around 1870 until the Revolution of 1917, the powerful and numerous Populists (Narodniks) held that a Socialist revolution could come about in the countryside patterned after the historic model of the *mir,* a communal village of medieval times. Lenin and other Marxists opposed this idea vigorously, arguing that the industrial proletariat was the only class that could be relied upon.

Peasants and guerrillas

The attitude of the Chinese Communists was completely different. Much of the population of rural China had been engaged for hundreds of years in intensive agriculture, and at the same time it had developed craft specialties and a great deal of commerce and wage labour as well. In China there was little of the stagnant rural idiocy of Marx's peasantry. The necessity for working among peasants led the Chinese Communists to argue that in an area like China the only way to continue revolutionary struggle was through guerrilla warfare on a rural base.

The success of Mao's tactics in China was paralleled in some areas of Mexico during its revolution in 1910. The peasants led by Emiliano Zapata were united in a struggle to regain the lands that had been gradually taken from them by the *hacendados.* Such aims are not different from the peasant struggles of late medieval Europe, but the point is that the Zapatistas waged successful guerrilla warfare that helped to overthrow a 20th-century political state.

The Castro-led revolution in Cuba provides a spectacular example of the success of rural-based guerrilla warfare, and was probably as powerfully influenced by earlier Mexican revolts as by Chinese-Marxist ideology. Similarly, the success of peasant-based warfare in Vietnam against Japanese, French, and American troops is familiar. And the French could not hold their colony in Algeria with regular troops against the guerrillas.

These modern rural revolts differ from the earlier revolts in that rural peoples have become involved in modern nation-states, which themselves are undergoing vast changes. The rural cultivator no longer is simply a member of a small isolated community, protected or exploited by landowners or nobility. He is more often a rural proletarian than a peasant, notably so in the case of Cuba. And his allies, friends, and enemies are numerous.

All of the modern revolutionary nations share one historical fact in common: they have all been colonialized in one way or another by powerful industrialized states. In consequence, various anticolonial (nationalistic or patriotic) elements in the population aligned themselves with the rural people. Modern agriculturalists in those former colonial nations have become, in one way or another, much more of a citizenry than ever was visualized in the conceptions of peasantdom as a tradition-bound, isolated folk society.

BIBLIOGRAPHY. R.B. LEE *et al.* (eds.), *Man the Hunter* (1968), is an intensive survey by professional anthropologists of nomadic hunting-gathering society; L.H. GARRARD, *Wah-To-Yah and the Taos Trail* (1938; new ed. 1955, reprinted 1966), is a classic account of Plains Indian life; F.R. SECOY, *Changing Military Patterns on the Great Plains* (1953), is a superb historical analysis of the rise of Plains Indian nomadic equestrian societies. The best general account of the sedentary fishing societies is P. DRUCKER, *Cultures of the North Pacific Coast* (1965); and an interesting analysis of the forms of economic exchange among those societies is by H. CODERE, *Fighting with Property* (1951). Pastoral societies are depicted in three different regions by O. LATTIMORE, *Inner Asian Frontiers of China* (1951); L. KRADER, "Ecology of Central Asian Pastoralism," *Swest. J. Anthrop.*, 11:301–326 (Winter 1955); and for Africa, E.E. EVANS-PRITCHARD, *The Nuer* (1940, reprinted 1968). A grand survey of the consequences of the domestication of plants and animals in early times is found in R.J. BRAIDWOOD and G.R. WILLEY (eds.), *Courses Toward Urban Life* (1962); and many of the modern primitive horticulturalists are described analytically by M.D. SAHLINS, *Tribesmen* (1968). The rise of peasantry in relation to urban centres or other outside powers is analyzed neatly in relation to other evolutionary levels by W. GOLDSCHMIDT in *Man's Way: A Preface to the Understanding of Human Society* (1959). Important general works on peasants are R. REDFIELD, *Peasant Society and Culture* (1956); and a compilation by J.M. POTTER, M.N. DIAZ, and G.M. FOSTER (eds.), *Peasant Society: A Reader* (1967). Peasantry in medieval Europe is described and analyzed by M.L.B. BLOCH, *Les Caractères originaux de l'histoire rurale française* (1966; Eng. trans. *French Rural History,* 1966); J.H. CLAPHAM and E. POWER (eds.), *The Cambridge Economic History of Europe from the Decline of the Roman Empire* (1941); G.C. HOMANS, *English Villagers of the Thirteenth Century* (1941); and H. PIRENNE, *Histoire économique de l'occident médiéval* (1933; Eng. trans. *Economic and Social History of Medieval Europe,* 1936). Studies of peasantries in different world areas have sometimes led to important theoretical arguments, perhaps most notably in the Indonesia area, where J.H. BOEKE proposed the important concept of the "dual society" in his *Economics and Economic Policy in Dual Societies* (1953); which was followed by J.S. FURNIVALL, *Netherlands India: A Study of Plural Economy* (1939); and C. GEERTZ, *Agricultural Involution: The Process of Ecological Change in Indonesia* (1963). In Latin America R. REDFIELD innovated comparative field studies involving a conception of historical stages from a "folk" primitive society through intermediate peasant-like villages toward an urban pole, described in *The Folk Culture of Yucatan* (1941). Other important analyses of Latin American Indian peasantries are: C.J. ERASMUS, "Community Development and the Encogido Syndrome," *Human Organization,* 27:65–74 (Spring 1968); G.M. FOSTER, *Tzintzuntzan: Mexican Peasants in a Changing World* (1967); G.M. MCBRIDE, *Chile: Land and Society* (1936); and C. WAGLEY, *The*

Latin American Tradition (1968). C.M. ARENSBERG initiated anthropological study of Irish peasantry in his classic *The Irish Countryman* (1937). In the Far East, a classic was written by FEI HSIAO-TUNG, *Peasant Life in China* (1939); and S.C. DUBE wrote interestingly on modern changes in *India's Changing Villages* (1958); while T.C. SMITH traces peasant history in his *Agrarian Origins of Modern Japan* (1966). Modern political problems are discussed in C.C. BRINTON, *The Anatomy of Revolution* (1965); in D. BROKENSHA and M. PEARSALL (eds.), *The Anthropology of Development in Sub-Saharan Africa* (1969); and by G. DALTON, *Economic Anthropology and Development* (1970).

(E.R.Se.)

Human-Factors Engineering

The term human-factors engineering is used to designate equally a body of knowledge, a process, and a profession. As a body of knowledge, human-factors engineering is a collection of data and principles about human characteristics, capabilities, and limitations in relation to machines, jobs, and environments. As a process, it refers to the conception of designing machines, machine systems, work methods, and environments to take into account the safety, comfort, and productiveness of human users and operators. As a profession, human-factors engineering includes a range of scientists and engineers from several disciplines that are concerned with man at work.

The terms human-factors engineering and human engineering are used interchangeably on the North American continent. In the U.S.S.R. the term engineering psychology is preferred; in Europe, Japan, and most of the rest of the world the prevalent term is ergonomics, a word made up of the Greek words, *ergon,* meaning "work," and *nomos,* meaning "law." Despite minor differences in emphasis, the terms human-factors engineering and ergonomics may be considered synonymous. Human factors and human engineering were used in the 1920s and 1930s to refer to problems of human relations in industry, an older connotation that has gradually dropped out of use. Some small specialized groups prefer such labels as bioastronautics, biodynamics, bioengineering, manned-systems technology, and many more; these represent special emphases whose differences are much smaller than the similarities in their aims and goals. A 1970 survey of the field revealed that human-factors engineering is the term most widely used and accepted.

The term ergonomics

The data and principles of human-factors engineering are concerned with human performance, behaviour, and training in man-machine systems; the design and development of man-machine systems; and systems-related biological or medical research. Because of its broad scope, human-factors engineering draws upon parts of such social or physiological sciences as anatomy, anthropometry, applied physiology, environmental medicine, psychology, sociology, and toxicology, as well as parts of engineering, industrial design, and operations research.

The man-machine model. Human-factors engineers regard man as an element in systems, and a man-machine model is the usual way of representing that relationship. The simplest model, a man-machine unit, consists of an individual operator working with a single machine. In any machine system, the human operator first has to sense what is referred to as a machine display, a signal that tells him something about the condition or the functioning of the machine. A display may be the position of a pointer on a dial, a light flashing on a control panel, the readout of a digital computer, the sound of a warning buzzer, or a spoken command issuing from a loudspeaker.

Having sensed the display, the man interprets it, perhaps performs some computation, and reaches a decision. In so doing, he may use a number of human abilities, including the ability to remember and to compare what he perceives with past experiences, to coordinate what he perceives with strategies he may have formed in the past, and to extrapolate from his perceptions and past experiences to the solution of novel problems. Psychologists commonly refer to these activities as higher mental functions; human-factors engineers generally refer to them as information processing.

Having reached a decision, the human operator normally takes some action. This action is usually exercised on some kind of a control—a pushbutton, lever, crank, pedal, switch, or handle. Man's action upon one or more of these controls exerts an influence on the machine and on its output, which in turn changes the displays, so that the cycle is continuously repeated.

A man-machine system does not exist in isolation; it exists in an environment of some sort. Since the nature of this environment influences man's efficiency and performance, the human-factors engineer must be concerned with such environmental factors as temperature, humidity, noise, illumination, acceleration, vibration, and noxious gases and contaminants.

Driving an automobile is a familiar example of a simple man-machine system. In driving, the operator receives inputs from outside the vehicle (from traffic, obstructions, and signals) and from displays inside the vehicle (from the speedometer, fuel indicator, and temperature gauge). The driver continually evaluates this information, decides on courses of action, and translates those decisions into actions upon the vehicle's controls—principally the accelerator, steering wheel, and brake. Finally, the driver is influenced by such environmental factors as noise, fumes, and temperature.

The simple man-machine model provides a convenient way or organizing some of the major content areas of human engineering: the selection and design of machine displays and controls; the layout and design of workplaces; design for maintainability; and the work environment.

Human factors in large systems. No matter how important it may be to match an individual operator to his machine, some of the most challenging and complex human problems arise in the design of large man-machine systems and in the integration of man into these systems. Examples of such large systems are a modern jet airliner, an automated post office, an industrial plant, a nuclear submarine, and a space vehicle launch and recovery system. In the design of such systems, human-factors engineers study, in addition to all the considerations previously mentioned, three factors: personnel, training, and operating procedures.

Personnel, training, and operational procedures

Systems are generally designed for particular kinds of operators. A space vehicle, for example, is designed for a highly select handful of astronauts. Automobiles, on the other hand, are designed to accommodate a wide spectrum of people. In large systems, the specification of personnel requirements is an integral part of systems design.

Personnel are trained, that is, they are given appropriate information and skills required to operate and maintain the system. System design includes the development of training techniques and programs and often extends to the design of training devices and training aids.

Instructions, operating procedures, and rules set forth the duties of each operator in a system and specify how the system is to function. Tailoring operating rules to the requirements of the system and the people in it contributes greatly to safe, orderly, and efficient operations.

Applications. The basis of human-factors engineering —the consideration of information about human users in the design of tools, machines, jobs, and work environments—has always been present. One of the oldest and most efficient of human implements, the scythe, shows a remarkable degree of human-factors engineering, undoubtedly reflecting modifications made over many centuries: the adroitly curved handle and blade and the peg grasp for the left hand. All of this is in sharp contrast with the conventional snow shovel, a modern implement of generally poor design that has been blamed for many a wintertime heart attack.

The need for a more formal approach to these human problems was created when machines became vastly more complex than they had ever been. High-speed jet aircraft, computers, radar, nuclear submarines, communication satellites, space vehicles—all these are products of the last few decades. The fantastic growth in the number and complexity of machines has created entirely

new problems about the use of man and the way he can be integrated into systems. Moreover, the solution to these new problems can not be found in the collective wisdom of society. For example, only a few years ago no one had any way of predicting with any certainty how man could or would function in a weightless environment. Human-factors engineering is, therefore, a child of the times, born of a mechanized civilization.

Applications of human-factors engineering have been made to such simple devices as highway signs, telephone sets, typewriters, and stoves, and to a host of modern, sophisticated complexes such as data-processing systems, automated factories, and space vehicles.

The experience gained in devising these systems has contributed to the realization that even relatively simple devices raise unexpectedly important questions on human use—questions that conventional engineering practice frequently cannot answer.

Push-button telephone. The modern push-button telephone handset provides a good example of a relatively simple device that has required a great deal of human-factors engineering. The layout of the keys in the four rows of three buttons, for example, was selected only after extensive tests on a variety of arrangements: circular, two vertical rows of five buttons, two horizontal rows of five, and a diagonal pattern; the arrangement of the numerals and letters on the keys, in the order of left to right and from top to bottom, was chosen as superior to other arrangements such as that used on many adding machines and desk calculators, in which the numbers increase from bottom to top. The top-to-bottom design decision was not simply a matter of logic; tests showed that people actually made fewer errors and took less time with that arrangement than they did with the adding-machine arrangement. Other human-factor considerations in the design of the push-button keyset were the size and style of numerals and letters for maximum legibility, the optimum sizes and spacing of the keys, and the proper force-displacement characteristics of the keys to provide tactile feedback or "feel" with the button fully depressed.

Similar factors were considered in designing the shape of the handset itself. The locations, separations, and angles between the earpiece and mouthpiece were determined so that the assembly would fit comfortably around the greatest number of different human faces; and the weight of the handset was designed to be neither too light nor too heavy.

Space suit. The designing of a much more complicated device, such as a space suit, presents more intricate problems. A space suit is a complete miniature world, a self-contained environment that must supply everything needed for an astronaut's life, as well as comfort. The suit must provide a pressurized interior, without which an astronaut's blood would boil in the vacuum of space. The consequent pressure differential between the inside and the outside of the suit is so great that when inflated the suit becomes a distended, rigid, and unyielding capsule. Special joints were designed to give the astronaut as much free movement as possible. The best engineering has not been able to provide as much flexibility of movement as is desirable; to compensate for that lack, attention has been directed toward the human-factors design of the tools and devices that an astronaut must use.

In addition to overcoming pressurization and movement problems, a space suit must provide oxygen, a system for removing excess products of respiration, carbon dioxide and water vapour; protection against extreme heat, cold, and radiation; protection for the eyes in an environment in which there is no atmosphere to absorb the sun's rays; facilities for speech communication; and facilities for the temporary storage of body wastes. This is such an imposing list of human requirements that an entire technology has been developed to deal with them and, indeed, with the provision of simulated environments and procedures for testing and evaluting space suits.

Social problems. The telephone and the space suit are but two out of thousands of examples that might have been selected to show where human-factors engineering has been consciously applied to solve technological problems. The same human-factors principles and methods have lately been applied to a variety of social problems: education, medicine, law enforcement, architecture, city planning, highway and transport design, and pollution control. The modern concern with man's relationship to the total environment around him implies a much-broadened definition of human-factors engineering.

Applications to social problems

The human-factors approach to design. Two general premises characterize the approach of the human-factors engineer in practical design work. The first is that the engineer must solve the problems of integrating man into machine systems by rigourous scientific methods and not rely on logic, intuition, or common sense. In the past, the typical engineer was baffled by the complex and unpredictable nature of human behaviour; not understanding it, he was often inclined to ignore or to deal with it summarily by using his own best guesses. Human-factors engineers have tried to show that with appropriate techniques it is possible to identify man-machine mismatches and that it is usually possible to find workable solutions to these mismatches through the use of methods developed in the behavioral sciences.

The second important premise of the human-factors approach is that, typically, design decisions cannot be made without a great deal of trial and error. There are only a few thousand human-factors engineers out of the thousands of thousands of engineers in the world who are designing novel machines, machine systems, and environments much faster than behavioral scientists can accumulate data on how man will respond to them. More problems, therefore, are created than there are ready answers for them, and the human-factors specialist is almost invariably forced to resort to "trying things out" with various degrees of rigour to find solutions. Thus, while human-factors engineering aims at substituting scientific method for guesswork, its specific techniques are empirical rather than theoretical.

The profession. As a profession, human-factors engineering is very young. The first known course in engineering psychology was offered at Johns Hopkins University in 1947. In the 1970s, hundreds of educational institutions in the world offered human-factors programs, most of them either in schools or departments of engineering or in departments of psychology.

In the United States, the main professional societies are the Human Factors Society, the Society of Engineering Psychologists of the American Psychological Association, the Institute of Environmental Sciences, the Aerospace Medical Association, and the Man-Machine Systems Group of the Institute of Electrical and Electronics Engineers. Organizations outside the United States include the Ergonomics Research Society (with headquarters in Great Britain), the Ergonomics Section of the Czechoslovak Committee for Scientific Management, the Gesellschaft für Arbeitswissenschaft (Association for the Science of Work; Germany), the Human Factors Association of Canada, the Japan Ergonomics Research Society, the Nederlandse Vereniging voor Ergonomie, the Nordic Ergonomic Society, the Polish Committee on Ergonomics and Labour Protection, the Société d'Ergonomie de Langue Française, and the Societa Italiana di Ergonomia. These are, in turn, federated with the International Ergonomics Association (IEA), an organization (in 1970) with members in some 30 countries around the world. The principal journals in the field are *Human Factors* (published in the United States), *Ergonomics,* and *Applied Ergonomics* (published in Great Britain).

BIBLIOGRAPHY. A. CHAPANIS, *Man-Machine Engineering* (1965), a small, readable, but authoritative survey of the field; K.B. DE GREENE (ed.), *Systems Psychology* (1970), a discussion emphasizing those aspects of human factors that relate particularly to modern systems, both technological and social; E.J. MCCORMICK, *Human Factors Engineering,* 3rd ed. (1970), a large textbook covering all aspects of human factors engineering—the best of its kind; C.T. MORGAN *et al.* (eds.), *Human Engineering Guide to Equipment Design* (1963), a highly technical designer's guide; W.E. WOODSON and D.W. CONOVER, *Human Engineering Guide for Equipment Designers,* 2nd ed. (1964), a less technical guide.

Humanistic Scholarship, History of

Humanistic scholarship has been of decisive importance in the history of Western culture. For 25 centuries over a vast area of the earth, the study of Greek and Latin and knowledge of the ancient literature of the Mediterranean world have formed the core of all education. This ideal model has at times inspired an almost spell-like religious veneration. It has comprised a complex ensemble of knowledge and faith; of reason, emotion, and passion; of past, present, and eternity—and the living presence of a 1,000-year tradition suggests that it will endure. As an amalgam of facts and values, the system of humanistic scholarship employs three kinds of data:

Kinds of data employed

1. The history of the culture of antiquity (literature, fine arts, philosophy, customs, and monuments): its origins, development, and preservation.
2. The history of pedagogy: institutions, courses of study, programs, and relations between teachers and pupils.
3. The history of the humanist ideal: the ideal of humanist studies fits in with a view of man's nature that is based on dogma or even with a mythology of human personality.

This article is divided into the following sections:

THE HUMANITIES AS A DISCIPLINE

Meaning of humanistic scholarship. The English expressions "humanistic scholarship" or "classical scholarship" denote a many-faceted idea. According to the British historian John Edwin Sandys, scholarship may be defined as "the sum of the mental attainments of a scholar. . . . It is sometimes identified with 'learning' or 'erudition'; but it is often contrasted with it." By "classical scholarship" Sandys means "the accurate study of the language, literature and art of Greece and Rome, and of all that they teach us as to the nature and the history of man." The French scholar Salomon Reinach wrote that "classical philology"—as such scholarship is called on the Continent—"is the knowledge of the intellectual, moral, and material life of the Greeks and Romans." Concerned with culture and civilization as a whole, philology is different from linguistics, the study of language and languages, which limits itself to the scientific study of their vocabularies and grammars. The Humanists of the Renaissance used the Latin expression *humaniores litterae* in the sense of humanistic scholarship. This phrase was deemed incorrect, however, by Friedrich August Wolf (died 1824), a great German philologist, who proposed the German expression *Altertumswissenschaft* ("knowledge of antiquity").

Nature of humanistic scholarship. The diversity of terms designating humanistic scholarship reflects the ambiguousness of a discipline that closely links the knowledge of facts with the honouring of specific values. As early as the 2nd century AD, Aulus Gellius, a Latin rhetorician, stressed the need for literary studies as alone able to endow man with the fullness of his humanity, in accordance with the ideal of the Greek *paideia* (education) and the Roman *humanitas*. And even today, the *studia humanitatis* still constitute the privileged area of pedagogy, like some ancient revelation that has even resisted the revolutionary affirmation of the Judeo-Christian revelation. Literature and art, mythology and thought, and the history of classical civilization, consecrated by tradition, still comprise the mental decor of European education. According to the process metaphysician Alfred North Whitehead, all of "the European philosophical tradition . . . consists of a series of footnotes to Plato." Similarly, until the 19th century, the intellectual and moral consciousness of the West was little more than a never-ending commentary on classical culture.

Goethe wrote:

> May the study of the Greek and Roman Antiquity always remain the basis for all higher culture! The antiquities of China, India, and Egypt will never be more than curiosities; . . . they will never bear a great deal of fruit for our moral and aesthetic culture.

For Westerners, however, humanistic scholarship has always comprised their apprenticeship. Just as the Jews were molded by the sacred writings of the Torah and Talmud and the Muslims and other Oriental peoples by their own sacred texts, Europeans have discovered their spiritual identity and the secret of their humanist calling through the masterpieces of ancient culture.

Humanistic scholarship teaches no specific philosophical doctrine. It inspires, however, a mental and moral attitude that is characteristic of the West—an attitude that makes human consciousness the alpha and omega of all thinking. "Man is the measure of all things," said the Sophist Protagoras in the 5th century BC; the individual is a centre of values. Whereas the wise men of the Orient have tended to view the human personality as an illusion and an evil, Westerners have made it a major virtue.

Nevertheless, the teachings of humanistic scholarship have undergone declines and rebirths in the course of the past few thousand years. Their very meaning has been altered, and they have even on occasion been called into question. Since the scientific revolution of the 17th century, the primacy of literary values has been subjected to increasingly violent criticisms. Today classical studies no longer occupy their traditional place of honour. One of the major problems of the 20th century is to ascertain whether the old humanism is really outmoded and whether a new humanism can be developed.

THE HUMANITIES IN ANTIQUITY

Humanistic scholarship has been sharply circumscribed in both duration and extent. In the geography of humanism, the two focuses were at Athens and at Rome, and historically two centuries—the age of Pericles (mid-5th century BC), in which the Greek miracle occurred, and the age of Augustus (at the turn of the Christian Era), the high point of Latin culture—represent the most brilliant moments of 1,000 years. In view of the fact that the Homeric poems were composed around the mid-9th century BC, Emperor Hadrian—ruling from AD 117 to 138—was already an archaeologist, a lover of masterpieces of the distant past; and in his villa at Tibur replicas of classical monuments were built. His contemporary Plutarch meditated on the greatness and decline of the Greeks and Romans, while Pausanias wrote his *Description of Greece*, a detailed guidebook for sightseers. The age of creation was over, and a classicism that highlighted the riches of a culture consecrated by the veneration of generations had begun. Thenceforth the road to beauty and truth, to moral values, went by way of memory—drawing upon an inexhaustible reservoir of precedents, models, and examples to be imitated.

Historical focuses of classical creativity

Ancient Greece. From Homer through Aristotle (died 322 BC) humanistic scholarship revealed its rich resources.

The Homeric poems. The Homeric poems formed the ultimate backdrop for humanistic scholarship. The *Iliad* and the *Odyssey* mirror a more remote prehistory but give it a false appearance. It was only after AD 1870 that the stirring researches of Heinrich Schliemann, a German archaeologist, lifted the veil from the peoples of Troy, Mycenae, and Tiryns and revealed the specific details of those forgotten civilizations. Throughout the history prior to these findings, however, the masterpieces of the

blind Ionian poet Homer marked the magnificent starting point at which, in a single thrust, the treasures of humanistic scholarship arose.

The Homeric poems, which are viewed today as the culmination of a long, slow evolution, were long considered to have been the point of departure for a tradition that asserted itself all at once, like a gift from on high, fully ripened in all its wisdom and beauty. Actually, they perpetuate the memories of battles and adventures that occurred three to five centuries before the first elements of the traditional epic poem came into being. That vast saga was built by degrees by the gathering and organizing of dissimilar elements transmitted through memory by narrators and singers, probably at the beginning of the 9th century BC. These first epics, presented at civic and religious festivals throughout the Greek world, soon became praiseworthy models. In 594 BC a decree by Solon gave rules for the public recital of the Homeric poems. A little later, Peisistratus, who was in power from 560 to 527, set up a committee to codify Homer's text, to arrange its episodes in order, and to determine the exact wording, and he incorporated recitals from Homer into the Panathenaean festivals. The *Iliad* and *Odyssey* thus became part and parcel of the religious traditions, and their texts were endowed with canonical authority.

Textual redactions by the Alexandrian school

In due time, new revisions in the text were made by the critics and philologists of the Alexandrian school, particularly in the 3rd and 2nd centuries BC. These specialists, focussing their attention on verbal corrections and scientific interpretations, found factual errors and unwarranted additions, which they sought to correct. They explained the text and commented on it, clarifying the meaning or reconstructing it when it was lost. Zenodotus of Ephesus (died *c.* 234 BC) was probably the first to divide the epics into 24 books, which profoundly altered their rhythm. The late-3rd- and 2nd-century grammarians Aristophanes of Byzantium and Aristarchus worked tirelessly over the texts and issued greatly revised editions. It was this Hellenistic vulgate version that the West received, thanks to manuscripts from no earlier than the 13th century AD.

The story of the Homeric texts is as complicated as that of the Bible. Plato said of Homer that he had been the educator of Greece. By reading the poems and reciting them from memory, the feelings, imagination, and even the speech of the children and young people were molded. Thus, the Homeric ethic kept constantly alive a sense of chivalry in which the hero vied with the gods in glorifying their virtues. The characters in the *Iliad* teach a moral code of greatness and honour, in defeat as in victory, that seems to have survived all of the changes in civilization. Alexander the Great took the ancient poems with him during his military campaigns and sought zealously to reproduce the feats and the generosity of Achilles, son of Peleus. The ideal model of Homeric society—which was both aristocratic and fictitious—was to inspire university youth of the West for centuries; and the tales of the *Odyssey*, the first adventure novel in history, were to provide similar fascination.

Dionysian importations and early poets and dramatists. The limited horizon of the Homeric world was subsequently filled out, however, by various contributions from traditional wisdom and religion. The worship of Dionysus, an emotional god of fruitfulness, coming from Phrygia, Thrace, and the interior of Asia Minor and later giving rise to the Orphic mysteries, was grafted onto the Homeric poems. Onomacritus, a collector of the oracles of Orpheus and Musaeus, was a member of the committee appointed by Peisistratus to codify the Homeric texts; he is said to have been condemned for trying to insert into them some Orphic-like revelations.

Hesiod, Aeschylus, and Pindar

Hesiod's poems, said to have been written around 700 BC, flow naturally from the spiritual landscape of the Homeric epic. In his *Theogony*, which relates the genealogy of the gods of Mt. Olympus beginning with the primal chaos, the interplay of relations among the divine beings ends with the victory of Zeus, who maintains peace among gods and men according to the divine laws of the cosmos. As for the reality of human experience on earth, however, its principles are set forth in Hesiod's *Works and Days*, a poem on agriculture in which the cosmic rhythm of the seasons, marked by recurring festivals, determines the timetable according to which the earth is to be worked. Maxims and adages and proverbs and precepts set forth the rules of peasant wisdom, which ensure peace and prosperity.

The early-5th-century writer Aeschylus, first of the great Greek dramatists, wrote edifying plays that embodied this heritage of religion and myth and lyrical poems that paved the way for the humanization of mythology. The works of his contemporary Pindar, author of odes that extolled the victors in the Greek national games, developed the Homeric ethic of the hero who struggles and wins for the honour of his city, as well as his own glory, under the kindly gaze of the gods on Mt. Olympus. This wisdom, born of conflict and patriotism, had a high educational value; it furnished a repertory of themes and images that taught the youth the value of striving and the virtue of sacrifice, which led—through renunciation—to the highest achievements.

Thus, by the 5th century BC, humanistic scholarship possessed its epic framework, centring around the Homeric revelation. At that point, however, it was still simply an ensemble of mythological data, traditional precedents, and mental habits and attitudes that shaped the memory, sensitivity, and behaviour of the Greeks without rational reflection and expression.

The Sophists and Socrates. It was in Athens, thanks to the rise of the Sophists, the founding fathers of pedagogy, that the decisive step was made from *mythos* to *logos* (rational principles), from tradition to intellect. Thus, the Sophists—among whom must be included even their adversary Socrates—were the patriarchs of all Western intellectuals.

The rise of rationalism

The Sophists were humanists who sought to transmute the age of theology into that of rationalism. Curious about every aspect of humanity, they undertook a systematic study of human reality without any mythical or religious preconceptions. They analyzed traditional myths to reveal analogies and allegories of human existence. From that time on, pedagogy became the precondition for every reform in human understanding. According to the ancients, Socrates deserved the credit for having brought philosophy down from heaven to earth —*i.e.*, to the earthly abode of man. As teachers of wisdom, the Sophists prided themselves on preparing men to accomplish their human tasks within the framework of the city-state.

The art of pedagogy had as its goal the education of the political man. The technique of oratory, which enabled a citizen to manipulate his fellow citizens in accordance with the laws of public opinion, presupposed intellectual mastery. The concept of *paideia*, as the Sophists conceived it, denoted a complete education based on grammatical correctness and intellectual accuracy in dialectical thinking, with the molding of the adult's personality as a goal. The Sophists were the first to organize a course of systematic studies, the seven arts (later called the "liberal arts"), which formed the harmoniously united, well-rounded, thoroughgoing, and complete education that was transmitted by succeeding generations of rhetoricians. Quintilian, a Roman rhetorician who inherited this tradition in the 1st century AD, expressed its essence in the formula *orbis doctrinae*—*i.e.*, the circle of knowledge that brings the sciences together in perfect unity.

The pedagogical work of the Sophists brought about a synthesis of the achievements reached by the Greek genius in the age of Pericles, and the intellectual tradition of the West rests on that foundation. Thenceforth, the ideal of an encyclopaedic *paideia* was destined never to be wholly lost. The first enlightenment in European history, that of the 5th century BC, was carried over into the 4th century by philosophers of genius who, with their systematizations of knowledge, added an extra dimension of doctrinal depth and metaphysical clarity to the somewhat empirical and technical work of the Sophists.

Plato and Aristotle. Socrates' pupil Plato (died 348 or 347 BC) was a master of inner contemplation, attained through the conversion of the soul, which detached itself from perceptible realities and united with the transcendent Ideas that conferred eternity. Though in Plato's view the scientific disciplines are privileged—mathematics, for example, opening the way to a liberating asceticism—the arts of public speaking and poetry are fraught with suspicion because they expose thought to the dangers of illusion and of enslavement to the perceptible. Plato excluded the poets from the ideal city he conceived, and he retained the ancient myths only to the extent that allegorical interpretations could reveal the supreme intelligence in its mystic essence. The school founded by Plato, the Academy, was both a small university, a brotherhood, and a religious sect the members of which sought to realize an ideal of inner perfection. Throughout the history of the West, Platonism—ever and again reborn—dominated the royal road of mysticism.

Plato's suspicion of the arts

Aristotle (died 322 BC) represents the other pole of European thought. He was a genius in systematic thinking and an encyclopaedic mind keenly aware of the empirical realities of nature and humanity. As a theoretician he drew up systems of rules for good reasoning; as an observer he brought biological knowledge to a level not surpassed until Darwin; as a social scientist he described the various forms of the human community; as a critic he defined a new science for judging the creations of art and imagination. So great was his analytical genius that it visited a kind of paralysis upon those who for centuries thereafter looked to him for authority and were content simply to repeat his teachings. The break with Aristotelianism, on the threshold of the modern age, was seen by some as a symbolic murder of the father—with a resultant unleashing of passionate emotions.

The Hellenistic period. From Homer to Aristotle, the masterpieces of classical culture came forth: writers of comedies and tragedies rubbed shoulders with the historians Herodotus and Thucydides and the great orators Demosthenes, Aeschines, and Isocrates. But, with the death of Alexander the Great in 323 BC, cultural history came to a temporary halt, or rather changed its direction. The age of creators was over; now came the continuers, who inherited and exploited the riches that had been created. Since they could not equal the masters of the past, the inheritors were content to study their works and imitate them. Henceforth, these works were held up as objects of admiration for the generations to come. It was not, strictly speaking, a time of decadence but, rather, a new way of asserting intellectual energies.

Transition from creators to continuers

Alexandria and Pergamum as cultural centres. At the same time the centre of gravity of culture shifted. "The monarchical city of Alexandria," wrote Sandys, "took the place of democratic Athens as the literary centre of the Greek world." The Ptolemies, who ruled on the Nile, and the Attalids, who ruled in Pergamum, made science and literature an attribute of the power and glory of the state. For the first time knowledge took the form of a public institution subsidized by the prince. Scholars and scientists were considered to be government officials and led a privileged life. The Mouseion (Museum), or House of the Muses, in Alexandria was the prototype of Oxford and Cambridge. It was also a huge library with hundreds of thousands of volumes; it was an architectural complex in which porticoes alternated with gardens; it had a botanical garden, a menagerie, and an anatomical institute. Thus, a cultural utopia was actually built of stones, books, and men 2,000 years before Francis Bacon, in his *New Atlantis*, described the "Treasure Island" of scientific research.

Alexandria remained a cultural centre for at least seven centuries: pagans, Jews, and Christians with a thirst for knowledge all lived there until Christian intolerance and then the Arab conquest extinguished its glorious history. Euclid's *Elements* (300 BC), Ptolemy's great work on astronomy, the *Almagest* (AD 135–150), Strabo's *Geography* (*c.* AD 23), and Galen's medical works (AD 130–200) —all came from the scientific capital of Egypt. Literary studies also were written there. The very notion of humanistic scholarship—*i.e.*, the systematic study of a body of ancient works raised to the level of classical masterpieces—was developed by the scholars of the Museum and their colleagues in Pergamum. In the words of the French writer Raymond Queneau,

> In three centuries, in the literary field, the classical writers invented everything. In three more centuries, the Alexandrians made another, equally far-reaching discovery: they invented the Classics.

Literary and textual scholarship and criticism. The Hellenistic period was the age of scholars, librarians, commentators, compilers, lexicographers, and archivists of the human spirit. At Athens the concrete living culture had been public property, a product of everyday consumption. At Alexandria and Pergamum, culture was enclosed in libraries, like a dead plant in a herbal; by dint of close study one had to revive the letter as well as the spirit of the work. The critics were editors, concerned with restoring and perpetuating the original words. At the very moment (3rd century BC) when the definitive text of Homer was being prepared in Alexandria, the Greek version of the Hebrew Old Testament, called the Septuagint, was also being completed in that same city and with the same care. Textual criticism broadened out into literary criticism; philology was born as a science of interpretations; and new methods in grammar, analysis, and prosody made possible a new approach to great works of literature. And the canon of classical literature was formed along with that of the Bible. Texts were carefully evaluated according to the criteria of taste, along the lines of Aristotle's *Rhetoric* and *Poetics*. "Rhetoric, from this time onwards," wrote George Saintsbury, a literary historian and critic, "more and more tends to become the Art of Literary Criticism generally, and to absorb Poetics within itself." In the libraries of Alexandria and Pergamum, culture became what it has since remained: an imaginary museum of hallowed masterpieces, tirelessly commented upon by scholars who watch jealously over correctness of wording and accuracy of interpretation. Hellenistic classicism was, thus, the first version of Scholasticism.

Development of a canon of definitive editions

Although Alexandria was also the centre of Neoplatonic philosophy, the Alexandrian philologists were especially proficient in textual criticism. At Pergamum, whose parchments competed with Egypt's papyruses, the ideas of the Stoic school of philosophy were dominant. There a cosmopolitan spirit encouraged freer interpretation, tinged with allegory. Reaching out from the Mediterranean centres, the new culture spread eastward—*e.g.*, to Syria, where (beginning with the 2nd century BC) Antioch became a centre of study and a transmission point for Greek thought—and it remained in the Mesopotamian region and beyond until the Arab conquest. Muslim culture then fell heir to this culture; thus the works of Aristotle, Galen, and the rest were first transmitted to the West by way of translations made in Muslim countries.

Latin culture. Roman culture was merely the extension of Hellenic culture into the western part of the Mediterranean Basin; the Latin language never made its mark in the East. Victorious on land and sea, the people of Rome quickly found themselves at the height of power, even though they remained intellectually and artistically underdeveloped. Miraculously, the decline of Greece in civil and military matters did not signify the end of Hellenism. Roman supremacy went hand in hand with a genuine cultural conversion of the conquerors in the course of the 2nd century BC: Rome became the pupil of Greece, and all of the masterpieces of Latin civilization—from Cicero to Horace, Livy, Virgil, and Ovid—were simply imitations or pastiches of classical models, a kind of Western postscript to the Greek miracle. The Roman national epic, the *Aeneid*, acknowledged this connection by borrowing its hero from the camp of the vanquished in the *Iliad*. Similarly, the great Latin writers were simply epigones (imitators) of Hellenism.

The pedagogic model of Latin *humanitas*, brought to Rome by Greek professors, was only a renewal of the liberal arts program along the lines of *paideia*. The culture of the Romans bore a pragmatic stamp; it developed

the intellectual tools needed by an elite of jurists and officials and administrators and soldiers who devoted themselves to organizing and governing the world according to universal norms. Whereas the Greek genius was one of contemplation, the Roman genius proved itself in action. Thus, the creative spontaneity of the great writers of the classical age of Rome—the Augustan age—was under the discipline of a political operation of national recovery.

The ideal of *humanitas* and rhetoric

Rhetoric, as it has come down to the West, was codified by Quintilian, a Roman rhetorician and writer, in his *Institutio oratoria* (Eng. trans., *The Institutio Oratoria*, 4 vol., 1920–22) around AD 95. In the art of oratory the elements of general culture, from poetry to philosophy, were gathered together in a synthesis as a way for men to influence their fellow humans. According to Saintsbury:

> The *Institutes of Oratory* contain the . . . most satisfactory applications of criticism to literature, as it presented itself to an intelligent and thoroughly educated person . . . when, except for a few belated authors, mostly of curiosities, the list of the great writers of antiquity was all but closed.

Thenceforth, the system of humanistic scholarship constituted a private preserve that the teachers of rhetoric exploited in order to train scholars. The platitudes (*topoi*) of literature were used as themes for discussion, whose various stages and technical procedures were strictly defined and expressed. Rhetoric, an epitome of classicism, dominated medieval Scholasticism; it inspired university teaching until the end of the 18th century.

Varro, Pliny the Elder, and Plutarch

Apart from rhetoric, Rome's contribution to the Western tradition remained limited. The Latin compilers and encyclopaedists were distinctly inferior to those of Alexandria. The works of Marcus Terentius Varro, an immensely learned and prolific scholar, are almost all lost, except for several precious books of his *De lingua Latina*. The *Historia naturalis* of Pliny the Elder (died AD 79), a scholar and civil servant, reveals by contrast Aristotle's genius. Nevertheless, the classical heritage did include the works of the great Roman historians in which memories of the Res Publica Romana and the Imperium Romanum were kept alive as models. The genius of Rome, which was great in action rather than in meditation, was embodied in the legendary virtues of its great men: Sallust, Livy, Tacitus, and Suetonius were teachers of a concrete morality that honoured self-sacrifice and greatness of soul. To these must be added the writings of Plutarch (died *c.* AD 119), a Greek biographer and moralist, who compared the heroes of Greek history with those of Rome. Plutarch was largely instrumental in keeping alive the century-long worship of energy and the public-spirited republicanism that, paradoxically, the later Scholastic civilization nostalgically associated with its evocations of Roman grandeur.

THE MEDIEVAL PERIOD

Cultural divergence into Byzantium and the Roman West

In the history of classical scholarship, the medieval period witnessed the divergence of the two branches of the culture of antiquity—the Greek and the Latin—that coincided with the long decline and final fall of the overexpanded Roman Empire. It was the period in which Christianity, having become the state religion, caused its values to take precedence over pagan teachings, which involved a complete restructuring of mental and spiritual attitudes.

In AD 330 the emperor Constantine chose Constantinople (Byzantium) as the new capital of the Roman world. Byzantium was destined to become the sanctuary of Greek-language culture and to be separated thereafter from the Latin culture that continued in the West, a separation that defined the intellectual order of the medieval world. The Middle Ages ended, however, in 1453, with the fall of Constantinople to the Turkish army. As a result, Byzantine scholars returned to the West with their manuscripts, which in turn kindled a rebirth of literature and a new ardour for the humanities, with emphasis on their literal integrity and spiritual inspiration. The Christianity that was based at Rome had retained the common heritage of classicism, but in its Latin form it had been weakened and diluted by Scholasticism. The return to Greek sources, however, signalled the advent of the humanities in their modern form.

The compromise of the Church Fathers. Early in the Christian Era, the inevitable problem of the new faith's accommodation with classical culture arose.

The antipathy between Athens and Jerusalem. The consolidation of Christianity, which prolonged the Hebrew–Christian tradition, led eventually to a fundamental questioning of the traditional pagan culture of Hellenic orthodoxy. A polemic ensued, one that lasted for several centuries. It was a dialogue fraught with emotion that marked the death throes of paganism. In the course of the controversy, professors, writers, even emperors—such as Marcus Aurelius and Julian the Apostate, upholders of a glorious past—confronted the learned doctors who had received the teachings of Christ. The masterpieces of ancient art and thought clashed with the revolutionary challenge of the Nazarenes; and to the Greeks, the notion of the good tidings of the crucified Jesus was scandalous and insane. The English historian Edward Gibbon summed it up in his famous statement: "I have described the triumph of barbarism and religion." In AD 391, under Theodosius I, the Sarapeum of Alexandria, a library and research centre, as well as a temple to Sarapis, was turned into a monastery; in 415 Hypatia, daughter of the last known member of the Mouseion who was herself a noted philosopher and mathematician in the pagan tradition, was murdered by a fanatical mob. Finally, in 529, the emperor Justinian ordered the philosophical school of Athens, the last refuge of the pagan mind, to be closed; and in that same year St. Benedict, patriarch of the monks of the West, founded the monastery of Monte Cassino in Italy.

The closing of the last pagan school

Thus, between Athens and Jerusalem and between humanistic scholarship and Jesus Christ, no understanding seemed possible; the radical alternative would have entailed the total loss of classical culture, which was incompatible with the new religious requirements.

The accommodation between Athens and Jerusalem. But the victorious new faith did not possess a system of Christian scholarship that could be counterposed to classical scholarship. Lacking such a system of their own, the Christians realized the need to utilize pagan doctrine if they were to avoid slipping into barbarism. Thus, as early as AD 96, the formula *en Christō paideia* appeared, which avowed the possibility of a cultural conversion by which works of Hellenic inspiration could be subordinated to religious faith. The Christian Church now took charge of the intellectual and aesthetic values of the past.

The principal achievement of the Church Fathers was to bring about this cultural updating. They soon appropriated, like war booty taken from a defeated enemy, not only the language and literature but also the aesthetic structures and ideas of ancient paganism. Humanistic scholarship was thus saved and put to new uses to serve the Christian revelation. The bases of Western culture are the result of this alliance between two spiritual outlooks, alien to each other.

According to the Church Fathers, the Judeo-Christian tradition, because it alone went back to the creation of the world, was the source of all culture and could thus absorb the pagan tradition. In their view the genealogical tree of knowledge passed from Moses through the Egyptians (of whom he was the teacher) to the Greeks, whose works could therefore be considered divinely inspired. Such was the claim of the Christian scholar Justin Martyr (died *c.* 165), who acknowledged that the Word of God could have inspired the great pagan authors. About the turn of the following century, Clement of Alexandria, the founder of Christian philosophy, asserted that pagan wisdom to the Greeks was the equivalent of the Old Testament to the Jews prior to the revelation of the Son of God. The new culture represented a fulfillment of, not a breach with, the old culture. Around the turn of the 5th century, Jerome (*c.* 347–420) and Augustine, the most prestigious figures among the Christian intelligentsia and scholars of the highest quality, had a profound respect for classical humanism; and, at a time when barbarians were besieging the Roman Empire on

every side, these men smoothed the transition from the Imperium Romanum to the medieval Romania by seeking to save what could be preserved of the venerable treasure of antiquity.

The Church Fathers played a key role in the history of humanistic scholarship. They were responsible for the peaceful coexistence of the double heritage—the pagan and the Christian—that molded the consciousness of the West. Thanks to them, Christianity entered into the domain of pagan culture, which thus ceased to be viewed as a danger to human minds and emotions. In the 15th century, the tradition of Christian humanism was continued by Marsilio Ficino, founder of the Florentine Academy, and by Giovanni Pico della Mirandola, notable for his *Oratio de hominis dignitate;* in the 16th century, by Erasmus, John Colet, and Juan Luis Vives; and in the 17th century, by the Cambridge Platonists.

Byzantium. It is to the scholars of Byzantium that modern scholars are indebted for the preservation of Greek culture.

Political and religious conditions. During the Middle Ages the unity of the Imperium Romanum, at the height of its expansion, was split into three distinct areas, which differed in religion and language, as well as in politics. All during the Middle Ages (*i.e.*, until 1453), Romania, Byzantium, and Islām were in a continuous state of action and reaction, with military expeditions going hand in hand with cultural and commercial exchanges.

Moreover, the three cultures, despite their religious differences, possessed in common the spiritual tradition of religions of the book. They also shared the treasures of the profane writings of antiquity. Arab scholars and their Jewish colleagues translated, copied, and commented on the great Greek works and were largely responsible for preserving and transmitting them to the farthest reaches of Christendom. Thus, the medieval period, though beset by military struggles and internal contradictions, kept its unity as far as respect for the cultural tradition of humanistic scholarship was concerned.

The political unity of the West was the first of the three to be broken—as a result of the barbarian invasions but also in large measure because of its own inner decay. This great region now found itself wrenched apart and reduced to a state of cultural stagnation. For more than 1,000 years the principal role of Byzantium was to ensure the survival of the Greek culture and its language (which had become virtually forgotten in the West). Christianity had undoubtedly triumphed, and its spiritual and theological preoccupations left their mark on the civilization as a whole. The controversy over Iconoclasm (727–850)—*i.e.*, opposition to the religious use of likenesses of the divinity—was a Christian backlash against pagan culture, the effects of which were also discernible in the literary field. During these many centuries, cultural life had its peaks and valleys, but the updating carried by the Church Fathers generally remained valid; the most brilliant moments of the Byzantine Empire were its revivals of Greek studies.

The two golden ages of Byzantium

The development of Byzantine scholarship. The first great century of Byzantium, that of the renowned emperor Justinian (reigned 527–565), is associated with his success in re-establishing the unity of the empire by reconquering provinces from the barbarians. The dedication of Hagia Sophia, the cathedral in Constantinople (537), was one of the highlights of his reign. As a Roman emperor, Justinian upheld the rights of the Latin language in Byzantium. It was basically in Latin that the major task of codifying Roman law—the Codex Justinianus, or Justinian Code—was accomplished. The Hellenization of the empire was achieved in the 7th century. Renouncing the West, Byzantium then became the capital of Greek power in the East, at the very moment when Islām began its rise. Byzantium's second golden age, which occurred between 867 and 1081 under the Macedonian dynasty, was highlighted in its earlier years by the philological studies of Patriarch Photius and later by the literary, philosophical, and historical writings of Michael Psellus, both of whom were staunch upholders of the pure Hellenic tradition.

Byzantium also had its dark centuries and its long, slow agony. It witnessed wanton destruction and sometimes irreparable losses in the legacy of ancient writings. In this respect, the capture of Constantinople by Western crusaders in 1204 had the most appalling consequences. But by and large, the role of the Byzantine scholars, who were not conspicuously creative, was that of being conscientious preservers of the great works of the classical canon established in Alexandria. Like the teachers of Alexandria, they became the respectful heirs of the texts, which they studied with care, making abridged editions and anthologies of them. Since a manuscript's life is limited in time, the mere fact that they served as copyists was salutary. The only field in which they were innovators was that of history. Eusebius of Caesarea (died *c.* 340), Constantine's historian, was also the author of *Historia ecclesiastica* (a Christian church history), the first of its kind and source of all the others. Eusebius' work was based on a chronology of world history beginning with the creation. This type of overall design, carried over to the West by Jerome, a Latin Church Father, served as a guide for viewing European history in perspective. Even in Byzantium this historical tradition was preserved for many centuries, and works of this genre were written by a historian, Leo Diaconus, near the end of the 10th century and continued by a philosopher, Michael Psellus.

In the history of humanistic scholarship, the Byzantine scholars were above all preservers of Greek culture. In the words of Frederic Harrison, an English writer:

> The peculiar, indispensable service of Byzantine literature was the preservation of the language, philology, and archaeology of Greece. It is impossible to see how our knowledge of ancient literature or civilisation could have been recovered if Constantinople had not nursed through the early Middle Ages the vast accumulations of Greek learning . . . ; if [they] had not poured out their lexicons, anecdotes, and commentaries; if the *Corpus scriptorum historiae Byzantinae* had never been compiled; if indefatigable copyists had not toiled in multiplying the texts of ancient Greece. Pedantic, dull, blundering as they are too often, they are indispensable.

The Western tradition. While Byzantium maintained the continuity of political power in the Hellenized East, the Romania of the West saw its cultural heritage, like its civil authority, shattered by the barbarian onslaught.

Political and cultural conditions. The power groups that slowly emerged with the advent of feudalism did not include a lettered aristocracy. Brought to power in a time of dire distress, the new authorities found themselves in a cultural void. Consequently, responsibilities were transferred to the only power capable of rescuing what was salvageable—the church—which, with the withering of secular authority, represented the only cultured class, as well as the only power with wide-ranging authority. Thus, the church became the sole patron of all the fields of art, knowledge, and education; theology now became the science of sciences, and its demands in matters of learning became law.

Nostalgia for the Imperium Romanum in the Middle Ages

Under those conditions the Latin Middle Ages, even in their darkest periods, were haunted by the nostalgic myth of the Imperium Romanum and subjected to a feeling of inferiority with regard to a grandiose past. Characteristically, throughout the Middle Ages the task of renewing the empire was linked with that of renewing learning. A cultural renaissance was included along with the political renaissance in the same plan of restoration. Thus, Theodoric the Great, king of the Ostrogoths who ruled over Italy through the early 6th century, undertook to repair the ancient monuments; in about the same period Boëthius, a philosopher, and Cassiodorus, a historian and statesman, translated and digested in Latin the great works of ancient Greece. Charlemagne, emperor of the West from 800 to 814, took steps to remedy the wretched state of culture: his Carolingian renaissance brought to the fore the Anglo-Saxon scholar Alcuin and his disciple Rabanus Maurus, and Einhard the Frank. A short time later, Emperor Otto I, called "the Great," who ruled from 936 to 973 and who, in turn, sought to rebuild the Roman Empire, similarly tried to foster a cultural re-

vival, in which the outstanding name was that of Gerbert of Aurillac, later Pope Sylvester II. Gerbert was a great scholar: proficient in Greek and Latin, he was fond of ancient manuscripts; and, as tutor to the young Otto III, he dreamed along with his imperial pupil of restoring the splendid empire of Constantine the Great. The flowering of medieval culture in the 12th and 13th centuries was characterized by the same desire to revive the past.

Medieval culture was rooted in the memory of a golden age. Its men were like dwarfs perched on the shoulders of the giants who had preceded them. Progress could only mean recouping the lost treasures of classical scholarship. In the meantime, men had to be satisfied with manuals and digests and collections of selected passages. Thus, the authorities became such men as Macrobius (start of the 5th century), a Neoplatonist, who prepared a commentary on Cicero's *Somnium Scipionis* in which Homer, Plato, Cicero, and Virgil are canonized, and Martianus Capella, a North African pagan, who composed between 410 and 439 an allegorical novel, *De nuptiis Philologiae et Mercurii*. Other compilers, who mingled pagan wisdom with Christian doctrine—thus ineptly perpetuating the memory of the vanished high-classical culture—enjoyed widespread renown. In the West, as in Byzantium, scholars dwelt amid a humanistic scholarship that was revised by the Church Fathers. But the West suffered under two severe handicaps: (1) the major setback caused by the barbarian invasions and (2) the fact that not a single scholar had access to the Greek originals, which were known solely through partial Latin translations, some of which had reached them by way of the Arab world. Thus, the Western feeling of inferiority was based on reality. It is therefore understandable why they idolized Aristotle, whose genius ranged far above their own.

Creative scholarship in the universities. There was, nevertheless, one field in which medieval civilization demonstrated its creative ability: in the founding of the university. In the West, schools had previously developed in the monasteries and cities under the sponsorship of the ecclesiastical authorities, who saw that the priests were educated in church doctrine. Some of these centres were for specialized studies: Salerno, for example, was a centre of medical education from the 9th century, and Bologna was the legal capital of the West, long before its status as a university was established. After protracted struggles between the local civil and religious authorities, the universities received their written charters from the Holy See. Thus the University of Paris received its charter in 1215 and thereby initiated a new era in the intellectual history of the West.

In the medieval system, the university was a corporation, but it was also a seat of culture in which knowledge was gathered and enunciated. In this manner its autonomous intellectual function was recognized and consecrated; thus, alongside the religious *sacerdotium* and the political *imperium*, the *studium* was the site reserved for the full pursuit of knowledge. Undoubtedly, the uses of reason were subordinated to the preconditions of theology, but the latter was itself thoroughly permeated with the rational spirit as refined by the practices of Scholasticism.

The Scholastic method

Despite its eventual decline, Scholasticism represents the first attempt to set up the general principles of knowledge as a whole, thanks to the establishment of a universe of systematic discourse. Within the confines of the university, learning was regulated according to the rituals and prescriptions of the community of scholars. Before the advent of the printed book, truth was established orally; it arose in conformity with fixed rules amid the exchange of arguments, of which Scholasticism defined the code. In the ceremony of the *disputatio* ("debate"), the themes of the *quaestiones disputatae* were presented, and the systematic analyses of these themes enabled one to arrive at *summae* (syntheses), in which the mastery of the great doctors of learning shone forth.

The new contributions—the university as an institution and the Scholastic method—still retained the preconditions of humanistic scholarship. The intellectual dialectic of Scholasticism—in matters of rhetoric, science, and philosophy—was based upon themes formulated by masters of the past, whose teachings were authoritative; and the process of argumentation quickened as soon as it fastened upon the text of a good writer. Truth was a truth of repetition and commentary; it was contained, essentially, in the works of the ancients, specifically in the writings of Aristotle—a profane revelation comparable in authority to that of the sacred religious texts. As for the system of knowledge, which formed the essentials of the university, it carried on the ideal of the *enkyklios* ("comprehensive") *paideia* as defined by the Sophists and developed by the Roman rhetoricians. The faculty of arts —charged with the studies prerequisite to those in theology, medicine, and law—included in its program the seven liberal arts: the literary *trivium* (grammar, rhetoric, dialectics) and the scientific *quadrivium* (arithmetic, geometry, harmony, astronomy). Thus, the pattern of the *paideia* that prevailed in Plato's time survived for 2,000 years.

The *trivium* and the *quadrivium*

The Romania of the West—vaster and more cohesive and surer of its fate than the Byzantine Empire—constituted a unified cultural whole. Under the authority of the Roman Catholic Church, the network of European universities dotted Europe like magical mountain peaks. Professors and students travelled all over the West, thus ensuring the free circulation of ideas despite political barriers. Unity of language guaranteed the community and communication of thought everywhere. From one end of Christendom to another, as the language of the church, Latin modulated the communion of prayer and the liturgies of faith, as well as those of reason.

THE RENAISSANCE: HUMANISM REBORN

Greek culture as another sacred history. As a capital event in the development of Western culture, the Renaissance represents a dramatic turn in the history of humanistic scholarship.

Impact of manuscripts from the East. A transformation of the European consciousness was seemingly made imperative by the establishment of a new and direct relationship with the heritage of Hellenic antiquity. Even before the fall of Constantinople to the Turks in 1453, cultural exchanges had occurred between Eastern and Western Christianity. During the first half of the 15th century, the political and religious powers of Byzantium, faced with the extreme gravity of the Turkish peril, had sought aid from the West, even if the price of it had to be an adherence of the Eastern Church to Roman orthodoxy. The occasion of negotiations to this end brought a certain number of Byzantine scholars to the West; others came to escape the Ottoman menace. First in Italy and then in western Europe, they re-established the knowledge of the Greek language, which had become quite rare. With these professors came the texts: many manuscripts passed from East to West, carried by refugees or purchased at the source by specialists sent as emissaries by potentates now seized with a passion for Humanism.

The Renaissance comprised a return to the Hellenic sources of Western culture, whose authentic meaning had been deformed and diminished by Scholastic Latinism. The doctors of the Middle Ages had paid tribute to the ancients, but they knew little or nothing of their works, except through recent adaptations or selections done by mediocre minds in an uncertain vocabulary. The Latin translations acted as a screen masking the Greek original; and medieval Latin itself, moreover, was corrupted by ecclesiastical and Scholastic overlays and thus was only distantly akin to the language of the masters of Rome. The rediscovery of the authentic texts meant the revelation of a hidden treasure that Byzantine scholars had held in charge for 1,000 years. It was the accident by which the texts were transferred from Constantinople to the West that brought about the resurrection of the ancient ideals of *paideia* and *humanitas* in the form of Renaissance Humanism.

Resurrection of *paideia* and *humanitas*

A complete break now took place with medieval culture, which had been discredited by the degeneration of

Scholasticism, which, beginning in the 14th century, had turned more and more into an artificial kind of dialectics. The sanctification by means of culture now tended to replace the religious sanctification. The ancient masterpieces brought to mankind new reasons to live and to hope and a new ideal model of personality. And there now began to take shape the modern type of cultivated man, distinguishable by the fact that, in his youth, he had visited the imaginary museum of the masterpieces of art. Thus consecrated, culture became the faith of the 15th- and 16th-century Humanists: their life was a passionate search for available manuscripts, statues, and coins—with, at the same time, an indefatigable delving into their meanings. Greek and Roman antiquity took its place as a second sacred history, not obliterating the Bible but sometimes overshadowing it. This devotion to the past at times reached the proportions of an abdication of personality: the old became a parasite on the new; humanity was living a double life, and the more important of the two was not that of the here and now. As emphasized by the Italian Leonardo Bruni, an early-15th-century Humanist: "I have the feeling that the days of Cicero and Demosthenes are much closer to me than the sixty years just past."

The dignity of the free man. Humanistic scholarship thus became the innovative source of a spiritual conversion. The Renaissance scholar, in the mirror of the ancient texts, discovered an unsuspected humanity. The clerics of the Middle Ages had known their Ovid and Virgil; but they had read the *Ars amatoria* (*Art of Love*), as they did the Song of Solomon, as mystically embodying divine love. Renascent philology, however, exposed the all-too-human evidences. The literary and philosophical treasure of antiquity now offered for investigation a humanity free of Christian dogmatism, as well as of Scholastic axiomatics.

The literature of antiquity, purged of its Christian overlays, revealed the worth of the human being in the free expansion of his nature no longer weighted down by a corrupting heritage of original sin. If Renaissance Humanism in its highest embodiments—as in Erasmus or John Colet—aroused the enthusiasm, as it were, of a new golden age, it was because it celebrated the sacrosanct worth of man. Man thus took unto himself the attributes of divinity, in the very first instance the power of creation. And his most wonderful creation was man himself in the full excellence of his humanity. The praise of the human condition was the theme of the *De dignitate et excellentia hominis* (written 1452) by Giannozzo Manetti, a Florentine philologist, and the *Oratio de hominis dignitate* (1486) by the young and brilliant Humanist Giovanni Pico della Mirandola. Christian faith, however, was not necessarily repudiated. The devotees of Humanism such as Marsilio Ficino and Erasmus himself were also Christian believers—but believers in a Christianity that had seen a rebirth of the spirit and had been aerated and put on its guard against the perils of superstition. The association of Socrates with Christ, implicit in Erasmus' temptation to canonize Socrates, implied a profound alteration in the traditional image of Christ, as well as a new reading of the gospel—often in a Platonic spirit.

The universal Renaissance scholar

Humanistic philology. The Renaissance *homo universale* (or "universal man")—at the same time philologist, artist, creator, and encyclopaedic genius in the spirit of the ancient *paideia*—appeared as a new ideal type of the human condition brought into being by the renewal of humanistic scholarship. The knowledge of humanistic scholarship was the privileged path to spiritual formation; philology as science became associated with philology as value. Apprenticeship to the ancient languages became the surrogate for ascetic monasticism. Philology then passed over into hermeneutics—*i.e.*, into the search for meaning according to the various modes of approach offered by the study of antiquities. The Humanists were engaged in the huge task of establishing authentic texts through the collation of manuscripts. The invention of the printing press in the middle of the 15th century provided for the rapid circulation of the ancient literature. Philology, as an interdisciplinary science, now covered the history of men and institutions, the study of civilization in its various aspects—religion and philosophy but also mores and customs, fine arts, techniques, public works, weights and measures, coinage, and so on. The fervour of the philologists, such as the Italians Lorenzo Valla and Marsilio Ficino and the Frenchmen Robert Estienne, Guillaume Budé, and Julius Caesar Scaliger, was sustained by the devotion of the printers of Venice, Lyons, and the Netherlands. A common market of the humanities thus arose outside the network of the universities, which, for the most part, were reluctant to welcome the new learning.

Repudiation of medieval Latin and Scholasticism

As a source of values and a way of life, humanistic scholarship rejected the barbarous and degenerate medieval Latin of the church and the university. The scholars effected a return to the classical language, modelled after Cicero and the poets of the Augustan century. This development was decisive for the future of culture: through it, humanistic philology, breaking away from the living continuity of Scholastic expression, prepared the death of the Latin language, which occurred in the 15th century. Ciceronianism, with its servile imitation of the classical models, entered into the pedagogical customs, as new exercises in Latin speech, Latin composition, and Latin verse were adopted.

The dawn of a new culture. Thus, a new definition of culture was formulated.

The common culture of European schools. Education, having escaped from the control of the Scholastic system, now took on a new structure. The colleges disseminated the curriculum of Humanist education through all of Europe. By action of the Jesuits the number of such institutions increased. Everywhere they established the same prototype, consisting of an education in Latin based upon the study and imitation of classical models. Within the shelter of the school, the educated youth of the West lived an anachronistic existence in the imaginary setting of a stereotyped antiquity. The myths of Homer's Greece, Pericles' Athens, Alexander's epic campaigns, and the Roman Republic all molded their personalities and excited their imaginations according to the basic requirements of style considered as a capital virtue. Romulus and Remus, Paris and Helen, Dido and Aeneas, Augustan clemency, Nero's evil ways, and the heroism of Regulus replaced the golden legend of medieval saints with that of ancient gods, heroes, and great men. Such was the imaginary backdrop against which, in modern Europe, drama and tragedy and opera and comic opera would be projected. Such schools were the crucibles for both authors and audiences of Shakespeare's *Julius Caesar* and *Coriolanus*, such operas as Claudio Monteverdi's *Orfeo* and Christoph Gluck's *Alceste*, the tragedies of Pierre Corneille and Jean Racine, Goethe's *Iphigenie auf Tauris*, Jean Anouilh's *Antigone*, and Eugene O'Neill's *Mourning Becomes Electra*, not to mention Jacques Offenbach's *Belle Hélène*.

This restoration of humanistic scholarship, essentially in its Latin form, helped to establish a new common cultural feeling in the West. The Humanists ensured the unity and universality of European education for centuries to come at the very time when the Reformation was dividing Christendom against itself. Educated men, despite their religious differences, could find communion in the educational ideals that had formed them all equally. Though members of the Reformed churches of Germany, England, and France would henceforth read Holy Scripture in their native tongues, they would continue to read the sacred writings of Humanism in the original Latin.

Exposure of classicism's provincialism

Broadening horizons of discovery, invention, and science. Through a paradoxical coincidence, the provincialism of Latin classicism was increasing at the very time that the limits of the Old World were being surpassed: for the 15th century saw the beginning of the great adventure by land and by sea, undertaken by the Portuguese and the Spanish, that opened up new worlds in distant places. The growth of knowledge, both through technical inventions, as well as through explorations, went hand in hand with a growth of power. The dis-

covery of the horizons of the globe had as a consequence the discovery of mankind, in its full variety of forms, as represented by the "savages" of the world. And the scientists studying the faraway reaches of sky and earth and the human body and the ordering of nature were continually discovering new facts that gave the lie to the Scholastic order but that had also escaped the notice of antiquity.

Thus, a veneration for the prestigious genius of the ancients developed at the very time when the intellectual situation clearly revealed the shortcomings of ancient culture in terms of the understanding of the real world. According to Francis Bacon (died 1626), author of the inductive method, the geographical New World demanded the elaboration of a new mental world. Unquestionably the classical heritage retained its value on the aesthetic and moral levels, but in Bacon's view modern men, writing in their own tongues, could also compose masterpieces to set alongside the classics. And on the scientific level, the superiority of the moderns was apparent without argument. Bacon clearly described the need for a new culture and a plan for it that, while giving the ancients their due respect, would prepare a synthesis of the newly acquired knowledge and organize its future development. The 17th century would be, in Bacon's perspective, the century of scientific academies and societies: the Accadèmia del Cimento in Florence, the Royal Society in London, and the Académie des Sciences in Paris.

According to Galileo (died 1642), the book of nature was written in mathematical signs—implying that it was not written in Latin. Bacon's *Novum Organum* (1620) was to replace Aristotle's *Organon*, using different principles. Mechanistic thinking portended a swift cultural revolution. Humanistic scholarship, being backward looking, stood in grave danger for want of due attention to the present. That was the true significance of the quarrel of the ancients and the moderns, which broke out in 1687 with the reading of a poem by Charles Perrault, author of several favourite fairy tales, at the Académie Française and spread throughout Europe. It was the opening blast of the great crisis of Western education, for which no solution has yet been found.

FROM THE 18TH TO THE 20TH CENTURY

From belles lettres to archaeological reality. During the 18th century, humanistic scholarship passed from the sacralized ideal of belles lettres to the scientific investigation of what antiquity really was.

Perpetuation of traditional classical schooling. In the century of the Enlightenment, humanistic scholarship continued to define the common pedagogical law of European teaching.

Jesuit, Pietistic, and national schools

The Jesuit type of school—duplicated hundreds of times in Europe, America, and Asia and imitated by responsible non-Catholic authorities—remained in force everywhere. It might have seemed that the persecution of the Jesuits, their expulsion from Europe, and the banning of their society by the Holy See (1773) should have been the occasion for an active reconsideration of teaching problems in view of the need to fill the resulting pedagogic vacuum. But the primacy of classical Latinism remained essentially untouched. The only significant innovation was the proliferation in Germany of *Realschulen* ("practical schools")—technical institutes or modern secondary schools developed under the influence of Lutheran Pietism. These institutions were meant for the children of the lower bourgeoisie and of craftsmen, to whom they offered a concrete curriculum in which geography, mathematics, experimental and natural sciences, and modern languages predominated, as befitted the current utilitarian concerns. At the end of the 18th century, the authorities created by the French Revolution set up a system of modern "national education," which was also freed of the fascination of the classical humanities. The latter regained the major part of their prestige, however, with the educational reforms instituted by the Napoleonic regime and then maintained by the monarchy restored in the 19th century.

Thus the social elite of European youth continued to study a curriculum inspired by the Humanists of the 16th century and codified by the Jesuit masters, despite the rapid transformations of the technological and industrial revolution. The intellectuals of the Enlightenment, themselves trained in the selfsame schools, were on familiar terms with the ancient authors, who continued to mold their intellectual sensibilities—as is amply proven by the examples of Alexander Pope, David Hume, and Samuel Johnson in England; Montesquieu and Voltaire in France; and Gotthold Lessing, Immanuel Kant, and Friedrich Klopstock in Germany. Jean-Jacques Rousseau was much absorbed in the reading of Plutarch, and the republican civic feeling of the French revolutionaries never ceased to imitate textbook oratory or to depend upon ancient examples.

Desacralization and rediscovery of antiquity. But while the classical humanities retained their status as teaching models, the progress being made in philological studies conducted on a scientific level was little by little eroding the system of myths and legends on which the model rested. The critiques of the scientists destroyed the pretty pictures perpetuated by the professors for their pupils. As portrayed by the teachers, the distant past melted into a single panorama; the heroes, playing out their roles in the same settings and in the same costumes, seemed as interchangeable as the characters of tragedy. From the time of the Renaissance, however, another school of Humanists had been rediscovering actual antiquity in its historical reality. Archaeology challenged the classicism of the professors, re-examining all of the trite old images and received ideas.

Parallel between classical and biblical scholarship

There is a striking parallel between the evolution of classical scholarship and that of biblical scholarship. In both areas, a venerable tradition with canonized texts and themes, supported by temporal authorities, dictated an overall view and an understanding that were fixed once and for all. But the biblical literature, translated into the Latin Vulgate of Jerome, was called into question again at the time of the Reformation, when scholars insisted on a return to its Hebrew and Greek sources. This thaw in the studies brought with it a new reading of the received texts, a critique of their authenticity, and a revision of their interpretation. The work done on the Old Testament by Benedict de Spinoza, a mid-17th-century Rationalist philosopher and a good Hebraist, and on the whole of Scripture by Richard Simon, a Catholic religious of the later 17th century, brought about a sort of desacralization of the holy text, which—even if it had been inspired by God—carried many traces of historical alterations and human intervention. The same method of philological criticism accomplished a concomitant desacralization of classical writings. The ideal of belles lettres had hidden and distorted the authenticity of texts, works, and men. Thus, the cult of a transcendental revelation of the True, the Beautiful, and the Good in its Greco-Roman guise had to give way to the demand for a historical investigation ready to unmask the best established prejudices and conventions and to lay open positive knowledge of the ancient civilizations.

This patient labour of restitution found its place not in classroom teaching but at a higher level, in universities, where the masters were free to devote a major part of their efforts to research. Inasmuch as the universities of Catholic countries had been held suspect and paralyzed since the Council of Trent (1545–63), which had crystallized the doctrines and reforms of the Counter-Reformation, the Protestant universities would have to serve as the seats of development of modern philology. At Leiden and elsewhere in Holland, numerous Protestant scholars were at work as indefatigable researchers and editors of texts, dictionaries, encyclopaedias, and literary and historical works. Their work renovated the image of antiquity in the complexity of its ages and forms.

Classical research at Dutch and German universities

The 18th century saw the supremacy of the German philologists at the old University of Leipzig as well as at the modern universities of Halle and Göttingen, where several notable scholars edited and commented upon the ancient texts, facilitating their comprehension by every

possible means, and brought about the institution of a seminary of philology in which—in an atmosphere of critical erudition and exact science—professors would be trained who were moved by a new spirit.

Philology and humanistic scholarship as modern disciplines. These studies achieved the status of a modern discipline at the close of the 17th century.

The founding fathers. In England the great name of enlightened philology was that of the royal librarian Richard Bentley, a dignitary both in the church and in science and also a master of Trinity College in Cambridge. Bentley established his reputation during the years 1697 to 1699 by demonstrating, by rigorous methods and in one stunning stroke, that the *Epistles of Phalaris*, a traditionally respected text that depicted the cruel tyrant of ancient Acragas (in Sicily) as a humane and cultured man, were a spurious counterfeit of relatively recent date. An indefatigable (though occasionally mistaken) worker, Bentley took as his field all of Greek and Roman literature. His most remarkable intuitions appeared especially in his Homeric studies. Having worked on biblical texts as well, Bentley drew a parallel between "Moses," author of the Pentateuch (the earliest books of the Bible), and "Homer," author of the *Iliad* and the *Odyssey*. In each instance the work attributed to an author designated by name had to be understood as a regrouping, at a certain time in history, of the elements of an earlier tradition. Behind the author's name lay in reality a collective work. Moreover, in order to resolve certain difficulties of ancient metrics, Bentley restored to the Homeric text a letter, *digamma*, which had been dropped since the classical period. This discovery was one of the starting points of historical linguistics.

Bentley's true successor in this work, at the end of the 18th century, was the German philologist Friedrich August Wolf. German historians like to assign the birthdate of modern philology to April 8, 1777, the day when young Wolf was accepted, not without difficulty, into the University of Göttingen as a *studiosus philologiae;* this was an unprecedented departure, for, until then, philology had not been an independent course of studies; only students in theology had attended the courses of the seminary of philology. Wolf, however, considered philology to be a discipline sufficient unto itself. But his enrollment was only a symbolic gesture; his real glory was assured when he wrote the *Prolegomena ad Homerum* (1795), which transferred Homeric studies from the realm of legend to that of science. The mythical personage of the old blind bard of Ionia was definitively rejected; and the texts that he was supposed to have created were now seen to be compilations based on pre-existing elements, which throughout history had been subjected to complex revisions, elaborations, and alterations in transmission. It is true that the theory itself had already been advanced by Bentley and that the French Hellenist J.-B.-G. d'Ansse de Villoison had discovered evidence that reinforced it. But Wolf radicalized the theory: he presented a demonstration that, going back over the earliest steps of the historical elaboration of the text, forever destroyed the conventions established by the respectful veneration of centuries of Humanism. The scandal was such among the adherents of traditional belles lettres that Wolf's theory was given the name of "Homeric atheism."

New spirit in contemplating antiquity

Wolf's critical work inaugurated the era of modern positive philology. It obliterated the conventional image of antiquity that had been perpetuated in the schools and helped to provide a new understanding of the origins of mankind and of the ancient epochs of culture. The Homeric epic was seen as perpetuating the memory of the earliest times of Greek civilization. As early as the beginning of the 18th century, the Neapolitan thinker Giambattista Vico, in his *Scienza nuova* (1725, expanded in 1730 and 1744), was exalting the heroic eras of human society, of which the *Iliad* was one example among others. Although Vico's book had not been widely read, Enlightenment scholars, enthralled by the discovery of savages, in whom they saw a reminder of the beginnings of mankind, established a relationship between these primitives and the persons of the ancient epics, whether classical or barbarian. The popularity of certain old Germanic texts that recently had been uncovered inspired the imitations that the Scottish poet James Macpherson made and falsely attributed to the early Gaelic bard Ossian: *Fingal. An Ancient Epic Poem* (1762) and *Temora* (1763). The immense success of these compositions throughout Europe led to a new reading in which the infancy and youth of the Hellenic world came alive again. As early as the *Geschichte der Kunst des Altertums* (1764; "History of Ancient Art") of the art historian Johann Joachim Winckelmann, there was evidence of a new spirit in the contemplation of ancient works of art. The romantic vision of the world introduced a breath of life into the interpretation of the past, which had to be recaptured in the authenticity of its presence. Poetic license might often interfere with the methodological rigour of philological science, but at the same time it would preserve these studies from the funereal dullness of erudition. The archaeological passion of Heinrich Schliemann (died 1890), excavator of Troy and Mycenae, was romantic in its essence.

The development of Sanskrit studies. Another decisive development in the history of humanistic scholarship was brought on by the study of Sanskrit language and literature, beginning at the end of the 18th century. English Orientalists, encountering the culture of India, became conscious of the fact that the languages of Europe derive from Sanskrit. Beginning in 1784, two British Orientalists, William Jones and (later) Henry Thomas Colebrooke, were responsible for creating an enthusiasm for Orientalism, shared subsequently by many scholars, including the German Friedrich von Schlegel, a Romantic critic. Philology was thenceforth to be a comparative science; thus, classical philology became a branch of Indo-European philology. This was the consummation of the desacralization of Greek and Latin, which ceased now to have an absolute value in themselves and to warrant the respect due to mother tongues. The classical civilizations, now merely two civilizations among others that had also flourished, had to be transferred from an ideal realm to one of historical relativity. Classicism could no longer be viewed as an eternal affirmation of the True, the Good, and the Beautiful; it was now merely an abstraction drawn from the study of certain works produced by the geniuses of a certain place and time.

The final desacralization of Greek and Latin

Specialization and expansion as a technology. Thus deposed from their dignity as an artificial paradise, the classical humanities became, in the 19th century, an ensemble of specialized disciplines, enclosed more and more within their own respective technicalities. German science, with the University of Berlin as its privileged locus, now played a preponderant role. Modern scholars ceased being all-around or general scholars; they became specialists either in Greece or in Rome. And they often narrowed their interests down to a certain period within a civilization. Such a division of labour also applied to the various ways of approaching the study of ancient culture. Henceforth there were often separate departments devoted to literary history, philological criticism of texts, the history of art, political and social history, archaeology (with its adjuncts—such as epigraphy, the science of inscriptions, and numismatics, the study of medals and coins), the history of ancient law, the history of ancient philosophy, and even prehistory, which meant doing research *in situ* on the origins of classical civilizations. Scholars became more numerous, and the great cultural powers increased the numbers of scholarly journals, specialized institutes, and schools of archaeology in Greece, Italy, and the Middle East. This technological expansion was accompanied by a fragmentation of knowledge, however, so that no one today can claim to have a full knowledge of the whole domain of humanistic scholarship. For a review of the humanities as they have existed in the late 19th and 20th centuries, see the article HUMANITIES.

CONCLUSION

The unity and identity of humanistic scholarship are now finally shattered. The myth of antiquity, propagated by

the venerable ideal of belles lettres, remains a forgotten dream. Thus disappeared the program of *paideia*, which, from the Sophists and Socrates onward, had inspired pedagogic uniformity in the West. Unfortunately, this outdated and discredited program has not been replaced by anything else; modern education is in a crisis and has been seeking in vain for a new foundation on which to base the training of individuals in contemporary society. Some theoreticians have attempted to create a substitute for classical studies in "modern humanities," based upon the exact sciences and on techniques. But the positive sciences do not supply that sense of peculiarly human values that was derived from the study of ancient literatures. The present-day proliferation of theories of pedagogy has too often developed within an abstract space from which the face of man has been banished. This pedagogic malaise reflects the crisis of civilization.

The need for a broader humanism

Humanistic scholarship had made the human form the centre and measure of all things. When man ceases to be the principal concern of mankind, barbarism threatens. It is now known that classical studies deal with only one civilization among many. But, even thus relativized, it must still be admitted that Hellenic culture was an unusual success, though it is no longer the only success. Perhaps the solution to the present crisis may lie in a generalization of classical humanism. Instead of tying all teaching to the theme of a conventionalized image of the Greco-Roman world, the effort could be made to reconstruct the various forms of human presence upon the face of the earth. The great civilizations and those not so great would all have a place within such studies, and humanistic scholarship, thus made relative, would become one chapter in the overall study of anthropology. In order to bring together tradition and modernity and to merge classical culture and universal culture, the time has come now for a new updating of the study of man.

Humanities

The humanities is a term that refers to one of the administrative divisions of the college and of the graduate school of arts and sciences, as organized especially in the large, modern American university.

IDENTITY AND SCOPE OF THE HUMANITIES

This division brings together those educational disciplines not included within the divisions of the natural sciences and of the social sciences and combines with them to comprise the arts and sciences taught in the nonprofessional schools of the university (outside of such schools as those of law and medicine). In a less pragmatic but also less definite sense, the term is used for a division of knowledge itself apart from the simple concern for administrative convenience. The humanities are considered to constitute a distinct kind of knowledge that is humanistic—*i.e.*, which is concerned with human values and expressions of the spirit of man—and are thus appropriately grouped together in one administrative division separate from that of the sciences. It has been found difficult, however, to establish identifying criteria for the humanities, and disagreement has frequently occurred about whether or not a given discipline, such as history or the fine arts, should be included within the humanities.

The wide scope given to the term can be seen from the language used by the United States Congress in the law establishing the National Endowment for the Humanities, which declares that

> The term "humanities" includes, but is not limited to, the study of the following: language, both modern and classic; linguistics; literature; history; jurisprudence; philosophy; archeology; the history, criticism, theory, and practice of the arts; and those aspects of the social sciences which have humanistic content and employ humanistic methods.

This enumeration, however, includes a greater diversity of subjects than is found in the humanities divisions of even the largest universities.

Alternative criteria of the humanities

Although it is not unusual for the humanities to be identified with certain disciplines and subject matters, it is often argued that such a definition is inadequate. Some subjects so identified, it is said, may be pursued and studied in a way that has nothing humanistic about it—so the study of language often carried on in linguistics belongs to mathematics and science rather than to humanities; and on the other hand, subjects not identified as humanities may be studied in a humanistic way—as science is when its history and philosophy is the object of study. This being so, the criteria for distinguishing the humanities must be sought elsewhere than in the nature of subject matters. Some locate their characteristic feature in the fact that they are arts and methods of analysis or of criticism that, because they transcend all subject matters, can be applied to any subject, while others claim that their distinguishing mark lies rather in the end, or purpose, that the scholar has in view in the study and pursuit of his subject, whatever it may be—a method or end that somehow is concerned about human values. Still others hold that they are to be distinguished from other disciplines by the language that they employ, by the special faculty of mind that they use (*e.g.*, the imagination), or by the kind of experience on which they are based and to which they appeal, which is usually particular and nonscientific. Each of these positions or approaches has been taken as a basis for elaborating a general theory of the humanities.

THE HUMANITIES AS AN EDUCATIONAL PROGRAM

Humanitas or *paideia*

The term humanities derives from the doctrine of *humanitas* that Cicero developed in an account of the education of an ideal orator. In Latin, *humanitas* may mean "humanity" or "humaneness"; but as Cicero used it in his work *On the Orator*, it also refers to a special kind of educational program. In fact, the authority of a later Latin grammarian, Aulus Gellius (2nd century AD), is cited for identifying it with the Greek *paideia—i.e.*, the general and liberal education used in preparing a free man for manhood and citizenship, which developed from its origin in the mid-5th century BC, when the first itinerant Sophists offered private tutoring to young men in the Greek city-states. As further developed by Greek and Roman rhetoricians, it constituted the basic program of classical education. Then, turned to Christian ends by St. Augustine and other Church Fathers, it became the basic education of the Christian Middle Ages. Thus, *humanitas*, or *paideia*, was originally identical with a program comprising studies called *artes, bonae artes* ("good arts"), or *artes liberales* ("liberal arts"), which included mathematical and linguistic arts, as well as some science, history, and philosophy.

The term *humanitas*, which dropped out of educational parlance during the Middle Ages, was revived in the 15th century by Italian Humanists, so called because they claimed to devote themselves to, and teach, *studia humanitatis* (the study of *humanitas*, or the humane disciplines). Coluccio Salutati, a Florentine chancellor who may have been the first to use the term, contrasted it with *studia divinitatis* ("divine studies"). The program of studies pursued by the Humanists included grammar, rhetoric, poetry, history, and moral philosophy, studied in the language and literature of the ancient Greeks and Romans. Such emphasis was placed upon imitating the language and models of the ancient classics that *studia humanitatis* came to mean little more than the study of Latin and some Greek, and, as such, it was criticized and attacked by educational reformers, such as D. Diderot and J. d'Alembert, the 18th-century French Encyclopaedists (see in their *Encyclopédie*, under "College"). The program of classical studies, often combined with mathematics, provided the basic liberal education of the 19th century in the American as well as the English college and, on the European continent, in the *lycée* and *gymnasium*.

General and liberal studies

The fact that, in their origin and for a great part of their long history, the humanities stood for an entire educational program helps explain several features common to the contemporary discussion of the humanities. A program of general and liberal studies has no hard and fast lines demarcating the subjects to be studied from those that are not. According to time and place, different studies have come to be included, and the priority of emphasis has varied from one discipline to another. The program proposed by Cicero as well as by St. Augustine included mathematics and some science, along with the verbal arts of grammar, logic, and rhetoric; whereas the programs recommended by the Renaissance Humanists concentrated upon the study of language and literature. For all, however, the end envisioned was to train a man to be skilled and raised to the peak of his capacities in all that is most distinctively human. It was a program of "more humane letters," as indicated by the title of the Oxford classical degree in litterae humaniores. Although this program might be highly specialized in some respects, its teachers claimed to be educating a person in the best that had been thought and said on almost all of the great concerns of man. As comprising the elements of a liberal education, the humanities are as much a subject of dispute, and provide as wide an area of disagreement, as liberal education itself, and invoke much discussion that is inseparable from issues in general and liberal education; thus, the relevant discussions in the various education articles should also be consulted.

THEORIES OF THE HUMANITIES

Theories of the humanities are usually developed on a basis somewhat narrower than that of the elements of an educational program; thus, the humanities are now considered and analyzed as a fundamental division of the world of knowledge. The Renaissance Humanists, as already noted, contrasted them with divine studies; but since the 19th century they have more commonly been opposed to the sciences.

Nineteenth-century theories. Indeed, the first modern attempts at elaborating a general theory of the humanities are seen in the efforts of certain 19th-century German philosophers to stake out and defend certain areas of knowledge as lying outside of, and beyond, the reach of the natural sciences. Wilhelm Dilthey, a pioneer in this endeavour, called these studies *Geisteswissenschaften*, sometimes translated as "human sciences"; whereas a Neo-Kantian philosopher, Heinrich Rickert, preferred the term *Kulturwissenschaften*, or "cultural sciences," which has also been translated as "humanities." (Thus, the *Logik der Kulturwissenschaften* [1942] of another Neo-Kantian, Ernst Cassirer, was published in English translation as *The Logic of the Humanities* [1961].)

Dilthey's *Geisteswissenschaften*

Rickert held that method, not subject matter, provides the distinguishing feature of the cultural sciences. Unlike the natural sciences, which are "nomothetic" in that they aim to reach general laws, these studies are "idiographic" in that they are concerned with what is individual and with its unique value. According to Dilthey, on the other hand, it is subject matter that makes the decisive difference: the human studies have for their objects the work and actions of men, and these, he claimed, are fundamentally different from natural phenomena and call for a different kind of analysis and explanation. All merely natural entities can be explained from without, as it were; indeed, they must be, since it is impossible for man to know from within what it is, for example, to be a stone or a cat. The works of men are essentially different in that all of them are expressions of human purpose and cannot be fully accounted for unless they are understood as such. To be sure, man is a part of nature and can be studied as such by the natural sciences; but, in addition, man is also a product of his culture and of his own drives and choices, and in these respects he cannot be known without an understanding and comprehension of purpose and meaning.

So far, however, these German scholars have provided no criterion for distinguishing the humanities from the social sciences. In fact, the work of these same scholars, and especially that of Dilthey, has contributed importantly to the development of the social sciences. For this reason, the term human studies, as used in the 19th century, might better be taken to mean not only the humanities but also the social sciences, at least in certain respects, and the term is still used in this sense in continental Europe. More recent theories, on the other hand, are as much concerned to separate the humanities from the social sciences as from the natural sciences.

Twentieth-century theories. Of these theories, four can be singled out as representative of the work done in the third quarter of the 20th century: those that view the humanities as (1) constituting certain general arts and methods applicable to any subject matter; (2) employing and emphasizing certain language function over others; (3) based on a distinct faculty of mind; and (4) based on, and appealing to, a general experience available to any man and not just to the specialist. Each of these theories represents a distinctive approach to the humanities and provides a developed account and defense of them as constituting a unified field of study distinct from both the natural and the social sciences. On one proposition all four theories are in basic agreement, viz., that the humanities form an important and valid area of knowledge distinct from that of the sciences. They differ, however, concerning the characteristics that make the humanities distinctive and set them off from the sciences, and concerning their relation to the sciences. In the special faculty and general experience theories, there is a radical separation, even an opposition, between the two; whereas in the general arts and language function theories, there is continuity and a difference of emphasis rather than a decisive break.

Theories denying a radical difference between the humanities and the sciences. According to the general arts theory, the humanities cannot be identified with any one special method, subject matter, or end inasmuch as they transcend all and yet apply to all. They are "serving sciences," claimed Ronald Crane, a proponent of this view, since they are

General arts theory

> oriented to uses and ideals which can be stated apart from the specific nature of the subject matters or objects of study by which the uses and ideals are to be attained.

Thus, of any subjects whatsoever, a scholar can discuss and analyze the language and literature, the history, and the philosophy. As applicable to a multiplicity of subjects and endeavours, the humanities might thus be looked upon as general arts or techniques.

There are four principal groups of humanistic methods or arts, according to Crane: the arts of language for coping with symbolic expressions; arts of the analysis and appreciation of ideas; arts of literary and aesthetic criticism; and arts of knowing the historical situations. Although these arts pertain to all subjects, they predominate more in some than in others; and such subjects are more humanistic because in them the arts come closer to providing a complete account of their nature.

There is no sharp separation, in this view, between the humanities and the sciences. The sciences, especially in the teaching of them, have to employ the humanistic arts. The difference between them must be sought rather in the direction in which they move in providing analysis and explanation: the sciences move from diversity and particularity toward unity, uniformity, simplicity, and necessity; whereas the humanities stress uniqueness, unexpectedness, complexity, and originality.

According to the general arts view, it is no accident that the humanities are so named: they have the capacity to deal with those aspects of experience that are most distinctively human and are not fully accounted for by the natural processes and social forces and structures to which the sciences appeal. As addressing what remains after the sciences have rendered their account, the humanities are concerned with the nature and value of human achievement—with "that kind of unprecedented excellence," as Crane has expressed it, "that calls forth wonder as well as admiration"—and hence are ineradicably normative as well as descriptive.

Language function theory

According to a second theory, the best approach to an understanding of the humanities lies in an analysis of language. Language as used in any utterance or expression is, in this view, a highly complex structure that satisfies many diverse needs and has many different functions. William T. Jones, for instance, an advocate of this view, names a few typical functions: language, he claims, "may satisfy curiosity, convey information, complement personal deficiencies, relieve anxieties, obviate loneliness." For certain purposes, it may be useful to isolate and consider just one of these functions—for example, the cognitive function of providing information and knowledge. But such an isolation, Jones emphasizes, is an abstraction and simplification, since

> it is not true that some particular segment of discourse satisfies a pure cognitive function, that this other piece of discourse satisfies a pure emotive function, that this third piece of discourse satisfies a pure appeal function;

the most that can be said is that in any given instance one function is more dominant than another. Since language simultaneously fulfills many different functions, it should be envisioned, according to this theory, as forming a spectrum or continuum, ranging from the cognitive, designative function at one end to the noncognitive and expressive function at the other.

It is claimed that reference to this linguistic model provides the best means of distinguishing the humanities from the sciences. Though no use of language ever satisfies only one function, language can be directed more to one than to another. The sciences are characterized by a language that is more designative and cognitive than expressive, the humanities by a language that tends toward the expressive, evaluative, and noncognitive. The sciences and humanities are different languages with different functions. Hence, each has its own standards of adequacy and value and should be judged accordingly. Neither is truer or better or more valuable than the other, but each serves in its own way to form man's view of reality. To be sure, the sciences and humanities are, on this basis, admittedly opposed in many respects to each other. But it is claimed that this opposition rests on the misunderstanding and misapprehension that comes from attempting to judge one by the standards of the other; in principle, they can be reconciled within one world, since they do not contradict but supplement each other.

Theories asserting a radical difference between the humanities and the sciences. In the special faculty and general experience theories, the sciences and humanities may supplement each other, but they do so because they belong to radically different, even antagonistic, ways of approaching and understanding the world. In the special faculty view, they reflect a basic and antagonistic division—in the words of Albert W. Levi, "a real dualism, . . . a split within the structure of the human mind"; they belong to different faculties of the mind, operate with different sets of concepts, and express themselves in different forms of language. The sciences are the expressions and product of the rational understanding, employing concepts such as fact, law, cause, chance, and prediction, communicated through an impersonal, referential, objective language; and the humanities, in contrast, are the work of the imagination, which has its proper concern with the things of man through such concepts as appearance and reality, destiny and free will, fortune, fate, happiness, peace, and tragedy, expressed in a language that is dramatic, emotional, and purposive. Each has its own preferred mode of operation, its own values, its own particular contribution to man's knowledge of himself and the world; yet the two are incommensurable as representing basically discordant approaches to human experience.

Special faculty theory

The humanities, in this view, are arts and approaches rather than subject matters. In fact, they are identified with the liberal arts, but these arts are redefined as those of communication, continuity, and criticism, which, in turn, can be correlated most closely with the disciplines of language and literature, history, and philosophy. Levi claims, however, that they must not be identified with these disciplines as such, since to each of them there is also a scientific side. Language, for example, studied and used as an art of communication, is a liberal art; taken as a physical phenomenon and analyzed mathematically, however, it is a scientific study. In this view, no subject or discipline is intrinsically scientific or humanistic; there is a humanistic tendency in every science and a scientific tendency in every humanity.

The world of learning thus divides into the arts on one side and the sciences on the other. Each of these also divides into two: the arts into the fine arts, concerned with making, and the liberal arts, which are those of learning and teaching; and the sciences into the natural and social sciences, concerned, respectively, with natural and cultural phenomena.

General experience theory

In the general experience theory, the characterizing feature of the humanities is their everyday, "natural" logic. The mathematical form of logic that has proved highly successful in mathematics and the sciences has been of little help to the humanities. Though some would conclude that these disciplines fail to achieve any real knowledge worth the name and amount to little more than a gratification of taste, defenders of this fourth theory conclude instead that they operate with, and appeal to, a different kind of logic, which they call a "what logic" because it deals mainly with the "whats" and "whys" of everyday experience, as contrasted with the "relating logic" characteristic of science, in which the main interest lies in relations, patterns, and structures.

The difference between the humanities and sciences, in this view, is not restricted to matters of method but extends also to the kinds of concern that they reflect and the objects of these concerns, as well as to the source of the evidence to which they appeal. Unlike the sciences,

the humanities are based on the common experience of men that is open and available to all; and they aim, according to the champion of this view, Henry B. Veatch, at "simply a knowledge of man, of human nature, of ourselves, and still more broadly of our human situation and of the real world in which we find ourselves." The data of the humanities are given in ordinary experience, in which nothing is so obscure, recondite, or uncommon as to call for specialized investigative techniques and highly artificial and contrived experiments. Such common experience is primordial; it is the most basic experience of all, underlying all of man's knowledge, constituting what he knows best, and providing him with the criteria of his surest knowledge. These features also explain why the humanities, unlike the sciences, continue to cherish and use the great works of the past: as monuments of human achievement, they speak to, and reflect, a concern with elements that are permanent in human experience and thus retain an abiding relevance.

Clearly, these four theories represent different approaches to the humanities and diverse ways of defending their value and importance. The conflicts among them reflect differences more of emphasis than of irreconcilable opposition and rest ultimately upon different philosophies. The patterns of agreements and disagreements among these theories help point out where the major problems concerning the humanities are to be found.

PROBLEMS ABOUT THE HUMANITIES

The role and function of the humanities in education. It is in their role as an educational program that the humanities have the longest tradition, and it is upon this basis, too, that the proponents of the humanities are most agreed, since they hold that the humanities should provide the basis of a general and liberal education. Education in the humanities is nonvocational, nonprofessional, aiming at the maturation of the person as man and citizen, not as a worker in some specialized field; and, for that reason, humanistic education is concerned with preserving and developing the arts and skills that find their expression in the great objects, problems, and values of human interest.

The study of language and literature has long been a strong point in education in the humanities. There are disagreements, however, regarding the form that such a study should take. Greek and Latin have long lost the monopoly that they once enjoyed; and, although emphasis is still placed on the expressive as well as on the cultural value of acquiring some command of a foreign language, it is ceasing to be required as extensively as it once was in the college curriculum. The proponents of foreign language study hold that it is needed not only to gain an entry into another culture and to study its literary monuments at first hand but also to expand the mind beyond the limited scope of one language and especially to gain a knowledge of language so as not to mistake words for things and become the dupe of one's native tongue. Against this view it is argued that especially in the United States, where there is little need for any language but English, the time and effort spent on a foreign language in high school and college are largely wasted as judged by the meagre results that are achieved; any command of a foreign language is much more readily obtained by living where the language is spoken, and hence "study years abroad" have been instituted by many American universities. The classics of Greece and Rome —in translation now rather than in the original—continue to exert their pervasive influence. The study of literature, however, has been broadened to include the major achievements in other languages; and comparative and world literature now command considerable interest.

The extensive use of "great books" in humanities programs represents not only the perennial importance of literature but also a reaction against an overspecialized and professionalized approach to its study. Literature, understood in an extended sense as including history, philosophy, and theology as well as imaginative literature, becomes a meeting place of subject matters and hence of interests that extend beyond any one academic department. So, too, unified courses in the humanities are sometimes offered as a better way of meeting the needs of liberal education than through departmental courses in single disciplines. The demands of students for "relevance" in the courses that they take are often, in part, a protest against the professionalization of the curriculum that converts it into preparation for the academic profession. When taught and studied professionally as preparation for an academic career, literature, history, and philosophy can be as specialized and narrow as any professional course in science. For the humanities no less than for the sciences, there is need for studies and courses for the nonspecialist and nonprofessional student.

A concern with expression and aesthetic value is generally agreed to be a feature of the humanities. Much disagreement exists, however, regarding the way of studying and of teaching this feature. At issue, in particular, is the place and role of the practice of the fine and performing arts. Some teachers maintain that the actual practice of these arts is a necessary and essential part of the study of the "expressive function." Others claim, however, that, so far as their humanistic values are concerned, the fine arts, on their practical side, are in the same position as the sciences; for both, it is only the study of their history and philosophy and of their contribution to, and their place in, the total human achievement that belongs to the humanities.

Interdisciplinary graduate programs

The interdisciplinary interest that has long been characteristic of the humanities has received renewed emphasis in recent years in the development of graduate programs in the humanities. Although these programs have different names—such as "humanistic studies," "joint program in the humanities," "institute of the liberal arts," "humanities program for the preparation of college teachers"—all have two features in common: one is the claim that humanistic disciplines, such as history, philosophy, and literature, while distinct as disciplines, are so closely related that the study of any one of them requires some insight into the other two; and the other is the belief that a broader study of this kind comprises a better preparation for undergraduate college teaching than a narrow and intensive specialization in one discipline can provide. At that level of education the student is endeavouring to discover his way and find his bearings within the world of learning. One of the requirements of the graduate program is, then, that he achieve some competence in mapping that world and showing what are the interrelations between the various areas of knowledge.

The humanities and the conflict of cultural ideals. The attention now being concentrated upon the humanities is characteristic of those times in history in which cultural ideals have come into open conflict. Such times occur when there are differing and opposed ideals about the kind of knowledge that is most important and about the form and method that express the highest cultural achievement. Western history contains a number of such conflicts: the fight that occurred in the ancient world between philosophy and poetry and that between rhetoric and philosophy, described, respectively, by Plato and Cicero; the struggle between pagan and Christian learning in the time of the Early Church and the battle of the liberal arts in the Middle Ages; the Humanists' attack upon Scholasticism in the Renaissance; the battle of the ancients and moderns in the 17th and 18th centuries and of religion and science in the 19th century. In all of these conflicts, the humanities have been present in one guise or another.

Humanities versus the sciences

In the contemporary world, the conflict of cultural ideals has come to the fore as that between the humanities and the sciences. Perhaps the greatest public notice has come from the controversy aroused by the English scientist and novelist C.P. Snow, who, in the essay *The Two Cultures and the Scientific Revolution* (first published in 1959 but still continuing with new additions in 1970), described, criticized, and lamented the polarity that he observed between a literary and a scientific cul-

ture, each spurning the other but each also unable to communicate with the other. Though Snow called for establishing new lines of communication between the two disciplines to improve understanding in both directions, his own sympathies were unmistakably with the scientists. For a century and more, science has provided what might be called the cultural paradigm of the day, and the defense of the humanities has been, at most, a rear guard action. There have recently been increasing signs, on the other hand, of malaise and of doubt at the high price that is being paid for the achievements of science and of its offspring, technology, and the current interest in the humanities is one manifestation of this development.

BIBLIOGRAPHY

The recent sources: The most recent full-length accounts of the humanities as a unified field of studies are those of R.S. CRANE, "The Idea of the Humanities" and "Shifting Definitions and Evaluations of the Humanities from the Renaissance to the Present," in *The Idea of the Humanities, and Other Essays Critical and Historical*, vol. 1, pp. 3–170 (1967); W.T. JONES, *The Sciences and the Humanities* (1965); A.W. LEVI, *The Humanities Today* (1970), and a longer philosophical justification of his position in *Literature, Philosophy, and the Imagination* (1962); and H.B. VEATCH, *Two Logics: The Conflict Between Classical and Neo-Analytic Philosophy* (1969).

The older German tradition: This tradition is well represented by ERNST CASSIRER, *Zur Logik der Kulturwissenschaften* (1942; Eng. trans., *The Logic of the Humanities*, 1961). H.M. JONES provides a good analysis of the social and practical importance of the humanities in *One Great Society: Humane Learning in the United States* (1959). One of the best of many symposia is *The Knowledge Most Worth Having*, ed. by W.C. BOOTH (1967).

The conflict between the sciences and the humanities: Much recent consideration of this conflict has resulted from the writing of the English novelist C.P. SNOW, *The Two Cultures and the Scientific Revolution* (1959), to which "a second look" was added (*The Two Cultures: And, A Second Look*, 2nd ed., 1964), which gave rise to a lively controversy, initiated by the English literary critic F.R. LEAVIS, *Two Cultures? The Significance of C.P. Snow* (1962), which is well documented in D.K. CORNELIUS and E. ST. VINCENT (comps.), *Cultures in Conflict: Perspectives on the Snow-Leavis Controversy* (1964). The controversy was taken up again in the columns of *The Times Literary Supplement* during the spring and summer of 1970 with essays by both Snow and Leavis and a host of letters in support of each. See also ALDOUS HUXLEY, *Literature and Science* (1963); and M.E. PRIOR, *Science and the Humanities* (1962).

Histories: Though many histories of individual disciplines exist, there is no general history of the humanities as such. Crane's book is the only one of those cited that provides considerable history—which, however, is devoted mostly to the modern period. For the ancient period the fullest accounts are to be found in WERNER JAEGER, *Paideia: The Ideals of Greek Culture*, trans. from German, vol. 1, 2nd ed; vol. 2–3, 1st ed. (1943–45); and H.I. MARROU, *Histoire de l'éducation dans l'antiquité* (1948; Eng. trans., *A History of Education in Antiquity*, 1956). For the medieval period, ETIENNE GILSON, *History of Christian Philosophy in the Middle Ages* (1955), with its very extensive bibliographies, provides many leads.

Human Rights

When, in the last third of the 20th century, people speak of "human rights," "the rights of man," or "*les droits de l'homme*," they really mean those rights drawing their formulation from the last decades of the 18th century and the American and French revolutions. But the idea of the inalienable rights of the human being is much older and, in fact, was known to poets, philosophers, and politicians in antiquity and in the Middle Ages. When Sophocles' Antigone—the play was composed about 442 BC—says to King Creon:

> But all your strength is weakness itself against
> The immortal unrecorded laws of God

she invokes the higher law, the law of nature, the natural rights of man. Throughout the centuries there has been a close connection and interdependence between the idea of "natural law" and the idea of the natural rights of man. These ideas may be found in the works of the Stoics, both Greek and Roman, and in the teaching of early Christianity, St. Thomas Aquinas, and medieval English scholars of the law. They are encountered in the writings of Spanish theologian-lawyers of the 16th century and in the 17th century in the works of the Dutch Hugo Grotius, the founder of modern international law, and of John Milton and John Locke, the ideological architects of the English revolution of that century.

HISTORICAL ORIGINS

The first codifications. Ancient legal codes failed to recognize any area of individual freedom from state interference, and the first codifications of something akin to a catalog of rights—if not yet of all men, then at least of the nobles of the land—began to emerge in compacts between princes and feudal assemblies. One of the earliest of these came in 1188, when the Cortes, the feudal assembly of the Kingdom of Leon (on the Iberian Peninsula), received from King Alfonso IX his confirmation of a series of rights, including the right of the accused to a regular trial and the right to the inviolability of life, honour, home, and property. In the Golden Bull of King Andrew II of Hungary (1222), the King guaranteed, among other things, that no noble would be arrested or ruined without first being convicted in conformity with judicial procedure. The most famous and influential commitment of this kind was in the English Magna Carta, accepted by King John at Runnymede in 1215. Though it was exacted by his feudal barons in their own selfish interest and was by no means intended to assert rights and liberties for all, several of its provisions, among them the famous clause 39 stating that "no freeman shall be taken or imprisoned . . . or exiled or in any way destroyed . . . except by the lawful judgement of his peers or (and) the law of the land," gave expression to the idea of individual freedom and became the symbol of this freedom for centuries to come.

Magna Carta: the rights of free men

The English, American, and French revolutions. In 17th-century England the "immemorial rights of Englishmen" were successfully fought for, the landmarks of the struggle being the English Petition of Right (1628) and the English Bill of Rights (1689). The rights set forth in these instruments found their way to the New World colonies. The American Declaration of Independence (1776), the Virginia Declaration of Rights (1776), and the American Bill of Rights (1791) carried not only the ideas of the earlier English documents but in some cases their very text as well. Nor was it only England that exported its doctrine of rights; the powerful influence of the French philosophers of the Enlightenment is visible among all the American revolutionaries. If the French philosophes had helped provide the Colonies with an ideology, the Revolution of the Colonies, in its turn, gave the French an example to follow and had an enormous impact on the events in France. The French Declaration of the Rights of Man and of the Citizen (1789) was directly inspired by earlier American examples.

Constitutions of the 19th and 20th centuries. In the course of the 19th and 20th centuries, the example set by the United States and France adopting bills of rights or otherwise guaranteeing individual liberties was followed on the entire continent of Europe and eventually throughout the Americas, Asia, Africa, and the Caribbean. Great Britain, following the tradition of its unwritten constitution, did not enact constitutional guarantees.

The Russian Revolution of 1917, though following the American and French precedent in the form of its pronouncements, gave them a fundamentally different substance. The difference lay not in the emphasis on economic and social rights in addition to the traditional political and civil rights (for such provisions are found in other constitutions—in the Mexican constitution of 1917, the Weimar constitution of Germany of 1919, and the constitution of the Republic of Spain of 1931) but in the complete transformation of the meaning of political and civil rights.

This basic difference in concepts becomes clear in a

Human rights in the Soviet and U.S. constitutions

comparison of the provisions of the first Soviet constitution. The First Amendment to the American Constitution provides, among other things, that Congress shall make no law abridging the freedom of speech or of the press. The Russian constitution of 1918 "for the purpose of securing freedom of expression to the toiling masses" abolishes all dependence of the press upon capital and turns over to the working people and the poorest peasantry "all technical and material means for the publication of newspapers, pamphlets, books," etc. The U.S. Constitution prohibits abridgment of the right of the people peaceably to assemble, while the Lenin constitution, in order to ensure complete freedom of assembly to the working class and to the poorest peasantry, offers "all premises convenient for public gatherings together with lighting, heating and furniture."

The Soviet constitution of 1936, while changing the wording, has by and large maintained this general approach. Western constitutional ideas were designed to prevent interference with fundamental rights mainly, though not exclusively, by the public authorities. The Soviet concept ignores this aspect and promises to make available technical facilities without promising freedom in the choice of the purposes for which they will be used. In trying to draw conclusions from the existence in so many legal systems of catalogs of rights, these differences of basic concept must be kept in mind.

THE BEGINNINGS OF INTERNATIONAL CONCERN

If these were some of the important landmarks in the effort to enshrine respect for the rights and freedoms of the individual in the various national systems, it is necessary next to examine some of the history of efforts to maintain the human rights of the citizens and inhabitants of states by international action: the so-called humanitarian intervention and the conclusion of international treaties.

Humanitarian intervention. Under traditional international law, the sovereign state had discretionary power in the treatment of its nationals. When, however, the treatment meted out by a state to its own population, particularly to religious or ethnic minorities, was so arbitrary and so persistently abusive and cruel that it shocked the conscience of mankind, other states frequently took it upon themselves to threaten or even to use force in order to come to the rescue of the oppressed minority. A major example of such "humanitarian intervention" was the action, including military action, agreed on in 1827 by Great Britain, France, and Russia against the Ottoman Empire, assertedly to bring to an end the sufferings of the Greek population then under Turkish rule. This eventually led to the independence of Greece in 1830. Similar interventions were undertaken by several European powers to end massacres of Christians in Syria (1860), to bring relief to the persecuted population in Crete (1866–68), and, in the last third of the 19th century, to end the persecution by Turkey of Christian populations in various Balkan countries under Turkish sovereignty. Other examples of humanitarian intervention include the representations made in the last decade of the 19th century and in the first decade of the 20th by various Western powers on behalf of the Jewish population of Romania and representations made by the United States government to the Russian government on behalf of the Jewish citizens of that state.

Limitations of unilateral action

There is a danger of abuse inherent in humanitarian intervention because the intervening state or group of states decides unilaterally whether the intervention is justified and how to intervene. For this reason, the doctrine underlying the concept of humanitarian intervention has never become a fully acknowledged part of international law. Since the coming into effect of the Charter of the United Nations, with its prohibition of the unilateral use of force in international affairs, the status of humanitarian intervention has become even more precarious than it was in earlier periods.

International treaties. The use of international treaties for the protection of the rights of religious minorities can be traced back to the 17th century, when the Treaty of Westphalia (1648), which concluded the Thirty Years' War, established the principle that there should be equality of rights for both the Roman Catholic and Protestant religions in Germany. In the same century, various Catholic governments stipulated in peace treaties for the rights of Roman Catholic subjects of Protestant princes. In 1774 Turkey undertook, vis-à-vis Russia, to protect the Christian religion and its churches within its territory. The Congress of Vienna of 1815 provided for the free exercise of religion and for equality, irrespective of religion, in various cantons of Switzerland as well as for the equality of Christian denominations in Germany. The same congress also agreed on what probably was the first provision in an international treaty aiming at the improvement of the civil status of Jews. When, during the 19th century, Montenegro, Serbia, and Romania achieved their independence from Turkey, they, as well as Turkey itself, were forced to guarantee religious freedom and equality of rights to all inhabitants irrespective of religion (1878).

Prohibition of the slave trade. Throughout the 19th century and beginning with the Peace Treaty of Paris (1814), the universal prohibition of the slave trade had been an object of international effort and concern. Various treaty arrangements to this end were undertaken in 1815, in 1822, and again in 1862, 1885, and 1890. Gradually the movement undertook to combat and suppress slavery as well as the slave trade. In 1926 the Assembly of the League of Nations approved and opened for signature the International Slavery Convention, by which the contracting parties undertook to prevent and suppress the slave trade and to bring about, progressively and as soon as possible, the complete abolition of slavery in all its forms. Since then, the fight against slavery, which persists in one form or another, has continued under the auspices of the United Nations.

International social and labour legislation. Toward the end of the 19th century, a number of philanthropists, social reformers, and economists succeeded in arousing interest in, and enlisting the support of some governments for, the idea of international social legislation. To this end, a conference with a large and ambitious program of international measures of social reform and an impressive representation from European countries, including the great powers of the day, convened in Berlin in 1890. Despite the fact that the congress did not go beyond the adoption of some timid recommendations, its moral effect was nevertheless great. Once again on the initiative of private individuals and associations, governments were persuaded to meet in 1905 and 1906 in Bern, where the first two multilateral labour conventions, which were also the first international conventions for the protection of the human person, were concluded. One of the conventions prohibited night work for women in industrial employment, the other the use of the highly poisonous and inflammable white (yellow) phosphorus in the manufacture of matches. While the actual provisions of these conventions were not in themselves far reaching, the principle involved lent them a symbolic and moral effect that made them landmarks in the development of modern civilization.

The humanitarian law of war. It was also in the second half of the 19th century that the conclusion of multilateral treaties covering aspects of the conduct of hostilities and the protection of the rights of victims of war began. Due largely to the efforts of two Swiss citizens and a Swiss society that took up their ideas and later became the nucleus of what is now the International Committee of the Red Cross, the Convention for the Amelioration of the Condition of the Wounded in Time of War was signed at Geneva in 1864. It provided that military wounded and sick must be cared for whatever their country and that wounded who are captured must be sent home if they are incapable of further military service. The Declaration of St. Petersburg (1868) produced a consensus that the progress of civilization should be used to alleviate as many of the calamities of war as possible. To this end, the signatories undertook to maintain the prin-

Attempts at a minimum standard

ciples then established and to try to reconcile the necessities of war with the laws of humanity. These beginnings of the humanitarian law of war were further elaborated at congresses at Brussels (1874) and at The Hague (1899, 1907). Further legal developments followed during the interwar period (1925, 1929) and after World War II by the four Geneva conventions for the protection of war victims of 1949.

BETWEEN THE TWO WORLD WARS

The Covenant of the League of Nations. When, at the end of World War I, representatives of the victorious coalition assembled in Paris in 1919 to draft the peace treaties with Germany and its allies—treaties that were also to contain the Covenant of the League of Nations—Japan, one of the victorious powers, moved that a provision be inserted obliging the members of the League not to discriminate in law or in fact on the ground of race or nationality. This proposal met with stiff resistance on the part of the British and United States governments and was not approved. Japan later proposed the insertion of a provision on similar lines in the preamble of the Covenant. Although supported by important states, including France, Italy, and China, this proposal was also defeated. As a result, the Covenant of the League of Nations did not deal with or formally recognize the fundamental rights of man and did not lay down any principle of nondiscrimination. The Covenant, nevertheless, did contain certain elements suggesting a recognition of the rights and welfare of man on the international level. Among these were provisions by which members of the League (1) accepted an obligation to secure and maintain fair and humane conditions of labour for men, women, and children; (2) undertook to secure the just treatment of the native inhabitants of their colonies; (3) entrusted the League of Nations with general supervision of the execution of agreements regarding traffic in women and children; and (4) pledged themselves to take steps in matters of international concern for the prevention and control of disease. Those of the victorious powers who as mandatories were entrusted by the League with the tutelage of colonies formerly governed by Germany and Turkey accepted as "a sacred trust of civilization" responsibilities for the well-being and development of the inhabitants. The mandatory powers were thus made accountable to the international community represented by the League of Nations for their conduct of the mandates—an arrangement that has had repercussions even half a century later in regard to the mandate entrusted to South Africa over the territory of South West Africa.

The International Labour Organisation. The Treaty of Versailles and the other peace treaties ending World War I also established the International Labour Organisation, with part XIII of the Treaty of Versailles as its constitution. The aspect that distinguishes the International Labour Organisation from other international governmental organizations is the fact that its organs consist of representatives not only of governments but also of employers and workers. By and large, the structure and aims of the organization are the same now as when they were laid down in 1919. The International Labour Organisation has made a signal contribution to the promotion of human rights through international action not only in fields traditionally associated with labour law and labour relations (such as industrial health, safety, and welfare; hours of work; and annual holidays with pay), but, particularly after World War II, when it became a specialized agency of the United Nations, also in regard to matters at the very core of a system of guarantees of human rights, such as the abolition of forced labour, the elimination of discrimination in employment and occupation, freedom of association, and equal remuneration for work of equal value.

Labour and human rights

The protection of minorities under the post-World War I treaties. In some of the peace treaties, in special so-called minorities treaties, and in declarations made after World War I, a number of states of central and eastern Europe and one state in the Middle East (Iraq) were made to accept a series of obligations toward their racial, linguistic, and religious minorities: all of their nationals were to be equal before the law and were to enjoy the same civil and political rights without distinction as to race, language, or religion. Nationals who belonged to racial, religious, or linguistic minorities in these countries were guaranteed adequate facilities for the use of their languages before the courts and for meeting their educational needs.

The system of minorities protection instituted by these treaties was not general. Germany, although one of the defeated powers, was not among those required to accept provisions for the protection of minorities, apart from an obligation undertaken for a 15-year period in regard to the population of that part of Upper Silesia that at its partition in 1922 fell to Germany. All the relevant treaties provided that their stipulations constituted obligations of international concern rather than domestic matters, and all were placed under the guarantee of the League of Nations.

SINCE WORLD WAR II

Whatever progress had been achieved through the establishment of the League of Nations, the International Labour Organisation, and the other measures taken after World War I was wiped out by the horrors of Fascism, National Socialism, and other totalitarian systems, as well as by the ordeals of World War II itself.

In a series of statements and proclamations (among them the Atlantic Charter of August 14, 1941, and the Declaration by the United Nations signed by all the Allied powers on January 1, 1942), the preservation of human rights and justice was made one of the peace aims of the victorious grand alliance.

Trial of war criminals

At the end of the war, the victorious great powers (Great Britain, the United States, France, and the Union of Soviet Socialist Republics) established the International Military Tribunal for the Trial of German Major War Criminals. Under its charter, the tribunal had jurisdiction to try not only crimes against peace and war crimes but also "crimes against humanity" committed against any civilian population, whether or not in violation of the law of the country where perpetrated. The charter of the tribunal provided that the fact that the defendant acted pursuant to orders of his government or of a superior officer should not free him from responsibility. While the tribunal, which sat in Nuremberg from 1945 to 1946, applied a cautious and restrictive approach to the concept of "crimes against humanity," the treatment by a state of its own citizens was nevertheless made the subject of criminal proceedings in a court that functioned as an organ of the international community. The principles on which the tribunal established at Nuremberg acted were subsequently endorsed by the General Assembly of the United Nations.

Human rights in the Charter of the United Nations. The Charter of the United Nations (1945) contains the reaffirmation of "faith in fundamental human rights, in the dignity and worth of the human person, in the equal rights of men and women and of nations large and small." "Promoting and encouraging respect for human rights" and "assisting in the realization of human rights and fundamental freedoms" are words that appear, with some variations in different contexts, at several places in the Charter. There are two articles in which all members pledge themselves to take joint and separate action in cooperation with the organization for the achievement of universal respect for, and observance of, human rights and fundamental freedoms for all without distinction as to race, sex, language, or religion. The Charter is intentionally vague in its expressions on these subjects, and a proposal at the San Francisco Conference that the United Nations should ensure not only "the promotion" but also "the protection" of human rights was not accepted. Moreover, the Charter contains the often-quoted domestic jurisdiction clause, which says that nothing in it shall authorize the United Nations to intervene in matters that

are essentially within the domestic jurisdiction of any state. The reconciliation of the human rights provisions of the Charter with the domestic jurisdiction clause has created certain difficulties, giving rise to legal argument and political controversy.

The debate about obligations

Because human rights have traditionally come within the domestic jurisdiction of states and because of the vagueness of some of the human rights clauses, some authorities have concluded that in becoming parties to the Charter, states have not, in effect, accepted any obligations as to the human rights field and that the United Nations has no standing to insist on safeguards for human rights in member states. Others insist that the human rights provisions of the Charter are by no means devoid of an element of legal obligation, that the "pledge" made by member states cannot be ignored, and that the domestic jurisdiction clause does not apply because human rights have ceased to be "essentially within the domestic jurisdiction" of states.

It can be said, however, that in the actual practice of the various organs of the United Nations over the first 25 years of its existence, the difficulty of solving the apparent contradiction between the "human rights provisions" and the "domestic jurisdiction clause" has been far less formidable than the differences between the opinions of scholars and the statements by governments would lead one to assume. In practice, neither the vagueness and generality of the clauses of the Charter nor the domestic jurisdiction clause have prevented the United Nations from considering, investigating, and judging concrete human rights situations, provided there was a majority strong enough to force such action.

Though it is undoubtedly true that governments are usually jealous of their own domestic jurisdiction and of the authority of their allies and friends, the General Assembly and other United Nations organs have repeatedly dealt with human rights developments occurring within individual states, such as the race conflict in South Africa, forced labour in eastern Europe, respect for freedom of association and trade-union rights, and discrimination against the Buddhists in Vietnam (1963).

Whatever the merits of the opposing contentions as to the interpretation of the Charter may be, there has been general agreement from the beginning that an international bill of human rights should be prepared to supplement the human rights provision of the Charter. The Charter provides for the establishment of a Commission on Human Rights to be entrusted with the task of preparing such a document and other international treaties and instruments in this field.

United Nations organs for the promotion of human rights. The Charter of the United Nations vests responsibility for the guarantee of human rights in the General Assembly and, under the General Assembly's authority, in the Economic and Social Council. The Trusteeship Council is concerned with human rights in trust territories, and the Security Council can take jurisdiction over human rights questions when it holds that international peace and security are endangered. The Commission on Human Rights and its sister organ, the Commission on the Status of Women, are subsidiary bodies of the Economic and Social Council. Both commissions consist of government representatives. Proposals that the members of these commissions should be individual experts, independent of governments, were not accepted. Both commissions have, in the course of years, prepared a number of international instruments, some of which will be dealt with below.

The International Bill of Rights. When the Commission on Human Rights was established, it was decided that the preparation of an International Bill of Rights should be its first preoccupation. The plan that was adopted called for the bill to consist of the following documents: a declaration, a covenant, and "measures of implementation." Though the first part, known as the Universal Declaration of Human Rights, was proclaimed by the General Assembly in 1948, it was not until 1966 that the rest of the International Bill of Rights, consisting of three international treaties in addition to the Universal Declaration of 1948, was ready for signature and ratification. The three additional treaties are the International Covenant on Economic, Social and Cultural Rights; the International Covenant on Civil and Political Rights; and the Optional Protocol to the latter creating the important right of communication or petition.

The Universal Declaration of Human Rights. The catalog of rights set out by the Universal Declaration of Human Rights is scarcely less than the sum of all the important traditional political and civil rights of national constitutions and legal systems. Among these are equality before the law; protection against arbitrary arrest; the right to a fair trial and freedom from ex post facto criminal laws; the right to own property; freedom of thought, conscience, and religion; freedom of opinion and expression; and freedom of peaceful assembly and association.

To these lists of civil and political rights the declaration has added economic, social, and cultural rights, such as the right to work and to choose one's work freely, the right to earn equal pay for equal work, and the right to education. The declaration is not an international treaty and was meant to proclaim a common standard of achievement rather than enforceable legal obligations. But to the degree that it has filled a gap caused by the delay in the completion and entry of the covenants into force, the Universal Declaration has acquired a different and more important status than was originally intended. It has been widely used by international organizations, conferences, and governments as a means of judging how well governments have carried out their obligations under the United Nations Charter with respect to questions of human rights.

The uses of the declaration

The International Covenant on Civil and Political Rights and the Optional Protocol. In the International Covenant on Civil and Political Rights, each state party undertakes to respect and to ensure to all individuals within its territory and subject to its jurisdiction the rights recognized in the covenant without any distinction because of race, colour, sex, language, religion, political or other opinion, national or social origin, property, birth, or other status. The catalog of civil and political rights guaranteed by the covenant, though it contains the traditional rights guaranteed in national constitutions and legislation and proclaimed in the Universal Declaration of Human Rights, does not fully coincide with the latter. Some rights listed in the Universal Declaration, such as the right to own property and the right to asylum, are not included among the rights recognized in the covenant. On the other hand, the covenant defines a number of rights not listed in the declaration, among them the right of all peoples to self-determination and the right of ethnic, religious, or linguistic minorities to enjoy their own culture, to profess and practice their own religion, and to use their own language.

Work of the Human Rights Committee

The covenant provides for the establishment of an international organ called the Human Rights Committee. The functions and prerogatives of the committee, which consists of 18 persons elected by the parties and serving as individuals, are of a limited character. The committee is called on to study reports submitted by states on measures they have adopted to give effect to the rights recognized in the covenant. Among states that have expressly accepted this function of the committee, the committee may also respond to allegations by one party that another party is not giving effect to the provisions of the covenant. If the committee is not able to resolve such dispute, the matter is referred to an ad hoc Conciliation Commission, which eventually reports its findings on all questions of fact and its views on the possibilities of an amicable solution. States that become parties to the Optional Protocol thereby recognize, in addition, the competence of the Human Rights Committee to receive and consider communications from individuals who claim to be victims of a violation of the covenant. At the conclusion of these proceedings, the Human Rights Com-

mittee forwards its views to the state concerned and to the individual.

The International Covenant on Economic, Social and Cultural Rights. While the states that are parties to the Covenant on Civil and Political Rights undertake to accept immediately applicable and—within the described limits—enforceable international obligations, the parties to the Covenant on Economic, Social and Cultural Rights undertake only to take steps toward achieving progressively the full realization of the rights recognized in that covenant. These rights are based on those proclaimed in the Universal Declaration and include those economic, social, and cultural rights that were listed above. One obligation undertaken by states becoming parties to the Covenant on Economic, Social and Cultural Rights is, however, of immediate application: the prohibition of discrimination in the enjoyment of those rights because of race, colour, sex, language, religion, political or other opinion, national or social origin, property, birth, or other status. The international measures of supervision that apply to the covenant oblige the parties to report to the Economic and Social Council of the United Nations on the measures they have adopted and the progress they have made in achieving the recognition of the enumerated rights.

Both covenants provide that they shall become effective three months after ratification or accession by the 35th state. By the early 1970s the number of 35 ratifications or accessions had not been reached and the covenants were, therefore, not yet in force.

Other worldwide international conventions under the auspices of the United Nations. *The Convention on the Prevention and Punishment of the Crime of Genocide.* The concept of genocide is closely connected with the principles applied after World War II by the International Military Tribunal that sat at Nuremberg and found some of the major German war figures guilty of crimes against peace, war crimes, and crimes against humanity. In the Genocide Convention of 1948 the contracting parties confirm that genocide, whether committed in time of peace or in time of war, is a crime under international law, which they undertake to prevent and to punish. Genocide is defined as any of several kinds of acts committed with intent to destroy, in whole or in part, a national, ethnic, racial, or religious group, as such. Among the prohibited acts are "killing members of the group," "causing serious bodily or mental harm to members of the group," and "deliberately inflicting on the group conditions of life calculated to bring about its physical destruction in whole or in part." "Imposing measures intending to prevent births within the group" and "forcibly transferring the children of the group to another group" are also punishable as genocide, as is conspiracy, direct and public incitement and attempt to commit genocide, and complicity in genocide. One of the significant results of the convention is that the parties to it place it beyond doubt that genocide, even if perpetrated by a government in its own territory against its own citizens, is not a matter within the domestic jurisdiction of states but a matter of international concern.

Genocide as an international crime

The Supplementary Convention on the Abolition of Slavery, the Slave Trade, and Institutions and Practices Similar to Slavery. Supplementing the International Slavery Convention of 1926, adopted under the auspices of the League of Nations and referred to above, a conference of plenipotentiaries convened by the Economic and Social Council in 1956 prepared and opened for signature a supplementary convention outlawing certain practices similar to slavery such as debt bondage, serfdom, purchase of brides, and exploitation of child labour. It emphasizes the criminality of the slave trade and provides for penal sanctions for some other practices such as mutilating, branding, or otherwise marking a slave or a person of servile status.

The Convention Concerning the Abolition of Forced Labour. In this convention, adopted by the International Labour Conference in 1957, the parties undertake to suppress and not make use of any form of forced or compulsory labour as a measure of political coercion or "education"; as a punishment for holding or expressing political views or views ideologically opposed to the established political, social, or economic system; as a method of mobilizing or using labour for purposes of economic development; or as a means of racial, social, national, or religious discrimination.

The Discrimination (Employment and Occupation) Convention. Three major international instruments are devoted to the fight against discrimination. The first, in time, is the Convention Concerning Discrimination in Respect of Employment and Occupation adopted in 1958 by the International Labour Conference. Under its provisions, states parties undertake to declare and pursue a national policy designed to promote, by methods appropriate to national conditions and practice, equality of opportunity and treatment in employment and occupation and the elimination of any discrimination in that respect. This convention prohibits discrimination, exclusion, or preference on the basis of race, colour, sex, religion, political opinion, national extraction, or social origin that has the effect of nullifying or impairing equality of opportunity or treatment in employment or occupation.

The Convention Against Discrimination in Education. The Convention Against Discrimination in Education adopted by the General Conference of the United Nations Educational, Scientific and Cultural Organization (UNESCO) in 1960 embodies functions similar to those of the 1958 convention in regard to access to education. Parties to the convention of 1960 agree to abrogate any statutory provisions and any administrative instructions and to discontinue any administrative practices that involve discrimination in education or in the admission of pupils to educational institutions. The establishment or maintenance of separate education systems or institutions for pupils of the two sexes does not constitute discrimination if these systems or institutions offer equivalent access to education, provide teaching staffs with qualifications of the same standard, and afford the opportunity to take the same or equivalent courses of study.

Supervision and control of employment regulations

The convention on discrimination in employment is subject to the measures of supervision provided by the constitution of the International Labour Organisation (reporting by states, representations by workers' or employers' organizations, complaints, commissions of inquiry, and reference to the International Court of Justice). The states that are parties to the Convention Against Discrimination in Education undertake to submit periodic reports on the legislative and administrative provisions they have adopted and any other action they have taken for the application of the convention. In addition, in 1962, the General Conference of UNESCO adopted a protocol instituting a Conciliation and Good Offices Commission to be responsible for seeking a settlement of any disputes that may arise between parties to the convention of 1960. The arrangements under the protocol are similar to those provided for in the International Covenant on Civil and Political Rights.

The International Convention on the Elimination of All Forms of Racial Discrimination. In 1965 the General Assembly adopted the International Convention on the Elimination of All Forms of Racial Discrimination. The scope of this convention, which entered into force in 1969, is limited to discrimination based on race, colour, descent, or national or ethnic origin and thereby differs from the two conventions of 1958 and 1960 that also prohibit discrimination on other grounds, such as sex, religion, political or other opinion, etc. On the other hand, the Racial Discrimination Convention is more comprehensive than the two earlier conventions insofar as it is not restricted to any particular fields such as employment and education but prohibits discrimination in regard to human rights and fundamental freedom in all the political, economic, social, and cultural areas of public life. The convention's provisions are far reaching: under them, states undertake not to engage in any act or practice of racial discrimination; to take effective mea-

sures to review governmental, national and local policies; and to amend, rescind, or nullify any laws and regulations that have the effect of creating or perpetuating racial discrimination wherever it exists. The dissemination of ideas based on racial superiority or hatred, incitement to racial discrimination, and incitement to acts of violence against any race are made punishable offenses. Organizations and propaganda activities that promote racial discrimination are declared illegal, and participation in them made punishable. These provisions have on occasion been seen to pose constitutional difficulties for some states because of the serious limitations they impose on rights to freedom of expression and freedom of association. A Committee on the Elimination of Racial Discrimination established under the convention consists of 18 experts serving as individuals in their personal capacity. Its functions are similar to those of the Human Rights Committee under the Civil and Political Rights Covenant. In becoming parties to this convention, however, states have automatically accepted the committee's right to consider complaints by any party who alleges that another party is not observing the provisions of the convention. The convention also provides for the appointment of an ad hoc Conciliation Commission with prerogatives similar to those established for the commission under the Civil and Political Rights Covenant. Any dispute between two or more parties with respect to the interpretation or application of the convention that is not settled by negotiation or by the procedures provided for in the convention will be referred to the International Court of Justice for decision, unless the disputants agree to another mode of settlement. Parties to the convention may also recognize the competence of the committee to receive and consider communications from individuals or groups claiming to be victims of a violation of any of the rights set forth in the convention. A special provision contemplates activities of the committee in regard to petitions received by United Nations bodies from non-self-governing territories.

Procedure for complaints on racial discrimination

Conventions on the status of women. In the Convention on the Political Rights of Women (1952), the signatory states have guaranteed that women shall be entitled to vote in all elections on equal terms with men, shall be eligible for election to all publicly elected bodies established by national law on equal terms with men, and shall be entitled to hold public office and to exercise all public functions established by national law without any discrimination.

The Convention of 1962 on Consent to Marriage, Minimum Age for Marriage and Registration of Marriages is of particular importance for developing countries, mainly in Asia and Africa. It provides that no marriage shall be legally entered into without the full and free consent of participants, such consent to be expressed by them in person after due publicity and in the presence of the authority competent to solemnize the marriage and of witnesses. The parties are also obligated to take legislative action to specify a minimum age for marriage and to provide for the official registration of all marriages.

The Convention relating to the Status of Refugees of 1951 and the Protocol of 1967. The Convention on the Status of Stateless Persons, 1954. Two principles form the basis of the Refugees Convention of 1951: first, that there should be as little discrimination as possible between nationals and refugees; second, that there should be no discrimination at all based on race, religion, or country of origin among refugees. The parties have undertaken to apply "national treatment" to refugees—*i.e.*, treatment at least as favourable as that accorded to their own nationals with regard to certain rights such as freedom of religion, access to courts, elementary education, and public relief. With regard to other rights (wages, employment, and the right of association), refugees are entitled to the "most-favoured-nation treatment"—*i.e.*, the most favourable treatment accorded to nationals of a foreign country. In other respects (*e.g.*, self-employment and higher education), refugees receive treatment as favourable as possible and, in any event, not less favourable than that accorded to aliens generally. The Convention relating to the Status of Stateless Persons (1954) provides for protective measures for stateless persons similar to those applicable to refugees under the convention of 1951.

Solemn declarations of the United Nations. In addition to developing the law relating to human rights by the preparation and adoption of international treaties, the most important of which have been described in the preceding section, the General Assembly, impressed by the effect of the Universal Declaration of Human Rights of 1948, has used the technique of proclaiming declarations on other occasions as well. A declaration adopted in the form of a resolution of the General Assembly is not binding upon member states in the sense of a treaty, but the solemnity and significance of such a "Declaration" creates a strong expectation that members of the international community will abide by it, particularly when it is used to enunciate principles of great and lasting importance. The best known of these declarations adopted by the General Assembly subsequent to the Universal Declaration of Human Rights is the Declaration on the Granting of Independence to Colonial Countries and Peoples (1960), which, with the machinery established for its implementation in the following years, had a far-reaching impact on the process of decolonization. Other declarations in the human rights field, which can only be listed here, are the Declaration of the Rights of the Child of 1959, the United Nations Declaration on the Elimination of All Forms of Racial Discrimination of 1963, the Declaration on the Elimination of Discrimination against Women of 1967, and the Declaration on Territorial Asylum of the same year.

The effect of UN declarations

Regional developments in the field of human rights. *The European Convention on Human Rights.* The Charter of the United Nations and the Universal Declaration of Human Rights have inspired action for the international protection of human rights within two important regions of the world. Members of the Council of Europe agreed, in 1950, to a European Convention for the Protection of Human Rights and Fundamental Freedoms. This convention together with five additional protocols represents the most advanced and successful experiment in the field. The substantive provisions of the European convention are based on an earlier draft of what is now the United Nations International Covenant on Civil and Political Rights. The instrumentalities created under the European convention are the European Commission on Human Rights, a body much like the Human Rights Committee under the covenant, and the Committee on the Elimination of Racial Discrimination. Members sit as individuals, and any party to the convention may refer to the commission any alleged breach of the provisions by another party. The commission may (but only when its legal competence to do so has been recognized) receive petitions from any person, nongovernmental organization, or group of individuals claiming to be the victim of a violation of the convention. In such cases, the commission is charged with ascertaining the facts and with placing itself at the disposal of the parties to secure a friendly settlement on the basis of respect for human rights. In the event that no solution is reached, the commission is called upon to draw up a report and to state its opinion as to whether the facts found disclose a breach of the obligations under the convention. In 1971 there were 17 parties to the European Convention, of which 11 had accepted the competence of the commission to examine petitions.

The European convention also established the European Court of Human Rights. Eleven states have agreed to accept its compulsory jurisdiction. Either the commission or a state party whose national is alleged to be a victim of a violation, the state party which referred the case to the commission, or the state party against which the complaint has been alleged can refer a case to the court. The judgment of the court is final.

The Court of Human Rights

If a question is not, or cannot be, referred to the court, then a political organ, the Committee of Ministers of the

Council of Europe, makes the final decision on human rights complaints.

The European Commission on Human Rights has, over the years, developed a considerable body of case law on questions regulated in the convention; and the provisions of the convention are, in some European states, automatically part of the constitutional or statutory law. Where this is not the case, the western European states have taken other measures to bring their internal law in line with their obligations under the convention.

The American Convention on Human Rights. In the Western Hemisphere, the Organization of American States has, for many years, taken comprehensive action in the human rights field on a regional basis. Within the framework of the Organization of American States, a special organ, the Inter-American Commission on Human Rights, was established in 1959. Since that time it has undertaken important activities in regard to human rights situations that have arisen in some of the American states. In November 1969 the Inter-American Specialized Conference on Human Rights meeting at San José, Costa Rica, adopted an instrument entitled American Convention on Human Rights (also called Pact of San José, Costa Rica).

The American Convention makes the existing Inter-American Commission on Human Rights an organ for its implementation and also establishes the Inter-American Court of Human Rights. Both the substantive law and the procedural arrangements of the American convention on Human Rights of 1969 are strongly influenced by the United Nations Covenants and by the European Convention on Human Rights. An important difference between the American Convention on Human Rights and its European and United Nations predecessors consists in the fact that under the American Convention the right of petition of individuals applies automatically while under the European system a special declaration by the states concerned is required; and under the United Nations system, the right of petition is applicable only when the state concerned has become a party to the Optional Protocol (on communications) to the International Covenant on Civil and Political Rights. The system of interstate complaints applies under the American convention only among states that have expressly agreed to accept it.

BIBLIOGRAPHY

General: UNITED NATIONS, *Human Rights: A Compilation of International Instruments of the United Nations* (1967), contains the texts of all human rights treaties and other instruments established under the auspices of the UN. The *United Nations Yearbook on Human Rights* (pub. annually since 1946), documents the national and international developments in the human rights field. The classic works on the subject are H. LAUTERPACHT, *An International Bill of the Rights of Man* (1945), and *International Law and Human Rights* (1950, reissued 1968). Writings on human rights under the Charter of the United Nations, the International Bill of Rights, and other instruments established by the UN include: J. Humboldt, Alexander von

Explorer and scientist, Alexander von Humboldt gained worldwide renown as the chief propagator in his time of the study of the earth sciences—geography, geology, geomagnetism, climatology—and of the relation of plants and animals to their physical surroundings, now known as the science of ecology. He perceived and identified ecological relationships; he established the connection between geological faults and the related phenomena of volcanoes and earthquakes; he promoted the use of graphic representation of scientific data for ease of comprehension; and through a lifetime of tireless effort he furthered the cause of science by his publications, his support of international collaboration in scientific projects, and the advice he gave young scientists at the formative stages of their careers. With his book *Kosmos*, a survey of astronomy and the earth sciences, he made a valuable contribution to the popularization of science.

Humboldt, oil painting by Friedrich Georg Weitsch, 1806. In the Staatliche Museen zu Berlin.

Early life. Alexander von Humboldt was born on September 14, 1769, in Berlin, then the capital of the kingdom of Prussia. His father was an officer in the army of Frederick the Great; his mother belonged to a family of Huguenots (French Protestants) who had left France after Louis XIV's revocation, in 1685, of religious liberty for Protestants. After the elder Humboldt's death in 1779, the education of his two sons, Wilhelm and Alexander, was left in the hands of their mother, an unemotional woman of strict Calvinist beliefs. They were privately educated; instruction in political history and economics was added to the usual courses in classics, languages, and mathematics, as their mother intended them to be qualified for high public positions. Alexander, a sickly child, at first was a poor student. He was restless, thought of joining the army, and followed his courses only under parental pressure. After futile studies in economics at the University of Frankfurt an der Oder, he spent a year in Berlin where he obtained some training in engineering and suddenly became passionately interested

in botany. He began to collect plant specimens in the surroundings of Berlin, and learned to classify them. But the poor flora of the province of Brandenburg did not provide much stimulus for an ardent botanist, and Humboldt soon dreamed of journeys to more exotic lands.

Work in mineralogy and geology

A year spent at the University of Göttingen, from 1789 to 1790, finally opened the world of science to him; he became particularly interested in mineralogy and geology and decided to obtain a thorough training in these subjects by joining the School of Mines in Freiburg, Saxony, the first such establishment. Although founded only in 1766, the school had already acquired an international reputation. There, buttressed by a prodigious memory and driven by an unending thirst for knowledge, he began to develop his enormous capacity for work. After a morning spent underground in the mines, he attended classes for five or six hours in the afternoon, and in the evening scoured the country for plants.

He left Freiburg in 1792 after two years of intensive study but without taking a degree. A month later he obtained an appointment in the Mining Department of the Prussian government and departed for the remote Fichtel Mountains in the Margraviate of Ansbach-Bayreuth, which had only recently come into the possession of the Prussian kings. Here Humboldt came into his own; he travelled untiringly from one mine to the next, reorganizing the partly deserted and totally neglected pits, which produced mainly gold and copper. He supervised all mining activities, invented a safety lamp, and established, with his own funds, a technical school for young miners. Yet he did not intend to make mining his career.

Expedition to South America. The conviction had grown in Humboldt that his real aim in life was scientific exploration, and in 1797 he resigned from his post to acquire with great single-mindedness a thorough knowledge of the systems of geodetic, meteorological, and geomagnetic measurements. The political upheavals caused by the Napoleonic Wars prevented the realization of several scientific expeditions in which Humboldt had been given an opportunity to participate. At last, dispirited by his disappointments but refusing to be deterred from his purpose, he obtained permission from the Spanish government to visit the Spanish colonies in Central and South America. These colonies were then accessible only to Spanish officials and the Roman Catholic mission. Completely shut off from the outside world, they offered enormous possibilities to a scientific explorer. Humboldt's social standing assured him of access to official circles, and in the Spanish prime minister Mariano de Urquijo he found an enlightened man who supported his application to the king for a royal permit. In the summer of 1799 he set sail from Marseilles accompanied by the French botanist Aimé Bonpland, whom he had met in Paris, then the liveliest scientific centre in Europe. The estate he had inherited at the death of his mother enabled Humboldt to finance the expedition entirely out of his own pocket. Humboldt and Bonpland spent five years, from 1799 to 1804, in Central and South America, covering more than 6,000 miles (9,650 kilometres) on foot, on horseback, and in canoes. It was a life of great physical exertion and serious deprivation.

Starting from Caracas, they travelled south through grasslands and scrublands until they reached the banks of the Apure, a tributary of the Orinoco River. They continued their journey on the river by canoe as far as the Orinoco. Following its course and that of the Casiquiare, they proved that the Casiquiare River formed a connection between the vast river systems of the Amazon and the Orinoco. For three months Humboldt and Bonpland moved through dense tropical forests, tormented by clouds of mosquitoes and stifled by the humid heat. Their provisions were soon destroyed by insects and rain; the lack of food finally drove them to subsist on ground-up wild cacao beans and river water. Yet both travellers, buoyed up by the excitement provided by the new and overwhelming impressions, remained healthy and in the best of spirits until their return to civilization, when they succumbed to a severe bout of fever.

After a short stay in Cuba, Humboldt and Bonpland returned to South America for an extensive exploration of the Andes. From Bogotá, Colombia, to Trujillo, Peru, they wandered over the Andean Highlands—following a route now traversed by the Pan-American Highway, in their time a series of steep, rocky, and often very narrow paths. They climbed a number of peaks, including all the volcanoes in the surroundings of Quito, Ecuador; Humboldt's ascent of Chimborazo (20,561 feet; 6,265 metres) to a height of 19,280 feet, but short of the summit, remained a world mountain-climbing record for nearly 30 years. All these achievements were carried out without the help of modern mountaineering equipment, without ropes, crampons, or oxygen supplies; hence, Humboldt and Bonpland suffered badly from mountain sickness. But Humboldt turned his discomfort to advantage: he became the first person to ascribe mountain sickness to lack of oxygen in the rarefied air of great heights. He also studied the oceanic current off the west coast of South America that was originally named after him but is now known as the Peru Current. When the pair arrived, worn and footsore, in Quito, Humboldt, the experienced mountaineer and indefatigable collector of scientific data, had no difficulty in assuming the role of courtier and man of the world when he was received by the viceroy and the leaders of Spanish society.

Ascent of Chimborazo

In the spring of 1803, the two travellers sailed from Guayaquil to Acapulco, Mexico, where they spent the last year of their expedition in a close study of this most developed and highly civilized part of the Spanish colonies. After a short stay in the United States, where Humboldt was received by President Jefferson, they sailed for France.

Humboldt and Bonpland returned with an immense amount of information. In addition to a vast collection of new plants, there were determinations of longitudes and latitudes, measurements of the components of the Earth's geomagnetic field, and daily observations of temperatures and barometric pressure, as well as statistical data on the social and economic conditions of Mexico. Whenever Humboldt had found himself in a centre of commerce in America, he had sent off reports and duplicates of his collections to his brother, Wilhelm, who had become a noted philologist, and to French scientists; unfortunately, the continental blockade then enforced by British ships prevented the greater part of his mail from reaching its destination.

Professional life in Paris. The years from 1804 to 1827 Humboldt devoted to publication of the data accumulated on the South American expedition. With the exception of brief visits to Berlin, he lived in Paris during this important period of his life. There he found not only collaborators among the French scientists—the greatest of his time—but engravers for his maps and illustrations, and publishers for printing the 30 volumes into which the scientific results of the expedition were distilled. Of great importance were the meteorological data, with an emphasis on mean daily and nightly temperatures, and Humboldt's representation on weather maps of isotherms (lines connecting points with the same mean temperature) and isobars (lines connecting points with the same barometric pressure for a given time or period) —all of which helped lay the foundation for the science of comparative climatology. Even more important were his pioneering studies on the relationship between a region's geography and its flora and fauna, and, above all, the conclusions he drew from his study of the Andean volcanoes concerning the role played by eruptive forces and metamorphosis in the history and ongoing development of the Earth's crust. These conclusions disproved once and for all the hypothesis of the so-called Neptunists, who held that the surface of the Earth had been totally formed by sedimentation from a liquid state. Lastly, his *Political Essay on the Kingdom of New Spain* contained a wealth of material on the geography and geology of Mexico, including descriptions of its political, social, and economic conditions, and also extensive population statistics. Humboldt's impassioned outcry in this work against the inhumanities of slavery remained unheard, but his descriptions of the Mexican silver mines

led to widespread investment of English capital and mining expertise in the mines.

Influence on scientific community

During his years in Paris, Humboldt enjoyed an extraordinarily full life. He had the ability to cultivate deep and long-lasting friendships with well-known scientists, such as the renowned physicist and astronomer François Arago, and to evoke respect and admiration from the common man, an ability that reflected his generosity, humanity, and vision of what science could do. A gregarious person, Humboldt appeared regularly in the salons of Parisian society, where he usually dominated the conversation. He lived simply, in a modest apartment at the top of an old house in the Latin Quarter. His fortune had been seriously depleted by the cost of his expedition and the publication of his books, and for the rest of his life he was often in financial straits. He was, moreover, always willing and anxious to assist young scientists at the beginning of their careers. Due to his magnanimity, generosity, and wise judgment, poor but promising students were given the necessary encouragement, financial assistance, and introductions to the scientific community to insure a successful start in life. Such men as the German chemist Justus von Liebig and the Swiss-born zoologist Louis Agassiz owed to Humboldt the means to continue their studies and embark on an academic career. The best proof of his wide interests and affectionate nature lies in his voluminous correspondence: 8,000 letters remain.

Return to Berlin. The happy years in Paris came to an end in 1827. Humboldt's means by then were almost completely exhausted; unable to maintain his financial independence, he had to return to Berlin, where the King impatiently demanded his presence at court. Until a few years before his death, Humboldt served as a tutor to the Crown Prince, as a member of the privy council, and as a court chamberlain. He made use of his position to acquaint the young Prince and the royal family with scientific methods and the scientific ideas of his time. His enthusiasm for the popularization of science prompted him to give a course on physical geography to the professors and students of all faculties of the University of Berlin, part of which he repeated in a public lecture to an audience of more than 1,000. In the autumn of the same year, 1828, he also organized, in Berlin, one of the first international scientific conferences. Such large gatherings of possibly liberal-minded people were frowned upon by governments in the wake of the Napoleonic Wars and the attendant rise of democratic expectations, and it is a tribute to Humboldt's adroitness that he was able to overcome the misgivings of official Prussian circles.

Expedition to Russia

In 1829 Humboldt was given the opportunity to visit Russia and Siberia. On the initiative of the Russian minister of finance, Count Yegor Kankrin, he was invited to visit the gold and platinum mines in the Urals, as an adviser to the government on the techniques and organization of mining. But Humboldt had to pledge himself to refrain from commenting on the political situation of the country whose despotism he abhorred. This expedition, lasting only one summer, was very different from the South American journey; the members, Humboldt and two young scientists, were accompanied throughout by an official guard, since they were guests of the tsar. Humboldt and his companions had to endure tiresome receptions at the imperial court and in the homes of provincial governors. They travelled in carriages as far as the Altai Mountains and the Chinese frontier. The resulting geographical, geological, and meteorological observations, especially those regarding the Central Asian regions, were of great importance to the Western world, for Central Asia was then to a large degree unknown territory.

Humboldt passed the last 30 years of his life in Berlin. Once a year he travelled to Paris, where he renewed his contacts with the French scientists, enjoyed daily discussions with his friend, Arago, and breathed the cosmopolitan air he so sadly missed in Berlin.

Even before his visit to Russia, he had returned to an investigation of a phenomenon that had aroused his interest in South America: the sudden fluctuations of the Earth's geomagnetic field—the so-called magnetic storms. With the help of assistants, he carried out observations of the movement of a magnetometer in a quiet garden pavilion in Berlin; but it had been clear to him for a number of years that, to discover whether these magnetic storms were of terrestrial or extraterrestrial origin, it would be necessary to set up a worldwide net of magnetic observatories. The German mathematician Carl Friedrich Gauss had already begun to organize simultaneous measurements of the magnetic field by several observatories in Germany, England, and Sweden. In 1836 Humboldt, still interested in the problem, approached the Royal Society in London with the request that it establish an additional series of stations in the British possessions overseas. As a result, the British government provided the means for permanent observatories in Canada, South Africa, Australia, and New Zealand and equipped an Antarctic expedition. With the help of the mass of data produced by this international scientific collaboration, one of the first of its kind, the English geophysicist Sir Edward Sabine later succeeded in correlating the appearance of magnetic storms in the earth's atmosphere with the periodically changing activity of sunspots, thus proving the extraterrestrial origin of the storms.

During the last 25 years of his life, Humboldt was chiefly occupied with writing *Kosmos*, one of the most ambitious scientific works ever published. Four volumes appeared during his lifetime. Written in a pleasant, literary style, *Kosmos* gives a generally comprehensible account of the structure of the universe as then known, at the same time communicating the scientist's excitement and aesthetic enjoyment at his discoveries. Humboldt had taken immense pains to discipline his inclination to discursiveness, which often gave his writing a certain lack of logical coherence. He was rewarded for his effort by the success of his book, which, within a few years, had been translated into nearly all European languages.

On May 6, 1859, still working on the fifth volume of *Kosmos* with hardly diminished vitality and enthusiasm and with an unimpaired memory, Humboldt died in his 90th year, in Berlin.

Biographies: HANNO BECK, *Alexander von Humboldt*, 2 vol. (1959–61), the definitive biography (in German), giving a detailed account of Humboldt's life and work with complete bibliography; L. KELLNER, *Alexander von Humboldt* (1963), the first English biography since 1872, puts equal emphasis on life and work and on historical background; C.F. GAUSS, *Briefe zwischen Alexander von Humboldt und Gauss* (1877).

Correspondence: Briefe von Alexander von Humboldt an Varnhagan von Ense, aus den Jahren 1827 bis 1858, 2nd ed. (1860; Eng. trans., *Letters of Alexander von Humboldt to Varnhagan von Ense, from 1827 to 1858*, 1860); *Briefwechsel mit Berghaus*, 3 vol. (1863); *Briefe Alexander's von Humboldt an seinen Bruder Wilhelm* (1880); *Lettres Américaines d'Alexandre de Humboldt*, ed. by E.T. HAMY (1905); *Correspondance d'Alexandre de Humboldt avec Francois Arago*, ed. by E.T. HAMY (1907); *Briefwechsel zwischen Alexander von Humboldt und Graf Georg von Cancrin* (1869), all give a very good idea of Humboldt's personal relations and the development of his scientific views.

Works: Ansichten der Natur, mit wissenschaftlichen Erläuterungen, (1808; Eng. trans., *Aspects of Nature, in Different Lands and Different Climates*, 1849), descriptions of scenic aspects and a sketch of the geography of plants for the general reader; *Voyage de Humboldt et Bonpland aux Regions Équinoxiales du nouveau Continent, fait en 1799–1804*, 23 vol. (1805–34; Eng. trans., *Personal Narrative of Travels to the Equinoctial Regions of the New Continent During the Years 1799–1804*, 7 vol., 1814–29), a very well-known account of the journey through the grasslands of Venezuela and the Orinoco Basin that had great influence on Darwin; *Asie Centrale*, 3 vol. (1843), an important book for its report on relatively unknown regions and for its ideas on comparative climatology.

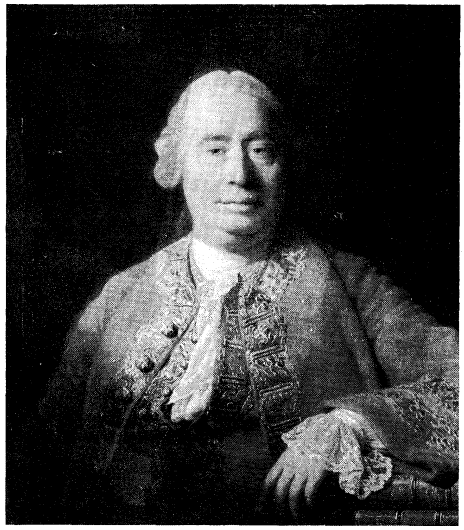
(C.L.K.)

Hume, David

David Hume was an 18th-century British Empiricist philosopher, historian, economist, and essayist, who conceived of philosophy as the inductive, experimental sci-

ence of human nature. Taking the scientific method of the British physicist Sir Isaac Newton as his model, Hume tried to describe how the mind works in acquiring what is called knowledge. He concluded that no theory of reality is possible; there can be no knowledge of anything beyond experience. Despite the enduring impact of his theory of knowledge, Hume seems to have considered himself chiefly as a moralist.

By courtesy of the Scottish National Portrait Gallery



Hume, oil painting by Allan Ramsay, 1766. In the Scottish National Portrait Gallery, Edinburgh.

Early life and works. Hume was the younger son of Joseph Hume, the modestly circumstanced laird, or lord, of Ninewells, a small estate adjoining the village of Chirnside, about nine miles distant from Berwick-upon-Tweed on the Scottish side of the border. The family seems to have had some remote connection with the earls of Home, an influential border family whose ancestral stronghold was in Berwickshire. David's mother, Catherine, a daughter of Sir David Falconer, president of the Scottish court of session, was in Edinburgh when he was born, on May 7 (April 26, old style), 1711. In his third year his father died. He entered Edinburgh University when he was about 12 years old and left it at 14 or 15, as was then usual. Pressed a little later to study law (in the family tradition on both sides), he found it distasteful and instead read voraciously in the wider sphere of letters. Through the intensity and excitement of his intellectual discovery, he had a nervous breakdown in 1729, from which it took him a few years to recover.

Composing the *Treatise*

In 1734, after trying his hand in a merchant's office in Bristol, he came to the turning point of his life and retired to France for three years. Most of this time he spent at La Flèche on the Loire, in the old Anjou, studying and composing *A Treatise of Human Nature*. The *Treatise* was Hume's attempt to formulate a full-fledged philosophical system. It is divided into three books: book I, on understanding, aims at explaining man's process of knowing, describing in order the origin of ideas, the ideas of space and time, causality, and skepticism with regard to the senses; book II, on the "passions" of man, gives an elaborate psychological machinery to explain the affective, or emotional, order in man and assigns a subordinate role to reason in this mechanism; book III, on morals, describes moral goodness in terms of "feelings" of approval or disapproval that man feels when he considers human behaviour in the light of the agreeable or disagreeable consequences either to himself or to others. Although the *Treatise* is Hume's most thorough exposition of his thought, at the end of his life he vehemently repudiated it as juvenile, avowing that only his later writings presented his considered views. The *Treatise* is badly constructed, in parts oversubtle, confusing because of ambiguity in important terms (especially "reason"), and marred by willful extravagance of statement and rather theatrical personal avowals. His mature condemnation of it was only severe, not misplaced. Nevertheless, book I has been more read in academic circles than any other of his writings.

Returning to England in 1737, he set about publishing the *Treatise*. Books I and II were published in two volumes in 1739; book III appeared the following year. The negligent reception of this, his first and very ambitious work, depressed him; but his next venture, *Essays, Moral and Political* (1741–42), won some success. Perhaps encouraged by this, he became a candidate for the chair of moral philosophy at Edinburgh in 1744. Objectors alleged heresy and even atheism, pointing to the *Treatise* as evidence. Unsuccessful, Hume left the city, where he had been living since 1740, and began a period of wandering: a sorry year near St. Albans as tutor to the mad Marquess of Annandale (1745–46); a few months as secretary to Gen. James St. Clair, a member of a prominent Scottish family, throughout an abortive expedition to Brittany (1746); a little tarrying in London and at Ninewells; and then some further months with General St. Clair on an embassy to the courts of Vienna and Turin (1748–49).

Mature works. During his years of wandering, Hume was earning the money that he needed to get leisure for his studies. Some fruits of these studies had already appeared before the end of his travels, viz., a further *Three Essays, Moral and Political* (1748) and *Philosophical Essays Concerning Human Understanding* (1748). The latter is a rewriting of book I of the *Treatise* (with the addition of his essay "On Miracles," notorious for its denial that a miracle can be proved by any amount or kind of evidence); it is better known as *An Enquiry Concerning Human Understanding*, the title Hume gave to it in a revision of 1758. The *Enquiry Concerning the Principles of Morals* (1751) was a rewriting of book III of the *Treatise*. It was in these works that Hume expressed his mature thought.

Theory of knowledge

The *Inquiry Concerning Human Understanding* is an attempt to define the principles of human knowledge. It presents in logical form the significant questions about the nature of all reasoning in regard to matters of fact and experience, and it solves the problems by recourse to association. The basis of his exposition is a twofold classification of objects of awareness. In the first place, all such objects are either "impressions," ultimate data of sensation or of internal consciousness, or "ideas," derived from the data by compounding, transposing, augmenting, or diminishing. That is to say, men do not create any ideas. From this Hume infers a theory of meaning: a word that does not stand directly for an impression has meaning only if it brings before the mind an object that can be gathered from an impression by one of the mental processes mentioned. Secondly, all objects of awareness are either "relations of ideas" or "matters of fact." Ideas can be held before the mind simply as meanings, and their logical relations to one another can then be detected by rational inspection. The idea of a plane triangle, for example, entails the equality of its internal angles to two right angles, and the idea of motion entails the ideas of space and time, irrespective of whether there really are such things as triangles and motions. Only on this level of mere meanings, Hume asserts, is there room for demonstrative knowledge. Matters of fact, on the other hand, objects believed to exist, come before us merely as they are, revealing no logical relations; their properties and connections have to be accepted as they are given. That primroses are yellow, that lead is heavy, and that fire burns things are facts, each shut up in itself, logically barren. Each, so far as reason is concerned, could be different: the contradictory of every matter of fact is conceivable. Therefore, any demonstrative science of fact is impossible.

Hume's doctrine of causality and belief

From this basis Hume develops his distinctive doctrine about causality. The idea of causality is alleged to assert a necessary connection among matters of fact. From what impression, then, is it derived? Hume observes no causal relation among the data of the "external" senses, for, when a man regards any events as causally con-

nected, all that he does and can observe is that they frequently and uniformly go together. In this sort of togetherness, it is a fact that the impression or idea of the one event brings with it the idea of the other. A habitual association is set up in the mind; and, as in other forms of habit, so in this one, the working of the association is felt as compulsion. This feeling, Hume concludes, is the only discoverable impressional source of the idea of causality. But there is also the question of belief. When one sees a glass fall, he not only thinks of its breaking but expects and believes it; or, starting from an effect, when he sees the ground to be generally wet, besides thinking of rain, he believes that there has been rain. Hume claims that he was the first to investigate the nature of belief. He uses this term in the narrowed sense of belief in matters of fact, in anything as existing. He describes belief as a sort of liveliness or vividness possessed by some of the immediate objects of awareness, originally by impressions and the simple memory images of them. How does it come to belong to certain ideas? By association. This is the essence of causal inference: the observer passes from an impression to an idea regularly associated with it. Hume confidently asserts that in the process the aspect of liveliness proper to the impression infects the idea.

Hume has not claimed to prove that the propositions, (1) that events themselves are causally related and (2) that they will be related in the future in the same ways as they were in the past, are false. He firmly believed both of these propositions and insisted that everybody else does, will continue to do, and must do so in order to survive. They are natural beliefs, inextinguishable propensities of man's nature, madness apart. What he has claimed to prove is that they are not obtained and cannot be illuminated either by empirical observation or by reason, whether intuitive or inferential. Reflection shows that there is no evidence for them and shows also both that we are bound to believe them and that it is sensible or sane to do so. *This* is Hume's Skepticism: it is an affirmation of that tension, a denial not of belief but of evidence.

Theory of morals and historical writing

The *Enquiry Concerning the Principles of Morals* is a refinement of Hume's thinking on morality, in which he views sympathy as the fact of human nature lying at the basis of all social life and personal happiness. Defining morality as those qualities that are approved (1) in whomsoever they happen to be and (2) by virtually everybody, he sets himself to discover the broadest grounds of the approvals. He finds them, as he found the grounds of belief, in "feelings," not in "knowings." Moral decisions are grounded upon moral sentiment. Qualities are valued either for their utility or for their agreeableness, in each case either to their owners or to others. Hume's moral system aims at the happiness of others (without any such formula as "the greatest happiness of the greatest number") and at the happiness of self. But regard for others accounts for the greater part of morality. His emphasis is on altruism: of the moral sentiments that he claims to find in man, he traces them, for the most part, to a sentiment for and a sympathy with one's fellows. It is man's nature, he holds, to laugh with the laughing and to grieve with the grieved and to seek the good of others as well as his own. Two years after the *Enquiry* was published, Hume confessed, "I have a partiality for that work"; and at the end of his life he judged it "of all my writings incomparably the best." Such statements, along with other indications in his later writings, make it possible to suspect that he regarded his moral doctrine as his major work. He here writes as a man having the same engagements as his fellows. The traditional view that he was a detached scoffer is deeply wrong: he was skeptical not of morality but of much theorizing about it.

A settled spell (1751–63), spent in Edinburgh, with two breaks in London, followed the publication of these works. It opened with an attempt to get him appointed as successor to Adam Smith, the Scottish economist (later to be his close friend), in the chair of logic at Glasgow. The rumour of atheism prevailed again. In 1752, however, he was made keeper of the Advocates' Library at Edinburgh. There, "master of 30,000 volumes," he could indulge a desire of some years to turn to historical writing. His *History of England*, extending from Caesar's invasion to 1688, came out in six quarto volumes between 1754 and 1762, preceded by *Political Discourses* (1752). His recent writings had begun to make him known, but these two brought him fame, abroad as well as at home. He also wrote *Four Dissertations* (1757), which he regarded as a trifle, although it included a rewriting of book II of the *Treatise* (completing his purged restatement of this work) and an able study of "the natural history of religion." In 1762 James Boswell, the biographer of Samuel Johnson, called Hume "the greatest writer in Britain," and Rome paid him the attention of putting all his writings on the *Index*, the list of forbidden books in the Roman Catholic Church, in 1761.

Hume's reception in Paris

The most colourful episode of his life ensued: in 1763 he left England to become secretary to the British embassy in Paris under the Earl of Hertford. The society of Paris accepted him, despite his ungainly figure and gauche manner. He was honoured as eminent in breadth of learning, in acuteness of thought, and in elegance of pen and was taken to heart for his simple goodness and cheerfulness. The salons threw open their doors to him, and he was even given a distinguished reception at court. For four months in 1765, he acted as chargé d'affaires at the embassy. When he returned to London at the beginning of 1766 (to become, a year later, undersecretary of state), he brought Jean-Jacques Rousseau, the French philosopher and author, with him and found him a refuge from persecution in a country house at Wootton in Staffordshire. This pathetic genius, under one of his delusions, suspected a plot, took secret flight back to France, and spread a report of Hume's bad faith. Hume was partly stung and partly persuaded into publishing the relevant correspondence between them with a connecting narrative (*A Concise and Genuine Account of the Dispute Between Mr. Hume and Mr. Rousseau*, 1766).

In 1769, somewhat tired of public life and of England too, he again established a residence (he never married) in his beloved Edinburgh, deeply enjoying the company —at once intellectual and convivial—of friends old and new, as well as revising the text of his writings. He issued five further editions of his *History* between 1762 and 1773 as well as eight editions of his collected writings (omitting the *Treatise*, *History*, and ephemera) under the title *Essays and Treatises* between 1753 and 1772, besides preparing the final edition of this collection, which appeared posthumously (1777), and *Dialogues Concerning Natural Religion*, held back under pressure from friends and not published until 1779. His curiously detached autobiography, *The Life of David Hume, Written by Himself* (1777; the title is his own), is dated April 18, 1776. After a long illness he died in his Edinburgh house on August 25, 1776, and was buried on Calton Hill.

Adam Smith, his literary executor, added to the *Life* a letter that concludes with his judgment on his friend as "approaching as nearly to the idea of a perfectly wise and virtuous man as perhaps the nature of human frailty will permit." His distinguished friends, with ministers of religion among them, certainly admired and loved him, and there were younger men indebted either to his influence or to his pocket. The mob had heard only that he was an atheist and simply wondered how such an ogre would manage his dying. Yet Boswell has recounted, in a passage in his *Private Papers*, that, when he visited Hume in his last illness, the philosopher put up a lively, cheerful defense of his disbelief in immortality.

Significance and influence. That Hume was one of the major figures of his century can hardly be doubted. So his contemporaries thought, and his achievement, as seen in historical perspective, confirms that judgment, though with a shift of emphasis. Some hints of the reasons for the assessment may be given under four heads:

As a writer. Hume's style was praised in his lifetime and has often been praised since; but not so much in the 20th century. It seems in retrospect to be little, if any-

thing, more than the style of his day at a high level of competence. It lacks individuality and the pulse of variety and power. Hume's quill never becomes a wing, nor does it ever plunge into depths; and the pathetic was beyond him, for he was always proudly on guard against his emotions. The touch is light, except on slight subjects, where it is rather heavy. Yet in his philosophical works—those later than the *Treatise*—he gives an unsought pleasure. Here his detachment, levelness (all on one plane), smoothness, and daylight clearness are proper merits. It is as one of the best writers of scientific prose in English that he stands in the history of style.

As a historian. Library catalogs still list Hume as "Hume, David, the Historian." Between his death and 1894, there were at least 50 editions of his *History;* and an abridgment, *The Student's Hume* (1859; often reprinted), remained in common use for 50 years. Though now outdated, its generations of readers entitle the *History* to be regarded as an event of cultural importance. Moreover, in its own day it was an innovation, soaring high above its very few predecessors. It was fuller and set a higher standard of impartiality. It saw in the nation the mental interests of the educated citizens as well as the deeds of kings and statesmen, as may be seen, for instance, in the pages on literature and science at the end of chapter 3 under the Commonwealth and at the end of chapter 2 under James II. It was unprecedentedly readable, in structure as well as in phrasing, persons and events being woven into causal patterns that furnished a narrative with the goals and resting points of recurrent climaxes. That was to be the plan and march of future history books for the general reader. No one, however, would place Hume near to the English historian Edward Gibbon.

As an economist. Hume steps forward as an economist in the *Political Discourses* incorporated in *Essays and Treatises* as part 2 of *Essays Moral, Political and Literary*. How far he influenced his friend Adam Smith, 12 years his junior, remains uncertain: they have broadly similar principles, and both have the excellent habit of illustrating and supporting these from history. How far he was original is also uncertain: *The Querist* (1735–37) by the Irish Empiricist philosopher George Berkeley and some of the private correspondence of the period leave the impression that there was more economic sense alive than the histories of economic thought suggest. Still, in the eliciting of general principles, in sense of evidence, and in lucidity of exposition, Hume wrote ahead of his day, though, unlike Smith, whose *Wealth of Nations* he just lived to see, he did not work out a system. His level of insight can be gathered from his main contentions: that wealth consists not of money but of commodities; that the amount of money in circulation should be kept related to the amount of goods in the market (two points made by Berkeley); that a low rate of interest is a symptom not of superabundance of money but of booming trade; that no nation can go on exporting only for bullion; that each nation has special advantages of raw materials, climate, and skill, so that a free interchange of products (with some exceptions) is mutually beneficial; and that poor nations impoverish the rest just because they do not produce enough to be able to take much part in that exchange. He welcomed advance beyond an agricultural to an industrial economy as a precondition of any but the barer forms of civilization.

Main contentions in economics

As a philosopher. This is the essential Hume, for even outside his philosophy all his serious work is either the seed or the fruit of his conception of philosophy as the inductive science of human nature, as well as of his philosophical conclusion that man is more a creature of sensitive and practical sentiment than of reason. It is also the Hume that has been most vigorously alive since his physical death. On the continent of Europe he is seen as one of the few classical philosophers of Great Britain, with only Francis Bacon, an early-16th-century philosopher and essayist, and John Locke, a 17th-century Empiricist, for company. For some Germans his title to fame is that, by putting the problem of causal inference devastatingly, he stung the German thinker Immanuel Kant into creating the "critical" philosophy. He was one of the factors that led Auguste Comte, a 19th-century French mathematician and philosopher, to Positivism. In Great Britain he has been and remains the symbol of a cause, of a type of philosophy that must be either exalted or disgraced. The Scottish school of common-sense philosophy, from its beginning in his lifetime under Thomas Reid until Thomas Brown in the early 19th century, recoiled from his skeptical treatment of belief in causality and in a material world, and the British Hegelian Idealists in the latter part of the 19th century attacked his Empiricism and naturalism generally. His positive influence is instanced in Jeremy Bentham, an early-19th-century British jurist and philosopher, who was confessedly moved to Utilitarianism (the moral theory that right conduct should be determined by the usefulness of its consequences) by book III of the *Treatise*, and more extensively in John Stuart Mill, a British philosopher and economist who lived later in the 19th century. By the middle of the 20th century, he was again on his pedestal, regarded by the antimetaphysicians in England as one of the few philosophers of the past still worth reading.

MAJOR WORKS

PHILOSOPHY AND RELIGION: *A Treatise of Human Nature*, 3 books in 2 vol. (1739–40); *Philosophical Essays Concerning Human Understanding* (1748; from 1758 entitled *An Enquiry Concerning Human Understanding*), mainly a rewriting of book I of the *Treatise of Human Nature; Four Dissertations* (1757), including a rewriting of book II of the *Treatise; Dialogues Concerning Natural Religion* (1779).

POLITICS AND MORALS: *Essays, Moral and Political*, 2 vol. (1741–42); a further *Three Essays, Moral and Political* (1748); *An Enquiry Concerning the Principles of Morals* (1751), a rewriting of book III of the *Treatise; Political Discourses* (1752).

HISTORY: *The History of England*, 6 vol. (1754–62; vol. 1 reprinted 1970).

OTHER WORKS: *A Concise and Genuine Account of the Dispute Between Mr. Hume and Mr. Rousseau* (1766); *The Life of David Hume, Written by Himself* (1777).

BIBLIOGRAPHY. T.E. JESSOP, *A Bibliography of David Hume and of Scottish Philosophy from Francis Hutcheson to Lord Balfour* (1938, reprinted 1966).

Life and letters: Hume's own autobiography is scarcely a narrative of his life. The definitive biography is E.C. MOSSNER, *The Life of David Hume* (1954, reprinted 1970); a competent shorter one is J.Y.T. GREIG, *David Hume* (1931). *The Letters of David Hume*, ed. by GREIG, 2 vol. (1932); and *New Letters of David Hume*, ed. by R. KLIBANSKY and E.C. MOSSNER (1954), supersede older collections.

Texts: Hume's final text is in the 1777 edition of his own collection, *Essays and Treatises*, which has been often reprinted—most recently as *Essays Moral, Political and Literary* (1872, 1963). *The Philosophical Works of David Hume*, ed. by T.H. GREEN and T.H. GROSE, 4 vol. (1874–75), has also gone through several editions and reprints. A complete critical edition is yet to be produced. The most carefully edited text of the *Treatise* and of the two *Enquiries* is by L.A. SELBY-BIGGE (1888 and 1894, both still in print). An *Abstract* of the *Treatise* (1740, really an introduction to it) was found, identified as by Hume, and reprinted by J.M. KEYNES and P. SRAFFA (1938). The best edition of the *Dialogues Concerning Natural Religion* is by N. KEMP SMITH, 2nd ed. (1947, reprinted 1964). Collections of Hume's texts on special fields are: *Hume: Theory of Knowledge*, ed. by D.C. YALDEN-THOMSON, and *Hume: Theory of Politics*, ed. by F. WATKINS (both 1951); *Hume's Writings on Economics*, ed. by E. ROTWEIN (1955); *Hume on Religion*, ed. by R. WOLLHEIM (1963); and *David Hume, Philosophical Historian*, ed. by D.F. NORTON and R.H. POPKIN (1965).

On his philosophy: General introductions are D.G.C. MACNABB, *David Hume: His Theory of Knowledge and Morality*, 2nd ed. (1966); A.P. CAVENDISH (A.H. BASSON), *David Hume* (1958, reprinted 1968); and J.V. PRICE, *David Hume* (1968). In the considerable technical literature, outstanding books are: C.W. HENDEL, *Studies in the Philosophy of David Hume* (1925, reprinted with additions, 1963); CONSTANCE MAUND, *Hume's Theory of Knowledge* (1937); H.H. PRICE, *Hume's Theory of the External World* (1940); N. KEMP SMITH, *The Philosophy of David Hume* (1941, reprinted 1966); and J.A. PASSMORE, *Hume's Intentions*, rev. ed. (1968).
