Metamorphic Rocks

Metamorphic rocks are rocks that have recrystallized as a result of changes in the physical environment. Such changes may occur by reactions involving only the solid state (*i.e.*, the mineral grains) or, more commonly, by reaction in a fluid medium, which makes up a very small percentage of the volume of the rock at any given instant. Commonly, the fluid medium is an aqueous film present in rock pores and on the boundaries between mineral grains. In a sense, metamorphic rocks are the most common rock types of the solid Earth, primarily because the Earth is a dynamic system whose temperatures and pressures tend to fluctuate in space and time. Because the pressure–temperature (*P–T*) conditions to which rocks of all igneous and sedimentary types may be subjected are almost infinite, the variety of metamorphic rock types is very large indeed.

Mineral response to metamorphism

A very simple mineralogical system and its response to changing pressure and temperature provide a good illustration of what occurs in metamorphism. An uncomplicated sediment at the Earth's surface, a mixture of the clay mineral kaolinite [$Al_4Si_4O_{10}(OH)_8$] and the mineral quartz (SiO_2), provides a good example. Most sediments have small crystals or grain sizes but great porosity and permeability, and the pores are filled with water. As time passes, more sediments are piled on top of the surface layer, and it becomes slowly buried. Accordingly, the pressure to which it is subjected increases because of the load on top, or overburden. For rocks with a density of two to three grams per cubic centimetre, the pressure will increase by 200 to 300 bars (one bar equals atmospheric pressure at an altitude of about 100 metres [300 feet] above sea level) for each kilometre of overburden. At the same time, the temperature will increase because of radioactive heating within the sediment and heat flow from deeper levels within the Earth. On the average, the temperature increases by about 30° C for each kilometre (87° F per mile) of burial.

In the first stages of incremental burial and heating, few chemical reactions will occur in the sediment layer, but the porosity decreases, and the low-density pore water is squeezed out. This process will be virtually complete by the time the layer is buried by five kilometres of overburden. There will be some increase in the size of crystals; small crystals with a large surface area are more soluble and less stable than large crystals, and throughout metamorphic processes there is always a tendency for crystals to grow in size with time, particularly if temperature is rising, because it increases the speed of reaction.

Eventually, when the rock is buried to a depth at which temperatures of about 300° C (600° F) obtain, a chemical reaction sets in, and the kaolinite and quartz are transformed to pyrophyllite and water:

kaolinite + quartz → pyrophyllite + water

$$Al_4Si_4O_{10}(OH)_8 + 4SiO_2 \rightarrow 2Al_2Si_4O_{10}(OH)_2 + 2H_2O.$$

The exact temperature at which this occurs depends on the fluid pressure in the system, but in general the fluid and rock-load pressures tend to be rather similar during such reactions. The water virtually fights its way out by lifting the rocks. Thus, the first chemical reaction is a dehydration reaction leading to the formation of a new hydrate. The water released is itself a solvent for silicates and promotes the crystallization of the product phases.

If heating and burial are continued, another dehydration reaction sets in at about 400° C, in which the pyrophyllite is transformed to andalusite and quartz and water:

A second dehydration reaction

pyrophyllite → andalusite + quartz + water

$$Al_2Si_4O_{10}(OH)_2 \rightarrow Al_2SiO_5 + 3SiO_2 + H_2O.$$

After the water has escaped, the rock becomes virtually anhydrous, containing only traces of fluid in minute and small inclusions in the product crystals. Both of these dehydration reactions tend to be fast, because water, a good silicate solvent, is present.

Although the mineral andalusite is indicated as the first product of dehydration of pyrophyllite, there are three minerals with the chemical composition Al_2SiO_5. Each has unique crystal structures, and each is stable under definite *P–T* conditions (Figure 1). Such differing forms

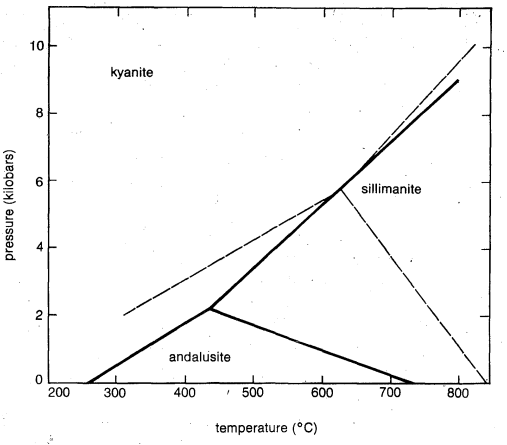

Figure 1: Pressure–temperature regions where the three polymorphic modifications of Al_2SiO_5 are stable. The dashed and solid lines are boundaries provided by different laboratories (see text).

with identical composition are called polymorphs. If pyrophyllite is dehydrated under high-pressure conditions, the polymorph of Al_2SiO_5 formed would be the mineral kyanite (the most dense polymorph). On the other hand, if the original temperature gradient persists, then at a depth of burial corresponding to about 700° C (1,300° F) the polymorphic transformation from andalusite to sillimanite will occur:

andalusite → sillimanite

$$Al_2SiO_5 \rightarrow Al_2SiO_5$$

Sillimanite is more stable than andalusite at high temperatures, but, unless a small amount of water is present in the rock, this reaction may not go to completion even in geological time. If sillimanite does form, however, then the temperature range within the Earth's crust will preserve the sillimanite–quartz assemblage unchanged.

If the forces leading to burial and sinking are reversed when the base of the sedimentary column has reached the sillimanite stage, then the thick column may be pushed up into a mountain range, permitting its observation. The reactions that proceeded during burial tend not to be reversed: with the water of the original sediments gone, the hydrates cannot reform, and chemical reaction rates are always faster in response to rising than to lowering temperatures. The re-exposed column would reveal the metamorphic history of the pile of sediments.

The types of reaction cited here are typical of all metamorphic changes. Gases are lost (hydrates lose water, carbonates lose carbon dioxide), and mineralogical phases undergo polymorphic or other structural changes; low-volume, dense mineral species are formed by high pressures, and less dense phases are favoured by high temperatures. Considering the immense chemical and mineralogical complexity of the Earth's crust, it is clear that the number of possible reactions is vast. In any given complex column of crustal materials some chemical reaction is likely for almost any incremental change in pressure and temperature. This is a fact of immense importance in unravelling the history and mechanics of the Earth, for such changes constitute a vital record and are perhaps the primary reason for the study of metamorphic rocks.

Observations show that pressure is only rarely hydrostatic (equal in all directions) at any point within the Earth's crust. In real cases, consequently, stresses operate that may lead to flow or fracture of materials. Such occurrences produce certain characteristic fabrics or structures in metamorphic rocks that may be observed at the level of the orientation of small crystals in a rock or as a pattern of folds in a mountain range. One of the principal characteristics of most metamorphic rocks is that the arrangement of crystals is not isotropic, or random, but that there is a strong preferred orientation related to the direction of stress components of pressure.

Economic aspects of metamorphic rocks

Many metamorphic reactions result in the gain or loss of water and other volatile compounds, such as the gaseous forms of hydrogen sulfide, carbon dioxide, and hydrochloric acid. At moderate temperatures and pressures, a good solvent for silicates is water; for carbonates, carbon dioxide in water; and for sulfides and elements such as gold, sodium chloride in water. Because large quantities of fluids may take part (perhaps 5 percent by weight of the rocks) in metamorphism, these fluids may transport economically important quantities of other minerals, which either may form deposits in veins or be disseminated in more permeable rocks. Various types of veins often have a very simple mineralogy and are characteristic of metamorphic rocks.

A large number of ore deposits are formed in metamorphic rocks. Practically all gold concentration occurs during metamorphism, even though sedimentary processes may lead to reworking and further concentration. Most important among the many other elements characteristically associated with metamorphic processes are copper, tungsten, zinc, lead, and mercury.

Other metamorphic rocks have useful application as building materials, often because of their peculiar grain sizes and fabrics. Thus, slates characterized by their ability to split or show slaty cleavage have applications wherever erosion- and corrosion-resistant thin materials are wanted. The uses of marble are associated with the increased grain size resulting from the metamorphism of limestones. Serpentines find application because of their beauty when polished; they form during metamorphism by the hydration of certain classes of basic igneous rocks (peridotites and dunites). At times, nickel deposits form during this process. Some metamorphic minerals are of value because of their physical properties or purity. Thus, garnet is often used in abrasives and kyanite as a source of pure aluminum silicate in certain refractory materials.

This article includes treatment of the formation of metamorphic rocks, their physical and chemical characteristics, and their occurrence and distribution as metamorphic facies—*i.e.*, rocks that are associated with a particular set of formative conditions that has given rise to distinctive mineral assemblages or other rock characteristics. For further information on the properties of rocks and minerals and the processes of metamorphism, see MINERALS; SILICATE MINERALS; ROCKS, PHYSICAL PROPERTIES OF; ROCK METAMORPHISM, PRINCIPLES OF; and GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES. See also IGNEOUS ROCKS and SEDIMENTARY ROCKS for an overview of rock types that become subject to metamorphism; and ROCK DEFORMATION; MOUNTAIN-BUILDING PROCESSES; and ORE DEPOSITS for coverage of topics intimately related to metamorphic processes.

FORMATION AND CLASSIFICATION OF METAMORPHIC ROCKS

The common metamorphic rocks observed on the Earth's surface, in mountain ranges and areas of deep erosion, are formed from materials within the crust. The average thickness of the crust is around 30 kilometres (20 miles) under the continents and six to eight kilometres (four to five miles) under the oceans. These thicknesses correspond to load pressures on the order of ten kilobars and two to three kilobars, respectively (one kilobar is very nearly 1,000 atmospheres pressure). Occasionally, crustal thickness may approach 60 kilometres (40 miles), and, hence, pressures may approach 20 kilobars. From place to place on the Earth's surface, thermal gradients are quite variable. The average figure quoted is about 30° C per kilometre of depth, but in some regions the thermal gradient is much less (about 10° C per kilometre), and in some active hydrothermal regions it may exceed 100° C per kilometre (300° F per mile) (see EARTH, HEAT FLOW IN). If the temperature at any point in the crust becomes very high, melting will commence, and metamorphic processes will give way to igneous processes. Thus, the melting temperatures of common rocks (800° C [1,500° F] for granites; 1,200° C [2,200° F] for basalts) represent the upper limits of metamorphic temperatures, and in a general way the limits of formation of common metamorphic rocks can be considered to be 100°–1,200° C (200°–2,200° F) and 1–20,000 bars.

Thermal gradients and pressures

Because most of the Earth's mantle (the region beneath the crust) is solid, metamorphic processes may also occur there. Mantle rocks are seldom observed at the surface, because they are too dense to rise, but occasionally a glimpse is presented by their inclusions in solid volcanic materials and in rapid gaseous volcanic extrusions. Such rocks may represent samples from a depth of a few hundred kilometres, where pressures of about 100 kilobars may be operative. The class of rocks known as kimberlites, which contains diamond, the high-pressure form of carbon, is an example. Experiments at high pressure have shown that few of the common minerals that occur at the surface will survive at depth within the mantle without changing to new high-density phases in which atoms are packed more closely together. Thus, the common form of SiO_2, quartz, with a density of 2.65 transforms to a new phase, stishovite, with a density of 4.29. Such changes are of critical significance in the geophysical interpretation of the Earth's interior.

Geologists believe the Earth is about 4,600,000,000 years old. This is also the age of meteoric materials and probably the age of the Moon. The oldest rocks on Earth are found on the continents; ages of about 3,500,000,000 years from Africa and the Soviet Union have been substantiated. These ages were obtained from analyses of igneous rocks, but the rocks themselves intrude metamorphosed sedimentary rocks. The oldest rocks found on earth at this time are metamorphic rocks from Greenland with an age of 3,800,000,000 years. It may be argued, therefore, that the oldest rocks on Earth are metamorphic and that metamorphic processes of the same type as those existing today have been operating since the earliest times, when the Earth was cool enough to allow fragments of the crust to survive. Thus, metamorphic processes affect almost all rocks except those that are being formed at the surface today.

The Earth's oldest rocks

Because metamorphism represents a response to changing physical conditions, those regions of the Earth's surface where dynamic processes are most active will also be regions where metamorphic processes are most intense and easily observed. The vast region of the Pacific margin, for example, with its seismic and volcanic activity, is also a region in which materials are being buried and metamorphosed intensely. In fact, the margins of continents and regions of mountain building are also regions where metamorphic processes proceed with intensity. But in quiet places, where sediments may accumulate at slow rates, less spectacular changes occur; these record changing conditions of pressures and temperatures that act upon each mineral grain. Metamorphic rocks are therefore distributed throughout the geologic column.

Types of metamorphism. It is convenient to distinguish several general types of metamorphism in order to simplify the description of the various metamorphic phenomena. Recognized here are contact, regional, hydrothermal, dynamic, and retrograde metamorphism, each of which will be described in turn.

Contact metamorphism. Whenever the crust is invaded at any level by silicate melts (magmas, from which igneous rocks crystallize within the Earth), they perturb the normal thermal regime and cause a heat increase in the vicinity. If a mass of basaltic liquid coming from the upper mantle is trapped in the crust and crystallizes there, it will heat up the surroundings; and the amount of heating and its duration will be a direct function of the mass of igneous material and its shape. Contact-metamorphic phenomena thus occur in the vicinity of hot igneous materials and at any depth. Under such circumstances pressure and temperature are not simply correlated. Thermal gradients are often very steep unless the igneous mass is very large. Contact aureoles—the surrounding zones of rock that become altered or metamorphosed—vary in thickness from inches (around tabular bodies such as dikes and thin sills) to several kilometres (around large granitic intrusions).

Contact-aureole thickness

If small fragments of rock are totally enclosed in a magma, they may be heated to the temperature of the magma itself. Their metamorphism represents an upper limit to temperature and is sometimes called pyro-metamorphism.

Regional metamorphism. The general term applied to large-scale metamorphism that affects either sedimentary or igneous rocks that are subject to burial is regional metamorphism. Normally there is a simple relationship between depth of burial, pressure, and temperature. Metamorphic rocks are developed on the scale of a mountain range, but among systems (*e.g.*, the Alps or the Urals) the pattern of thermal gradients may differ. Stress is normally operative, and the rocks produced by regional metamorphism have a well-developed fabric.

When low pressures are associated with regional metamorphism, the term burial metamorphism is applied. It occurs on a large scale, and the general distinguishing feature is the presence of a rather low-temperature mineral assemblage and often a lack of any pronounced mineral fabric.

Hydrothermal metamorphism. Changes that occur in rocks near the surface, where there is intense activity of hot water, are categorized as hydrothermal metamorphism. Such areas include Yellowstone National Park, United States; Wairakei, New Zealand; and the Salton Sea, California. It is now generally recognized that the circulating groundwaters that often become heated by proximity to igneous materials produce the metamorphism. Migration of chemical elements, vein formation, and other kinds of mineral concentration may be extreme on account of the large volumes of water circulated.

Dynamic metamorphism. When directed pressure or stress is the dominant agent of metamorphism, it is termed dynamic; other terms are dislocation, kinematic, and mechanical metamorphism. Mineralogical changes occurring on a fault plane provide an obvious example. In some such cases, the action may simply be a grinding up of existing grains or realignment of minerals that have non-equidimensional crystals. If the action is intense, friction may even lead to melting.

Retrograde metamorphism. Two reasons explain why metamorphic reactions that occur in response to rising pressure and temperature are not reversed when the rocks ultimately are returned to the Earth's surface, when pressures and temperatures are lower. First, if prograde (initial) reactions involve loss of volatile constituents such as water and carbon dioxide, then, unless these can be supplied again during unloading (erosional stripping away of the overlying rocks), the changes cannot be reversed. This is the most general case. Second, reaction rates generally increase with temperature; thus, prograde reactions are faster than retrograde reactions. Nevertheless, there are few metamorphic rocks that do not show at least some traces of retrograde processes, and these traces may record details of the unloading history.

The general irreversibility of metamorphic reactions

Metamorphic grade refers to the pressure–temperature relations that are associated with particular metamorphic minerals or mineral assemblages. High-grade metamorphism involves minerals produced under high temperatures and pressures; low-grade metamorphism, the reverse. When rocks are subjected to more than one metamorphic event, the first event may be of a higher or lower grade than subsequent events. If the first metamorphic event affected a given rock at a higher grade than conditions of a later event, the rock may be quite unresponsive chemically, even though new deformation structures may appear. But, if the later metamorphic phase carries the rock into higher grades, the first event may be obliterated, totally or partly. Careful studies of rock textures may reveal the primary metamorphism. Rocks that are products of dry metamorphism, such as eclogites and granulites, are highly susceptible to later events. Low-grade facies such as glaucophane–lawsonite schists are also likely to be altered by later, higher grade changes.

Types of metamorphic rocks. Because of the diverse chemistry, mineralogy, and primary origin of metamorphic rocks and because of the diverse fabrics or textures that may develop depending on the stresses that may operate during their formation, there is no simple, universally used classification of these rocks. In addition, different countries may have their own special terms. In general, any classification of metamorphic rocks tends to stress either their fabric, mineralogy, or primary origin. Some of the most common metamorphic rock types will be described here. Rocks in which metamorphic minerals are easily seen by eye or hand lens and in which the mineral grains have a highly orientated fabric are called schists (Figure 2). Grains of acicular (needlelike) or platy minerals (amphiboles and micas) tend to lie with their long directions parallel or their planar directions parallel. Often the rocks show a pronounced mineralogical layering; quartz layers a few millimetres or centimetres in thickness may lie between mica layers, for example. Other words often qualify schist: greenschist is a schist rich in the green mineral chlorite; blueschist is rich in the blue amphibole, glaucophane; mica-schist is rich in mica; and a graphite-schist is rich in graphite. Schists that are rich in the amphibole hornblende and are often derived by metamorphism of common igneous rocks of the basalt–gabbro type are called amphibolites.

Rock types according to structures and fabrics

A very fine grained metamorphic rock (usually developed from clay-rich sediments) exhibiting perfect planar layering and perfection of splitting into layers (slaty cleavage) is slate. Such rocks are normally rich in micas

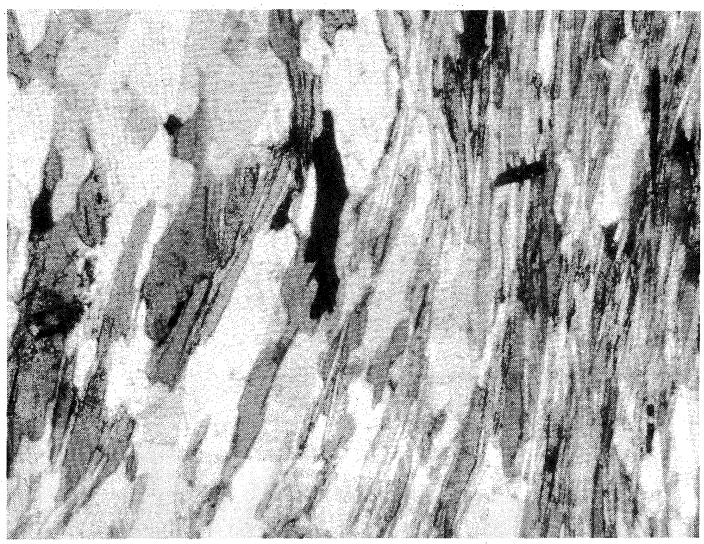

Figure 2: Photomicrograph of a staurolite–biotite schist from Scotland showing strong orientation of biotite crystals (dark) in a matrix of quartz and feldspars (magnification 50 X).

and chlorites. As the intensity of metamorphism increases, a few large crystals may grow (porphyroblasts); such slates are sometimes termed spotted slates. As metamorphism proceeds, the average crystal size increases, and mineral segregation develops; the rock then may be termed a phyllite (Figure 3).

By courtesy of W.S. Fyfe

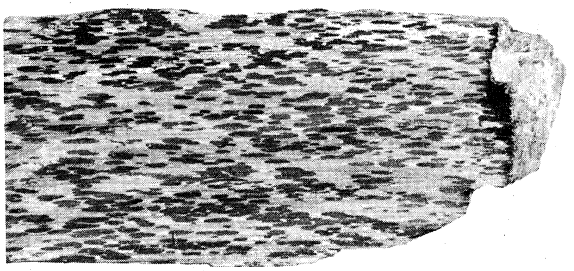

Figure 3: Cross-sectional view of a spotted phyllite from Cornwall, showing the intense stretching of spots (chlorite) in the quartz-rich (white) matrix.

A gneiss is produced by intense metamorphism, at high temperature and pressure. The grain size is coarser than that in schists, and layering is often well developed; mineral orientation is less perfect than in schists, however. Very common granitic gneisses (Figure 4) of Precambrian (more than 570,000,000 years in age) areas have been derived from metamorphism of granitic igneous rocks.

Hornfelses, formed by contact metamorphism, often show little sign of the action of directed pressure. They are fine-grained rocks in which crystals show little orientation. Granulites are products of ultrametamorphism (perhaps often the residue from partial fusion and melting). They tend to be coarse-grained and lack minerals such as amphiboles and micas capable of exhibiting strong orientation. Often they may resemble igneous rocks in appearance.

Rocks derived from the metamorphism of carbonate sediments containing calcite or dolomite are marbles (*q.v.*). The main result of metamorphism is an increase in grain size. Because of the rather equidimensional habit of calcite and dolomite crystals, they rarely appear schistose unless they contain other minerals such as mica.

Mylonites and cataclasites are rocks in which the texture is the result of mechanical shattering of grains. Often they show only slight if any development of new minerals. They form on fault planes or in zones of intense shearing. If the crustal rocks have an appropriate composition, phyllonites may develop where new mica crystals grow parallel to the shearing direction. If shearing is extreme, melting may occur, locally producing a pseudotachylite. Tachylite is a term applied to certain types of glasses formed by rapid cooling of molten rocks.

By courtesy of W.S. Fyfe

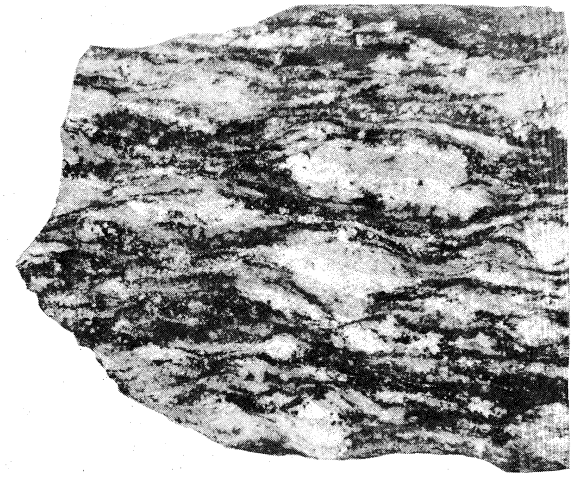

Figure 4: Typical granitic gneiss from Africa with large crystals of feldspar and a matrix containing dark biotite flowing around them.

Most of the above terms indicate structural or fabric classification of metamorphic rocks. Sometimes terms are used to indicate chemical features. Several types of schists, for example, include the following: pelitic schists contain much Al_2O_3 and often are derivatives of clay-rich sediments; quartzofeldspathic schists are high in SiO_2 and feldspars and often are derivatives of sandstones or quartz-rich igneous rocks; calcareous schists have a high content of lime (CaO) and often are derivatives of impure limestones, dolomites, or calcareous muds; and basic schists contain the elements of basic igneous rocks, namely, calcium, magnesium, and iron.

Rock types according to chemistry and primary origins

In addition to the fabric and chemical features of rocks, the primary origin of the material that has been metamorphosed serves as the basis of such names as meta-graywacke, the metamorphic product of the voluminous sediment type called graywacke (a sandstone with muddy matrix and profuse rock fragments); meta-basalt, which is derived from basalt; and meta-sediment, a general term stressing the sedimentary origin of the metamorphic rocks.

PHYSICAL AND CHEMICAL CHARACTERISTICS

Metamorphic minerals. It is clear that many more metamorphic minerals than igneous or sedimentary minerals might be expected to exist, simply because the conditions of formation of metamorphic minerals cover a much wider range of temperatures and pressures than those of igneous or sedimentary environments. The most common characteristic minerals of metamorphic rocks are listed in the accompanying Table. Generally, if such minerals are found well developed in a rock, then the rock will be metamorphic. Under some conditions, however, a sediment may contain such mineralogical debris, as from metamorphic rocks that are being weathered and eroded. In such a case, fabric and microscopic study may be needed to identify the rock as metamorphic. To stress changes that occur in response to increasing temperature and pressure, the common metamorphic minerals are listed in that order—*e.g.*, quartz is associated with the lowest temperatures and pressures. Minerals marked with an asterisk may have a wide range of stability; quartz, for example, may be stable in sediments, igneous melts, or almost any type of metamorphic rock. Phases marked with a dagger (†) are minerals of a composition for which more than one form (polymorph) may be found. In some cases a single mineral may be characteristic of a metamorphic facies, but more commonly an assemblage is needed to indicate conditions of metamorphism.

Metamorphic minerals display the complete range of silicate structural types from low-density, open-type structures (*e.g.*, zeolites) to high-density phases, such as garnets and jadeite. Changes in the atomic structural arrangement reflect the geothermal regime quite clearly.

Rock composition. Common metamorphic rock types have essentially the same chemical composition as what must be their equally common igneous or sedimentary precursors. Common greenschists have essentially the same compositions as basalts; marbles are like limestones; slates are similar to mudstones or shales; and many gneisses are like granodiorites. In general, then, the chemical composition of a metamorphic rock will closely reflect the primary nature of the material that has been metamorphosed. If there are significant differences in composition between a parent material and the metamorphic equivalent, such differences tend to affect only the most mobile (soluble) or volatile elements; water and carbon dioxide contents change significantly, for example. An impure limestone in the system $CaCO_3$–SiO_2 (calcium carbonate–silica) may end up in the system CaO–SiO_2 (calcium oxide–silica). An extreme example is provided by buried salt deposits. In their primary state the chemistry of evaporites (*q.v.*) commonly falls in the system $CaCO_3$–NaCl–$CaSO_4$–H_2O (calcium carbonate–sodium chloride–calcium sulfate–water). They are not represented in the more advanced stages of metamorphism except perhaps by rocks in the system $CaCO_3$–$CaSO_4$ (calcium carbonate–calcium sulfate). Often the greatest part of the rock has been dissolved by metamor-

Relation of metamorphic and original rock composition

Common Minerals of Metamorphic Rocks

mineral	composition
Quartz*†	SiO_2
Kaolinite	$Al_4Si_4O_{10}(OH)_8$
Montmorillonite	$(\frac{1}{2}Ca, Na)_{0.7}(Al, Mg, Fe)_4[(Si, Al)_8O_{20}](OH)_4 \cdot nH_2O$
Albite*	$NaAlSi_3O_8$
Calcite*†	$CaCO_3$
Dolomite*	$CaMg(CO_3)_2$
Analcite	$NaAlSi_2O_6 \cdot H_2O$
Laumontite*	$CaAl_2Si_4O_{12} \cdot 4H_2O$
Adularia†	$KAlSi_3O_8$
Chlorite*	$(Mg, Al, Fe)_{12}[(Si, Al)_8O_{20}](OH)_{16}$
Prehnite	$Ca_2Al(AlSi_3O_{10})(OH)_2$
Pumpellyite	$Ca_4(Mg, Fe^2)(Al, Fe^3)_5O(OH)_3(Si_2O_7)_2(SiO_4)_2 \cdot 2H_2O$
Stilpnomelane	$(K, Na, Ca)_{0\text{-}1.4}(Fe^3, Fe^2, Mg, Al, Mn)_{5.9\text{-}8.2}(Si_8O_{20})(OH)_4(O, OH, H_2O)_{3.6\text{-}8.5}$
Epidote*	$Ca_2Fe^3Al_2O(OH)(Si_2O_7)(SiO_4)$
Muscovite*	$KAl_2(AlSi_3O_{10})(OH)_2$
Magnetite*	Fe_3O_4
Hematite*	Fe_2O_3
Pyrite	FeS_2
Glaucophane	$Na_2Mg_3Al_2(Si_8O_{22})(OH, F)_2$
Jadeite	$NaAlSi_2O_6$
Omphacite	a complex solid solution mainly of $NaAlSi_2O_6 - CaMgSi_2O_6 - NaFeSi_2O_6$
Lawsonite	$CaAl_2(Si_2O_7)(OH)_2 \cdot H_2O$
Aragonite†	$CaCO_3$
Magnesite	$MgCO_3$
Tremolite	$Ca_2Mg_5(Si_8O_{22})(OH)_2$
Actinolite	$Ca_2(Mg, Fe)_5(Si_8O_{22})(OH)_2$
Talc	$Mg_3(Si_4O_{10})(OH)_2$
Serpentine†	$Mg_3(Si_2O_5)(OH)_4$
Hornblende*	$(Na, K)_{0\text{-}1}Ca_2(Mg, Fe^2, Fe^3, Al)_5(Si_{6\text{-}7}Al_{2\text{-}1}O_{22})(OH, F)_2$
Plagioclase*	$(NaAlSi_3O_8, CaAl_2Si_2O_8)$
Kyanite†	Al_2SiO_5
Sillimanite†	Al_2SiO_5
Andalusite†	Al_2SiO_5
Microcline†	$KAlSi_3O_8$
Garnet*	a complex solid solution of pyrope $Mg_3Al_2Si_3O_{12}$ almandine $Fe^2{}_3Al_2Si_3O_{12}$ spessartite $Mn_3Al_2Si_3O_{12}$ grossularite $Ca_3Al_2Si_3O_{12}$ andradite $Ca_3Fe^3{}_2Si_3O_{12}$
Staurolite	$(Fe^2, Mg)_2(Al, Fe^3)_9O_6(SiO_4)_4(O, OH)_2$
Chloritoid	$(Fe^2, Mg, Mn)_2(Al, Fe^3)Al_3O_2(SiO_4)_2(OH)_4$
Anthophyllite	$Mg_7Si_8O_{22}(OH)_2$
Orthoclase†	$KAlSi_3O_8$
Anorthite	$CaAl_2Si_2O_8$
Diopside	$CaMgSi_2O_6$
Phlogopite*	$KMg_3(AlSi_3O_{10})(OH)_2$
Scapolite	$(Na, Ca, K)_4[Al_3(Al, Si)_3Si_6O_{24}](Cl, SO_4, CO_3OH)$
Biotite*	$K_2(Mg, Fe^2)_{6\text{-}4}(Fe^3, Al, Ti)_{0\text{-}2}(Si_{6\text{-}5}Al_{2\text{-}3}O_{20})(OH, F)_4$
Cordierite	$Al_3(Mg, Fe^2)_2(Si_5AlO_{18})$
Wollastonite	$CaSiO_3$
Forsterite	Mg_2SiO_4
Hypersthene	$(Mg, Fe)SiO_3$
Enstatite	$MgSiO_3$
Tridymite†	SiO_2
Corundum	Al_2O_3
Periclase	MgO
Mullite	$3Al_2O_3 \cdot 2SiO_2$
Sanidine†	$KAlSi_3O_8$
Larnite	Ca_2SiO_4

phic fluids, which have carried it to the surface. These fluids, rich in halides, or salts, may play a key role in the transport of ore minerals.

Metamorphic rocks only rarely exhibit a chemical composition that is characteristically "metamorphic." This statement is equivalent to saying that diffusion of materials in metamorphism is a slow process, and various chemical units do not mix on any large scale. But occasionally, particularly during contact metamorphism, diffusion may occur across a boundary of chemical dissimilarity leading to rocks of unique composition. If a granite is emplaced into a limestone, the contact region may be flooded with silica and other components leading to the formation of a metasomatic rock. Often such contacts are chemically zoned. A simple example is provided by the metamorphism of magnesium-rich igneous rocks in contact with quartz-rich sediments. A zonation of the type serpentine–talc–quartz may be found such as:

$$Mg_6(Si_4O_{10})(OH)_8/Mg_3(Si_4O_{10})(OH)_2/SiO_2.$$

In this case the talc zone has grown by silica diffusion into the more silica-poor environment of the serpentine. Economic deposits are not uncommon in such situations; *e.g.*, the formation of the $CaWO_4$ (calcium tungstate) scheelite when tungstate in the form of WO_3 moves from a granite into a limestone contact. The reaction can be expressed as:

$$\underset{\text{calcite}}{CaCO_3} + WO_3\ (\text{solution}) \rightarrow \underset{\text{scheelite}}{CaWO_4} + CO_2\ (\text{gas}).$$

Metamorphic facies. Metamorphic petrologists working on contact metamorphism early in the 20th century introduced the idea of metamorphic facies to correlate metamorphic events. The concept was first defined in 1914 by a Finn, Pentti Eelis Eskola, as any rock of a metamorphic formation that has attained chemical equilibrium through metamorphism at constant temperature and pressure conditions, with its mineral composition controlled only by the chemical composition. In current usage, a metamorphic facies (Figure 5) is a set of metamorphic mineral assemblages, repeatedly associated in space and time, such that there is a constant and therefore predictable relation between mineral composition and chemical composition.

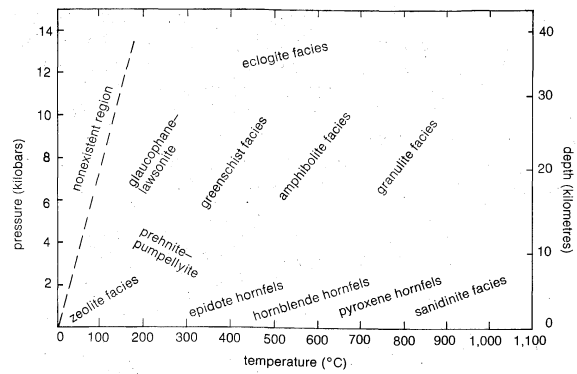

Figure 5: Approximate pressure–temperature regions of the major metamorphic facies (see text).

The facies concept is basically observational. In a layered sequence of sediments, for example, if each layer exhibits a different chemical composition, then it is reasonable to suppose that the different minerals within any single layer represent a response to similar conditions. In other words, the rocks belong to the same facies. In another region, in which the composition is equivalent to that in only one of the sediment layers in the first sequence, the facies concept permits correlation with the more complex assemblages. A facies is defined by a set of rock types, but the naming of facies tends to follow some single common type. The greenschist facies is named after schists formed from basaltic compositions; other facies, such as the zeolite facies, are named after some characteristic mineral type in the rock; still others are named after a textural feature. The definitions of facies suggest that during most metamorphic processes there is a close approach to some equilibrium state, and experimental studies of metamorphic processes substantiate this deduction.

Grades, zones, and facies series

The intensity of metamorphism is called metamorphic grade. A line on a map where the grade of metamorphism is similar would be called an isograd. During regional mapping of metamorphic rocks it is common to record where a particular mineral appears in progressive metamorphism. If the mineral was biotite or garnet in rocks of the greenschist facies, this would be recorded as the biotite or garnet zone. Zones of development of various minerals in contact metamorphism are often mapped and indicate the type of thermal gradient around an igneous intrusion.

If the thermal gradient is very low (high pressure at low temperature), transitions will occur from zeolite facies to glaucophane-schist facies with increasing burial. If the gradient is moderate, the transitions involve zeolite facies that lead to greenschist facies that lead to amphibolite facies that lead to facies of still higher grades. The concept of facies series arises from the attempt to describe and emphasize such major geothermal trends, which have

great significance in the major features of Earth dynamics. Thus, the zeolite–glaucophane-schist trend is found only when the rate of downbuckling of the crust is very fast. This type of motion occurs on continental margins and is associated with continental drift.

Textures and fabrics. The study of the fabric of metamorphic rocks has become a highly specialized subject. Modern work has been based on the classic investigation in 1930 of Bruno Sander of Innsbruck, Austria. The study of fabric or structure may reveal the nature and direction of forces acting during dynamic processes within the Earth. If hydrostatic forces prevailed, there would be no reason for the crystals in a rock to show pronounced preferred orientation of their axes, but such preferred orientation of crystals and mineral grains is perhaps the most striking difference between a metamorphic rock and other rock types.

The most obvious features of a metamorphic rock are certain planar features that are often termed s-surfaces. The simplest planar features may be primary bedding (akin to the layering in sedimentary rocks). As the rock crystallizes or recrystallizes under directed pressure, new crystals may grow in some preferred direction, sometimes subparallel to the primary bedding but often at new angles defining new planar structures. At the same time, folding of layers may occur, leading to folds on scales with amplitude of kilometres or millimetres. Fabric symmetry may be represented by nature of deformed fossils, pebbles in a conglomerate, or any objects with a known shape prior to deformation (Figure 6).

By courtesy of J. Ramsay, Imperial College, London

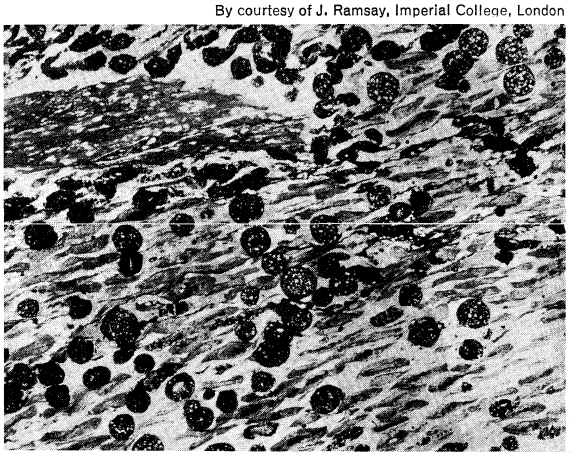

Figure 6: A deformed dolomite–calcite marble from Sardinia containing spherical fossil objects (oolites) about three millimetres in size. Oolites made of dolomite (black circles) are not deformed. Oolites made of calcite (gray), a weaker solid, are smeared out in S forms.

A few terms that commonly are used to describe several types of preferred orientation in metamorphic rocks include foliation, a general term describing any type of s-surface, bedding, or crystal orientation; slaty cleavage, a planar structure leading to facile cleavage that is normally caused by the preferred orientation of mica crystals; schistosity, a term used to describe repetitive and pronounced foliation of the type that is present in schists; and lineation, which is any linear structure, such as the axis of the fold, grooves on a fault plane, or the direction of stretching of pebbles.

Crystalloblastic fabric and laminations

The various mineral phases of a metamorphic rock have different physical properties and symmetries. When a rock is subjected to recrystallization in a stress field, different substances will behave differently according to such physical properties and symmetries. Some crystals always tend to grow in better formed crystals than others; rates of nucleation may differ, and this can lead to different patterns of growth of crystals—there may be a few large crystals or a mass of small crystals. Minerals can be arranged in order of their tendency to form crystals showing planar surfaces, namely, magnetite, garnet, epidote, mica, calcite, quartz, and feldspar. Crystals that tend to form large single crystals (*e.g.*, garnet) are termed porphyroblasts. Porphyroblastic crystals and their contained inclusions often record details of the mechanism of deformation and flow. A spectacular example is provided by the so-called snowball garnets, which have spiral trails of inclusions that indicate rotation during growth (Figure 7).

By courtesy of J. Ramsay, Imperial College, London

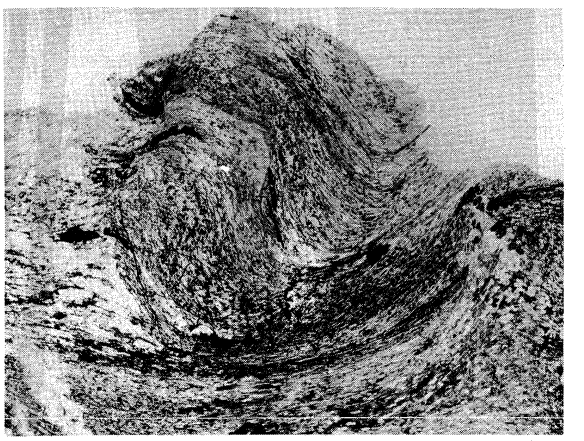

Figure 7: A large garnet crystal (enlarged; one centimetre) growing in a quartz–mica matrix. The garnet contains trails of inclusions and has rotated during growth in the flowing rock medium.

There is a distinct tendency for many types of metamorphic rocks to become laminated, and the separate laminae may have distinct chemical compositions. A rather homogeneous sediment may become inhomogeneous on a scale of millimetres or centimetres. When graywackes are metamorphosed within the greenschist facies, for example, laminae rich in quartz and feldspar alternate with others rich in epidote, chlorite, and muscovite. The precise causes of this process are not well-known, but it must result from a combination of extensive deformation accompanied by recrystallization. In a sense, it is a type of flow unmixing. It is often important to recognize that this structure need have no relation to original bedding in the unmetamorphosed sediments.

ROCKS OF THE PRINCIPAL FACIES

Facies associated with contact metamorphism. Possibly the simplest of all types of metamorphic processes to envisage are those in which hot silicate liquids are intruded into rocks at rather shallow depths. The hot liquids heat up the originally cool rocks, and the extent of the aureole that is formed depends on the size of the intruding igneous body and its temperature. The contact metamorphic rocks of the aureole zone often lack any obvious schistosity or foliation. The facies associated with contact metamorphism include the sanidinite, pyroxenite–hornfels, hornblende–hornfels, and albite–epidote–hornfels facies.

Sanidinite facies. Rocks of the sanidinite facies are represented by small fragments of aureole materials that have often been totally immersed in silicate liquids or by the aureole rocks surrounding volcanic pipes. Very high temperatures are attained, often at very low pressures. The dominant feature of the mineralogy of this facies is an almost complete lack of minerals containing water or carbon dioxide. Many of the minerals show similarity to those of igneous rocks themselves. If the duration of heating is short, adjustment to the imposed temperature is often imperfect.

Typical pelitic rocks

Pelitic rocks (high in Al_2O_3) contain minerals such as mullite, sillimanite, sanidine, cordierite, spinel, hypersthene, anorthite, tridymite, and even glass. One of the classic localities of such rocks is the island of Mull, off the west coast of Scotland, but in most regions of volcanism such rocks can be found.

Calcareous rocks (originally impure limestones or dolomites) tend to lose almost all their carbon dixoide, but pure calcite may survive. Typical metamorphic minerals are: quartz, wollastonite, anorthite, diopside, periclase,

and in some places (the classic is Scawt Hill in Northern Ireland) an array of complex calcium silicates such as spurrite, larnite, rankinite, melilite, merwinite, and monticellite. These minerals result from the addition of varying amounts of silica to impure mixtures of calcite and dolomite. In a general way the minerals of this facies are reminiscent of those of industrial slags.

Pyroxene–hornfels facies. Rocks of the pyroxene–hornfels facies are characteristically formed near larger granitic or gabbroic bodies at depths of a few kilometres or at pressures of a few hundred bars. The mineral assemblages are again largely anhydrous, but, unlike the sanidinite facies, the minerals reflect distinctly lower temperatures. One of the classic descriptions of such rocks is from the Oslo district of Norway.

In pelitic rocks, minerals such as quartz, orthoclase, andalusite, sillimanite, cordierite, hypersthene, and plagioclase occur. Sometimes the hydrate biotite is developed. In calcareous rocks the minerals found include plagioclase, diopside, grossularite, vesuvianite (a hydrate), wollastonite, and sometimes the more complex calcium silicates monticellite, melilite, spurrite, tilleyite, and clinohumite.

Hornblende–hornfels facies. A generally deeper level of contact metamorphism where pressures of a few kilobars may be active is represented by the hornblende–hornfels facies. Hydrated phases become stable, and the transition to regional metamorphism becomes apparent. Because of the generally greater depth, this type of aureole is often superposed on a more normal metamorphism, and the rocks may appear schistose and show the development of new thermally generated minerals on a pre-existing assemblage. This type of metamorphism develops the classic "spotted" texture in which new porphyroblasts grow in slates and phyllites of a previous episode of metamorphism. Typically, these rocks are developed near most of the world's large granite batholiths, where these have moved to higher levels in the Earth's crust.

Typical minerals of pelitic assemblages include quartz, muscovite, biotite, andalusite, sillimanite, cordierite, plagioclase, microcline, and staurolite. Calcareous assemblages include calcite, quartz, diopside, grossularite, plagioclase, wollastonite, brucite, talc, forsterite, tremolite, and clinozoisite. Basaltic compositions include plagioclase, hornblende, diopside, quartz, biotite, and almandine garnet.

Formation of spectacular skarns

When rather pure limestone and dolomite come into direct contact with granitic rocks, elements such as silicon, iron, magnesium, and aluminum diffuse into the limestone, forming spectacular rocks termed skarns. These rocks often consist of large garnet crystals (grossularite) with green diopside and vesuvianite or epidote.

Albite–epidote–hornfels facies. Rocks of the albite–epidote–hornfels facies are characteristically found as the outer zones of contact aureoles where the thermal episode fades out and the rocks pass into their regional grade of metamorphism. The mineral assemblages are quite similar to those found in regional greenschist-facies metamorphism, except for the presence of low-pressure phases such as andalusite. Characteristic minerals include quartz, muscovite, biotite, chlorite, andalusite, actinolite, calcite, dolomite, albite, and epidote.

Conditions of formation of the contact facies. The mineralogical reactions included in the rocks described above are varied, and laboratory studies have provided a rather exact picture of the conditions of formation of these facies. It should be stressed that all correspond to conditions of pressure and temperature such that a thermal accident or abnormal thermal gradient is necessary to produce the observed mineral phases. This accident is the rise of silicate melt from depth.

Facies associated with regional metamorphism. Regional metamorphism is associated with the major events of Earth dynamics, and the vast majority of metamorphic rocks are so produced. They are the rocks involved in the cyclic processes of erosion, sedimentation, burial, metamorphism, and mountain building, events that are all related to major convective processes in the Earth's mantle. Two particular trends of facies can be noted: a cold trend, in which the geothermal gradient is low (about 10°–15° C per kilometre [30°–45° F per mile]), leading from zeolite facies to glaucophane schist facies; and the more general trend for normal gradients (20°–30° C per kilometre [57°–87° F per mile]), from zeolite facies to greenschist facies to amphibolite facies to a zone of crustal fusion. In almost all such crustal events at different times and places, however, there is uniqueness as well as conformity to a general pattern. Metamorphic events in the European Alps, the Urals, and the Himalayas all show specific differences: to unravel such differences and their significance is a great task of metamorphic petrology.

Zeolite facies. In the zeolite facies, sediments and volcanic debris show the first major response to burial. Reactions are often not complete, and typical metamorphic fabrics may be poorly developed or not developed at all. This is the facies of burial metamorphism.

The facies of burial metamorphism

The zeolite facies was first described from southern New Zealand, but similar rocks have now been described from the rocks of many younger mountain regions of the Earth, particularly around the Pacific margin and the European Alps. Typically, the rocks are best developed where reactive volcanic materials (often partly glassy) are common and the characteristic minerals include zeolites, which are low-density, hydrated silicates, stable at temperatures rarely exceeding 300° C (600° F). Typical mineral assemblages include heulandite, analcite, quartz with complex clay minerals (montmorillonite), micaceous phases such as chlorite and celadonite, and the potassium feldspar, adularia. At higher grades of metamorphism, the zeolite laumonite and the feldspar albite dominate the mineral assemblage. In New Zealand these are developed in a rock column that is about 15 kilometres (nine miles) thick. Calcareous rocks (impure limestones) show very little response to this grade of metamorphism.

Prehnite–pumpellyite facies. Along with the zeolite facies, the prehnite–pumpellyite facies received little attention until about 1950. The first rocks of the facies were described in New Zealand and the Celebes. The facies is transitional, bridging the path to the glaucophane–lawsonite facies or the greenschist facies. It is particularly well developed in graywacke-type sediments. The two minerals prehnite and pumpellyite replace the zeolite minerals of the zeolite facies and are themselves replaced by epidote minerals in the greenschist facies and by lawsonite and pyroxenes in the glaucophane–lawsonite facies. Typical minerals in this facies are quartz, albite, prehnite, pumpellyite, chlorite, stilpnomelane, muscovite, and actinolite. Almost all the minerals are hydrated, and, except for chlorite, they bear little resemblance to the minerals of sediments. Again, the facies has been most described from younger mountain ranges of the Pacific margin.

Glaucophane–lawsonite schist facies. Rocks of the glaucophane–lawsonite schist facies are known to represent deep metamorphism under conditions of a low thermal gradient. The characteristic locale for this type of metamorphism appears to be along a continental margin being underthrust by an oceanic plate. Regions in which glaucophane schists are to be found are also regions of great seismic and volcanic activity, such as the Pacific margin. The best described examples of this class of metamorphism come from California, Japan, New Caledonia, Celebes, the Alps, and the Mediterranean region. At present there are no known examples of glaucophane schists predating the Paleozoic Era (570,000,000 to 225,000,000 years ago). Because of the common presence of the blue amphibole glaucophane (this facies is also sometimes termed the blueschist facies) and minerals such as garnet and jadeite, these schists are among the most attractive of metamorphic rocks.

Characteristic minerals of the facies include quartz, glaucophane, lawsonite, jadeite, omphacite, garnet, albite, chlorite, muscovite, paragonite, epidote, and kyanite. In calcareous rocks, calcite may be replaced by the high-pressure polymorph aragonite. Lawsonite, aragonite, and jadeite are found in no other metamorphic facies. In general, the facies is characterized by many high-density minerals reflecting a high pressure of formation.

Greenschist facies. The greenschist facies was once considered the first major facies of metamorphism proper. The name comes from the abundance of the green mineral chlorite in such rocks (Figure 8). Because chlorite and muscovite are ubiquitous and because both exhibit a platy crystal habit, these rocks normally show a highly developed foliation and often exhibit strong metamorphic differentiation. They have been described from practically every metamorphic terrain on Earth from earliest Precambrian to the young mountain regions. In fact, many of the Earth's oldest rocks (about 3,000,000,000 years old) of the continental-shield areas are in this facies, classic examples of which are in the Appalachians, Scottish Highlands, New Zealand, the European Alps, Japan, and Norway.

By courtesy of W.S. Fyfe

Figure 8: A typical greenschist from Scotland; the gray minerals are biotite and chlorite showing strong preferred orientation. The black crystals are magnetite, and the white areas are albite–quartz. Epidote and calcite are also present (magnification 50 X).

The dominant minerals of greenschists formed from silicate-rich sediments include quartz, albite, muscovite, chlorite, epidote, calcite, actinolite, magnetite, biotite, and paragonite. Minerals less common include the manganese-rich garnet spessartite, stilpnomelane, kyanite, rutile, sphene, pyrophyllite, and chloritoid. Calcareous rocks are dominated by calcite, dolomite, and quartz; the major carbonate minerals are thermally stable. It is only when large quantities of water flush away carbon dioxide or keep its partial pressure low that carbonate–silicate reactions take place liberating carbon dioxide. The typical minerals of this facies have low water contents as compared to the zeolite facies minerals.

Amphibolite facies. The amphibolite facies is the common high-grade facies of regional metamorphism, and, like the greenschist facies, such rocks are present in all ages from all over the world. Their characteristic feature is the development of the most common amphibole, hornblende, in the presence of a plagioclase feldspar and garnet. The rocks are normally highly foliated or schistose. Many zones or isograds subdividing the facies have been recognized, and classic studies have been made in the Scottish Highlands, New Hampshire, Vermont, Switzerland, and the Himalayas.

Hornblende, the most common amphibole

Characteristic minerals derived from pelitic rocks are quartz, muscovite, biotite, garnet, plagioclase, kyanite (sillimanite), staurolite, and orthoclase. Minerals derived from basaltic rocks include hornblende, plagioclase, garnet, epidote, and biotite. Those derived from calcareous rocks are calcite, diopside, grossularite (garnet), zoisite, actinolite (hornblende), scapolite, and phlogopite. Minerals from magnesium-rich ultrabasic rocks are chlorite, anthophyllite, and talc. In most common types, water is present only in minerals of the mica and amphibole families, and, with their water contents of only about 1 to 3 percent, dehydration is nearing its metamorphic climax.

Conditions of formation of the regional metamorphic facies. Most workers on the metamorphic facies of regional metamorphism considered above agree that progressive metamorphic reactions occur in a regime in which fluid pressure is about the same as the lithostatic (rock) pressure. Furthermore, because water is the common fluid phase and will be diluted by CO_2 (carbon dioxide) only in exceptional circumstances, the fluid pressure will approximately equal the pressure of water. Current thought on the regions of formation of metamorphic facies is shown in Figure 5, where the coordinates are the pressure of water and temperature. No matter how imperfect these estimates are in absolute terms, there is little doubt about their relative significance: they emphasize the uniqueness of metamorphic events.

The eclogite and granulite facies. The fact that the eclogite and granulite facies have no hydrated phases has led to considerable debate as to the place of such rocks among other metamorphic facies. They could represent dry equivalents of other metamorphic rocks, or their conditions of formation may be unique. Experimental studies have shown the extreme thermal stability of hornblende in rocks of basaltic composition. If a crustal rock contains this mineral, then at moderate pressures its dehydration reactions may lead to partial melting of the crust and the onset of igneous phenomena.

Eclogite facies. Eclogite facies are recognized only in rocks whose composition is near that of basalt. Two minerals dominate the mineralogy—omphacite pyroxene and garnet. The garnet is rich in the high-pressure species pyrope, and the omphacite is rich in the high-pressure pyroxene jadeite. Small amounts of minerals such as kyanite, the hydrate zoisite, and hornblende may be present. The rocks are of high density and frequently show little or no schistosity.

Because of the high density and composition, it was proposed long ago that part of the upper mantle might be made of eclogite. Such a view is supported by eclogitic intrusions in volcanic rocks and by eclogitic inclusions in diamond-bearing kimberlite, which must come from the upper mantle. Some workers also think that eclogites found in metamorphic terrains in Norway, California, and the European Alps could also come from the mantle by tectonic processes (crustal movements). Some eclogites are known to have been produced within the crust from former surface materials (*e.g.*, basalt lava flows). It also is known that eclogites form over a wide range of temperatures, perhaps from 400° to 1,000° C (750° to 1,800° F). These conditions overlap greenschist, amphibolite, and granulite facies temperatures.

Upper mantle as source of eclogite

Experimental studies have demonstrated that eclogites can be stable (except under certain upper-mantle conditions) only if water pressure is much lower than load pressure. The facies represents dry, high-pressure metamorphism of basaltic materials. The exact mechanism by which these metamorphic reactions take place is still a matter of considerable argument.

Granulite facies. The granulite facies is an anhydrous facies that develops gradationally from amphibolites but without any suggestion of a desiccated environment. Granulite-facies rocks are often found best developed in ancient Precambrian-shield areas of the continents. No large-scale development of such rocks has been observed in post-Cambrian metamorphism.

Rocks of this facies frequently have a granular texture quite similar to plutonic igneous rocks. Schistosity is only weakly developed. Typical minerals of the facies are quartz, alkali feldspar, garnet, plagioclase, cordierite, kyanite, sillimanite, and hypersthene. In calcareous members, dolomite, calcite, diopside, and forsterite occur; and it is in this facies that minerals of the scapolite family are best developed. Small amounts of hornblende are often present. A rare mineral occurring in this facies is sapphirine. The rock type charnockite (from Madras, India), essentially a hypersthene granite, is normally included in this facies.

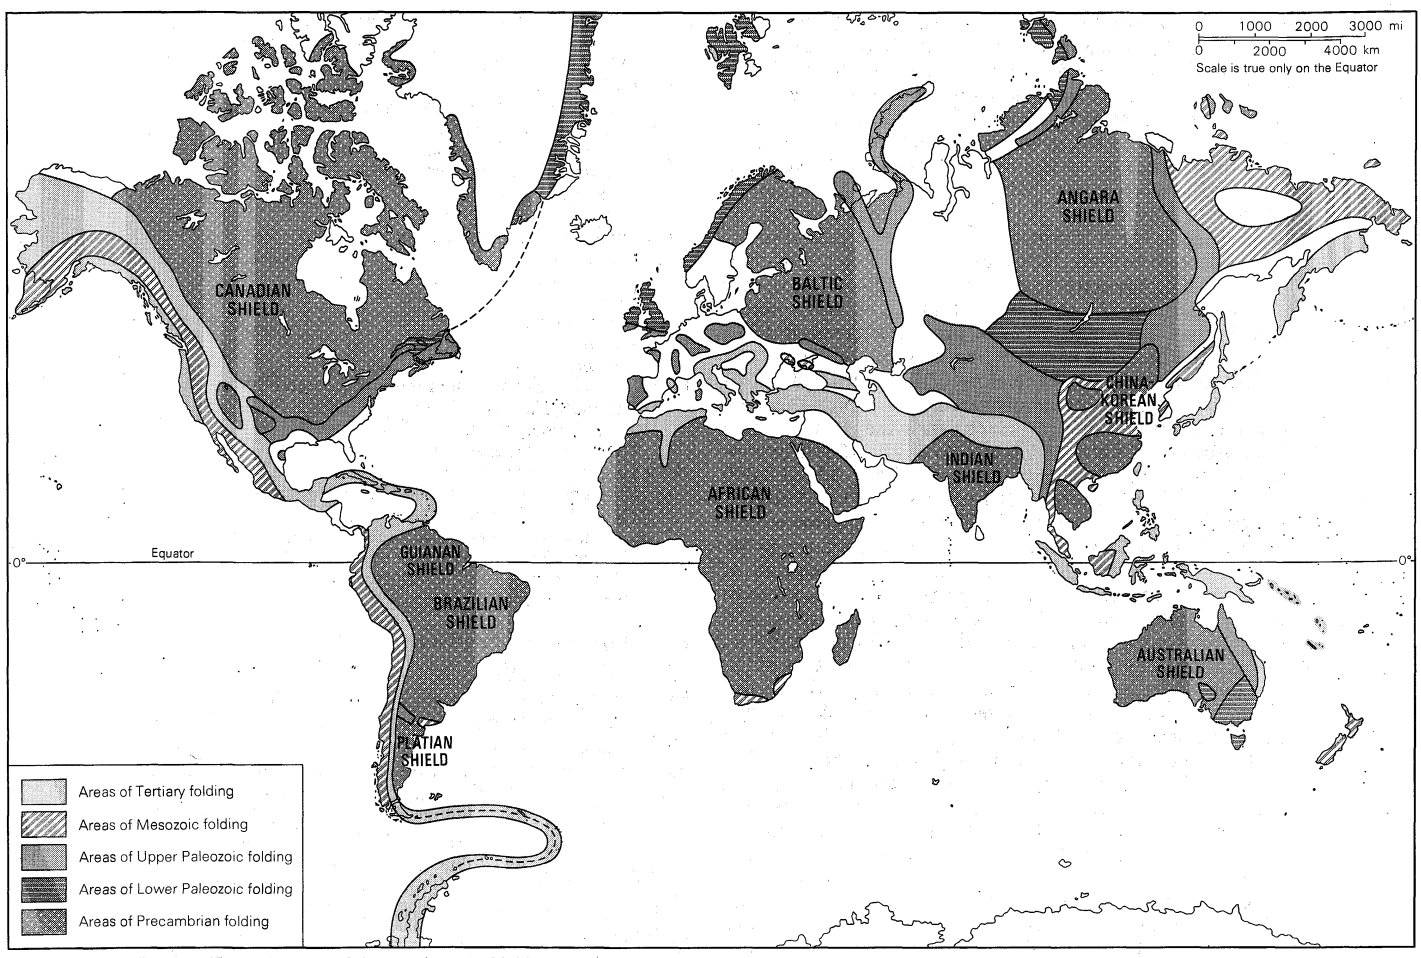

Figure 9: Tectonic units of the continents: shields and orogenic (fold) belts.
From J. Umbgrove, *The Pulse of the Earth*

It appears from experimental studies that during ultrametamorphism, when melting starts, the basic reactions to take place are of the type:

biotite + other minerals → melt + residue
hornblende + other minerals → melt + residue.

The first melts to form are partly wet granitic or granodioritic melts, and phases such as biotite and hornblende break down by producing a partly wet melt from the least refractory phases in the rocks. They would persist to much higher temperatures in systems of their own composition. The residue in the above equations is a granulite-facies metamorphic rock containing phases such as pyroxene and sillimanite or kyanite. Thus it is probable but certainly not universally proved that most granulites are formed only in the presence of a silicate liquid. This liquid may, of course, move to higher crustal levels. As with eclogites, this facies represents metamorphism in which the partial pressure of water is lower than total pressure. Granulites may be very common rocks in the base of the crust. The lowering of pressure is caused by solution and dilution of water in a silicate melt. Rocks whose appearance suggests that they were once a mixture of liquid and solid parts are often called migmatites.

The probable process of granulite formation

DISTRIBUTION OF METAMORPHIC ROCKS

A high-grade metamorphic rock is one that formed at a depth of tens of kilometres and subsequently returned to the surface. Hence, metamorphic regions are also regions of former or recent intense orogeny (mountain building). More stable regions of the Earth's crust tend to be covered with sediments, and only deep drilling will reveal the metamorphic rocks below.

The Earth's crust is made up of two basic units, the continents and ocean basins. Exploration of ocean floors has revealed that old, thick sedimentary piles are missing. Doubtless this is related to the processes of continental drift or sea-floor spreading (*qq.v.*); sediments are continuously swept up by continental motion and are added to the continents or returned to the upper mantle. Nearly all studies of metamorphic rocks have concentrated on the continents for this reason.

There are few large areas of the Earth's crust that are not affected by some type of igneous event from time to time. Although the intensity of volcanism may be focussed in certain geographic regions (*e.g.*, the Pacific margin), volcanism appears to be a rather random phenomenon, at times even occurring in the stable shield areas of the continents. In this sense, contact-metamorphic events may be found almost everywhere at almost any time on Earth. But these metamorphic events are of trivial volumetric significance compared to those of regional or burial metamorphism.

Belts of mountain building and shield areas

During the past 500,000,000 years or so of Earth history, major tectonic, seismic, igneous, and metamorphic events have been concentrated on continental margins (Figure 9). This has been a period of depression and uplift of the Earth's crust associated with the formation of the present continental distribution. The processes are still going on at dramatic rates in ocean trench environments. These modern regions of activity form immense linear belts. One such belt runs virtually around the entire Pacific margin and another through the Mediterranean and southern Asia to fuse with the circum-Pacific belt. It is in these belts that the spectacular development of zeolite facies, prehnite–pumpellyite facies, glaucophane-schist facies, and, occasionally, eclogite facies, as well as the more universal facies of regional metamorphism, have occurred. The granulite facies is almost missing.

The central and often dominant feature of most continents is their vast Precambrian-shield area; examples include the Canadian Shield, Brazilian Shield, African

Shield, and Australian Shield. In these rocks, dating reveals ages of 1,000,000,000 to 3,500,000,000 years, and they have been little affected by tectonic events postdating the Cambrian. But these shield areas are themselves complex. They consist of vast areas of granitic or granodioritic gneisses. Inside them, between them, and overlapping onto them are belts of sedimentary rocks quite like those in modern sedimentary belts of the Pacific margin or European Alps. These rocks are frequently metamorphosed in the greenschist, amphibolite, and granulite facies. Low-temperature facies and, in particular, low-temperature–high-pressure facies are missing—or have not yet been found. From marginal areas of these stable shield areas, a complex array of processes has been documented covering the past few hundred million years. The Caledonian orogeny (at the close of the Silurian Period) produced tectonic–metamorphic events along the east coast of North America, Greenland, the British Isles, Fennoscandia, Central Asia, and Australia. The Hercynian, or Variscan, orogeny followed about 300,000,000 years ago, affecting subparallel regions and the Urals and European Alps. In fact, the shield margins appear to have been subjected to a more or less constant battering by forces both destroying and rebuilding the margins of these protocontinents. As geologists study Precambrian areas in greater detail, the number of metamorphic and orogenic events recognized on a global scale increases.

It is the great task and problem of those who study metamorphic rocks to deduce the record of Earth dynamics and thermal history from metamorphic rocks. Among the questions to be answered are (1) whether the pattern of facies development through time—*e.g.*, the granulite facies in the Archean to glaucophane–lawsonite facies in the Tertiary—is a reflection of a cooling Earth and the decline of radioactivity in the crust and (2) whether the increase in size of global tectonic–metamorphic belts through time reflects changes in convective patterns in the mantle.

As understanding of the pressure–temperature regimes of metamorphism increases, and as knowledge of rock mechanics and fluid motion during metamorphism also increases through field and laboratory studies, it may become possible to understand the details of the motion of the chemical elements during such processes and hence much of the subject of economic geology or the search for man's essential raw materials.

BIBLIOGRAPHY. Fundamental texts treating all aspects of the mineralogy and petrology of metamorphic rocks include the following: T.F.W. BARTH, C.W. CORRENS, and P. ESKOLA, *Die Entstehung der Gesteine* (1939); W.A. DEER, R.A. HOWIE, and J. ZUSSMAN, *An Introduction to the Rock-Forming Minerals* (1966); W.S. FYFE, F.J. TURNER, and J. VERHOOGEN, *Metamorphic Reactions and Metamorphic Facies* (1958); A. HARKER, *Metamorphism*, 2nd ed. (1939); B. MASON, *Principles of Geochemistry*, 3rd ed. (1966); F.J. TURNER, *Metamorphic Petrology* (1968); J. VERHOOGEN *et al.*, *The Earth* (1970); H. WILLIAMS, F.J. TURNER, and C.M. Metaphysics

Metaphysics is the philosophical study whose object is to determine the real nature of things—to determine the meaning, structure, and principles of whatever is insofar as it is. Although this study is popularly conceived as referring to anything excessively subtle and highly theoretical, and although it has been subjected to many criticisms, it is presented by metaphysicians as the most fundamental and most comprehensive of inquiries, inasmuch as it is concerned with reality as a whole.

This article is divided into the following sections:

I. Nature and scope of metaphysics
  Origin of the term
  Characterizations of metaphysics
  Metaphysics and other branches of philosophy
  Metaphysics and analysis
II. Problems in metaphysics
  The existence of Forms, categories, and particulars
  The existence of God
  The soul, mind, and body
  Nature and the external world
  Space and time
  The conception of spirit
III. Types of metaphysical theory
  Platonism
  Aristotelianism
  Thomism
  Cartesianism
  Idealism
  Materialism
IV. Argument, assertion, and method in metaphysics
  Metaphysics as a science
  Initial metaphysical insights
  Metaphysical arguments
V. Criticisms of metaphysics
  Metaphysics as knowledge of the supersensible
  Specific criticisms
VI. Tendencies in contemporary metaphysics
  Tendencies in the United States
  Tendencies in continental Europe
  The thought of Whitehead

I. Nature and scope of metaphysics

ORIGIN OF THE TERM

Etymologically, the term metaphysics is quite unenlightening. It means "what comes after physics"; it was the phrase used by early students of Aristotle to refer to the contents of Aristotle's treatise on what he himself called "first philosophy," and was used as the title of this treatise by Andronicus of Rhodes, one of the first of Aristotle's editors. Aristotle had distinguished two tasks for the theoretical philosopher: first, to investigate the nature and properties of what exists in the natural or sensible world, and second, to explore the characteristics of "Being as such" and to inquire into the character of "the substance that is free from movement," or the most real of all things, the intelligible reality on which everything in the world of nature was thought to be causally dependent. The first constituted "second philosophy" and was carried out primarily in the Aristotelian treatise now known as the *Physica;* the second, which Aristotle had also referred to as "theology" (because God was the unmoved mover in his system), is roughly the subject matter of his *Metaphysica.* Modern readers of Aristotle are inclined to take both the *Physica* and the *Metaphysica* as philosophical treatises; the distinction their titles suggest, between an empirical and a conceptual inquiry, has little real foundation. Aristotle was not indifferent to factual material either in natural or in metaphysical philosophy, but equally he was not concerned in either case to frame theories for empirical testing. It seems clear, nevertheless, that if the two works had to be distinguished, the *Physica* would have to be described as the more empirical, just because it deals with things that are objects of the senses, what Aristotle himself called "sensible substance"; the subject matter of the *Metaphysica,* "that which is eternal, free of movement, and separately existent," is on any account more remote. It is also evident that the connection marked in the original titles is a genuine one: the inquiries about nature carried out in the *Physica* lead on naturally to the more fundamental inquiries about Being as such that are taken up in the *Metaphysica* and indeed go along with the latter to make up a single philosophical discipline.

The background to Aristotle's divisions is to be found in the thought of Plato, with whom Aristotle had many disagreements but whose basic ideas provided a framework within which much of his own thinking was conducted. Plato, following the early Greek philosopher Parmenides, who is known as the father of metaphysics, had sought to distinguish opinion or belief from knowledge and to assign distinct objects to each. Opinion, for Plato, was a form of apprehension that was shifting and unclear, similar to seeing things in a dream or only through

their shadows; its objects were correspondingly unstable. Knowledge, by contrast, was wholly lucid; it carried its own guarantee against error, and the objects with which it was concerned were eternally what they were, and so were exempt from change and the deceptive power to appear to be what they were not. Plato called the objects of opinion phenomena or appearances; he referred to the objects of knowledge as noumena (objects of the intelligence) or quite simply as realities. Much of the burden of his philosophical message was to call men's attentions to these contrasts and to impress them with the necessity to turn away from concern with mere phenomena to the investigation of true reality. The education of the Platonic philosopher consisted precisely in effecting this transition: he was taught to recognize the contradictions involved in immediate appearances and to fix his gaze on the true realities that lay behind them, the realities that Plato himself called Forms or Ideas. Philosophy for Plato was thus a call to recognize the existence and overwhelming importance of a set of higher realities that ordinary men—even those, like the Sophists of the time, who professed to be enlightened—entirely ignored. That there were such realities, or at least that there was a serious case for thinking that there were, was a fundamental tenet in the discipline that later became known as metaphysics. Conversely, much of the subsequent controversy about the very possibility of metaphysics has turned on the acceptability of this tenet and on whether, if it is rejected, some alternative foundation can be discovered on which the metaphysician can take his stand.

Appearances and realities for Plato

CHARACTERIZATIONS OF METAPHYSICS

Before considering any such question, however, it is necessary to examine, without particular historical references, some ways in which actual metaphysicians have attempted to characterize their enterprise, noticing in each case the problems they have in drawing a clear line between their aims and those of the practitioners of the exact and empirical sciences. Four views will be briefly considered; they present metaphysics as: (1) an inquiry into what exists, or what really exists; (2) the science of reality, as opposed to appearance; (3) the study of the world as a whole; (4) a theory of first principles. Reflection on what is said under the different heads will quickly establish that they are not sharply separate from one another, and, indeed, individual metaphysical writers sometimes invoke more than one of these phrases when asked to say what metaphysics is—as, for example, the British Idealist F.H. Bradley does in the opening pages of his work *Appearance and Reality* (1893).

An inquiry into what exists. A common set of claims on behalf of metaphysics is that it is an inquiry into what exists; its business is to subject common opinion on this matter to critical scrutiny and in so doing to determine what is truly real.

Unreliability of common opinion

It can be asserted with some confidence that common opinion is certainly an unreliable guide about what exists, if indeed it can be induced to pronounce on this matter at all. Are dream objects real, in the way in which palpable realities such as chairs and trees are? Are numbers real, or should they be described as no more than abstractions? Is the height of a man a reality in the same sense in which he is a reality, or is it just an aspect of something more concrete, a mere quality that has derivative rather than substantial being and could not exist except as attributed to something else? It is easy enough to confuse the common man with questions like these and to show that any answers he gives to them tend to be ill thought out. It is equally difficult, however, for the metaphysician to come up with more satisfactory answers of his own. Many metaphysicians have relied, in this connection, on the internally related notions of substance, quality, and relation; they have argued that only what is substantial truly exists, although every substance has qualities and stands in relation to other substances. Thus, this tree is tall and deciduous and is precisely 50 yards north of that fence. Difficulties begin, however, as soon as examples like these are taken seriously. Assume for the moment that an individual tree—what might be called a concrete existent—qualifies for the title of substance; it is just the sort of thing that has qualities and stands in relations. Unless there were substances in this sense, no qualities could be real: the tallness of the tree would not exist unless the tree existed. The question can now be raised what the tree would be if it were deprived of all its qualities and stood in no relations. The notion of a substance in this type of metaphysics is that of a thing that exists by itself, apart from any attributes it may happen to possess; the difficulty with this notion is to know how to apply it. Any concrete thing one picks on to exemplify the notion of substance turns out in practice to answer a certain description; this means in effect that it cannot be spoken of apart from its attributes. It thus emerges that substances are no more primary beings than are qualities and relations; without the former one could not have the latter, but equally without the latter one could not have the former.

There are other difficulties about substance that cannot be explored now—*e.g.*, whether a fence is a substance or simply wood and metal shaped in a certain way. Enough has already been said, however, to indicate the problems involved in defining the tasks of metaphysics along these lines. Nevertheless, there is an alternative way of understanding the notion of substance: not as that which is the ultimate subject of predicates but as what persists through change. The question "What is ultimately real?" is, thus, a question about the ultimate stuff of which the universe is made up. Although this second conception of substance is both clearer and more readily applicable than its predecessor, the difficulty about it from the metaphysician's point of view is that it sets him in direct rivalry with the scientist. When the early Greek philosopher Thales inquired as to what is ultimately real and came up with the surprising news that all is water, he might be taken as advancing a scientific rather than a philosophical hypothesis. Although it is true that later writers, such as Gottfried Wilhelm Leibniz, a German Rationalist philosopher and mathematician, were fully aware of the force of scientific claims in this area and nevertheless rejected them as metaphysically unacceptable, the fact remains that the nonphilosopher finds it difficult to understand the basis on which a Leibniz rests his case. When Leibniz said that it is monads (*i.e.*, elementary, unextended, indivisible, spiritual substances that enter into composites) that are the true atoms of nature and not, for example, material particles, the objection can be raised as to what right he has to advance this opinion. Has he done any scientific work to justify him in setting scientific results aside with such confidence? And if he has not, why should he be taken seriously at all?

The ultimate stuff of the universe

The science of ultimate reality. To answer these questions, another description of metaphysics has been proposed: that it is the science that seeks to define what is ultimately real, as opposed to what is merely apparent.

The contrast between appearance and reality, however, is by no means peculiar to metaphysics. In everyday life, people distinguish between the real size of the sun and its apparent size, or again between the real colour of an object (when seen in standard conditions) and its apparent colour (nonstandard conditions). A cloud appears to consist of some white, fleecy substance, although in reality it is a concentration of drops of water. In general, men are often (though not invariably) inclined to allow that the scientist knows the real constitution of things as opposed to the surface aspects with which ordinary men are familiar. It will not suffice, therefore, to define metaphysics as knowledge of reality as opposed to appearance; scientists, too, claim to know reality as opposed to appearance, and there is a general tendency to concede their claim. It seems that there are at least three components in the metaphysical conception of reality. One characteristic, which has already been illustrated in Plato, is that reality is genuine as opposed to deceptive. The ultimate realities that the metaphysician seeks to know are precisely things as they are—simple and not variegated, exempt from change, and therefore stable objects of knowledge. Plato's own assumption of this position perhaps reflects certain confusions about the knowability of things that

Components in the metaphysical conception of reality

change; one should not, however, on that ground exclude this aspect of the concept from metaphysical thought in general. Ultimate reality, whatever else it is, is genuine as opposed to sham. Second, it is original in contrast to derivative, self-dependent rather than dependent on the existence of something else. When Aristotle sought to inquire into the most real of all things, or when medieval philosophers attempted to establish the characteristics of what they called the *ens realissimum* ("the most real being"), or the original and perfect being, they were looking for something that, in contrast to the everyday things of this world, was truly self-contained and could accordingly be looked upon as self-caused. Likewise, the 17th-century Rationalists defined substance as that which can be explained through itself alone. Writers like René Descartes and Benedict de Spinoza were convinced that it was the task of the metaphysician to seek for and characterize substance understood in this sense; the more mundane substances with which physical scientists were concerned were, in their opinion, only marginally relevant in this inquiry. Third, and perhaps most important, reality for the metaphysician is intelligible as opposed to opaque. Appearances are not only deceptive and derivative, they also make no sense when taken at their own level. To arrive at what is ultimately real is to produce an account of the facts that does them full justice. The assumption is, of course, that one cannot explain things satisfactorily if he remains within the world of common sense, or even if he advances from that world to embrace the concepts of science. One or the other of these levels of explanation may suffice to produce a sort of local sense that is enough for practical purposes or that forms an adequate basis on which to make predictions. Practical reliability of this kind, however, is very different from theoretical satisfaction; the task of the metaphysician is to challenge all assumptions and finally arrive at an account of the nature of things that is fully coherent and fully thought out.

The task of the metaphysician

It should be obvious that, to establish his right to pronounce on what is ultimately real in the sense analyzed, the metaphysican has a tremendous amount to do. He must begin by giving colour to his claim that everyday ways of thinking will not suffice for a full and coherent description of what falls within experience, thus arguing that appearances are unreal—although not therefore nonexistent—because they are unstable and unintelligible. This involves a challenge to the final acceptability of such well-worn ideas as time and space, thing and attribute, change and process—a challenge that metaphysicians have not hesitated to make, even though it has been treated with skepticism both by ordinary men and by some of their fellow philosophers (*e.g.*, G.E. Moore, a 20th-century British thinker who has greatly influenced modern Analytic philosophy). Second, granted that there are contradictions or incoherencies in the thought of common sense, the metaphysician must go on to maintain that they cannot be resolved by deserting common sense for science. He will not deny that the concepts of science are in many respects different from those of everyday thought; to take one aspect only, they are altogether more precise and sharply defined. They permit the scientist to introduce into his descriptions a theoretical content that is lacking at the everyday level, and in so doing to unify and render intelligible aspects of the world that seem opaque when considered singly. The metaphysician will argue, however, that this desirable result is purchased at a certain price: by ignoring certain appearances altogether. The scientist, in this way of thinking, does not so much offer a truer description of the phenomena of which ordinary thought could make no sense; he merely gives a connected description of a selected set of phenomena. The world of the scientist, restricted as it is to what can be dealt with in quantitative terms, is a poor thing in comparison with the rich if untidy world of everyday life. Alternatively, the metaphysician must try to show that scientific concepts are like the concepts of common sense in being ultimately incoherent. The premises or presuppositions that the scientist accepts contain unclarities that cannot be resolved, although they are not so serious as to prevent his achieving results that are practically dependable. Many ingenious arguments on these lines have been produced by philosophers, by no means all of whom could be said to be incapable of a true understanding of the theories they were criticizing. (Leibniz, for example, was a physicist of distinction as well as a mathematician of genius; G.W.F. Hegel, a 19th-century German Idealist, had an unusual knowledge of contemporary scientific work; and Alfred North Whitehead, a pioneer of 20th-century metaphysics in the Anglo-Saxon world, was a professor of applied mathematics, and his system developed from physics and contained a wealth of biological ideas.) The fact remains, nevertheless, that few if any practicing scientists have been seriously troubled by such arguments.

Even if the metaphysician were thus able to make good the negative side of his case, he would still face the formidable difficulty of establishing that there is something answering to his conception of what is ultimately real and of identifying it. The notion of an original being, totally self-contained and totally self-intelligible, may not itself be coherent, as the 18th-century British philosopher David Hume and others have argued; alternatively, there may be special difficulties in saying to what it applies. The fact that different metaphysicians have had widely different accounts of what is ultimately real is certainly suspicious. Some have wanted to say that there is a plurality of ultimately real things, others that there is only one; some have argued that what is truly real must be utterly transcendent of the things of this world and occupy a supersensible realm accessible only to the pure intellect, while others have thought of ultimate reality as immanent in experience (the Hegelian Absolute, for example, is not a special sort of existent, but the world as a whole understood in a certain way). That metaphysical inquiry should issue in definitive doctrine, as so many of those who engaged in it said that it would, is in these circumstances altogether too much to hope for.

The science of the world as a whole. Another way in which metaphysicians have sought to define their discipline is by saying that it has to do with the world as a whole.

The implications of this phrase are not immediately obvious. Clearly, a contrast is intended in the first place with the various departmental sciences, each of which selects a portion or aspect of reality for study and confines itself to that. No geologist or mathematician would claim that his study is absolutely comprehensive; each would concede that there are many aspects of the world that he leaves out, even though he covers everything that is relevant to his special point of view. By contrast, it might be supposed that the metaphysician is merely to coordinate the results of the special sciences. There is clearly a need for the coordination of scientific results in recent conditions in which scientific research has become increasingly specialized and departmentalized; individual scientific workers need to be made aware of what is going on in other fields, sometimes because these fields impinge on their own, sometimes because results obtained there have wider implications of which they need to take account. One can scarcely see metaphysicians, however, or indeed philosophers generally, performing this function of intellectual contact man in a satisfactory fashion. It might then be supposed that their concern with the world as a whole is to be interpreted as a summing up and synthesizing of the results of the particular sciences. Plato spoke of the philosopher as taking a "synoptic" view, and there is often talk about the need to see things in the round and avoid the narrowness of the average specialist, who, it is said, knows more and more about less and less. If, however, it is a question of looking at scientific results from a wider point of view and so of producing what might be called a scientific picture of the world, the person best qualified for the job is not any philosopher but rather a scientist of large mind and wide interests. Metaphysics cannot be satisfactorily understood as an account of the world as a whole if that description suggests that the metaphysician is a sort of superscientist, unlimited in his curiosity and gifted with a capacity for putting together other people's findings with a skill and imagina-

tion that none of them individually commands. Only a scientist could hope to become such a superscientist.

Metaphysics as an account of the world

More hope for the metaphysician can be found, perhaps, along the following lines. People want to know not only what the scientist makes of the world but also what significance to assign to his account. People experience the world at different levels and in different capacities: they are not only investigators but also agents; they have a moral and a legal, an aesthetic and a religious life on top of their scientific life. Man is a many-sided being; he needs to understand the universe in the light of his different activities and experiences. There are philosophers who appear to find no mystery here; they argue that there can be no question of the possibility of, say, a moral or a religious vision of the world that rivals the scientific vision. In this view, morals and religion are matters of practice, not of theory; they do not rival science, but only complement it. This neutralist attitude, however, finds little general favour; for most thinking people there is a question of choosing whether to go all the way with science, at the cost of abandoning religion and even morals, or to stick to a religious or moral world outlook even if it means treating scientific claims with some reserve. The practice of the moral life is often believed to proceed on assumptions that can hardly be accepted if science is taken to have the last word about what is true. Accordingly, it becomes necessary to produce some rational assessment of the truth claims of the different forms of experience, to try to think out a scheme in which justice is done to them all. Many familiar systems of metaphysics profess to do just that; among others there are Materialism, which favours the claims of science, Idealism, which sees deeper truth in religion and the moral life, and the peculiar dualism of the 18th-century German philosopher Immanuel Kant, which holds that science gives the truth about phenomena, while reserving a noumenal, or supersensible, sphere for moral agency.

This conception of metaphysics as offering an account of the world or, as is more often said, of experience as a whole accords more obviously with the practice of those who see ultimate reality as immanent, or inherent in what is immediately known, than of those who take it to be transcendent, or beyond the limits of ordinary experience. It is possible, in fact, to subscribe to the legitimacy of metaphysics as so understood without postulating the existence of any special entities known only to the metaphysician—a claim that plain men have often taken to connect metaphysics with the occult. This is not to say, of course, that metaphysical problems admit of easy solutions when understood along these lines. There is a variety of widely different ways of taking the world as a whole: each depends on which aspect or aspects of experience the individual metaphysician finds especially significant; each claims to be comprehensive and to confute the claims of its rivals, yet none has succeeded in establishing itself as the obviously correct account. Even systems that are widely condemned as impossible, such as Materialism, turn out in practice to command constantly renewed support, as new discoveries in the sciences suggest new ways of dealing with old difficulties. A cynic might take such facts as meaning that people subscribe to theories of this sort more as a matter of emotional than of rational conviction; metaphysics, as Bradley remarked with surprising frankness, consists in the finding of bad reasons for what one believes upon instinct.

The science of first principles. Another phrase used by Bradley in his preliminary discussion of metaphysics is "the study of first principles," or ultimate, irrefutable truths.

First principles as basic truths

Metaphysics could be said to provide a theory of first principles if it furnished men with a set of concepts in the light of which they could arrive at the connected account of experience as a whole just spoken of, and the two descriptions of the subject would thus be two sides of a single coin. The idea that metaphysics has to do with first principles, however, has wider implications.

The term first principles is a translation of the Greek word *archai*. An *archē* is something from which an argument proceeds—either a primary premise or an ultimate presupposition. Plato, in a famous passage in *The Republic*, contrasted two different attitudes to *archai:* that of the mathematician, who lays down or hypothesizes certain things as being true and then proceeds to deduce their consequences without examining them further; and that of the dialectician, who proceeds backward, not forward, from his primary premises and seeks to ground them in an *archē* that is not hypothesized at all. Unfortunately, no concrete details exist of the way in which Plato himself thought this program could be carried out; he spoke of it only in the most general terms. Nevertheless, the suggestion that metaphysics is superior to any other intellectual discipline in having a fully critical attitude toward its first principles is one that continues to be made, and it needs some examination.

As regards mathematics, for example, it might be said that mathematicians could be uncritical about the first principles of their science in the following ways: (1) They might take as self-evidently true or universally applicable some axiom or primary premise that turned out later not to possess this property. (2) They might assume among their first principles certain propositions about existence—to the effect that only certain kinds of things could be proper objects of mathematical inquiry (rational as opposed to irrational numbers, for example)—and time might show that the assumption was inappropriate. The remedy for both sorts of error, however, is to be found within mathematics itself; the development of the discipline has consisted precisely in eliminating mistakes of this kind. It is not clear even that the discovery and removal of antinomies in the foundations of mathematics is work for the metaphysician, although philosophically minded persons like Gottlob Frege, a German mathematician and logician, and Bertrand Russell, perhaps the best known English philosopher of the 20th century, have been much concerned with them. The situation is not fundamentally different when the empirical sciences are considered. Admittedly, the exponents of these sciences give more hostages to fortune insofar as they have to assume from the first the general correctness of the results of other disciplines; there can be no question of their checking on these for themselves. Mathematicians, too, assume the validity of common argument forms without making any serious attempt to validate them, and there is nothing seriously wrong with their doing so. If confidence in bad logic has sometimes been responsible for holding up mathematical advance, bolder mathematicians have always known in practice that the right thing to do is let the argument take them where it will on strictly mathematical lines, leaving it to logicians to recognize the fact and adjust their theory at leisure.

It thus seems that the assertion that a special science like mathematics is uncritical about its *archai* is false; there is a sense in which mathematicians are constantly strengthening their basic premises. As regards the corresponding claim about metaphysics, it has at one time or another been widely believed (1) that it is the business of metaphysics to justify the ultimate assumptions of the sciences, and (2) that in metaphysics alone there are no unjustified assumptions. Concerning (1), the question that needs to be asked is how the justification is supposed to take place. It has been argued that the metaphysician might, on one interpretation of his function, be said to offer some defense of science generally by placing it in relation to other forms of experience. To do this, however, is not to justify any particular scientific assumptions. In point of fact, particular scientific assumptions get their justification, if anywhere, when a move is made from a narrower to a more comprehensive science; what is assumed in, for example, geology may be proved in physics. But this, of course, has nothing to do with metaphysics. The difficulty with (2) is that of knowing how any intellectual activity, however carefully conducted, could be free of basic assumptions. Some metaphysicians (such as Bradley and his Scottish predecessor J.F. Ferrier) have claimed that there is a difference between their discipline and others insofar as metaphysical propositions alone are self-reinstating. For example, the Cartesian proposition *Cogito,*

Metaphysicians as self-critical

ergo sum ("I think, therefore I am") is self-reinstating: deny that you think, and in so doing you think; deny that you exist, and the very fact gives proof of your existence. Even if it could be made out that propositions of this kind are peculiar to metaphysics, however, it would not follow that everything in metaphysics has this character. The truth is, rather, that no paradox is involved in denying most fundamental metaphysical claims, such as the assertion of the Materialist that there is nothing that cannot be satisfactorily explained in material terms, or the corresponding principle of Aristotle that there is nothing that does not serve some purpose.

The view that metaphysics, or indeed philosophy generally, is uniquely self-critical is among the myths of modern thought. Philosophers rely on the results of other disciplines just as other people do; they do not pause to demonstrate the legitimacy of the principles of simple arithmetic before entering on calculations in the course of their work, nor do they refrain from employing the *reductio ad absurdum* type of refutation (*i.e.*, showing an absurdity to which a proposition leads when carried to its logical conclusion) until they have assured themselves that this is a valid way of confuting an opponent. Even in their own field they tend, like painters, to work within traditions set by great masters rather than to think everything out from scratch for themselves. That philosophy in practice is not the fully self-critical activity its exponents claim it to be is shown nowhere more clearly than in the reception that philosophers give to theories that are unfashionable; they more often subject them to conventional abuse than to patient critical examination. Nevertheless, it is from the conviction that philosophy, and especially metaphysical philosophy, operates without unjustified assumptions that current claims about the superiority of this branch of thinking derive their force. This conviction connects with the views already mentioned, that metaphysics is the science of first principles, and that the principles in question are ineluctable, in the sense that they are involved in their own denial.

METAPHYSICS AND OTHER BRANCHES OF PHILOSOPHY

The view of metaphysics as the queen of the sciences

It may be useful at this point to consider the question of the relations of metaphysics to other parts of philosophy. A strong tradition, derided by Kant, asserted that metaphysics was the queen of the sciences, including the philosophical sciences. The idea presumably was that those who worked within fields such as logic and ethics, as well as physicists and biologists, proceeded on assumptions that in the last resort had to be approved or corrected by the metaphysician. Logic could be conceived as a special study complete in itself only if the logician were allowed to postulate a correspondence between the neat and tidy world of propositions, which was the immediate object of his study, and the world existing in fact; metaphysics might and sometimes did challenge the propriety of this postulate. Similarly, ethics, like law, could get nowhere without the assumption that the individual agent is a self-contained unit answerable in general terms for what he does; metaphysics had the duty of subjecting this assumption to critical examination. As a result of such claims it was widely believed that any results obtained by logicians or ethicists must at best be treated as provisional; followers of Hegel, who advanced these claims with passionate conviction, were inclined in consequence to regard logic and ethics alike as minor branches of philosophy. It has been a feature of 20th-century philosophical thought, especially in Britain and the United States, to dispute these Hegelian contentions and argue for the autonomy of ethics and logic; that is, for their independence of metaphysics. Thus, formal logicians of the school of Frege and Russell were apt to claim that the principles of logic applied unequivocally to all thinking whatsoever; there could be no question of their having to await confirmation, still less correction, from the metaphysician. If metaphysical arguments suggested that fundamental laws of logic such as the principle of noncontradiction—that a statement and its contradictory cannot both be true—might not be in order, the only conclusion to draw was that such arguments must be confused: without observation of the laws of logic there could be no coherent thinking of any sort.

Similarly, G.E. Moore, in a celebrated section of his *Principia Ethica* (1903), tried to show that statements like "This is good" are *sui generis* and cannot be reduced to statements of either natural or metaphysical fact; the Idealist belief that ethics ultimately depends on metaphysics rested on a delusion. Moore perhaps failed to see the force of the Idealist challenge to the individualist assumptions on which much ethical thinking proceeds, and he did not note that, in one respect at least, ethical results can be dependent on those of metaphysics: if metaphysics shows that the world is other than it is initially taken to be, conclusions about what to do must be altered accordingly. Again, the reaction among logicians to Hegelian attempts to merge logic into metaphysics certainly went too far. There is a genuine philosophical problem about the relation between the world of logic and the world of fact, and it cannot be solved by simply repeating that logic is an autonomous discipline whose principles deserve respect in themselves. None of this, however, shows that metaphysics is the fundamental philosophical discipline, the branch of philosophy that has the last word about what goes on in all other parts of the subject.

METAPHYSICS AND ANALYSIS

Modern British and American philosophers commonly describe themselves as engaged in philosophical analysis, as opposed to metaphysics. The interests of a metaphysician, according to this view, are predominantly speculative; he wants to reveal hitherto unknown facts about the world and on that basis to construct a theory about the world as a whole. In so doing he is necessarily engaged in activities that rival those of the scientist, with the important difference that scientific theories can be brought to the test of experience, whereas metaphysical theories cannot. Eschewing this conception of philosophy as impossible, the critic of metaphysics believes that philosophy should confine itself to the analysis of concepts, which is a strictly second-order activity independent of science and which need involve no metaphysical commitment.

Analysis in philosophy

The notion of analysis in philosophy is far from clear. Analysis on any account is meant to result in clarification, but it is not evident how this result is to be achieved. For some, analysis involves the substitution for the concept under examination of some other concept that is recognizably like it (as Gilbert Ryle, an English Analyst, elucidated the concept of mind by replacing it with the notion of "a person behaving"); for others, analysis involves the substitution of synonym for synonym. If the latter understanding of analysis is required, as in Moore's classic example of the analysis of brother as male sibling, not much enlightenment is likely to ensue. If, however, the philosopher is permitted to engage in what is sometimes pejoratively described as "reductive analysis," he will produce interest at the cost of reintroducing speculation. Ryle's *Concept of Mind* (1949) is a challenging book just because it advances a thesis of real metaphysical importance—that one can say everything one needs to say about minds without postulating mental substance.

A further aspect of the situation that deserves mention is this. If it is the case, as is often claimed, that analysis can be practiced properly only when the analyst has no metaphysical presuppositions, by what means does he select concepts for analysis? Would it not be appropriate for him, in these circumstances, to take any concept of reasonable generality as a suitable subject on which to practice his art? It turns out, in fact, however, that the range of concepts commonly recognized as philosophical is more limited than that, and that those concepts to which Analytic philosophers give their attention are chosen because of their wider philosophical bearings. Thus, recent philosophers have paid particular attention to the concept of knowledge not just because it is a notion whose analysis has long proved difficult but also because on one account at least it involves an immediately experienced mental act—something that many Analysts would like to proscribe as mythical. Similarly, the celebrated analysis of the idea of causality put forward by David Hume was

not undertaken out of idle curiosity but with a wider purpose in mind: to undermine both the Aristotelian and the Cartesian views of the world and to substitute for them an atomism of immediate appearances in which all objects were "loose and separate"—that is, logically independent one of another. The insight into the constitution of nature promised in different ways by Aristotle and Descartes was an illusion, the truth being that scientific advance serves only to "stave off our ignorance a little." What Hume said about causation connects internally with his views about what exists. Despite his polemic against books of "divinity and school metaphysics," he had a metaphysics of his own to recommend.

Historical use of analysis by metaphysicians

The truth is that metaphysics and analysis are not separate in the way modern Analytic philosophers pretend. The speculative philosophers of the past were certainly not averse to analysis: witness the splendid discussion of the concept of knowledge in Plato's *Theaetetus*, or, for a more recent example, Bradley's account of the meanings of "self." The legend that a metaphysical philosopher has his eye so firmly set on higher things that he is entirely careless of the conceptual structure he seeks to recommend is absolutely without foundation. A metaphysical philosopher is a philosopher after all: argument and the passion for clarification are in his blood. Although some contemporary philosophers profess to undertake analysis entirely for its own sake and without explicit metaphysical motivation, it may be doubted if their claim is capable of being sustained. The "logical analysis" practiced by Russell in the early part of the 20th century was not metaphysically neutral, nor was the analysis of the Logical Positivists, who recommended a strongly scientific view of the world. Some current analytic work is motivated less by the desire to forward an overall theory than by a wish to destroy a prevailing or previously held theory that is considered objectionable. To seek to overthrow a metaphysical theory, however, is itself to engage in metaphysics—not very interesting metaphysics, perhaps, but metaphysics all the same.

It may be added, as a historical note, that the Rationalist philosophers of the 17th and 18th centuries, who emphasized the predominant role of reason in the construction of a system of knowledge, believed that the philosopher's task fell into two parts. He must first break down complex concepts into their simple parts; this was a matter of analysis. Then he must proceed to show how knowledge of these simples would serve to explain the detailed constitution of things; this would involve synthesis. That there are deep obscurities in this program—*e.g.*, whether it is a matter of analyzing concepts or getting down to the simplest elements of things—is less important in the present context than that analysis and synthesis were thus taken to be complementary. The classical statement of this point of view is to be found in Descartes's *Discours de la méthode* (1637; *Discourse on Method*, 1950), with the corresponding passages in the *Regulae ad Directionem Ingenii* (published posthumously 1701; *Rules for the Direction of the Mind*, 1961). That the idea persisted well into the 18th century is evidenced by the remarks made by Kant in his essay *Untersuchung über die Deutlichkeit der Grundsätze der natürlichen Theologie und der Moral* (1764; *Inquiry into the Distinctness of the Principles of Natural Theology and Morals*, 1949), in which he said that metaphysics was not yet in a position to pass beyond the stage of analysis to that of synthesis. He did not mean that for the time being philosophy must remain entirely nonmetaphysical, in the way some moderns suppose it can, but rather that it needs to go on elaborating a conceptual scheme, which, however, cannot be used constructively until it is complete. Actually, Kant belied his own professions at the time, insofar as he thought himself in possession of a definitive proof of God's existence, which he explained in his essay *Der einzig mögliche Beweisgrund zu einer Demonstration des Daseyns Gottes* (1763; "The Only Possible Ground for a Demonstration of the Existence of God"). This, however, only illustrates the not very surprising fact that philosophers are often less clear about the nature of their own activities than they think.

II. Problems in metaphysics

To give a comprehensive account of the main problems of metaphysics in the space of a few pages is clearly quite impossible. What follows is necessarily highly selective and to that extent misleading; nevertheless, it attempts to offer an introduction to metaphysical thinking itself, rather than reflection on the history of metaphysics.

THE EXISTENCE OF FORMS, CATEGORIES, AND PARTICULARS

Forms. The early Greek philosophers asked the question *ti to on*, "What is existent?" or "What is really there?" They originally interpreted this as a question about the stuff out of which things were ultimately made, but a new twist was given to the inquiry when Pythagoras, in the late 6th century BC, arrived at the answer that what was really there was number. Pythagoras conceived what is there in terms not of matter but of intelligible structure; it was the latter that gave each type of thing its distinctive character and made it what it was. The idea that structure could be understood in numerical terms was probably suggested to Pythagoras by his discovery that there are exact correlations between the lengths of the strings of a lyre and the notes they produce. By a bold extrapolation he seems to have surmised that what held in this case must hold in all cases.

Platonic theory

The Pythagorean theory that what is really there is number is the direct ancestor of the Platonic theory that what is really there is Forms or Ideas (*eidē*, or *ideai*). Plato's Forms were also intelligible structures and not material elements, but they differed from Pythagorean numbers by being conceived of as separately existent. There was, as Plato put it, a "place accessible to the intelligence," which was the place or realm of Forms. Each Form was a genuine existent, in the sense of being precisely what it pretended to be; the Form of Beauty, for example, was beautiful through and through. By contrast, the many particular things that partook of or resembled what was truly beautiful were one and all defective. However beautiful any one of them might be, it was also in another respect lacking in beauty. It turned out to possess contradictory characteristics, and as such could never be identified with true reality.

Plato had taken over from his predecessor Heracleitus, who flourished at about the beginning of the 5th century BC, the doctrine that the world of sensible things is a world of things in constant flux; as he put it in the *Theaetetus*, nothing *is* in this world because everything is in a state of becoming something else. Forms were needed to provide stable objects for knowledge as well as to answer the question of what is ultimately real. Although Plato played down the reality of sensible things, making them mere objects of opinion and describing them as falling between what is and what is not, he did not deny their existence. It was not his thesis that Forms alone exist. On the contrary, he appears to have held that God (who was certainly not a Form) had somehow fashioned the physical world on the model of the Forms, using space as his material. This is the description that is given in the *Timaeus*, in a passage that Plato perhaps meant his readers not to take quite literally but that stated his view as plainly as he thought it could be stated. In this passage God appears in the guise of the "Demiurge," although he is referred to freely in other Platonic dialogues. Souls were also distinct from Forms in Plato.

In the discussions that developed around the theory of Forms, many difficulties were revealed, most of them familiar to Plato himself. The question of how the one Form was supposed to relate to the many particulars that participated in or resembled it was nowhere satisfactorily answered. The difficulty turned on how the Form was to be thought of at once as an existent and as a structure. Plato seemed on occasion to think of it as a structure hypostatized, or given real existence. This thesis led to the antinomies exposed in the "third man" argument. According to this theory, particular men were alleged to be human because of their relationship to "Man himself"; *i.e.*, the Form of man. But whence did the latter derive its nature? Must there not be a second Form, to explain what the first Form and its particulars have in common,

and will not this generate an infinite regress? Again, the problem of the precise population of the world of Forms never got a definitive solution, perhaps because the theory of Forms was put to more than one purpose. Sometimes it was said that there is a Form answering to every general word, but elsewhere the theory was that what is merely negative (*e.g.*, being lifeless) has no need of a special Form, nor does what is manufactured. There is even a question as to whether trivial everyday things such as mud and hair and dirt have Forms, though it is agreed that there is a Form of man.

The problems just referred to were stated trenchantly in Plato's dialogue the *Parmenides*; the discussion there ends with the statement that the Forms must be retained if an account of intelligible discourse is to be given, but no indication is offered as to how the theory is to be refurbished. Some Platonic scholars have inferred that Plato virtually gave it up, but such evidence as there is suggests that he only transformed it into a theory of Form-numbers, more openly Pythagorean than the earlier version. There are many references in Aristotle to this theory of Form-numbers, but no writing of Plato's own on the subject has survived, and it is virtually impossible at this late stage to say what this theory really comprised.

One further feature of the theory of Forms must be mentioned here: the view that there is a supremely important Form, the Form of goodness, or of the Good, which somehow determines the contents of the world of Forms and brings order into it. In a celebrated but brief and tantalizing passage in *The Republic*, the Form of the Good is spoken of as being to the intelligible realm what the sun is to the visible realm; just as the sun makes living things grow and renders them visible, so the Good is responsible for the existence and intelligibility of Forms, though it is itself "on the other side of Being." This passage had a tremendous historical influence on the Neoplatonists, who saw it as anticipating the ultimate ineffable reality—the One, from which everything describable was in some way an emanation—in which they came to believe. It seems possible, however, that Plato had no such mystical thoughts in mind, but simply wanted to say that the world of Forms is ordered through and through, everything in it being there for a purpose. The Form of Good is, in fact, the counterpart of the *Nous* (Mind) of Anaxagoras, another of Plato's predecessors, which was supposed to arrange everything for the best.

Aristotelian doctrine

Categories and universals. The most famous critic of Plato's theory of Forms was Aristotle, who devised his doctrine of categories largely to counter it. According to this doctrine, "being is spoken of in many ways": one can say that there are such things as individual horses, but one can also say that there is such a thing as being a horse, or as being upside down. Expressions can be classified under various heads: predicates signify substances (*e.g.*, "man" or "horse"), qualities (*e.g.*, "white"), relations (*e.g.*, "greater"), quantities (*e.g.*, "three yards long"), time (*e.g.*, "last year"), and so on—sometimes Aristotle listed ten categories, sometimes only eight. The kind of being that any predicate possesses, however, is derivative in comparison with the being of an individual substance, a particular man or a particular horse. It is such things that exist in the primary sense, and it is upon their existence that the existence of other types of being depends. Or, to put the point in not quite Aristotelian terms, primary substances are the only concrete existents; Socrates, the bearer of a proper name, exists in a way in which humanity or whiteness or being greater do not. The latter are really no more than abstractions, and nothing but confusion can arise from neglecting that fact.

Mention has already been made of the difficulties into which this doctrine led when it came to describing primary substances; it appeared that these entities could not be characterized but only named or pointed to, a conclusion accepted much later by Ludwig Wittgenstein, a 20th-century philosopher, in his *Tractatus Logico-Philosophicus* and by Russell in his lectures on logical atomism. These difficulties, however, were not seen at the time the theory was promulgated, and it is more important now to emphasize the fact that it undermined any doctrine of the Platonic type. To argue that Forms, or numbers, alone are real is to argue for the reality of abstractions; to put the point succinctly, beauty exists only so long as something is beautiful, and that something must be a concrete individual. Or if this is not quite true (for, after all, it could be said that there is such a thing as having a million sides even if nothing in fact has a million sides), concrete existence must precede abstract existence in some cases at least: the "*X*" in "*X* is red" must sometimes be replaceable by an actual rather than a merely possible entity.

The problem of universals

A prominent subject of philosophical discussion in the Middle Ages was what came to be known as the problem of universals, which concerned the ontological status, or type of existence, to be assigned to the referents of general words. One of Plato's critics had said, "I see particular horses, but not horseness"; and Plato had answered, "That is because you have eyes but no intelligence." There can be no doubt that Plato thought that horseness, the Form of horse or Horse itself, to use his own expression, was something that existed separately; it could be discerned not by the bodily eyes but by the eye of the soul. The view that besides individual horses there also exists the Form of horse was known in the Middle Ages as Realism. Aristotle was also alleged to be a Realist, because he too thought that Forms were really there, although only as embodied in particular instances. More skeptical philosophers denied the reality of universals altogether, some identifying them with thoughts (conceptualists), others with mere names (nominalists).

The dispute about universals was in fact very confused. At least two quite separate issues were involved. First of all, there was the question about the status to be assigned to whatever it was that predicates referred to; this question seemed urgent just because, for example, geometricians were able to discuss the properties of the triangle or the circle. What and where were the triangle and the circle? In fact, the Aristotelian doctrine of categories had already indicated that the being of any predicate was necessarily different from that of primary substances; the circle did not and could not exist as this man or this horse did. When Aristotle is described as a Realist in the dispute about universals, the description is very misleading. In one sense he did not believe that universals are real at all; in another sense, however, he did, and this is where the second issue arose. Some people who denied the reality of universals wanted to say that all classification is artificial; the descriptions men give of things depend upon their interests as much as upon what is really there. Aristotle, by contrast, believed in a doctrine of natural kinds; he thought that every particular horse embodied the form or objective essence of horse, which was accordingly a genuine, if abstract, constituent of the world. The question of the extent to which classification is artificial is clearly quite different from that of the status of universals; it remains to be solved even if the latter problem is dismissed, as it is by modern philosophers who say that only proper names and individuating phrases have referents; general words do not. These differences, however, were not clearly seen either in the Middle Ages or during the 17th century, when the whole question was discussed at length by philosophers like Thomas Hobbes and John Locke. (For the problem of natural versus artificial classification, see CLASSIFICATION THEORY.)

Basic particulars. In discussions of the problem of universals it was often claimed, especially by nominalists, that only particulars exist. The notion of a particular is in many respects unclear. Strictly, the terms particular and universal are correlatives; a particular is an instance of universal (*e.g.*, this pain, that noise). It would seem from this that particulars and individuals should be the same, but there are writers who distinguish them. Bradley, in his *Principles of Logic* (1883), treated particulars as mere momentary instantiations of universals and contrasted them with individuals as continuants possessing internal diversity. An individual cannot merely be identified but re-identified; because it lasts through time,

it may possess incompatible attributes at different periods of its history. A particular, however, is nothing but an instantiation of an attribute and as such must possess that attribute if it is to be anything. Similarly, a particular can be met with once, but not again; as time moves on, it passes out of existence and is replaced by another particular that may resemble it but is not literally identical with it.

If particulars and individuals are thus distinguished, it is by no means clear that only particulars exist, or indeed that they exist at all; it could be that they are no more than abstract aspects of genuinely concrete entities such as persons or material things. But there are arguments on the other side, advanced in a variety of forms by David Hume and Bertrand Russell. Hume believed that the ultimate constituents of the world were either impressions or their fainter copies, ideas; both were species of perceptions. Impressions he defined as "internal and perishing existences"; they were of various kinds, embracing feelings as well as such things as experienced colours and smells, but all were at best extremely short-lived. Impressions arose in human consciousness from unknown causes; their existence could not, however, be denied. By contrast, the existence of continuing and independent material objects and of continuing minds was extremely precarious; analysis showed both to be no more than bundles of perceptions, united by certain relations, and Hume more than once referred to them as "fictions," although it turned out on examination that they were not fictions in the way ghosts are. Hume's reasons for advancing these views were primarily epistemological; he thought that statements about continuants were all open to doubt, although statements about the contents of immediate experience could not be challenged. When it was a question of what really existed, the only sure answer was items in consciousness—namely, impressions and ideas.

Hume's theory of particulars

Russell, who was generally sympathetic to this answer, added another argument derived from logic: proper names, he said, were names of particulars, which must accordingly exist. Ordinary proper names (such as "Socrates") had other functions than to denote, but logically proper names ("this" was Russell's example) served simply to pick out objects of immediate acquaintance. Russell was apparently unabashed by the consequence that such objects would be both private to the experience of particular persons and of very brief duration; he thought his doctrine of "logical constructions," which allowed for "inferred entities" on the basis of what is immediately certain, would provide the publicity and continuity necessary to do justice to actual experience. These assumptions, however, have met with serious criticism. P.F. Strawson, a British philosopher whose thought centres on the analysis of the structure of ordinary language, especially in his *Individuals: An Essay in Descriptive Metaphysics* (1959), not only attacked Russell's account of proper names but argued that experience demands a framework of basic particulars that are not Russell's momentary private objects but continuing public existents—in fact, individuals in the terminology explained above. If experience consisted of nothing but sounds, the minimum prerequisite of intelligibility would be that there should be a continuing master sound, an analogue in this medium of continuing material substance in the material order. Without such basic particulars as continuing material things, identification and reidentification would be impossible. Strawson conceded that persons as well as things were genuine continuants, but maintained all the same that the hypothesis that reality might consist of nothing but minds was quite untenable. Minds are no more than aspects of persons, and persons have bodies as well as minds. Strawson agreed that disembodied existence was logically possible, but added that such existence would make no sense except as a survival of embodied existence in a common public world.

Russell's theory of particulars

If this is correct, what exists cannot consist, as Hume supposed, of momentary items but must rather take the form of substances in the Aristotelian sense. These act as basic particulars in the actual intellectual scheme men adopt. Strawson, however, was not content merely to assert this fact; he wanted to argue that things must be like this if reference and description in their familiar form are to be possible at all. His main theory, which plainly owes a debt to Kant as well as to Wittgenstein, was worked out with primary reference to the physical world. It would be interesting to know if an examination of social reality would yield comparable results: whether individual persons or something larger—continuing societies or institutions—should be taken as basic particulars in that sphere. Many philosophers assert dogmatically that a society is nothing but an aggregate of its individual members. Nevertheless, men are members of society in virtue of their performance of a number of social roles, and role itself is a concept that makes sense only if the notion of society is presupposed. In one sense, a society is nothing apart from its members; remove them, and it would disappear. Equally, however, the members themselves are what they are because of their various roles; it is arguable that they would be nothing apart from their social relations. Hence, the force of Bradley's remark is evident, namely, that "the 'individual' apart from the community is not anything real."

It remains to add here that a number of philosophers have tried to argue that the basic items in reality should be described not as substances but in some other terms. Russell at one stage in his career spoke of the world as consisting of events; his former colleague A.N. Whitehead made the notion of process central in his metaphysics. Developments in modern physics undoubtedly lend a certain plausibility to these and similar views. Yet it remains difficult to understand what an event could be in which nothing was concerned, or how there could be a process in which nothing was in process. Event and process, in fact, are expressions that belong to derivative categories in the general Aristotelian scheme; like all other categories, they depend on the category of substance. If the latter is removed, as these metaphysicians propose to remove it, it is hard to know what is left.

THE EXISTENCE OF GOD

Perhaps the most celebrated issue in classical metaphysics concerned the existence of God. God in this connection is the name of "the perfect Being" or "the most real of all things"; the question is whether it is necessary to recognize the existence of such a being as well as of things that either are or might be objects of everyday experience. A number of famous arguments have been advanced from the time of the Greeks in favour of the thesis that such a recognition is necessary. The neatest and most ingenious was the a priori argument of St. Anselm in the 11th century, who said that "that than which nothing greater can be conceived" must exist in fact as well as in thought, for if it existed only in thought and not in fact, something greater than it could be conceived, namely the same thing existing in fact. God necessarily exists, because the idea of God is the idea of that than which nothing greater can be conceived. This is the argument later known as the ontological proof. Relatively few philosophical theologians, either in the Middle Ages or later, could bring themselves to accept this bold piece of reasoning (although Descartes, Spinoza, Leibniz, and Hegel all accepted it in principle); most preferred to ground their case for God's existence on premises that claimed to be empirical. Thus, St. Thomas Aquinas, perhaps the most influential Scholastic philosopher, in the 13th century argued that to explain the fact of motion in the world, the existence of a prime mover must be presupposed; that to account for contingent or dependent being the existence of something that is necessary or self-contained must be presumed; that to see why the world is orderly and why the different things in it fit together harmoniously, a situation that might not have obtained, a Creator who fashioned it on these lines must be postulated—adding in each case "and this all men call 'God'." These are versions of the first cause argument and the argument from design, which were to figure prominently in the thinking of later theistically inclined metaphysicians.

Proofs of the existence of God

The first cause argument should, perhaps, be examined

in somewhat greater detail, because it both has an immediate plausibility and lies at the basis of many different kinds of metaphysical systems (that of Hegel, for example, as well as that of Aquinas). The argument begins with the innocent-looking statement that something contingent exists; it may be some particular thing, such as oneself, or it may be the world in general (thus, the description of the proof as being *a contingentia mundi*, or "from the contingency of the world"). In describing oneself or the world as contingent, one means only that the thing in question does not exist through itself alone; it owes its being to the activity of some other thing, as a person owes his being to his parents. Contingent things are not self-complete; they each demand the existence of something else if they are to be explained. Thus, the move is made from contingent to necessary being; it is felt that contingent things, of whatever order, cannot be endlessly dependent on other contingent things but must presuppose a first cause that is self-complete and so exists necessarily. In Hegel the necessary being is not a separate existent but, as it were, an order of things; the loose facts of everyday life and even of science are said to point to a system that is all-embracing and in which everything is necessarily what it is. The principle of the argument, however, is unchanged despite the change in the conclusion.

Criticisms of proofs

Damaging criticism was brought against all the traditional arguments for God's existence by Hume and Kant in the 18th century. The ontological proof was undermined by the contention that "being is not a real predicate"; existence is not part of the concept of God in the way in which, for example, being all-powerful is. To say that something exists is not to specify a concept further but to claim that it has an instance; it cannot be discovered whether a concept has an instance by merely inspecting it. The first cause argument, it was contended, suffers from two fatal weaknesses. Even if it is correct in its assertion that contingent being presupposes necessary being, it cannot identify the necessary being in question with God (as happened in each of the Thomistic proofs) without resurrecting the ontological argument. If it is true, as supporters of the causal proof suppose, that God alone can answer the description of a necessary being, then whatever exists necessarily is God and whatever is God exists necessarily. Modern supporters of the causal proof have tried to meet this objection by saying that the equivalence is one of concepts, not of concept and existent; the existence of a necessary being is already established in the first part of the argument, and the equivalence in the second part of the argument is between the concept of necessary being and the concept of God. In other words, they distinguish between existence and essence. In the first part of the argument, the existence of a necessary being is proved; in the second part of the argument, the essence of that necessary being is identified with what men call God. Beyond this first contended weakness, however, there are grave difficulties in the move from contingent to necessary existence. Things in the experienced world are causally related, and some account of this relationship can be given in terms of the temporal relations of events; causal relations hold primarily between kinds of events, and a cause is, at least, a regular antecedent of a specific kind of effect. But when an attempt is made to extend the notion of causality from a relationship that holds within experience to one that connects the experienced world as a whole to something that falls wholly outside it, there is no longer anything firm on which to hold. The activities of God cannot precede happenings in the world because God is, by definition, not in time; and how the relationship is to be understood in these circumstances becomes highly problematic. Some metaphysicians, like some recent theologians, seek to evade the difficulty by saying that God is not the cause of the world but its ground, or again by distinguishing causes of becoming, which are temporal, from a cause of being, which is not. It is doubtful whether these moves do more than restate the problem in different terms.

The argument from design is itself a form of causal argument and accordingly suffers from all the difficulties mentioned above, together with some of its own, as Hume and Kant both point out. Even on its own terms, it is wrong to conclude the existence of a Creator rather than an architect. Furthermore, it infers that the being in question has unlimited powers, when all that the evidence seems to warrant is that its powers are very great. The argument retains a certain rhetorical appeal, although its force was much diminished by the publication of the English naturalist Charles Darwin's theory of natural selection. The unbroken reign of law throughout natural evolution is impressive, but as a line of reasoning it does not seem to bear close examination.

The metaphysical problem of God's existence is more of an issue today than the problem of universals; there are still thinkers who hope to restate the old proofs in more convincing ways. The ontological proof, in particular, has won renewed attention from thinkers as different as Norman Malcolm, a philosopher strongly influenced by Wittgenstein, and Charles Hartshorne, an American Realist whose form of theism is called panentheism (the doctrine of a God who has an unchanging essence but who completes himself in an advancing experience). Increasingly, however, philosophers of religion are preoccupied not with these metaphysical abstractions but with the status and force of actual religious claims. "The most real of all things" is no longer at the centre of their attention: what they seek to investigate is God as a suitable object for worship.

THE SOUL, MIND, AND BODY

Platonic and Aristotelian theories of the soul

The soul–body relationship. As well as believing in the reality of Forms, Plato believed in the immortality of the human soul. The soul was, he thought, an entity that was fundamentally distinct from the body, although it could be and often was affected by its association with the body, being dragged down by what he called in one passage "the leaden weights of becoming." The soul was simple, not composite, and thus not liable to dissolution as were material things; further, it had the power of self-movement, again in contrast to material things. Ideally, the soul should rule and guide the body, and it could ensure that this situation persisted by seeing that the bodily appetites were indulged to the minimum extent necessary for the continuance of life. The true philosopher, as Plato put it in the *Phaedo*, made his life a practice for death, because he knew that after death the soul would be free of bodily ties and would return to its native element. He also knew, incidentally, that the soul was "akin" to the Forms; it was through the intellect that the Forms were discovered.

Plato mentioned and attempted to refute alternative accounts of the relationship of soul and body, including a Pythagorean view that described the soul as an "attunement" of the body and thus tried to explicate it as a form or structure rather than an independently existing thing. A theory of this kind was worked out, but not taken to its logical conclusion, by Aristotle in his treatise *De anima* ("On the Soul"). Aristotle defined soul in terms of functions. The soul of a plant was concerned with nutrition and reproduction, that of an animal with these and with sensation and independent movement, that of a man with all these and with rational activity. The soul was, in each case, the form of some body, and the clear implication of this was that it would disappear as the body in question dissolved. To be more accurate, the soul was the principle of life in something material; it needed the material element to exist, although it was not itself either material or immaterial but, to put it crudely, an abstraction. Even though Aristotle was clearly committed by everything he said in the earlier parts of the *De anima* to the view that the soul is not anything substantial, he nevertheless distinguished toward the end of this work between what he called the active and the passive intellects and spoke of the former in Platonic terms. The active intellect was, it appears, separate from the rest of the soul; it came "from outside" and was in fact immortal. Moreover, it was essential to the soul considered as rational, for "without this nothing thinks." Aristotle thus showed the Platonic side of his thought in the very act of trying to emancipate himself from this aspect of Platonism.

The mind–body relationship. In more recent metaphysics less has been heard of the soul and more of the mind; the old problem of the relationship of soul and body is now that of the relationship of mind and body. Most, if not all, subsequent discussion of this subject has been affected by the thinking of Descartes. In his *Meditationes de Prima Philosophia* (1641), he argued that there was a total and absolute distinction between mental and material substance. The defining characteristic of matter was to occupy space; the defining characteristic of mind was to be conscious or, in a broad sense of the term, to think. Material substance was, so to speak, all one, although packets of it were more or less persistent; mental substance existed in the form of individual minds, with God as the supreme example. The mental and the material orders were each complete in themselves, under God; it was this fact that made it appropriate for him to use the technical term substance in this context: mental substance and material substance. The logical consequence of this view, drawn by some later Cartesians, was that there can be no interaction between mind and body; all causality is immanent, within one order or the other, and any appearance of mind affecting body or of body affecting mind must be explained as the result of a special intervention by God, who, on the occasion of changes in one substance, brings it about that there are corresponding changes in the other. There is nothing, however, to suggest that Descartes himself had any sympathy with this view, which was called occasionalism. On the contrary, he stated explicitly that he was not in his body as a pilot is in a ship but was "more intimately" bound up with it. Mind could affect body and vice versa because mind and body had a specially close relationship, which was particularly evident in the aspects of conscious life that have to do with sensation, imagination, and emotion as opposed to pure thought.

Cartesian theory

Descartes's conviction that, despite their intimate union in this life, mind is really distinct from body sprang from his confidence in the *cogito* argument. It was possible, he believed, to doubt the existence of his body (what was certain was only that he had the experience of having a body, and this might be illusory) but not the existence of his mind, for the very act of doubting was itself mental. That mind existed was evident from the immediate testimony of consciousness; that body existed was something that needed an elaborate proof, involving his doctrine of clear and distinct ideas and his attempt to establish the existence of a God who is no deceiver. Apart from this, Descartes appealed to arguments of a broadly Platonic type to bring out what was truly distinctive about mind. He admitted that sensation and imagination could be understood only if referred to the mind–body complex, but contended that acts of the pure intellect and of will (here his thought was influenced by that of St. Augustine, the great 5th-century Christian thinker) belonged to the mind as it was in itself. Descartes did not claim to have a philosophical proof of the immortality of the soul—that, in his view, required the assurance of revelation—but he did think that his theory prepared the way for that doctrine by establishing the separate existence of mind.

The Cartesian account of mind and body had many critics even in Descartes's own day. Hobbes argued that nothing existed but matter in motion; there was no such thing as mental substance, only material substance. Materialism of a sort was also supported by Descartes's correspondent Pierre Gassendi, a scientist and Epicurean philosopher. A generation later Spinoza was to refashion the whole Cartesian metaphysics on bold lines. In place of the two distinct substances, each complete in itself yet each liable to external interference should God will it, Spinoza posited a single substance, God or Nature, possessed of infinite attributes, of which the mental and the material alone are known to men. The "modes," or manifestations, of this substance were what they were as a result of the necessities of its nature; arbitrary will neither did nor could play any part in its activities. Whatever manifested itself under one attribute had its counterpart in all the others. It followed from this that to every mental event there was a precisely corresponding physical event, and vice versa. A man was thus not a mysterious union of two different elements but a part of the one substance that, like all other parts, manifested itself in different ways under different attributes. Spinoza did not explain why it was that physical events could be correlated with mental events in the case of a human being but not in that of, for example, a stone. His theory of psycho-physical parallelism, however, has persisted independently of his general metaphysics and has found supporters even in modern times.

Theory of Spinoza

One way in which Spinoza threw fresh light on the mind–body problem was in calling attention to the influence of the body on the mind and in taking seriously the suggestion that they be treated as a single unit. In this respect, his work on the subject was far in advance of the Empiricist philosophers of the next century. Hume notoriously dismissed Cartesian substance as a "chimera" and argued that minds and bodies alike were nothing but "bundles of perceptions," interaction between which was always possible in principle; in practice, however, he stuck to the old-fashioned view that mind is one thing and body another and did nothing to explore their actual relationships. Empiricist philosophy of mind, both in Hume and in his successors, such as James Mill, was generally crude; it consisted largely in an attempt to explain the entire life of the mind in terms of Hume's ontology of impressions and ideas. Nor did Kant make much, if any, advance in this particular direction, convinced as he was of the necessity of accepting an empirical dualism of mind and body. It was left to Hegel and the Idealists to look at the problem afresh and to bring out the way in which mental life and bodily life are intimately bound together. The accounts of action and cognition given by T.H. Green and Bradley, and more recently by R.G. Collingwood, are altogether more enlightening than those of Empiricist contemporaries just because they rest on a less dogmatic basis and a closer inspection of fact.

Modern theories

No metaphysical problem is discussed today more vigorously than that of mind and body. Three main positions are held. First, there are still writers (*e.g.*, H.D. Lewis in his work *The Elusive Mind* [1969]) who think that Descartes was substantially right: mind and body are distinct, and the "I" that thinks is a separate thing from the "I" that weighs 170 pounds. The testimony of consciousness is invoked as the main support of this conclusion; it is alleged that all men know themselves to be what they are, or at least who they are, apart from their bodily lives; it is alleged again that their bodily lives present themselves as experiences—*i.e.*, as something mental. The existence of mind, as Descartes claimed, is certain, that of body dubious and perhaps not strictly provable. Second, there are writers such as Gilbert Ryle who would like to take the Aristotelian theory to its logical conclusion and argue that mind is nothing but the form of the body. Mind is not, as Descartes supposed, something accessible only to its owner; it is rather something that is obvious in whatever a person does. To put it crudely, mind is simply behaviour. Finally, there are many philosophers who, although more generally sympathetic to the second solution than to the first, wish to provide for an "inner life" in a way in which Behaviourism does not; P.F. Strawson is a typical example. To this end they try to assert that the true unit is neither mind nor body but the person. A person is something that is capable of possessing physical and mental predicates alike. This is, of course, to say that the "I" that knows simple arithmetic and the "I" that has lost weight recently are the same. How they can be the same, however, has not so far been explained by supporters of this view.

Aside from these main positions, an interesting development is the stress laid by writers—such as Stuart Hampshire, an "ordinary language" philosopher—on self-activity as the distinguishing characteristic of mind. According to this view, a human being is a body among bodies but is, as Plato said, self-moving as material things are not. That this should be so—that human beings are possessed of wills and can in favourable circumstances act freely—is taken as an ultimate fact neither requiring nor capable of

explanation. It is often denied that any scientific discovery could give rational grounds for questioning this fact. It is also stressed that the causality of a human being is fundamentally different from that of a natural subject, intentional action being quite other than mere behaviour determined from without.

The problem of differentiating men and machines

Connected with these topics is the problem, much discussed in recent philosophy as a result of the rise of cybernetics, of what differentiates men from machines. Two answers used to be given: the power to think and consciousness. Now, however, there exist machines whose calculating abilities far surpass those of any human being; such machines may not literally think, but they certainly arrive at conclusions. Furthermore, it is not true that their operations are of a purely routine nature: there is a sense in which they can improve their performance in the light of their "experiences." They even have an analogue of consciousness in the sensitivity they show to external stimuli. These facts suggest that the gap between minds and machines is less wide than it has often been thought to be; they do not, however, destroy it altogether. Human beings possess powers of creative thought unlike anything found in machines; as Noam Chomsky, an American linguistics scholar, has stressed (and as Descartes urged in his *Discours de la méthode*), the ability of human beings to handle language in such a way that they comprehend any one of an infinite number of possible expressions is something that cannot be explained in mechanical terms. Again, as J.R. Lucas, a British philosopher, has argued, human beings have the ability to diagnose and correct their own limitations in a way to which there is no parallel in machines. As some older philosophers put it, man is a being with the power of self-transcendence; he can work within a system, but he can also move to another level and so see the shortcomings of the system. A machine can only work within a system; it operates according to rules but cannot change them of its own accord.

Finally, mention should be made of an extreme Materialist solution to the mind–body problem: this solution holds that states of mind are in fact states of the brain. Supporters of this theory agree that the two are separate in idea but argue that physiology shows that despite this they are contingently identical. What seems to be a state of mind, above all to its possessor, is really a state of the brain, and mind is thus reduced to matter after all. It is not clear, however, why physiologists should be granted the last word on a topic like this, and, even if it were agreed that they should be, the correlations so far established between mental occurrences and states of the brain are at best sketchy and incomplete. Central-state Materialism, as this theory is called, professes to have the weight of contemporary science behind it, but it turns out in fact to have drawn to a remarkable degree on what it thinks will be the science of tomorrow.

NATURE AND THE EXTERNAL WORLD

The problem of the existence of material things, first propounded by Descartes and repeatedly discussed by subsequent philosophers, particularly those working within the Empiricist tradition, belongs to epistemology, or the science of knowledge, rather than metaphysics; it concerns the question of how it can be known whether there is a reality independent of mind. There are, however, problems about nature and the external world that are genuinely metaphysical.

The reality of material things. There is first of all the question of the status or standing of material things, the kind of being they possess. It has been repeatedly suggested by metaphysical philosophers that the external world is in some way defective in reality, that it is a mere phenomenon, something that seems to be what it is not.

The external world as defective in reality

Plato, as has already been pointed out, held that objects of the senses generally answered this description; they each appeared to possess characteristics that they could not in fact have (water could not be at once hot and cold) and were to that extent delusive rather than real. There was no stability in the world of phenomena and therefore no true reality. In taking this view, Plato drew no contrast between the world of nature and the world of man, although he undoubtedly believed that souls had a superior status. Leibniz, a later philosopher who also followed this general line of thought, began by explicitly opposing souls to material things. To speak precisely, nothing truly existed except monads, and monads were souls, or spiritual beings: all had perceptions, although these varied enormously in degree of clarity (the perceptions of the monads constituting what is commonly called a stone were singularly faint). Although the final description of the world must thus be given in mental terms, it did not follow that nature as normally perceived is a total illusion. Men perceive as well as think, and although perception is in fact simply a confused form of thought it is not for that reason to be set aside altogether. The world of nature, the world of things in space and time, is, as Leibniz put it, a "well-founded phenomenon"; it is what all men must judge to be there, given that they are not pure intellects but necessarily remain to some extent prisoners of their senses.

A theory on somewhat similar lines was worked out by Kant in the *Kritik der reinen Vernunft* (*Critique of Pure Reason*), despite Kant's explicit dissent from Leibniz' account of perception as confused thinking. Kant contrasted a realm of things as they are in themselves, or noumena, with a realm of appearances, or phenomena. The former are unknown, and indeed unknowable, though it seems clear that Kant tended to think of them on lines like those of Leibniz; phenomena do not exist independently, but are dependent on consciousness, though not on any one person's consciousness. Kant expressed this position by saying that things phenomenal are empirically real but transcendentally ideal; he meant that they are undoubtedly there for the individual subject, though when examined from the point of view of critical philosophy they turn out to be conditioned by the mind through the forms of the understanding imposed upon them. Kant's most striking argument for this conclusion was that space and time are neither, as the English physicist Sir Isaac Newton supposed, vast containers inside which everything empirical is situated, nor, as Leibniz had suggested, relations between things confusedly apprehended, but are rather what he mysteriously called "pure intuitions," factors inherent in the sensibilities of observers. Without observers, space and time disappear, along with their contents; but once the human point of view is assumed, in the form of percipients who are directly aware of the world through their senses, space and time become as real as anything—indeed, more real because of their pervasive character. There is nothing that falls within experience that does not have temporal relations, and all the data of the external senses have spatial relations as well.

Kant's arguments in support of his revolutionary thesis about space and time unfortunately depend to a large extent on his mistaken philosophy of mathematics, and they have accordingly been discounted by later philosophers. In modern philosophy the issues raised in these discussions survive only in the form of an inquiry into the status of nature as investigated by the natural scientist.

Primary and secondary qualities of material things

Descartes already pointed out that material things in fact have properties different from those they seem to have; they appear to possess secondary qualities such as colour or smell, but turn out when thought about strictly to be colourless and odourless lumps of matter occupying and moving about in space. Locke endorsed this distinction between primary qualities (such as extension, motion, figure, and solidity) and secondary qualities; but George Berkeley, a major British Empiricist of the early 18th century, criticized it sharply as absurd: to imagine something that has primary but no secondary qualities is psychologically impossible. For Berkeley the world of the scientist was a fiction, and perhaps not even a necessary fiction at that. It seems clear, however, that Berkeley's arguments do not undermine the important distinction between primary and secondary qualities, where the former are treated as fundamental and the latter as derivative; they are valid only against Locke's mistaken claim that primary qualities are objective and secondary quali-

ties subjective. Whatever the explanation, the fact remains that the scientist often knows why the phenomena are as they are, in contrast to the plain man; to that extent nature, as he understands it, is truer, if not more real, than nature as it is taken to be in everyday experience. Why this should be is not satisfactorily explained by philosophers who follow Berkeley's lead on this question. Nor has either party to the controversy noted sufficiently the extent to which nature as commonly thought of is conceived as penetrated by mind, both when it is taken as intelligible and, still more interestingly, when poets ascribe to it moods or treat it as kindly or hostile. There is analytic work to be done here to which critical philosophers have still to address themselves.

The organizing principles of nature. Connected with the questions just discussed are problems about the organizing principles of nature; *i.e.*, about natural causality. It has been said that the Greeks thought of the world as a vast animal (indeed, the conceptual scheme that Aristotle devised for dealing with nature makes sense only if something like this is presupposed). Nature is the sphere in which different kinds of things are all striving to realize their characteristic form; purpose, though not perhaps explicit purpose, governs it throughout. Aristotle was not entirely insensitive to what are now known as the physical and chemical aspects of the universe, but he treated them as subordinate to the biological aspect in a way modern thinkers find surprising. Even the four elements —earth, air, fire, and water—were seen by him as each seeking its natural place in the cosmos. The contrast between this view and that favoured by Descartes could hardly be sharper. According to Descartes, nature is not an organism but a mechanism; everything in it, including animal and human bodies, although not including the human mind, must be understood on mechanical principles. In taking this line, Descartes was endorsing a way of thinking that was central in the new physical science developed by Galileo at the beginning of the 17th century and that was to remain central in the thought of Newton. Descartes himself was not a pure mechanist, because he believed that mind was governed by principles of its own; his work, however, undoubtedly encouraged the thought, frequently debated at the time of the Enlightenment, that mental life equally with the physical world must be explicable in mechanical terms. This was a position whose validity at the theoretical level Kant reluctantly admitted, only to try to turn its edge by his dichotomy of theory and practice. Everything in nature, including human behaviour, was subject to causal determination. The dignity and uniqueness of man, however, could be preserved because of the fact that in moral action man raised himself above the sphere of nature by thinking of himself as part of a world of free spirits.

Nature as mechanical or teleological

Kant also produced interesting thoughts on the subject of living phenomena. Reflection on the concept of an organism had convinced him that a being of this sort could never be accounted for satisfactorily in mechanical terms; it was futile to hope that someday in the future there would appear a Newton of biology capable of explaining mechanically the generation of even so apparently simple a thing as a blade of grass. To judge or speak of organic phenomena demanded a special principle that was teleological (*i.e.*, related to design or purpose) rather than mechanical. Kant, however, refused to allow that this principle had constitutive force. It belonged, he said, only to "reflective judgment" and thus did not rank alongside the principles of understanding that were so important in physical science. Men must have recourse to a principle of purposiveness in order to speak of living things, but they must not imagine that such recourse would enable them to explain their existence and behaviour in any strict sense of the term. They have insight only into what they can produce, and what they can produce are machines, not organisms. Many of Kant's detailed remarks on this subject seem outmoded in the light of subsequent scientific developments; nevertheless, the problem he raised is still the subject of vigorous debate among philosophically minded biologists. His emphasis on the uniqueness of the concept of an organism, which he says is only imperfectly explicated in the language of ends and purposes, is particularly valuable.

It remains to mention the seemingly eccentric view of nature taken by Hegel, who regarded it as at once the antithesis to and a prefiguration of the world of spirit. Nature had to exist to provide material for spirit to overcome, although it was a gross mistake to think of it as essentially a lifeless mechanism. Instead of reducing the organic to the inorganic, men should see the latter as pointing forward to the former, which in turn offered a foretaste of the rational structure exhibited by the world of mind. Hegel's disdain for scientists of proved ability, such as Newton and John Dalton, and his endorsement against them of amateur scientists such as the German writer Goethe, make it hard to take his philosophy of nature seriously. It contains, even so, some interesting points, not least the demonstration that in finding nature to be throughout subject to law the scientist is presupposing that it is thoroughly penetrated by mind. To understand these views properly, however, it is necessary to understand Hegel's system as a whole.

SPACE AND TIME

Many metaphysicians have argued that neither time nor space can be ultimately real. Temporal and spatial predicates apply only to appearances; reality, or what is real, does not endure through time, nor is it subject to the conditions of space. The roots of this view are to be found in Plato and beyond him in the thought of the Eleatic philosophers Parmenides and Zeno, the propounder of several paradoxes about motion. Plato conceived his Forms as eternal objects whose true location was nowhere. Similarly, Christian philosophers conceived of God as existing from everlasting to everlasting and as present in all parts of the universe. God was not so much in space and time as the source of space and time. Whatever falls within space and time is thereby limited, for one space excludes another and no two times can be simultaneous. God, however, is by definition an infinite being and so must exist timelessly and apart from space.

Theories of Kant and Bradley

Reference has already been made to the way in which Kant argued for an intimate connection between time and space and human sensibility: that human beings experience things as being temporally and spatially situated is to be connected with the nature of their minds, and particularly with their sensory equipment. Kant was entirely correct to describe space and time as "intuitions," by which he meant that they are peculiar sorts of particulars; he was right again to insist on the centrality in sensing of the notions of here and now, which can be indicated but not reduced to conceptual terms. It is highly doubtful, however, whether he had sufficient grounds for claiming a priori insight into the nature of space and still more that of time; his case for thinking that space and time are "pure" intuitions was palpably inadequate. The lesson to draw from his careful discussion of this subject might well be not that there must be a form of reality lying beyond space and time but rather that nothing can be real that does not conform to spatial and temporal requirements. Space and time are bound up with particularity, and only what is particular can be real.

It was only in a weak sense that Kant denied the reality of time and space. Other philosophers have certainly been bolder, though generally on the basis of a less solid grasp than Kant possessed of what it is to experience temporally and spatially. Thus, Bradley argued against the view that space and time are "principles of individuation" by alleging that no specification of spatial or temporal position, whether in terms of here and now or by the use of spatial coordinates or dating systems, could achieve uniqueness. Any descriptions such as "at 12 o'clock precisely on January 4, 1962" or "just 75 yards due north of this spot" might apply to infinitely many times or places in the universe, for there was nothing to prevent there being infinitely many temporal and spatial orders. Bradley forgot that the whole meaning of a spatial or temporal description is not exhausted when attention is given to the connotations of the terms used; what has to be considered is the words as used in their context, which

is that of a person who can indicate his position in space and time because of the fact that he is himself situated in space and time. One cannot express uniqueness in words as such, but he can use words to express uniqueness. Bradley's suggestion that it is possible to conceive of many temporal and spatial orders is by no means free from controversy. In general, men think of all events as happening before, simultaneously with, or after the moment that is called "now," all spatial positions as relating in some way or other to the point that is called "here." In circumstances where this cannot be done, as with events or places in a dream, men dismiss them as quite unreal. That there might be events or places with no relation to their own now and here is something they often refuse to take seriously, though there are theories in modern science that suggest that they are wrong to do so.

It was pointed out earlier that to say that something is unreal in a metaphysical context is often to say that it is unintelligible, and it is not surprising to find that arguments about the unreality of space and time have often turned on conceptual considerations. Thus, it is alleged that there is an incoherency in the notion of space because it claims to be a whole that is logically prior to its parts, and nevertheless turns out in practice to be merely an indefinitely extensible aggregate. Everything that occupies space falls within a wider spatial context; the thought of space as such is, as Kant saw, involved in any spatial description. Yet space as such is something that constantly eludes man's grasp; space, as man knows it, is just one spatial situation after another.

Theory of Bergson

The difficulties found in the notion of time turn on the combination in it of the idea that time is continuous and the idea that it is made up of discrete parts. Henri Bergson, a French philosopher who was concerned with the notions of duration and movement, said that time was experienced as continuous; it was only the "spatialized" time measured by clocks that was taken to have separable parts (minutes, hours, weeks, and so on), and this "public" time was merely conventional. This, however, seems altogether too easy a solution of the problem, for privately experienced time also goes by (one stretch of it follows another), and the thesis that public time is merely conventional is at best highly controversial. It must be allowed that time is commonly thought of as at once flowing and, as it were, subject to arrest. Whether this is, in fact, openly inconsistent may be doubted, but it is on points like this that the metaphysical case in question rests.

Few British or American philosophers discuss these questions now, largely because they have been persuaded by Moore that any attack on such central notions in men's thought as these must be mistaken in principle. As a result, little attention is given to a question that deserves investigation; namely, what is to take the place of space and time in metaphysical thought. Idealist writers constantly said that space and time qualified appearances, and that nothing that did so could fail to be taken up in the higher experience that was experience of reality. But how is this supposed to be done? Time is perhaps cancelled and yet preserved in the idea of eternity, space in the thought of something that is at once omnipresent yet not in any particular place. But what is there that is positive about these notions? The eternal, it is sometimes said, is not to be identified with what lasts through all time; it is, strictly, outside time altogether. But what does it mean to say this? When it is said, for example, that numbers or truths are eternal, the proper inference is that they have nothing to do with time; to inquire when they came into or will go out of existence is to ask a question that is ill posed. When God, however, is said to be eternal, the impression is often given that he has temporal characteristics, although in some higher form. What this higher form is deserves careful consideration, the result of which might be that it is not the conception of time that is incoherent but the conception of God.

THE CONCEPTION OF SPIRIT

As well as arguing for the separate existence of mental substance, metaphysicians have claimed that mind is, as it were, the key to the understanding of the universe. What exists is spirit, or at least is penetrated by spirit. This is the thesis of Idealism, a type of philosophy that is often derided but that, like its rival Materialism, has a constantly fresh appeal. This view is worth examining in more detail than has so far been possible.

It is best to begin by distinguishing the thesis of Idealism proper from some others with which it is readily confused. Leibniz said that the true atoms of nature were monads or souls; at bottom nothing existed except minds. Berkeley claimed that sensible things have no existence without the mind; there are spirits that experience, including an infinite spirit, and there are the contents of their experiences, but there is no independently existing world of matter. For the philosophers who followed Hegel, both Leibniz and Berkeley were "subjective" Idealists: they conceived of reality in terms of the experiences of individual minds. Hegel's view, by contrast, was that what exists is not so much pure mind as mind writ large; *i.e.*, the universe is penetrated by mind and exists for the sake of mind, and it cannot be understood unless this fact is grasped. Hegel was thus not committed to denying that there is an independent world of nature but, on the contrary, openly proclaimed it. Nature was there for mind to master it, and in so doing to discover itself.

Theory of Hegel

The field in which Hegel first worked out this theory was that of human affairs. The human world may be said to be mind made objective because it consists of a series of structures—examples would be a language, a set of moral or political procedures, a science, a practical art such as medicine—that constitute mental achievements. The mind involved in structures of this kind, however, is collective rather than personal. An art such as medicine or a science such as mathematics is not the invention of any particular individual; and although individuals have contributed and are contributing to the advancement of each structure, they do so not in their personal capacity but as embodying impersonal intelligence.

Because the human world thus embodies mind or spirit, it needs to be understood in a special way—in terms of what Hegel called "concrete universals." Concepts of this kind are in order when it is a question of grasping a particular sort of subject matter—one in which there are intimate connections between the data under consideration. Connections in nature are, on the surface at any rate, of a purely external character; striking a match, for example, has nothing internally to do with producing a flame. When, however, a historian considers the different stages of some movement or process, or when an anthropologist studies the various aspects of the life of a society, the material they confront is internally related just because it represents the work of mind—not, of course, of mind working in a vacuum, but of mind facing and reacting with greater or less intelligence to particular situations. It is not surprising in these circumstances to find that the conceptual structure employed by the student of human affairs is, in important respects, profoundly different from that employed by the student of nature. In the latter, what are in question are constant conjunctions, observed but not understood; in the former, men have insight into what happens or obtains, because they can re-enact in their own minds the thought that lay behind the material they have to study.

All this is, or should be, comparatively uncontroversial; it represents the truth behind the claim of Wilhelm Dilthey, a German philosopher and historian of ideas, that human affairs can be understood, as it were, from within, by means of what he called *Verstehen* ("understanding"). But of course it is one thing to say this and another altogether to argue that the universe at large should be construed as if it were mind writ large. What makes Hegelianism intriguing to some, and totally implausible to others, is precisely that it makes this extravagant claim. As has already been mentioned, the world of nature for Hegel is in one way independent of mind: its being is certainly not its being perceived. Nevertheless, it is relevant to mind in all sorts of important ways: in providing a setting in which mind can act, in constituting an obstacle that mind can overcome, in presenting mind

with something seemingly alien in which it can nevertheless find itself insofar as it discovers nature to be intelligible. If Hegel were asked why there was a world of nature at all, his answer would be "for the sake of mind." Just as man's social environment affords opportunities to the individual to come to full knowledge of himself by realizing his differences from and dependence upon others, so the world of nature affords similar opportunities. By transforming the natural scene, men make it their own. In so doing they come to know what they can do, and thus what they are.

All reality as spirit

There is, perhaps, more to this doctrine than appears at first sight. It is, however, easier to assent to it in general terms than to follow Hegel over it in detail. According to the Idealist account, there is in the end only one true description of the universe, that which is couched in terms of the concrete universal. Reality is a single self-differentiating system, all the parts of which are intimately connected; it is spirit expressing itself in the natural and human worlds and coming to consciousness of itself in so doing. Any other account of the matter—for example, that given by the scientist in terms of experienced uniformities—must be dismissed as inadequate. To Hume's objection that there is an absolute logical difference between propositions expressing matters of fact and existence and propositions expressing relations of ideas, Hegel replies brusquely that the distinction is untenable. At a certain level, perhaps, facts are taken as "brute." Even the scientist, however, never abandons his aspiration to understand them—it is only provisionally that he talks in terms of "ultimate inexplicabilities"—and the philosopher knows that the demand to incorporate all knowledge in a single system is not to be denied. It is a demand that, as Hegelians admit, can in practice never be met but that nonetheless ceaselessly makes itself felt. That such is the case is shown by the extraordinary fascination exercised by this strange but remarkable type of philosophy.

To try to understand the universe in terms of spirit is characteristic of philosophers whose main extra-philosophical interests are in the humanities, particularly in historical studies. Relatively few scientifically minded thinkers have followed this line of thought, and many Idealists of repute, including Bradley and Benedetto Croce (an Italian philosopher and literary critic whose major philosophical work was published in four volumes between 1902 and 1917 under the general title *Filosofia come scienza dello spirito*), have been least convincing when writing about science. Hegel himself, perhaps, had less sympathy with scientific than with historical aspirations; this is not to say, however, that he was ill-informed about contemporary science. He knew what was going on, but he saw it all from his own point of view, the point of view of one who was entirely convinced that science could not produce any ultimate answers. He valued science but rejected the scientific view of the world.

III. Types of metaphysical theory

To complement and, in a way, to correct this brief survey of the problems of metaphysics it will be useful at this point to insert a short summary of a number of overall metaphysical positions. Metaphysics, as already noted, professes to deal with "the world as a whole"; the thoughts of a metaphysician, if they are to make any impact at all, must be connected in a system. The object in what follows will be to present in outline metaphysical systems that have exercised and, indeed, continue to exercise a strong intellectual appeal. In all cases but one, these systems were given classical shape by particular philosophers of genius. Relatively little attention, however, will be paid to this fact here, because the present concern is with types of view rather than with views actually held. Thus, reference will be made to Platonism instead of to the philosophy of Plato, and so on in other cases.

PLATONISM

The essence of Platonism lies in a distinction between two worlds, the familiar world of everyday life, which is the object of the senses, and an unseen world of true realities, which can be the object of the intellect. The ordinary man recognizes the existence of the former and ignores that of the latter; he fails to appreciate the extent to which his beliefs both about fact and about values are arbitrarily assumed and involve internal contradictions. The philosopher, or rather the true philosopher, is in a position to show him how insubstantial is the foundation on which he takes his stand. The philosopher can demonstrate how little thought there is in popular conceptions of good and evil, and he can show that the very concept of sense knowledge involves difficulties, because knowledge presupposes a stable object, and the objects of sense are constantly changing. The claim, however, is that he can do more than this. Because of the presence in him of something like a divine spark, he can, after suitable preparation, fix his intellectual gaze on the realities of the unseen world and, in the light of them, know both what is true and how to behave. He will not attain this result easily—to get to it will involve not only immense intellectual effort, including the repeated challenging of assumptions, but also turning his back on everything in life that is merely sensual or animal. Yet, despite this, the end is attainable in principle, and the man who arrives at it will exercise the most important part of himself in the best way that is open to him.

Distinction between the world of appearances and the world of realities

That this type of view has an immediate appeal to persons of a certain kind goes without saying. There is ample evidence in poetry and elsewhere of the frequently experienced sense of the unreality of familiar things and the presence behind them of another order altogether. Platonism may be said to build on "intuitions" of this kind; as a metaphysics, its job is to give them intellectual expression, to transfer them from the level of sentiment to that of theory. It is important, however, to notice that Platonism is not just the intellectualizing of a mood; it is an attempt to solve specific problems in a specific way. In Plato's own case, the problems were set by loss of confidence in traditional morality and the emergence of the doctrine that "man is the measure of all things." Plato thought he could counter this doctrine by appeal to another contemporary fact, the rise of science as shown in the development of mathematical knowledge. Mathematics, as he saw it, offered certain truth, although not about the familiar world; the triangle whose properties were investigated by the geometrician was not any particular triangle but the prototype that all particular triangles presuppose. *The* triangle and *the* circle belonged not to the world of the senses but to the world of the intelligence; they were Forms. If this could be said of the objects of mathematical discourse, the same should also be true of the objects of morality. True justice and true goodness were not to be found in popular opinions or human institutions but should be seen as unchanging Forms, eternally existing in a world apart.

Modern philosophers have found much to criticize in this system: as indicated already, they have objected that Forms are not so much existents as abstractions, and they have found the argument from science to morality quite inconclusive because of what they allege to be an absolute dichotomy between fact and value. It may be that nobody today can subscribe to Platonism in precisely the form given it by Plato himself. The general idea, however, has certainly not lost its hold, nor have the moral perplexities to which Plato hoped to find an answer been dissipated by further thought.

ARISTOTELIANISM

For many people, Plato is the type of an other-worldly, Aristotle of a this-worldly philosopher. Plato found reality to lie in things wholly remote from sense; Aristotle took form to be typically embodied in matter and thought it his job as a philosopher to make sense of the here and now. The contrast is to some extent overdrawn, for Aristotle, too, believed in pure form (God and the astral intelligences—the intelligent movers of the planets—were supposed to satisfy this description), and Plato was sufficiently concerned with the here and now to want to change human society radically. It remains true, nevertheless, that Aristotelianism is in essentials a form of

Making sense of the here and now

immanent metaphysics, a theory that instructs men on how to take the world they know rather than one that gives them news of an altogether different world.

The key concepts in Aristotelianism are substance, form and matter, potentiality and actuality, and cause. Whatever happens involves some substance or substances; unless there were substances, in the sense of concrete existents, nothing could be real whatsoever. Substances, however, are not, as the name might suggest, mere parcels of matter; they are intelligible structures, or forms, embodied in matter. That a thing is of a certain kind means that it has a certain form or structure. But the structure as conceived in Aristotelianism is not merely static. Every substance, in this view, not only has a form but is, as it were, striving to attain its natural form; it is seeking to be in actuality what it is potentially, which is in effect to be a proper specimen of its kind. Because this is so, explanation in this system must be given in teleological rather than mechanical terms. For Aristotle, form is the determining element in the universe, but it operates by drawing things on, so that they become what they have it in themselves to be, rather than by acting as a constant efficient cause (*i.e.*, the agent that initiates the process of change). The notion of an efficient cause has a role in Aristotelianism—as Aristotle put it, it takes a man, a developed specimen of his kind, to beget a man; it is, however, a subordinate role and yields pride of place to a different idea, form considered as purpose.

For reasons connected with his astronomy, Aristotle postulated a God. His God, however, had nothing to do with the universe; it was not his creation, and he was, of necessity, indifferent to its vicissitudes (he could not otherwise have been an unmoved mover). It is a mistake to imagine that everything in the Aristotelian universe is trying to fulfill a purpose that God has ordained for it. On the contrary, the teleology of which use is here made is unconscious; although things all tend to an end, they do not in general consciously seek that end. They are like organs in a living body that fulfill a function and yet seemingly have not been put there for that purpose.

As this last remark will suggest, an important source of Aristotelian thought is reflection on natural growth and decay. Aristotle, who was the son of a doctor, was himself a pioneer in natural history, and it is not surprising that he thought in biological terms. What is surprising, and gives his system a continuing interest, is the extent to which he succeeded in applying ideas in fields that are remote from their origin. He was without doubt more successful in some fields than in others: in dealing with the phenomena of social life, for instance, as opposed to those of physical reality. His results overall, however, were impressive enough for his system not only to dominate men's minds for many centuries but to constitute a challenge even today. Men still, on occasions, think like Aristotle, and as long as that is so, Aristotelianism will remain a live metaphysical option.

THOMISM

Christian metaphysics

The advent of Christianity had important effects in philosophy as in other aspects of human life. Initially, Christians were opposed to philosophical claims of any kind; they saw philosophy as an essentially pagan phenomenon and refused to allow the propriety of subjecting Christian dogma to philosophical scrutiny. Christian truth rested on revelation and did not need any certificate of authenticity from mere reason. Later, however, attempts were made to produce a specifically Christian metaphysics, to think out a view of the universe and of man's place in it that did justice to the Christian revelation and nevertheless rested on arguments that might be expected to convince Christians and non-Christians alike. St. Thomas Aquinas was only one of a number of important thinkers in medieval times who produced Christian philosophies; others—such as the British philosophers John Duns Scotus in the late 13th century and William of Ockham in the first half of the 14th century—took significantly different views. In selecting the system of Aquinas for summary here, the factor that has weighed most has been its persistent influence, particularly in postmedieval times. Aquinas was not the only medieval philosopher of distinction, but Thomism is alive as other medieval systems are not.

The central claim of Thomism is that reflection on everyday things and the everyday world reveals it as pointing beyond itself to God as its sustaining cause. Ordinary existents, such as human beings, are in process of constant change. The change, however, is not normally the result of their own efforts, and even when it is, it does not depend on them exclusively. No object in the familiar world can fully account for its own *esse* (*i.e.*, its own act of existing), nor is it wholly self-sufficient; all are affected from without, or at least operate in an environment that is not of their own making. To say this is to say that they are one and all finite. Although finite things can be, and commonly are, stimulated to activity or kept in activity by other finite things, it does not follow that there might be finite things and nothing else. On the contrary, the finite necessarily points beyond itself to the infinite; the system of limited beings, each dependent for its activity on something else of the same kind, demands for its completion the existence of an unlimited being, one that is the source of change in other things but is not subject to change itself. Such a being would be not a cause like any other but a first or ultimate cause; it would be the unconditioned condition of the existence of all other things. Aquinas believed that human reason can produce definitive proofs of the existence of an infinite or perfect being, and he had no hesitation in identifying that being with the Christian God. Because, however, the movement of his thought was from finite to infinite, he claimed to possess only so much philosophical knowledge of the Creator as could be arrived at from study of his creation. Positive knowledge of the divine nature was not available; apart from revelation, man could only say what God is not, or conceive of his attributes by the imperfect method of analogy.

Aquinas worked out his ideas at a time when the philosophy of Aristotle was again becoming familiar in western Europe after a period of being largely forgotten, and many of his detailed theories show Aristotelian influence. He assumed the general truth of the Aristotelian picture of the natural world and the general correctness of Aristotle's way of interpreting natural phenomena. He also took over many of Aristotle's ideas in the fields of ethics and politics. He gave the latter, however, a distinctively different twist by making the final end of man not philosophical contemplation but the attainment of the beatific vision of God; it was Christian rather than Greek ideas that finally shaped his view of the *summum bonum* ("greatest good"). Similarly, his celebrated proofs of God's existence proceeded against a background that is obviously Aristotelian but that need not be presupposed for their central thought to have validity. Thomism can certainly be seen, and historically must be seen, as the system of Aristotle adapted to Christian purposes. It is important, however, to stress that the adaptation resulted in something new, a distinctive way of looking at the world that still has its adherents and still commands the respect of philosophers.

CARTESIANISM

Increased understanding of the physical world

René Descartes worked out his metaphysics at a time of rapid advance in human understanding of the physical world. He adopted from Galileo the view that physical things are not what they are commonly taken to be on the strength of sense experience—namely, possessors of "secondary" properties such as colour, smell, and feel—but are rather objects characterized only by the "primary" qualities of shape, size, mass, and mobility. To understand why a constituent of the physical world behaves as it does, what should be asked is where it is, how large it is, in what direction it is moving, and at what speed; once these questions are answered, its further properties will become intelligible. Descartes held further that all change and movement in the physical world is to be explained in purely mechanical terms. God was needed to give initial impetus to the physical system as a whole, but once it had got going it proceeded of its own accord. To pretend, as the Aristotelians had, to discern purposes in nature was to

make the impious claim to insight into God's mind. Descartes applied this theory to the movements of animals as much as to those of inanimate bodies; he thought of both as mere automatons, pushed and pulled about by forces over which they had no control.

Although Descartes thus acquiesced in, indeed emphasized, the mechanistic tendencies of contemporary science, he was far from being a Materialist. Besides material substance there was also thinking substance, and this was in fact wholly different from matter both in kind and in operation. Bodies had as their essence to occupy space; minds were not in space at all. Bodies, again, were determined in their movements; minds were in some sense free, because they possessed will as well as intelligence. Descartes was less explicit on this point than he might have been; the principles on which mental substance is supposed to operate are not made clear, with the result that critics have said that Descartes thought of mental activities in para-mechanical terms. Whether this is true or not, however, there was no reason for Descartes to be in any special difficulty over this point. All he needed to urge was that minds act in the strict sense of the term, which is to say that they take cognizance of their situation and respond more or less intelligently to it. That they can do this differentiates them fundamentally from material things, which are caused to do what they do and are entirely unaffected by rational considerations.

The main crux in Descartes's metaphysics was the difficulty of bringing together the two orders of being, once they were separated. Mention has already been made of the expedient to which later Cartesians were driven in trying to solve this difficulty: in effect, they made the unity of the universe a continuing miracle, dependent upon the grace of God. It is worth mentioning here another move in the same area that many have found instructive. Kant, who was in some respects both a latter-day Cartesian and a latter-day Platonist, argued that human activities could be looked at from two points of view. From the theoretical standpoint they were simply a set of happenings, brought about by antecedent events in precisely the same way as occurrences in the natural world. From the standpoint of the agent, however, they must be conceived as the product of rational decision, as proper acts for which the agent could be held responsible. The moment he began to act, a man transferred himself in thought from the phenomenal world of science to an intelligible world of pure spirit; he necessarily acted as if he were not determined by natural forces. The transference, however, was a transference in thought only (to claim any knowledge of the intelligible world was quite unjustified), and because of this the problem of the unity of the universe was dissolved. There was no contradiction in a man's thinking of himself both as a subject for science and as a free originator of action. Contradiction would appear only if he were present in both respects in an identical capacity. But appeal to the doctrine of the two standpoints was thought by Kant to rule this out.

Kantian development

It is only with some hesitation that one can speak of Kant as having put forward a metaphysics. He was in general highly suspicious of claims to metaphysical knowledge, and a principal aim of his philosophy was to expose the confusions into which professing metaphysicians had fallen. Nevertheless, it is clear that Kant had metaphysical convictions, for all his denial of the possibility of metaphysical knowledge; he was committed to the view that men can conceive a non-natural as well as a natural order and must necessarily take the former to be real when they act. The language he used—particularly his talk about man as phenomenon and man as noumenon—is not to the taste of present-day philosophers, but the thought behind it certainly survives. It is in this form, indeed, that Cartesianism may still be said to present a serious intellectual challenge.

IDEALISM

Descartes and Kant were both adherents of metaphysical dualism, though they worked out their dualisms in interestingly different ways. Many thinkers, however, find dualism unsatisfactory in itself; they look for a single principle by which to compass whatever exists. There are two broad steps that are open to the person who confronts a dualism of mind and matter and finds it unsatisfactory: he can either try to show that matter is in some sense reducible to mind, or conversely seek to reduce mind to matter. The first is the solution of Idealism, the second that of Materialism. Idealism has already been treated at length, and it will not be necessary to go into it again here. Only one point about it needs emphasis. As was pointed out, there are various forms of Idealism. In one version, this philosophy maintains that there literally is no such thing as matter; what the common man takes to be material things are, upon closer consideration, nothing but experiences in minds. Nothing exists but minds and their contents; an independently existing material world is strictly no more than an illusion. This was the view taken by Berkeley. In the more sophisticated Idealism of Hegel, however, it is not maintained that mind alone exists; material things are, in one way, taken to be as real as minds. The thesis advanced is rather that the universe must be seen as penetrated by mind, indeed as constituted by it. Spirit, to use Hegel's own word, is the fundamental reality, and everything that exists must accordingly be understood by reference to it, either as being directly explicable in spiritual terms or as prefiguring or pointing forward to spirit. Whatever the merits of this thesis, it is clear that it differs radically from that maintained by Berkeley. Idealism in the form espoused by Berkeley relies largely on arguments drawn from epistemology, though formally its conclusions are ontological, because they take the form of assertions or denials of existence. Hegel, however, had little or nothing to say about epistemology and was not even concerned to put forward an ontology. What he wanted to urge was a doctrine of first principles, a thesis about the terms in which to understand the world. The Hegelian "reduction" of matter to mind was thus reduction in a somewhat attenuated sense. It is important to get this point clear, if only because it has its parallel in the rival doctrine of Materialism.

Two solutions to the Cartesian dualism

MATERIALISM

The simplest form of Materialism is found in the claim that only matter exists. Stated thus baldly the claim is absurd, because it is clear that all sorts of things exist that are not of the nature of matter: thoughts and numbers and human institutions would be instances. In the light of these facts, the claim has to be revised to say that matter is the only substantial existent, with appeal being made to distinctions first worked out in Aristotle's doctrine of categories. According to this explanation, many things besides matter exist, but all of them are explicable (or so it is said) as modifications of matter. Thus, human institutions consist in patterns of movement among specific groups of human beings, and human beings in turn are nothing but highly complicated material bodies.

Matter as the only substantial existent

It is clear from these instances that Materialism is a controversial doctrine; it is also clear that its key word, modification, requires further explanation. When, for example, minds are said to be modifications of an underlying material substance, what is meant? A first and relatively easy point is that, like qualities and quantities, they could not exist separately. Unless there were material bodies, there could not be minds, because minds are—to put it crudely—states found in some material bodies. Minds are here equated with mentality, and mentality is clearly an abstraction. To say this, however, is not to remove the whole difficulty. When it is said that mentality is a state of some material body or bodies, is that meant literally or metaphorically? Bodies can often be described from the physical point of view as being in a certain state—for example, as being in a state of internal equilibrium. What is meant here is that the different particles of matter concerned stand in a certain relationship and as a consequence develop certain physical properties. But is mentality to be conceived as a physical property? It sounds extravagant to say so. Yet some such doctrine must be defended if Materialism is to be advanced as a form of ontology with a serious claim for attention. It is

interesting in this connection to notice the arguments advanced by scholars like J.J.C. Smart, which purport to identify states of mind with states of the brain. If the two are identical—literally the same thing described from two points of view—thoughts may really be modifications of matter, and Materialism may be tenable in a strong form. If, however, the identity cannot be made out—and very few philosophers are in fact ready to accept it—Materialism can be true at most in a modified form.

Naturalism

This modified form of Materialism is perhaps better described as naturalism. Naturalism holds not that all things consist of matter or its modifications but that whatever exists can be satisfactorily explained in natural terms. To explain something in natural terms is to explain it on scientific lines; naturalism is in fact a proclamation of the omnicompetence, or final competence, of science. It is not essential to this type of view to argue that phenomena can be spoken of in one way only; on this point, as on the point about ontological reducibility, the theory can afford to be liberal. It is, however, vital to make out that the scientific account of a set of happenings takes precedence over any other. Thus, the language in which men commonly speak of action and decision, which may be called for short the language of reasons, must be held to be secondary to the language in which scientists might speak of the same facts. Scientific language is basically causal, and the thesis of this form of Materialism is that causal explanations are fundamental. Naturalism is thus the obverse of Hegelianism; it is a theory of first principles, and it draws its principles from science.

If the question is raised why anyone should take this form of Materialism seriously, the answer lies in a number of significant facts. Physiologists have established correlations between general states of mind and general states of brain activity; their hope is to extend this to the point where particular thoughts and feelings can be shown to have their physiological counterpart. Cyberneticists have produced artifacts that exhibit mindlike behaviour to a remarkable degree; the inference that man is no more than a complicated machine is certainly strengthened by their achievements. Sociologists have shown that, whatever the explicit reasons men give for their beliefs, these are often intelligible in the light of factors of which they themselves take little or no account. The old assumption that human judgments are typically grounded in reason rather than merely caused, is called in question by the results of such investigations, which gain support from findings both in Freudian and in orthodox psychology. None of this evidence is decisive by itself; there are ways in every case of blocking the conclusions that Materialists tend to draw from it. Yet it remains true that, cumulatively, the evidence is impressive. It certainly has enough force to make it necessary to take this type of theory with the greatest seriousness. Metaphysical disputes in the modern world are fundamentally arguments for or against Materialism, and the other types of theory here explored are all seen as alternatives to this compelling, if often unwelcome, view.

IV. Argument, assertion, and method in metaphysics

Attention is now turned from description of the content of particular metaphysical views to more general treatment of the nature of metaphysical claims. The questions that will arise in this section concern such things as the nature and basis of metaphysical assertions, the character of metaphysical arguments and of what are taken to be metaphysical proofs, and the parts played in metaphysical thinking by insight and argument, respectively. They come together in the inquiry as to whether metaphysics can be said to be a science and, if so, what sort of a science it is.

METAPHYSICS AS A SCIENCE

Nature of an a priori science. Sciences are broadly of two kinds, a priori and empirical. In an a priori science such as geometry, a start is made from propositions that are generally taken to be true, and the procedure is to demonstrate with rigorous logic what follows if they are indeed true. It is not necessary that the primary premises of an a priori science should in fact be truths; for the purposes of the system they need only be taken as true, or postulated as such. The main interest is not so much in the premises as in their consequences, which the investigator has to set out in due order. The primary premises must, of course, be consistent one with another, and they may be chosen, as in fact happened with Euclidean geometry, because they are thought to have evident application in the real world. This second condition, however, need not be fulfilled; a science of this kind can be and commonly is entirely hypothetical. Its force consists in the demonstration that commitment to the premises necessitates commitment to the conclusions: the first cannot be true if the second are false.

Hypothetical nature of a priori sciences

This point about the hypothetical character of a priori sciences has not always been appreciated. In many classical discussions of the subject, the assumption was made that a system of this kind will start from as well as terminate in truths, and that necessity will attach to premises and conclusions alike. Aristotle and Descartes both spoke as if this must be the case. It is clear, however, that in this they were mistaken. The form of a typical argument in this field is as follows: (1) p is taken as true or given as true; (2) it is seen that if p, then q; (3) q is deduced as true, given the truth of p. There is no need here for p to be necessary or self-guaranteeing truth; p can be any proposition whatsoever, provided its truth is granted. The only necessity that needs to be present is that which characterizes the argument form, "If p is true, and p implies q, then q is true," that is $[p \cdot (p \supset q)] \supset q$, in which $\cdot$ symbolizes "and," and $\supset$ means "implies"; and this is a formula that belongs to logic. It is this fact that makes philosophers say, misleadingly, that a priori sciences are one and all analytic. They are not, because their premises need not answer this description. Nevertheless, they draw their lifeblood from analytic principles.

Metaphysics as an a priori science. It is clear that metaphysical philosophers have sometimes aspired to present their results in the form of a deductive system, to make metaphysics an a priori science. For this purpose they have taken a deductive system to require, not just that the premises entail the conclusions, but further that they themselves be necessarily true. Spinoza thus began the first book of his *Ethics* by laying down eight definitions and seven axioms whose truth he took to be self-evident, and then proceeded in the body of the text to deduce, as he thought with strict logic, 36 propositions that follow in order from them. He repeated the procedure in the rest of his work. That philosophical conclusions should thus be capable of being set out "in the geometrical manner" was something that Spinoza took as axiomatic; to be worthy of attention at all, philosophy must issue in knowledge as opposed to mere opinion, and knowledge proper had to be exempt from the possibility of doubt, which meant that it must either be intuitively evident or deducible from what was intuitively evident. Spinoza took this conception of knowledge from Descartes, who had himself toyed with the idea of presenting metaphysical arguments in the geometrical manner. Descartes, however, pointed out that, although there was no difficulty in getting agreement to the first principles of geometry, "nothing in metaphysics causes more trouble than the making the perception of its primary notions clear and distinct"; the whole trouble with this discipline is that its students fail to see that they must start from what are in fact the basic truths. Descartes himself spoke as if the problem were no more than pedagogical; it was a question of making people see as self-evident what is in itself self-evident. His own "analytic" approach in the *Meditationes* was chosen to overcome these difficulties; it was, he said, "the best and truest method of teaching." But it may well be that this account is too optimistic. The difficulty with a system such as those of Descartes and Spinoza is that there are persons who cannot be brought to see that the primary propositions of the system are self-evidently true, and this not because they are lacking in attention or insight but because they see the world in a different way. This suggests that in any such system there will necessari-

Deductive systems of Spinoza and Descartes

ly be an element that is arbitrary, or at least noncompulsive. However cogent the links that bind premises to conclusions, the premises themselves will lack a firm foundation. If they do, the interest of the system as a whole must be greatly diminished; it can be admired as an exercise in logic but not valued for more than that.

To avoid this unpalatable conclusion two expedients are possible. The first is to say that the first premises of a metaphysical system must be not merely self-evident but also self-guaranteeing; they must be such that any attempt to deny them can only result in their reaffirmation. Descartes believed that he could satisfy this requirement by grounding his system in the *cogito,* though strictly this was the primary truth only from the point of view of subjective exposition, and not according to the objective order of things. Aristotle somewhat similarly had argued that the logical principle of noncontradiction, which he took to express a highly general truth about the world, must be accepted as axiomatic on the ground that its correctness is presupposed in any argument directed against it.

Even the Idealists Bradley and Bernard Bosanquet at times spoke as if the first principles of their system were in some way logically compulsive; as Bosanquet put it, one had either to accept them or recognize that he could know nothing. Whatever the position may be about particular metaphysical propositions, however, it seems clear that not all truths that are taken as basic in metaphysics have the characteristic of being self-guaranteeing. A Materialist takes it as fundamental that whatever occurs happens as a result of the operation of natural causes; a theist sees things in the world as finite and thus as pointing beyond themselves to the infinite being who is their ground. No contradiction is involved in denying these positions, though of course for those who accept them the denial necessarily involves commitment to falsehood. It is, however, one thing for a proposition or set of propositions to be false, another altogether for it to be necessarily false. If the first principles of metaphysics were really self-guaranteeing, only one system of metaphysics could be coherent, and it would be true just because it was coherent. The very fact that there is an apparent choice between competing metaphysical systems, which may differ in plausibility but agree in being each internally self-consistent, rules this possibility out.

The alternative is to argue that fundamental metaphysical propositions, though not self-guaranteeing, are nevertheless not arbitrary; they have or, to be more cautious, can have a firm foundation in fact. Metaphysical speculation is not, as some opponents of metaphysics have suggested, essentially idle—*i.e.*, the mere working out of the logical consequences of premises that the metaphysician chooses to take as true. Or, rather, it does not necessarily answer this description, because a metaphysician can have insight into the true nature of things and can ground his system on that. This second position in fact involves arguing that metaphysics is not an a priori but an empirical science.

Reference to experience

Metaphysics as an empirical science. If metaphysics is an empirical science, the question of whether or not to accept a metaphysical theory must be answerable, in part at any rate, by reference to experience. It will not depend on experience alone, any more than does the acceptability of a scientific theory, because here, as in the scientific case, thinking comes into the reckoning too. A metaphysician can be mistaken in his deductions, just as a scientist can. But even if these are impeccable he will not necessarily succeed, on this view of his undertaking. It may be that he argues correctly from premises that are unacceptable—unacceptable because they lack the necessary foundation in fact. He will then be like a scientist who puts forward a hypothesis and deduces its consequences without mistake, only to find that experience fails to confirm the supposition on which he is working.

Scientific hypotheses are refuted, or at least called seriously into question, when predictions based on them fail to come true. As Karl Popper—who has emphasized that there is a unity of method in all generalizing or theoretical sciences—has insisted, every scientific hypothesis must be testable, and the way to test it is to look for circumstances in which it does not hold. To content oneself with favourable evidence is not enough; one must be searching all the time for unfavourable evidence. Further, it must be possible, if the hypothesis is genuinely scientific, to specify in advance what would count as unfavourable evidence; the circumstances in which the hypothesis needs to be abandoned, or at least modified, must be indicated precisely. In ideal conditions it is possible to devise a crucial experiment that will test a hypothesis definitively; the Michelson–Morley experiment, which disposed of the theory of the luminiferous ether, was such an experiment.

It can be asked, however, what parallels there are to this in metaphysics. The difficulty with testing a metaphysical thesis is twofold. First, metaphysical theories tend to be extremely general and as such highly unspecific. They announce, for example, that every event has some cause or other, or that every change is part of a process that serves some purpose. To find counterexamples to theses of such generality is on any account exceedingly difficult: how can one be sure that all the possibilities have been explored? There is, however, another and still more serious difficulty. The scientist, once he has laid down the conditions that would have to obtain for his hypothesis to prove false, makes no bones about their occurrence; it is, typically, a matter of whether or not a certain pointer reading is registered, and this is a simple question of ascertainable fact. Fact for the metaphysician, however, is altogether more slippery. Different metaphysicians see the world each in his separate way; what they take to be the case is coloured by their metaphysical conceptions. There is no neutral body of facts to which appeal can be made to show that a metaphysical theory falls down, and this being so, the attempt to assimilate metaphysics to science must fail.

That this should be the case is perhaps not surprising. Scientific thinking proceeds within a framework of presuppositions that it is the business of the scientist to use, not to argue for and still less to challenge—presuppositions to the effect, for example, that every change has a natural explanation. No doubt scientists can change their presuppositions, but they seldom do so consciously; their usual practice is to take them for granted. Metaphysicians, however, necessarily take a very different attitude toward presuppositions. It is their business to tell men how to understand the world, and this means that they must, among other things, put forward and argue for a set of interpretative principles. Metaphysicians differ radically in the interpretative principles they accept, and it is this that explains their failure to agree upon what to take as fact. It is naïve to suppose that the points at issue between, for example, a Thomist and a Materialist can be settled by observation or even by experiment; the facts to which one might appeal in support of his theory may be seen in a very different light by the other, or perhaps be dismissed as simple illusion. Reflection on the phenomenon of religious experience will illustrate what is meant here. That men undergoing this experience are affected mentally and physically in certain specific ways is perhaps common to both Thomist and Materialist. But the further description of their state is entirely controversial and owes its controversial character to the varying preconceptions that the disputants bring to their task.

INITIAL METAPHYSICAL INSIGHTS

Origin. If metaphysics is far from being a simple empirical discipline, however, it does not follow that it is wholly without foundation in fact. The true situation can perhaps be put as follows. Every metaphysic consists in an imaginative view of the world elaborated into a conceptual system. Metaphysics, like poetry, begins by being a matter of vision; a metaphysician sees the scheme of all things in a certain light; for example, as nothing more than a vast mechanism or as God's creation. As a metaphysician, however, he cannot be content to rest in a vision of this sort, as for example the Romantic poet William Wordsworth does in his "Intimations of Immortality." He needs to think out terms in which whatever

Metaphysics as a matter of vision

exists can be described so as to accord with his primary insight; he needs to produce and apply a conceptual system and to argue against possible alternatives. Whatever its origins, metaphysics is strictly intellectual in its development. It should not, however, be inferred from this that it is essentially idle speculation. For when the question is raised of the source from which metaphysicians gain their initial insights, the answer that occurs most readily is that they are derived from reflection on certain evident facts. Thus, the source of the Materialist view of the world is undoubtedly the practice of science; the Materialist proposes to give unrestricted validity to ways of thinking that scientists have found effective in a certain restricted sphere. The source of Idealist thought is to be found in the practice of history, or more generally in the interpersonal relations of beings who are at once rational and sensitive; the Idealist philosopher takes concepts that are appropriate in these limited areas to apply to the whole of reality. Every system of metaphysics is grounded in some real experience and owes its initial appeal to that fact. This is not to say, however, that the metaphysician builds on experience as does his scientific colleague. To think that is to take altogether too simple a view of the whole question.

Tests of validity. A question of immense importance is whether there are any means of comparing the validity of initial metaphysical insights. If it has to be answered negatively—if it has to be allowed that, as it were, all candidates in this field start and finish on an equal footing—the argument that each of them has a foundation in fact will be entirely discounted. Whatever respectability their concepts possess in their original homes will be lost once they fall into the hands of the metaphysician, because the procedure of the latter in taking them up and extending them is essentially arbitrary. For example, that one sees the sum of things as a vast machine may be suggested by what goes on in science, but this view can neither claim scientific warrant itself nor draw on scientific prestige, because it seems to spring from nothing better than mere whim. There are, however, two reasons for thinking that initial metaphysical insights are based not on mere whim but on valid grounds.

Insights as limited in number and subject to experience

First, the number of what may be called viable metaphysical insights is in practice limited: there are varying ways of taking the world as a whole, but not an infinite variety. In the outline account of metaphysical theories given above, six different kinds of view were distinguished, each of which may be said to be grounded in one or more areas of experience. It would be possible to extend the list, but probably not very far; further candidates might well turn out to be no more than variations on themes already considered. Thus, Leibniz might be seen as a latter-day Platonist, and Spinoza as offering a different version of the dualism of Descartes, one that is more sympathetic to Materialism than was Descartes himself. If these claims are true, they are certainly important; for the facts here adduced suggest that the experiences or visions on which different metaphysicians build are not peculiar to individual minds but occur commonly and regularly. They are not the product of passing moods, seized on and exploited for no good reason, but connect with thoughts that recur repeatedly in sensitive and intelligent reflection.

Second, there is a sense in which, despite everything said above, metaphysical theories are subject to the test of experience. That metaphysics aspires to give an account of the world as a whole means that each metaphysician claims that his fundamental insight illuminates every department of life. It may be that there are no neutral facts to which a metaphysician can appeal to show the shortcomings of his opponents; metaphysicians pronounce on what is to count as fact, and this puts them in the happy position of being judges in their own case. It remains true, however, that everyone who engages in that type of philosophy has the formal task of accounting for all the facts that he recognizes, and this is something that can be done more or less well. The value of different metaphysical insights is sometimes shown in the success with which they are applied. Furthermore, it is not quite true that the metaphysician need consult no opinion but his own when it comes to working out his views. What might be called public opinion has a part to play as well, though it has no absolute right to a hearing. A metaphysician who chooses to dismiss areas of experience or ways of thinking that are commonly accepted as being in order does so at his peril; he reduces the initial plausibility of his own theories the oftener he finds himself in this position. He could, of course, be right and common opinion wrong; no genuine metaphysician is put off by the thought of such a conflict. Though he is not put off, however, he has to be wary all the same. He may be able to say what in the end is to count as fact, but if this involves him in dismissing as illusory what instructed opinion generally takes to be real, his triumph may be hollow. Whether he likes it or not, he has to frame a theory that will carry conviction with experts in the different fields concerned, or, if that is going too far, one that will strike them as not wholly implausible. A metaphysician who exercises his veto past that point is simply failing to do his job.

The test of self-consistency of theory

It must be admitted that the tests one can apply to determine the value of a metaphysical theory are at best unsatisfactory. Often one is driven back onto the expedient of asking if the theory is internally self-consistent; a surprisingly large number of philosophical theories are not. To confute a philosopher out of his own mouth is, perhaps, the most effective form of confutation. If this expedient will not apply, however, the questioner is not quite helpless. Whatever the explanation, it is a well-known fact that a philosopher can purchase consistency at the expense of plausibility; he can put forward theories that evade difficulties by simply declaring them nonexistent. In so doing, he turns his back on what instructed opinion generally takes to be fact. His hope is, of course, to persuade others to see the situation as he does, and there is always the possibility that he will succeed. If, however, after a suitable interval he has not, that must surely count against him. It is by this test that one decides, for example, that the metaphysics of Hobbes is not worth prolonged study, despite the enormous ingenuity of its author; there is too much in this system that seems to be sheerly arbitrary. The same comment could be made of certain forms of Idealism, which are so intent on the omnipresence of spirit that they neglect the materiality of the material order. Admittedly, the test is harder to apply when attention is transferred to the major theories in their most persuasive form, because here the question concerns views that have stood the test of time. It is not, however, entirely inapplicable even there. An individual, at least, may feel that this or that view will not do precisely because it achieves comprehensiveness by turning its back on fact; and, though it is unsatisfactory to fall back on personal judgment in this way, there is perhaps no other alternative in this difficult area.

Role of personal or social factors. Some writers on the philosophy of philosophy, such as Dilthey, have suggested that the persistence of a plurality of metaphysical systems is to be explained in terms of personal or social factors. Certain kinds of metaphysical outlook appeal to certain types of human being, or gain currency in social circumstances of this kind or that; to understand why they are accepted, recourse must be had to psychology or sociology or both. In the above account, stress has been laid on the historical background against which a number of famous metaphysical theories got their classical formulations; it is idle to deny that each was originally designed to solve a problem deemed to be urgent at the time. Nevertheless, the problem was, of course, an intellectual problem, and the solution offered claimed to be true, not simply comforting. No doubt wishful thinking is as rife in the field of metaphysics as anywhere; it is all too easy here to confuse what men ought to believe with what they want to believe. Philosophies reveal something about their authors and even about their historical age, as works of literature do; they constitute historical evidence as books on mathematics, perhaps, do not. Yet all this can be admitted without agreeing that metaphysics is merely of psychological or historical importance. Science does not cease to be true because it is shown to be useful.

Nor is it true that metaphysical theories always in fact give comfort; there are cases in which men find themselves returning over and over again to possibilities that they would very much like to believe were not realized. A philosopher can commit himself to a view of the world that is not at all to his taste, simply because it seems to him on due consideration that this is how things are. That philosophers are godlike beings able to rise entirely above the limitations of their age seems unlikely. It is equally unlikely, however, that their opinions are determined throughout by nonrational factors, and thus that their thinking can lay no claim to truth.

METAPHYSICAL ARGUMENTS

Classes of metaphysical statements

Logical character of metaphysical statements. Metaphysical statements fall into two main classes: statements about what exists and prescriptions about how to take or understand what exists. It might seem obvious that the first is the more important; the metaphysician first lays down what he takes to exist, and then tells how to interpret it. This would be correct if metaphysics were a departmental inquiry like, for example, botany; but, of course, it is not. Metaphysicians possess no special resources for the detection of unfamiliar entities, and in consequence the realities they accept must all be argued for. The fundamental items that fill the metaphysical world are one and all theoretical; they are not so much palpable realities as artificial constructs. That being so, there is less of a gulf between the two types of metaphysical pronouncement than might at first appear. It could indeed be argued that the two go closely together to constitute what may be called a metaphysical point of view, a standpoint whose primary purpose is to provide understanding. In a metaphysical context, to say what exists is itself a step on the way to understanding; it is not something that antedates theory, but part of a theory itself.

It may be asked whether metaphysical pronouncements are empirical or a priori and, if the latter, whether they are analytic or synthetic. They are certainly not straightforwardly empirical, for reasons just set out, and cannot be merely analytic (*i.e.*, true in virtue of the definitions of their terms and of the laws of logic) if metaphysics is to retain any significance. The conclusion that they must be synthetic a priori (*i.e.*, such that, unlike analytic propositions, they convey new knowledge and yet claim complete universality and necessity) seems to follow, and it is just what the opponent of metaphysics wants the metaphysician to adopt. Metaphysics, as he sees it, is a wholly unwarranted attempt to say what the world must be like on the strength of pure thinking, an attempt that is doomed to failure from the start. Before this condemnation is accepted, however, the function that the metaphysician assigns to his principles should be considered. When this is done, it becomes plain that the charge that he claims factual knowledge of a nonempirical sort is false; in one way he recognizes exactly the same facts as anyone else. Where he claims superiority is in knowing how to take facts, and the burden of his message consists in the advocacy of principles that, he alleges, will provide overall understanding. One can describe these principles as synthetic a priori if one chooses. It is probably best, however, to avoid this misleading term and simply say that they are thought of by the metaphysician as applying unequivocally to whatever falls within experience. These metaphysical principles are instructive at least in the sense of having alternatives, and they are certainly treated as being necessary. It is not true, however, that they take the form of statements of fact, even highly general statements of fact; nor is their necessity the same as that which characterizes logical truths. The principles are prescriptions rather than statements, and their necessity arises from the role they play in the constitution of experiential knowledge. It is a necessity that is in one way absolute: nothing that can claim to be real can escape their jurisdiction, because they tell how to take whatever occurs. Nevertheless, in another way the necessity of the principles is merely conditional, for other ways of interpreting the same data can be conceived, and it is admitted that there are circumstances, however hard to specify exactly, in which it would have to be agreed that they do not apply.

Deductive and inductive arguments

Logical form of metaphysical arguments. There is also the question whether metaphysical arguments are inductive or deductive or whether they have some logical form peculiar to themselves. It is obvious that much metaphysical reasoning is, or purports to be, reasoning in the strict sense, which is to say that its form is deductive. Arguments like the first cause argument for God's existence claim to be demonstrations; their exponents believe that anyone who commits himself to the truth of the premises stands logically committed to the truth of the conclusions. This claim can stand, even if it turns out that the project to set out metaphysical results in the geometrical manner is a mistake. It may be impossible to model metaphysics on mathematics, but that does not make particular metaphysical arguments any less deductive.

As regards inductive arguments, it would be odd to find a metaphysician contending, as, for example, historians regularly do, that p is true and q is true and therefore it is reasonable to conclude that r is true. To assess probabilities in the light of established facts is too cautious for the average metaphysical mind. Yet it would be wrong to deny that metaphysicians are preoccupied with facts. Their objective is to give a reasoned account of what exists or obtains, and for this purpose attention to fact is of course indispensable. It figures in metaphysical thinking at two stages. First, at the beginning, when the metaphysician is concerned to formulate his main thesis; here there is a move from what holds in a restricted sphere (the sphere of physics, for example) to what is supposed to hold generally, a move that is possible only if the theorist concerned has an interest in the sphere in question. To arrive at his own position the metaphysician must extrapolate from what goes on outside metaphysics, and this means that he must be sensitive to significant developments in at least some of the main fields of learning and areas of practical activity. But he needs this extra-philosophical knowledge for a second purpose too: in estimating the success of his own theories. In principle he must show that his interpretation of experience covers the facts in an adequate way, and for this purpose what experts in the different spheres take to be established is of crucial importance. Metaphysics is not an empirical science—the element of speculation it includes is too strong for that—but the metaphysician can no more ride roughshod over facts than the scientist can. At the least he must explain away phenomena that seem to count against his thesis, or indicate how they might be explained away. Whether he explains or explains away, he needs to know what the main phenomena are.

Transcendental argument

It is sometimes said that metaphysics can make use of a form of argument that is neither deductive nor inductive but transcendental; a transcendental argument is supposed to proceed from a fact to its sole possible condition. The interest of these arguments as they appear in philosophy—in the philosophy of Kant, for example—lies in the kinds of things that are taken as starting points; in Kant's case it was such things as the possibility of pure mathematical knowledge, the possibility of making objectively true statements, the fact that there is a unitary system of time. Kant purported to prove a number of surprising propositions by the use of transcendental arguments; what he had to say under this head has attracted particular interest in recent years. It seems clear, however, that from the logical point of view no special significance attaches to this form of argument. A transcendental argument is simply a form of deduction, with the typical pattern: only if p then q; q is true; therefore, p is true. The interest of the argument, and its difficulty, reside not in the movement from premises to conclusion, which is absolutely routine, but in the setting up of the major premise. Kant tried to commend his major premises (for example, in his arguments about causality and substance) by showing what would result if the protasis (*i.e.*, p) did not hold. Though in this way he showed that a sufficient is also a necessary condition, he did not make clear why it should be taken as the

sole such condition. There is an important gap in his reasoning here, as there is in other metaphysical writers.

V. Criticisms of metaphysics

Metaphysics has many detractors. The man who aspires "to know reality as against mere appearance," to use Bradley's description, is commonly taken to be a dreamer, a dupe, or a charlatan. Reality in this context is, by the metaphysician's own admission, something that is inaccessible to sense; as Plato explained, it can be discovered only by the pure intelligence, and only if the latter can shake itself free of bodily encumbrances. The inference that the metaphysical world is secret and mysterious is natural enough. Metaphysics in this view unlocks the mysteries and lets the ordinary man into the secrets. It is, not to put too fine a point on it, a study of the occult.

Metaphysics as a study of the occult

METAPHYSICS AS KNOWLEDGE OF THE SUPERSENSIBLE

That there are aspects of metaphysics that lend colour to this caricature can scarcely be denied. The language of Plato, in particular, suggests an absolute distinction between the deceitful world of appearances, which can never be an object of knowledge, and the unseen world of Forms, each of which is precisely what it appears to be. Plato urged his readers not to take seriously the things of sense; he told them that everything having to do with the senses, including the natural appetites and the life of the body, is unreal and unimportant. The philosopher, in his view, needs to live an ascetic life, the chief object of which is to cultivate his soul. Only if he does this, and follows a rigorous intellectual training, has he any hope of getting the eye of his soul fixed on true reality and so of understanding why things are what they are.

Yet even this program admits of an innocuous, or relatively innocuous, interpretation. The "dialectician," as Plato called his metaphysical philosopher, is said in one place to be concerned to "give an account," and the only things of which he can give an account are phenomena. Plato's interest, despite first appearances, was not in the unseen for its own sake; he proposed to go behind things visible in order to explain them. He was not so much disdainful of facts as critical of accepted opinions; his attack on the acquiescence in "appearances" was an attack on conventional wisdom. That this was so comes out nowhere more clearly than in the fact that his targets included not just beliefs about what there is but also beliefs about what is good. It is the opinions of the many that need correction, and that can get it only if men penetrate behind appearances and lay hold on reality.

Plato is often presented as an enemy of science, on the ground that he was bitterly opposed to Empiricism and because he said that, if there was ever to be progress in astronomy, the actual appearances of the starry heavens must be disregarded. He understood by Empiricism, however, the uncritical acceptance of apparent facts, with the attempt to trace regularities in them; it is an attitude that, in his view, is marked by the absence of thought. As for the starry heavens, it is certainly difficult to take Plato quite literally when he compares their function in astronomy to that of a well-drawn diagram in geometry. Yet he was not wrong to suggest that no progress could be made in astronomical inquiries until appearances were seen to be what they were and not taken for absolute realities. The subsequent progress of astronomy has shown this view to be entirely correct.

There are respects in which Plato's attitude to phenomena was precisely the same as that of the modern scientist. Nevertheless, the fact remains that he believed in a realm of unseen realities and is of course far from being the only metaphysician to do so. Many, if not quite all, metaphysicians are committed to claiming knowledge of the supersensible, in some degree at least; even Materialists are alleged to make this claim, when they say that behind the familiar world of everyday experience there lies material substance that is not accessible to the senses. It has been a commonplace among critics of metaphysics since the early 18th century that no such claims can be justified; the supersensible cannot be known about, or even known of, whether directly or by inference.

SPECIFIC CRITICISMS

Hume. An early but powerful statement of these criticisms is to be found in the writings of David Hume, *A Treatise of Human Nature* (1739–40) and *An Enquiry Concerning Human Understanding* (1748). Hume argued first that every simple idea was derived from some simple impression, and that every complex idea was made up of simple ideas; innate ideas, supposed to be native to the mind, were nonexistent. There were eccentricities in Hume's conception of idea (and for that matter in his conception of impression), but these did not destroy the force of his argument that the senses provide the materials from which basic concepts are abstracted. A being that lacked sense experience could not have concepts in the normal sense of the term. Next, Hume proceeded to make a sharp distinction between two types of proposition, one knowable by the pure intellect, the other dependent on the occurrence of sense experiences. Propositions concerning matters of fact and existence answer the latter description; they either record what is immediately experienced through the senses or state what is taken to be the case on the basis of such immediate experiences. Such statements about matters of fact and existence are one and all contingent; their contradictories might have been true, though as a matter of fact they are not. By contrast, propositions of Hume's other type, which concern relations of ideas, are one and all necessary; reflection on the concepts they contain is enough to show that they must, in logic, be true. Though, in a sense, knowledge of these propositions is arrived at by the exercise of pure reason, no real significance attaches to this fact. It is not the case of some special insight into the nature of things; the truth is rather that these propositions simply make explicit what is implicit in the definitions of the terms they contain. They are thus what Kant was to call analytic propositions, and it is an important part of Hume's case that the only truths to which pure reason can attain are truths of this nature.

Necessity of sense experience

Finally, Hume sought to block the argument that, even if the supersensible could not be known directly, or through pure intellectual concepts, its characteristics could nevertheless be inferred. His analysis of causality had this as one of its aims. According to Hume, the only means by which men can go beyond the impressions of the memory and the senses and know what lies outside their immediate experience is by employing causal reasoning. Examination of the causal relation shows that it is, however, among other things, always a relation of types of events in time, one of which invariably precedes the other. Causality is not, as Descartes and others supposed, an intelligible relation involving an internal tie between cause and effect; it is a matter of purely factual connection and reduces on its objective side to nothing more than regular precedence and succession. The importance of this for the present inquiry lies in the consequence that causal relations can hold only between items, or possible items, of experience. According to Hume, if the temporal element is removed from causality, nothing concrete is left; if it is kept, it becomes impossible to argue that one can proceed by causal reasoning from the sensible to the supersensible. Yet it was precisely this that Aristotle, Aquinas, and Locke had all attempted.

Hume's own explicit pronouncements about metaphysics are ambivalent. There is a famous passage in which he urged men to consign volumes of divinity and "school metaphysics" to the flames, "as containing nothing but sophistry and illusion," but in at least one other place he spoke of the need to "cultivate true metaphysics with some care, in order to destroy the false and adulterate." "True metaphysics," in this connection, meant critical philosophical reflection.

Critical philosophical reflection

Kant. In Hume's successor Kant, there was a sharper distinction between metaphysics and critical philosophy. Much of Kant's philosophical effort was devoted to arguing that metaphysics, understood as knowledge of things supersensible, is an impossibility. Yet metaphysics, as a study of the presuppositions of experience, could be put on "the sure path of science"; it was also possible, and indeed necessary, to hold certain beliefs about God, free-

dom, and immortality. But however well-founded these beliefs might be, they in no sense amounted to knowledge: to know about the intelligible world was entirely beyond human capacity. Kant employed substantially the same arguments as had Hume in seeking to demonstrate this conclusion, but introduced interesting variations of his own. One point in his case that is especially important is his distinction between sensibility as a faculty of "intuitions" and understanding as a faculty of concepts. According to Kant, knowledge demanded both that there be acquaintance with particulars and that these be brought under general descriptions. Acquaintance with particulars was always a matter of the exercise of the senses; only the senses could supply intuitions. Nevertheless, intuitions without concepts were blind; one could make nothing of particulars unless he could say what they were, and this involved the exercise of a very different faculty, the understanding. Equally, however, the concepts of the understanding were empty when considered in themselves; they were mere forms waiting to be brought to bear on particulars. Kant emphasized that this result held even for what he called "pure" concepts such as cause and substance; the fact that these had a different role in the search for knowledge from the concepts discovered in experience did not give them any intuitive content. In their case, as in that of all other concepts, there could be no valid inference from universal to particulars; to know what particulars there were in the world, it was necessary to do something other than think. Thus is revealed the futility of trying to say what there is on the basis of pure reason alone.

Differences between Hume's and Kant's criticisms

Kant's distinction between analytic and synthetic propositions has peculiarities of its own, but for present purposes it may be treated as substantially identical with Hume's distinction set out above. Similarly, the important differences between Kant and Hume about causality may be ignored, seeing that they agreed on the central point that the concept can be properly applied only within possible experience. If it is asked whether there are substantial differences between the two as critics of metaphysics, the answer must be that there are, but that these turn more on temperament and attitude than on explicit doctrine. Hume was more of a genuine iconoclast; he was ready to set aside old beliefs without regret. For Kant, however, the siren song of metaphysics had not lost its charm, despite the harsh words he sometimes permitted himself on the subject. Kant approached philosophy as a strong believer in the powers of reason; he never abandoned his conviction that some of man's concepts are a priori, and he argued at length that the idea of the unconditioned, though lacking constitutive force, had an all-important part to play in regulating the operations of the understanding. His distinction between phenomena and noumena, objects of the senses and objects of the intelligence, is in theory a matter of conceptual possibilities only; he said that, just as one comes to think of things sensible as phenomena, so one can form the idea of a world that is not the object of any kind of sense experience. It seems clear, however, that he went beyond this in his private thinking; the noumenal realm, so far from being a bare possibility invoked as a contrast with the realm that is actually known, was there thought of as a genuine reality that had its effects in the sense world, in the shape of moral scruples and feelings. A comparison of what was said in Kant's early essay *Träume eines Geistersehers erläutert durch Träume der Metaphysik* (1766; *Dreams of a Spirit-Seer*), with the arguments developed in the last part of his *Grundlegung zur Metaphysik der Sitten* (1785; *Fundamental Principles of the Metaphysic of Morals*, 1949), would seem to put this judgment beyond serious doubt.

Though Kant remained convinced of the existence of things supersensible, he nonetheless maintained throughout his critical writings that there can be no knowledge of them. There can be no science of metaphysics because, to be true to fact, thinking must be grounded in acquaintance with particulars, and the only particulars with which human beings are acquainted are those given in sense. Nor was this all. Attempts to construct metaphysical systems were constantly being made; philosophers repeatedly offered arguments to show that there must be a first cause, that the world must consist of simple parts, that it must have a limit in space, and so on. Kant thought that all such attempts could be ruled out of court once and for all by the simple expedient of showing that for every such proof there was an equally plausible counterproof; each metaphysical thesis, at least in the sphere of cosmology —*i.e.*, the branch of metaphysics that deals with the universe as an orderly system—could be matched with a precise antithesis whose grounds seemed just as secure, thus giving rise to a condition that he called "the antinomy of pure reason." Kant said of this antinomy that "nature itself seems to have arranged it to make reason stop short in its bold pretensions and to compel it to self-examination." Admittedly, the self-examination led to more than one result: it showed on the one hand that there could be no knowledge of the unconditioned, and demonstrated on the other that the familiar world of things in space and time is a mere phenomenon, thus opening up the way to a doctrine of moral belief. Though this doctrine could not be expunged from Kant's philosophy without destroying it altogether, it is quite wrong to present it, as some modern German writers do, as amounting to the advocacy of an alternative metaphysics. What Kant was concerned with here is what must be thought, not what can be known.

Logical Positivists. Despite what has just been said, it must be admitted that Kant's constant talk about the supersensible makes many critics of metaphysics regard him as a dubious ally. This was certainly true in the case of the Logical Positivists, the philosophical school that has attacked metaphysical speculation most sharply in the 20th century. The Positivists derived their name from the "positive" philosophy of Auguste Comte, a 19th-century Frenchman who had represented metaphysical thought as a necessary, but now superseded, stage in the progression of the human mind from primitive superstition to modern science. Like Comte, the Logical Positivists thought of themselves as advocates of the cause of science; unlike Comte, they took up an attitude toward metaphysics that was uniformly hostile. The external reason for this was to be found in the philosophical atmosphere in the German-speaking world in the years following World War I, an atmosphere that seemed to a group of thinkers known as the Vienna Circle to favour obscurantism and impede rational thought. But there were, of course, internal reasons as well.

According to the Positivists, meaningful statements can be divided into two kinds, those that are analytically true or false, and those that express or purport to express matters of material fact. The propositions of logic and mathematics exemplify the first class, those of history and the natural and social sciences the second. To decide whether a sentence that purports to state a fact is meaningful, one must ask what would count for or against its truth; if the answer is "nothing," it cannot have meaning, or at least not in that way. Thus, they adopted the slogan that the meaning of a (nonanalytic) statement is the method of its verification. It was this verification principle that the Positivists used as their main weapon in their attacks on metaphysics. Taking as their examples statements from actual metaphysical texts—statements such as "The Absolute has no history" and "God exists"—they asked first if they were supposed to be analytically or synthetically true, and then, after dismissing the first alternative, asked what could be adduced as evidence in their favour or against them. Many metaphysicians, of course, claimed that there was empirical support for their speculative conclusions; thus, as even Hume said, "the order of the universe proves an omnipotent mind." The very same writers, however, proved strangely reluctant to withdraw their claims in the face of unfavourable evidence; they behaved as if no fact of any kind could count against their contentions. It followed, said the Positivists, that the theses in which they were interested were compatible with any facts whatsoever and thus were entirely lacking in significance. An analytic proposition, such as "It either will or will not rain tomorrow," tells nothing,

The verification principle

though there may be a point in giving voice to it. A metaphysical proposition claims to be very different; it purports to reveal an all-important truth about the world. But it is no more informative than a bare tautology, and if there is a point in putting it forward, it has to do with the emotions rather than the understanding.

In point of fact, the Positivists experienced great difficulty in devising a satisfactory formulation of their verification principle, to say nothing of a satisfactory account of the principle's own status. In the early days of the movement the demand for verifiability was interpreted strictly: only what could be conclusively verified could be significant. This had the effect of showing that statements about the past and propositions of unrestricted generality, to take only two instances, must be without meaning. Later a move was made toward understanding verifiability in a weak sense: a statement was meaningful if any observations bore on its truth. According to A.J. Ayer, an English disciple of the Vienna Circle, writing in 1936,

> It is the mark of a genuine factual proposition, not that it should be equivalent to an experiential proposition, or any finite number of experiential propositions, but simply that some experiential propositions can be deduced from it in conjunction with certain other premises without being deducible from those other premises alone.

As Ayer admitted in his second edition, however, this formulation lets in too much, including the propositions of metaphysics. From "The Absolute has no history" and "If the Absolute has no history, this is red," it follows that "This is red," which is certainly an experiential proposition. Nor were subsequent attempts, by Ayer and others, to tighten up the formulation generally accepted as successful, for in every case it was possible to produce objections of a more or less persuasive kind.

This result may seem paradoxical, for at first glance the Positivist case is extremely impressive. It certainly sounds odd to say that metaphysical sentences are literally without meaning, seeing that, for example, they can be replaced by equivalent sentences in the same or another language. But if the term meaning is taken here in a broad sense and understood to cover significance generally, the contention is by no means implausible. What is now being said is that metaphysical systems have internal meaning only; the terms of which they consist may be interdefinable, but perhaps do not relate to anything outside the system. If that were so, metaphysics would in a way make sense, but for all that would be essentially idle; it would be a game that might amuse but could hardly instruct. The Positivists confront the metaphysician with the task of showing that this criticism is not correct. Whatever difficulties are involved in formulating a principle of verifiability, the challenge can hardly be ignored.

Moore and Wittgenstein. The Positivists were not the only modern critics of metaphysics. G.E. Moore never argued against metaphysics as such, but nevertheless he produced criticisms of particular metaphysical theses that, if accepted, would make metaphysical speculation difficult, if not impossible. It was characteristic of a certain type of philosopher, according to Moore, to advance claims of a highly paradoxical nature—to say, for instance, that "Time is not real" or that "There are no such things as physical objects." Moore's case for rejecting such claims was that they go against the most central convictions of common sense, convictions that people accept unhesitatingly when they are not doing philosophy. Men constantly say that they did this before that, that things are better or worse than they were; from time to time they put off things until later or remark that tomorrow will be another day. Moore took these facts as definitive proof of the reality of time and definitive disproof of any metaphysical theory that denied it. Supporters of Bradley, the philosopher here criticized, replied that Moore had missed the point. Bradley never denied the truth of temporal propositions as used in the description of appearances; what he questioned was the coherence and ultimate tenability of the whole temporal way of thinking. As Rudolf Carnap, a Logical Positivist, was to put it, he raised an external question and was given an internal answer by Moore. It was an answer, however, that carried considerable conviction. The simple denial of what seem to be obvious facts had always been part of the stock in trade of metaphysicians; they make much of the distinction between appearance and reality. Moore may not have demonstrated the impropriety of this insistence, but at least he made it necessary for the metaphysician to be more circumspect, to explain explicitly what he was denying and what he was ready to accept, and so to make his own case sharper and thus easier to confirm or reject.

Common-sense criticisms

Moore's implied criticisms of metaphysics lead on naturally to those of Wittgenstein. Moore took his stand on common sense, whereas Wittgenstein based his on living language. Arguing that men are each involved in a multitude of language games or autonomous linguistic activities, insofar as they are scientific investigators, moral agents, litigants, religious worshippers, and so on, Wittgenstein asked in what language game the claims and questionings of philosophers arose. He replied that there was no genuine linguistic context to which they belonged; philosophical puzzlement was essentially idle. Philosophers were preoccupied with highly general questions; they aspired to solve *the* problem of meaning or *the* problem of reality. Against that, Wittgenstein argued that words and sentences have meaning as used in particular contexts; there is no single set of conditions that have to be fulfilled if they are to be thought meaningful. Equally, there is no single set of criteria that have to be satisfied by everything one takes to be real. Sticks and stones and men are taken as real in everyday discourse, but so are numbers in the discourse of mathematicians, and so is God in the discourse of religious men. There is simply no warrant for preferring one of these above the others—for saying, for example, with persons of an Empiricist turn of mind, that nothing can be real that does not have existence in space and time.

Language criticisms

Wittgenstein's antipathy to metaphysical philosophy was in part based on self-criticism; in his early work the *Tractatus Logico-Philosophicus,* published in 1922, he had himself tried to give a general account of meaning. At least one doctrine of that enigmatic book survived in his later thought: the distinction between saying and showing. Wittgenstein in the *Tractatus* sought to pronounce on "what can be said" and came to the conclusion that only "propositions of natural science" can be. Though at this stage he spoke as if metaphysical statements were senseless, his motives for doing so were very different from those of the Positivists. The latter saw metaphysics as an enemy of science; in their view, there was only one way to understand the world, and that was in scientific terms. But Wittgenstein, though agreeing that science alone can be clear, held that scientific thought has its limitations. There are things that cannot be said but can nonetheless be shown; the sphere of the mystical is perhaps a case in point. Unlike his Viennese contemporaries, Wittgenstein had no wish to rule out of court the thought that there are more things in heaven and earth than can be compassed in the language of science; writers whom he admired—such as Blaise Pascal, a 17th-century French scientist and writer on religious subjects, and Søren Kierkegaard, a Danish philosopher and theologian who is regarded as the founder of modern Existentialism —had discoursed of such matters in a way that was highly illuminating. They had made clear, however, that, just as one here went beyond the province of science, so also one went beyond that of philosophy. For them the idea that the metaphysician is privy to the most important of all things is absurd. There may be a sense in which men transcend everyday experience in moments of religious feeling or artistic insight, but there is no justification for thinking that when they do they arrive at the metaphysician's Absolute. As Kierkegaard said, the man who looks for speculative proofs in the sphere of religion shows that he does not understand that sphere at all.

Religious philosophers. It is important, in considering current criticisms of metaphysics, to appreciate that this discipline is now under double attack. In the first place, it must face the assault of those who regard it as a rival to science; it is against this assault that sympathizers like

R.G. Collingwood, a British philosopher, historian, and archaeologist, seek to defend it. But metaphysics is also in disfavour among many religious philosophers. In earlier days, partisans of religion, and more generally believers in a spiritual order, looked to metaphysics to vindicate their claims against skeptical attack; now they are altogether more reluctant to do so. The continuing controversy about metaphysics has no doubt influenced this result; it scarcely seems sensible to take refuge in a fortress whose walls are so frequently breached. There is, however, another motive that operates here: the feeling that metaphysics is not only dubious but, worse, unnecessary. In an age whose tendencies are antiphilosophical rather than philosophical, there is widespread acceptance of the view that religion and morals, and for that matter science and history, are their own justification; none of them stands in need of a certificate of respectability from philosophy, and any pretense by metaphysicians to supply or refuse such a certificate must be without foundation. Though this view is widespread, it is even so not unchallenged; there are persons who find the fragmentation it involves—belief in God on Sundays, belief in science for the rest of the week—intolerable. For such persons, at least, the search for metaphysical truth and metaphysical answers must retain its fascination. (W.H.W.)

VI. Tendencies in contemporary metaphysics

Background: the thought of Kant and Hegel

Kant's efforts to limit metaphysics opened new lines for its development. He had thought that reason is established by being limited and that some truths are certain independent of anything that can happen in experience because experience is structured by the interpretive categories reflected in the truths. Thus, it is possible to be certain of the world in its general structure, but only insofar as it is an experienced or phenomenal world—*i.e.*, a world known by man, not a world as it is in itself. Hegel, however, argued persistently that knowledge of a thing unknowable in itself is a contradiction and that reason can know all that is real if the mind first accepts the given thing as "always already within experience as other." The mutual implication of knowing mind and reality known is accepted, and a science of self-consciousness that relates all categories and all reality to the knowing subject is envisaged. Thus, Kant's mutual implication of knowing subject and phenomenal thing was given ultimate metaphysical validity by Hegel, and Kant's reformulations of traditional dualisms—*e.g.*, subject–object, appearance–reality, perceptual–categorial, immanent–transcendent, regulative–constitutive—became momentous for metaphysics.

TENDENCIES IN THE UNITED STATES

John Dewey. In this milieu, John Dewey, an American educational reformer and pragmatic philosopher, published his "Kant and Philosophic Method" in 1884 in the journal of a group known as the St. Louis Hegelians. Although Dewey later rejected the full-scale Hegelianism expressed in the article, he did so only after gathering up in a partial synthesis the thought of both Kant and Hegel. In this he sounded the thematic notes of much contemporary American and continental metaphysics. Whether or not this metaphysics is explicitly termed transcendental (*i.e.*, concerned with experience as determined by the mind's conceptual and categorial makeup), it does two things: (1) it affirms Kant's insight that physical particulars cannot first be identified and later interrelated by means of the categories, but to be identified at all they must be assumed to be already categorized, and reasoning must proceed to expose those categorial structures that make the actuality of knowledge possible; (2) it agrees with Hegel's critique at least to the extent that Kant's idea that the source of sensations is external to the mind in a noumenon is regarded as a transgression of Kant's own doctrine that the categories, particularly that of causation, can be applied only within phenomenal experience. Dewey thought that Kant confused the empirical and transcendental standpoints by mixing analysis of the organism as sensationally responsive with analysis of mind. Kant forgot that it is only because the knowing subject already grasps the world through its categories that it can self-deceivingly regard its sensations as subjective and as caused by something not known. Thus, for Dewey, "The relation between subject and object is not an external one; it is one in a higher unity that is itself constituted by this relation."

In Dewey's extended later thought, metaphysics became the study of "the generic traits of existence." Concern with God and immortality slips nearly from view, and this is typical of much contemporary philosophy. Even so, Dewey's rethinking of the subject–object relation engenders a concept of a democratic and scientific community of persons, bound to each other through common ideals, which has religious overtones. Vague and ambivalent as this concept may be, it helps undermine the whole contrast between immanent and transcendent, and leads metaphysics on new paths.

William James. The work of William James, a leader of the Pragmatic movement, was typical of many contemporary tendencies, one of which is the attempt to locate the role of science in knowledge and culture. Trained in medicine, James hoped to protect the autonomy of psychology as a science by adopting a dualistic view of mind and matter: He "supposes two elements, mind knowing and thing known, and treats them as irreducible. Neither gets out of itself or into the other, neither in any way is the other." He presumed that mental states could be identified independent of a commitment to the metaphysical status of the things known by them and that they could then be correlated to the brain. Ironically, his attempts to identify mental states involved him in commitments to the nature of the world as presented to mind. The only meaning that can be given things is in terms of the anticipated consequences of one's actions upon these things in the world; this anticipation also supplies the meaningfulness of thoughts. This is the basis of the "instrumental" view of thoughts—*i.e.*, reflecting upon thoughts as "tools," or as "plans of action," tells one something about the things known by them, the "tooled"; the converse also occurs.

Location of the role of science in knowledge

Each realm of the world is experienced in terms of temporal standards of thought natural to that realm; *e.g.*, standards of mathematics are peculiar because of their ideal, changeless objects. These criteria are not derived from mind alone or from things alone but from their relationship in what is termed experience. This is a "double-barrelled" term—*i.e.*, an experiencing of experienced things. The mind cannot be specified independent of things that appear to the mind, and things cannot be specified independent of their modes of appearing to the mind. Phenomena regarded abstractly as singular, or "pure," are neutral between mind and matter, which are different contexts of the very same pure experiences—contexts that comprise a single world.

James would not claim that his method is transcendental. Yet the fact remains that for him subject and object cannot be specified independent of each other, and James undercuts dualism and moves toward a transcendental explanation of the conditions of knowledge.

James tried to avoid what can be called logicism, physicalism, and psychologism. The last claimed that, because knowing is a psychical act, all that is known about must be subject to psychological laws. James replied that the known-about, the experienced, has its own autonomy, either as pure experience, a "specific nature" studied by philosophy, as a physical context studied by physics, or, finally, as a psychical context, a human history, studied by psychology. The latter two are both dependent, at least for their ultimate meaningfulness, upon the first. Physicalism attempts to infer the nature of the psychical directly from the physical, thus reducing it to the physical. Most logicisms claimed that pure reason can grasp the real in itself. James agreed that reason entertains ideal objects, the relations between which are fixed independent of the sequence of sensory experience, but asserted that this experience must decide which necessary truths apply to the world. Although some always do apply, the ascertainment of what is categorial for the world is always incomplete. Just when the world "plays into the hands of

logic" is decided in that endless interaction of "worlds" or "orders of experience"—such as the perceptual, the imaginary, the mathematical—occasioned by a thing experienced sifting through the orders trying to find one that can contain it without contradiction; Pegasus, for example, is a mythical creature just because it cannot find a place in the world of real horses. The world of perceptual things, experienced as experienceable by all and as existing simultaneously, serves as a paradigm of reality, even though other orders of experience are not reducible to it. Existence is an unusual predicate for James; it means that practical relationship of doing and concern within which things must be able to stand to men if they are to be counted as fundamentally real. James was not giving a subjectivistic account of reality, however, because he included in the fundamentally real all that can be related spatially and temporally to what can stand over against men's bodily selves. This was commonly forgotten by critics of James' popularized theory of truth, Pragmatism, which was thus systematically misunderstood.

James' contemporaries Charles Sanders Peirce and Josiah Royce stood in close dialectical exchange with him on these themes. Differences between them concerned the scope and conditions to be assigned experience. In general, Peirce argued that experience is to be construed more narrowly, in terms of mathematical logic and physics, whereas Royce argued that the understanding of truth, error, and meaning requires the assumption of an absolute knower or experiencer. Peirce was an authentic genius whose thoughts were often seeds in the more systematically developed philosophies of the other Americans.

TENDENCIES IN CONTINENTAL EUROPE

Edmund Husserl and Phenomenology. Edmund Husserl, the German philosopher, used the term Phenomenology to name a whole philosophy. In order to rid his transcendental investigation of empirical prejudgments and to discover connections of meaning that are necessary truths underlying both physical and psychological science, Husserl bracketed and suspended all judgments of existence and empirical causation. He did not deny them; rather, he no longer simply asserted them. He reflected upon their intended meaning. In reflection he claimed to see that things have meaning in terms of how they appear to men in their pre-reflective life and that awareness is in terms of this "how." In pre-reflective life, however, men are not aware of the "how" as such. By exposing this basic meaning through which men refer to things, he can free their eyes of the "cataracts" of the stereotyped and the obvious and can summon them "back to the things themselves."

Reflection on pre-reflective life

Husserl took traditional metaphysics to be infested with pre-critical commitments to existence, either physicalistic, psychologistic, or logistic. He used the term ontology, however, to apply to his study of objects of consciousness and even appropriated the Aristotelian term first philosophy. The world appears within the reflective bracket as existentially neutral (*i.e.*, as regards whether things have existence in themselves or exist for men) but ontologically ordered, because, if various orders of beings exist, then what they are can be nothing but what they are intended to be. And what they are cannot be known until all they are intended to be is known.

Husserl distinguished two types of ontologies: formal ontologies, which are the domain of meanings, or essences, such as "one," "many," "whole," or "part," that are articulated by formal logic and which Husserl referred to as empty; and material ontologies, which discover and map the meaning and structure of sensory experience through transcendental investigation. In material ontology, for example, the essence of any physical thing is discovered by varying in the imagination the object that is given within its strictly correlative mode of perceptual consciousness; the essence is that identical something that continuously maintains itself during the process of variation. It is intuited that the perceived thing cannot vary in the imagination beyond the point of something given perspectively and incompletely to any given perceiving glance; hence, this is the essence of any physical thing. This is a truth of eidetic necessity and comprises a first principle in Husserl's projected philosophical science; *e.g.*, numbers are what they are because of the ways in which they are not like things.

The Existentialists. Husserl had early distinguished the primary task of description of "morphological essences" (those with "floating" spheres of application in the sensory life) from description of essences like those in geometry, which described closed, or definite, manifolds; but the question of the theoretical status of the ordinary perceptual world, or lived world (*Lebenswelt*), became increasingly disputed among Existentialists. They asked whether there can be a philosophical science that has made all its presuppositions transparent to itself. If transcendental elucidation of the *Lebenswelt*, with its historically established sediments of meaning, is really essential to show how theoretical sciences are grounded, then one may reasonably ask how Phenomenology can be sure it has accomplished the elucidation completely, because it is itself a theory. The question was intensified by Husserl's nearly imperceptible slide into what appeared to be an Idealist position regarding the source of all meaning, a commitment to an absolute ego. If this ego is regarded as individual in any way, the problem arises of how any other individual can be as other, because it is constituted in this primal ego.

Husserl's theory of the ego was rejected by French Existentialists such as Jean-Paul Sartre and Maurice Merleau-Ponty. For the latter, the bracketing of meanings can never be completed, for consciousness is not an enclosed individual that could grasp through reflection all its possible motivations to experience and give meaning to a world. Knowers are subjects with bodies, whose perceptual life is articulated only incompletely and discloses the world in progressively surprising ways. More meaning is found in existence than can at any moment be predicted, and even the meaning of existence is not reducible to any definable set of meanings.

Husserl's approach was not nearly radical enough for Martin Heidegger, a German thinker sometimes called an Existentialist. In thinking that he could prescind so neatly from fact and retain the essence of facts, Husserl was still involved to some extent in the prejudgments—the psychologistic, physicalistic, and logistic dualisms—that he inveighed against. For Heidegger there is no realm of consciousness that constitutes meaning, and he does not think that some sharp but harmless line could be drawn between essence and fact. The ambiguity in Husserl between "object" as sense of the particular and as the encountered particular in its bodily presence is not harmless. It is unjustifiable to think that consciousness can once for all demarcate the essential sense of a thing. Thus, Heidegger discarded the very concept of consciousness, and proposed a "fundamental ontology" of human being (*Dasein*). Man as a subject in the world cannot be made the object of sophisticated theoretical conceptions such as "substance" or "cause"; furthermore, man finds himself already involved in an ongoing world that cannot as a whole be made the object of such conceptions; yet the structure of this involvement is the transcendental condition of any science of objects. For example, a man can band with other men in philosophical groups and can think about the metaphysical status of other men only because he is already essentially with others. He cannot hope to so purify his own thinking that it becomes that of an impersonal thinker, an absolute ego.

Ontology of *Dasein*

According to Heidegger, to rethink the problem of reality at its roots, it is necessary to rethink the fundamentally temporal, already-given structures of human involvement. Prejudice in the West, which construes reality, or being, on the basis of beings (*i.e.*, being as the most general feature of beings), must be overturned, and the problem of the real, the "transcendent," must be rethought on a ground on which distinctions between immanent and transcendent and between perceptual and categorial have been reconstructed. The being of the world transcends any constitution of the meaning of the

world and is a condition of experience. Thus, a sense is required of being not as object but as the underlying condition for the reality of the being of all objects.

Heidegger wanted to propose a genuine phenomenology, a study that would presuppose nothing of the traditionally formulated distinctions such as subjective–objective or phenomenal–real. The transcendence of the world can be understood only as it appears; *i.e.*, when encountered openly, things appear as appearing in part, as revealing and concealing themselves. If to the uneducated eye the sun appears to be smaller than it is, this can be corrected only by educating the person to interpret appearances—to calculate, for example, the speed and direction of light. The real is given in and through its appearances.

THE THOUGHT OF WHITEHEAD

The thought of Alfred North Whitehead is a distinctive variation on these contemporary themes. Dualisms are undermined by a phenomenology that does not bracket factual assertions. Logical and mathematical deductive schemes must be able to be interpreted in relationships crudely observable in experience, and abstractions of physics and common sense parading as realism (*e.g.*, that things exist separately within their own surfaces) must be revealed for what they are, namely, abstractions. The basic units of reality are organismic unities, "actual occasions," which are spatial and temporal extensions that cannot be exhaustively expressed in terms of distributions of matter at an instant. Their unity is constituted in a perception-like responsiveness to the universe that, though usually lacking consciousness or apprehension, is an appropriation to and for itself of the whole. This appropriation cannot be exhaustively expressed by point-instant mechanics (mechanics that is worked out in connection with the physics of relativity and thus measures not only the distance but also the time intervals between points), but is minimally a "prehension" (a term proper to Whitehead indicating the point-transcending function of perception and consciousness).

Organismic unities

Each enduring object of ordinary perception—tables, chairs, animals—is, for Whitehead, a "society" of actual occasions inheriting, through a process of appropriation and re-enactment in a predictable way, characteristics of its predecessors. Human perception is understood as a special case of prehension, in which qualities of the environment are mediated and projected on the basis of organic and affective experience of the perceiver's body, but in such a way that some of this process can be acknowledged by the percipient upon reflection. Because human consciousness is regarded as only a special case of prehensive relations, and because vacuous realisms and notions of transcendence are regarded as "fallacies of misplaced concreteness and simple location," mind–body dualisms are rejected.

Whitehead thought of "the primordial nature of God" as a general ordering of the process of the world, the ultimate basis of all induction and assertion of law, a "conceptual prehension" that functions in the selection of those "eternal objects," or repeatable patterns that are enacted in the world. God, however, does not create actual entities. He provides them with initial impetus, in the form of their subjective aim, to self-creation. Even God is the outcome of creativity, the process by which the events of the world are synthesized into new unities. It is the creative, not fully predictable, advance into novelty of a pluralistic process. The freedom of man and the determinism of nature were regarded by Whitehead as another artificial dualism.

The future of metaphysics is uncertain, not mainly because of 20th-century critics, the Logical Positivists, but because of its own not fully predictable nor controllable dynamisms. (B.W.W.)

BIBLIOGRAPHY. These works deal mainly with the nature and possibility of metaphysics.

PLATO'S *Republic*, Books V–VII, is the *locus classicus* for the idea that, over and above the particular sciences, there is a "synoptic" study concerned with "first principles"; the idea of "the Good" as the supreme object of knowledge is also briefly expounded. For the latter, see also PLATO'S *Symposium* and the *Seventh Letter*. ARISTOTLE, in his *Metaphysics*, book Λ, argued that "first philosophy" has to do with "nonsensible substance" and identified it with "theology"; in books Γ and E of the same work, however, he presented metaphysics as the study of "Being as such." For discussion of these apparently conflicting views, see W.D. ROSS (ed.), *Aristotle's Metaphysics*, 2 vol. (1924); and WERNER JAEGER, *Aristoteles, Grundlegung einer Geschichte seiner Entwicklung* (1923; Eng. trans., *Aristotle: Fundamentals of the History of His Development*, 2nd ed., 1948). Modern discussions of metaphysics spring from the preoccupation of 17th-century philosophers with method and with the origin of ideas. On the former, see especially RENE DESCARTES, *Philosophical Works*, trans. by E.S. HALDANE and G.R.T. ROSS, 2 vol. (1911–12; corrected ed., 1924, reprinted 1967), and *Philosophical Letters*, trans. and ed. by A. KENNY (1970). Descartes is particularly interesting in his discussion of whether metaphysical arguments can be set out in geometrical form (see Haldane and Ross, vol. 2), a view explicitly adopted by BENEDICT SPINOZA in his *Ethica* (1677; Eng. trans. by W.W. WHITE and A.H. STIRLING, 4th ed. rev., 1927). LEIBNIZ was more interested in doing metaphysics than in theorizing about it, whereas his academic follower CHRISTIAN WOLFF combined both in his voluminous metaphysical writings (*Vernünftige Gedanken von Gott, der Welt und der Seele der Menschen*, 1720, in German; *Philosophia Prima Sive Ontologia, Cosmologia Generalis, Psychologia Rationalis*, and *Theologia Naturalis*, various dates between 1729 and 1737, in Latin). ALEXANDER BAUMGARTEN'S compendium *Metaphysica* (1739), on which Kant lectured, was in effect a digest of these last four works. The problem of the origin of ideas was first posed in JOHN LOCKE, *An Essay Concerning Human Understanding* (1690), on which Leibniz wrote a critical commentary (not published until 1765; Eng. trans., *New Essays Concerning Human Understanding*, 1896). GEORGE BERKELEY, in criticizing Materialism in his *Treatise Concerning the Principles of Human Knowledge* (1710), pressed Locke's demand that every simple idea be derived from experience, and DAVID HUME applied this Empiricist principle with complete generality in *A Treatise of Human Nature*, 3 books (1739–40), and *Enquiry Concerning Human Understanding* (1748). IMMANUEL KANT first discussed metaphysical method in his *Untersuchung über die Deutlichkeit der Grundsätze der natürlichen Theologie und der Moral* (1764; Eng. trans., *Inquiry into the Distinctness of the Principles of Natural Theology and Morals*, 1949); he examined the whole question of the possibility of metaphysical knowledge in *Kritik der reinen Vernunft* (1781; *Critique of Pure Reason*, 1929), and *Prolegomena zu einer jeden künftigen Metaphysik die als Wissenschaft auftreten können* (1783; *Prolegomena to Any Future Metaphysics*, 1953). For a sustained criticism of Kant's critical point of view, see the writings of HEGEL, especially *Phänomenologie des Geistes* (1807; Eng. trans., *Phenomenology of Mind*, 2 vol., 1910; 2nd ed., 1 vol., 1949); and *Encyklopädie*, 3rd ed. (1830; Eng. trans.: *The Logic of Hegel*, 1892; *Hegel's Philosophy of Nature*, 1970; *Hegel's Philosophy of Mind*, 1894, enl. ed. 1971). Nineteenth-century philosophers added little to the fundamental criticisms of metaphysics developed by earlier writers. AUGUSTE COMTE in his *Cours de philosophie positive*, 6 vol. (1830–42), treated the metaphysical attitude as the precursor of the scientific. J.S. MILL in his influential *System of Logic*, 2 vol. (1843), produced a comprehensive restatement of Empiricism that was unremittingly hostile to a priori speculation. His views were sharply criticized by T.H. GREEN in *Prolegomena to Ethics*, and by F.H. BRADLEY in *Principles of Logic* (both 1883). In America, C.S. PEIRCE, though sharing Mill's interest in natural science, adopted an altogether more sympathetic attitude toward metaphysics—see his *Collected Papers*, 8 vol. (1931–35); and even WILLIAM JAMES, who presented Pragmatism as a form of "radical Empiricism," was less restrictive in his outlook than his orthodox British counterparts—compare, *e.g.*, *A Pluralistic Universe* (1909). JOHN DEWEY'S lengthy creative life rose to a number of climaxes, two of which are *Experience and Nature*, 2nd ed. (1929), in which he constructed a distant reinterpretation of Hegel's dialectic, and *Art as Experience* (1934), in which he maintained that a philosophy's aesthetics is the ultimate test of its ability to grasp the integrity of experience. There are interesting remarks on the philosophy of philosophy in the works of WILHELM DILTHEY; see his *Gesammelte Schriften*, 2nd ed., 12 vol. (1957–60), especially vol. 5. Twentieth-century criticisms of metaphysics derive mainly from the work of the Vienna Circle—for which see VIKTOR KRAFT, *Der Wiener Kreis der Ursprung des Neopositivismus* (1950; Eng. trans., *The Vienna Circle: The Ori-*

gin of Neo-Positivism, 1953); and from LUDWIG WITTGENSTEIN, *Tractatus Logico-philosophicus* (1921), which was read as an improved version of Empiricism. Among the authors who influenced these Logical Positivists were ERNST MACH, *Die Mechanik in ihrer Entwicklung historisch-kritisch dargestellt* (1883; Eng. trans., *The Science of Mechanics*, 1883); and BERTRAND RUSSELL, with A.N. WHITEHEAD, *Principia Mathematica*, 3 vol. (1910–13), and *Our Knowledge of the External World* (1914). A.J. AYER, in his anthology, *Logical Positivism* (1959), reprints in translation some of the most famous papers from the Circle's periodical *Erkenntnis*. Ayer's own book, *Language, Truth and Logic* (1936), was extremely successful in spreading Positivist ideas in America and Britain, where the work of G.E. MOORE—especially in his "Defence of Common Sense" (1925)—had created an atmosphere in which metaphysical claims were viewed with suspicion. Another influential book along the same lines as Ayer's was H. REICHENBACH, *The Rise of Scientific Philosophy* (1951); see also MORRIS LAZEROWITZ, *The Structure of Metaphysics* (1955), which attempts to explain the activities of metaphysicians in terms of psychoanalysis. For criticism of Positivist ideas, see W.H.F. BARNES, *The Philosophical Predicament* (1950); D.F. PEARS (ed.), *The Nature of Metaphysics* (1957); and K.R. POPPER, *Conjectures and Refutations*, 2nd ed. rev. (1965). R.G. COLLINGWOOD, *An Essay on Metaphysics* (1940), though it purports to answer Ayer, produces an unconventional account of metaphysics as historical analysis, of considerable interest. For further discussions, see W.H. WALSH, *Metaphysics* (1963); and Ayer's later thoughts in his *Metaphysics and Common Sense* (1969). Chief works of EDMUND HUSSERL's three phenomenological periods, each of which can be regarded as an introduction to Phenomenology, are *Logische Untersuchungen*, 1st ed., 2 vol. (1899–1901; Eng. trans., *Logical Investigations*, 2 vol., 1970); *Ideen zu einer reinen Phänomenologie und phänomenologischen Philosophie*, vol. 1 (1913; Eng. trans., *Ideas: General Introduction to Pure Phenomenology*, 1931, reprinted 1969); and *Die Krisis der europäischen Wissenschaften und die transzendentale Phänomenologie* (1954; Eng. trans., *The Crisis of European Sciences and Transcendental Phenomenology*, 1970). Among the Existentialists, important works include MARTIN HEIDEGGER, *Sein und Zeit* (1927; Eng. trans., *Being and Time*, 1962) and his later thought in *Einführung in die Metaphysik* (1935; Eng. trans., *An Introduction to Metaphysics*, 1959); MAURICE MERLEAU-PONTY, *Phénoménologie de la perception* (1945; Eng. trans., *Phenomenology of Perception*, 1962); and JEAN-PAUL SARTRE, *L'Être et le néant* (1943; Eng. trans., *Being and Nothingness*, 1956). A chief work of A.N. WHITEHEAD is *Process and Reality* (1929, reprinted 1960). For a discussion of metaphysics on an introductory level, see BRUCE W. WILSHIRE, *Metaphysics: An Introduction to Philosophy* (1969).

(W.H.W./B.W.W.)

Meteor

The word meteor, derived from the Greek *meteōros* for raised or lofty, originally meant any phenomenon or object in the air. It is now used in a more restricted sense to refer to the streak of light that results from the entry of a small interplanetary solid particle into the Earth's atmosphere.

Synonymous terms are shooting star or falling star. In a broader sense the word meteor is often used loosely for the solid particle itself, though this is more correctly termed a meteoroid. When a meteor is bright enough to attract the attention of the most casual observer, it is called a fireball.

The fireball

One of the most spectacular sights in the night sky is the fall of a very large fireball. Here the brilliance may rival that of the full moon, or, rarely, even that of the Sun. The dazzling head, often shaped like a teardrop, is followed by a scintillating trail that may exhibit all the colours of the rainbow, while it sheds sparks that fade from bright orange to red as they disappear in the darkness. In daylight or twilight conditions the observer may also see a dark cloud of dust and vapour left along the path of the fireball.

Frequently, after some minutes, detonations or rumblings may be heard, giving evidence of the arrival of shock waves and the sound of air collapsing into the semivacuum created along the trajectory. The object is then termed a detonating fireball or bolide, and a portion of the original meteoroid may survive its atmospheric passage to fall to earth as a meteorite. Such events, however, are rare and localized.

Interaction with the atmosphere. When a meteoroid first enters the upper atmosphere at high velocity, its surface collides directly with the atoms and the molecules of air, primarily nitrogen and oxygen. The energy of motion (kinetic energy) is very high. To illustrate: a 30-calibre rifle bullet weighing just under 10 grams may leave the muzzle of the gun with a velocity of 840 metres per second. A meteoroid of the same weight, entering the atmosphere in the low-speed range at 30 kilometres (about 19 miles) per second, has 1,250 times as much energy; and if it enters in the high-speed range at 60 kilometres per second, its energy is 5,000 times that of the rifle bullet. Collisions with the atmospheric gas particles dislodge material from the meteoroid surface and break up atoms and molecules of both meteoroid and atmosphere into positively and negatively charged particles. The latter, mainly electrons, form a dense column immediately behind the meteor head and act as a good radar target. Both neutral and ionized atoms are excited to produce visible luminosity. As the meteoroid penetrates lower in the atmosphere a dense, high-temperature gas cap builds up in front. Almost anywhere along the trajectory the meteoroid may start to crumble and fragment. A sudden breakdown of the solid structure may produce one or more luminous bursts, and a bright terminal burst frequently appears at the end of the visible path.

Physical structure. It is of interest to speculate on the nature of the particle that produces a visible meteor. Some 2,000 separate meteorite falls have been recognized on the basis of recovered specimens; a simple extrapolation from laboratory knowledge of these objects could be used to draw the conclusion that meteoroids are just more of the same. That this may not be so is shown by the fact that, although the majority of meteors seen are probably members of current or previously existing meteor showers (see below *Meteor showers*), not a single meteorite has been clearly identified with any particular shower. Also, physical theory, applied to the observed heights, velocities, decelerations, and luminosities, indicates that in most cases the mean densities of the meteoroids may be below that of water and that they have a fragile structure with a tendency to crumble or fragment. A small fraction, probably 1 or 2 percent and not greater than 10 percent, consists of denser, compact particles corresponding more closely to meteorites. These latter are either nickel-iron, with densities about eight times that of water, or heavy stone, with densities between three and four times that of water. It is likely that the easily fragmented types of meteoroids originated with the comets, while the denser objects are fragments of small planets that disintegrated hundreds of millions of years ago.

Densities of meteoroids

Historical appearances. From antiquity, meteors have been noted as a relatively common sight in the night sky, though a physical understanding of them has only been arrived at in the last hundred years or so. References in literature, though not numerous, are fairly widespread. In Shakespeare's play, *Richard II*, Act II, the Captain says:

> The bay trees in our country all are wither'd,
> And meteors fright the fixed stars of heaven.

Tennyson, in *The Princess*, Part VII, writes:

> Now slides the silent meteor on, and leaves
> A shining furrow, . . .

Great meteor showers, when thousands of meteors appear in a few minutes, are fairly uncommon, but given clear skies, they may be seen over a wide area and they have always made a marked impression on the watchers. One of the earliest records, from the Chinese classic *Ch'un Ch'iu* (Spring and Autumn Annals), describes an event in 687 BC: "Stars fell like a shower." The same type of occurrence is described in the Bible, Rev. 6:13: "the stars of heaven fell unto the earth." An early belief that a meteor shower foretold high winds and bad weather is indicated by Virgil, in 30 BC, in the *Georgics*, Book I:

> Oft you shall see the stars, when wind is near,
> Shoot headlong from the sky, and through the night
> Leave in their wake long whitening seas of flame.

In the early morning hours of Nov. 13, 1833, a startling shower of meteors was visible over most of eastern North

America. An eye-witness account from South Carolina bears testimony to the effect produced.

> I then opened the door, and it is difficult to say which excited me most—the awfulness of the scene, or the distressed cries of the negroes. Upward of one hundred lay prostrate on the ground—some speechless, and some with the bitterest cries, but with their hands raised, imploring God to save the world and them. The scene was truly awful; for never did rain fall much thicker than the meteors fell towards the earth.

Meteor showers. It was first noticed on the occasion just described that practically all the meteors seemed to be radiating outward from a point in the constellation Leo. As Leo rose in the east so did this position, called the radiant of the shower. A shower is customarily named after the constellation in which the radiant is located, hence the November meteors are known as the Leonid shower. Other examples are the Perseid shower in the middle of August, radiating from Perseus, and the Geminid shower, which comes in the middle of December with a radiant in Gemini. The meteors of any one shower are, in reality, all moving along parallel trajectories. The effect of radiation is a result of the viewer's perspective, and the radiant shows the direction in space from which the meteors move down through the atmosphere.

Some meteor showers, including the Perseids and the Geminids, are quite regular and return with about the same strength every year but never become very spectacular. Others, like the Leonids, are remarkable at their peak but in some years few or none are seen. A search of old records, particularly those from China, Korea, and Japan, showed that the Leonid meteors had been observed since AD 902. It was found that there was a strong tendency for the great Leonid showers to occur at intervals of 33 or 34 years. On the basis of these calculations a good return was predicted for either 1866 or 1867, and large numbers of meteors appeared on the expected date in both of these years. Also in 1866, the Comet Tempel-Tuttle was discovered, and calculation revealed the remarkable fact that the meteoroids forming the Leonid stream were moving along almost the same orbit as the comet. Other associations of this type soon became known, and now over ten examples of comets and meteor streams sharing the same orbit are recognized. There is good reason to believe that shower meteoroids are the fragments of comets that are steadily disintegrating, scattering their substance along their orbits. When the Earth crosses such an orbit it collides with large quantities of these comet fragments.

Association of meteors with comets

One of the strongest Leonid returns of the 20th century came early on the morning of November 17, 1966. Unfortunately, most of eastern United States and Canada were cloud bound so that only radar records were secured in these areas. In the American Southwest, where clear skies prevailed, 40 Leonid meteors per second was estimated as the rate for a single visual observer at the shower maximum. Notable meteor showers were provided by the Draconid (Giacobinid) meteor shower, on Oct. 9, 1933, and on Oct. 10, 1946. A number of the easily recognized meteor showers are listed in the table.

Annual Meteor Showers

shower	average date of maximum	normal duration in days	visual strength, northern hemisphere	associated comet

Leonid	November 17	¼–2	irregular	Temple-Tuttle
Geminid	December 14	4	strong	—

Although scientific study of meteors began early in the 19th century, their rapid motion, combined with the unpredictable nature of the appearance of an individual meteor, made it difficult until the 1940s to use instruments for securing accurate information. Most of the work before that decade was carried out visually and was subject to large errors. The best observational data have been secured since 1945 with fast new meteor cameras of radical design, and with radio techniques. Radar records can be obtained in daylight and during periods of cloudy weather, and have greatly increased the information available. One of the first results of using radar to study meteors was the discovery of a new group of meteor showers. These have radiants that are only above the horizon during daylight hours and so could never be observed optically. More recently electronic image intensifiers have been used to record meteors, thus extending the optical range to fainter limits.

Techniques of observation

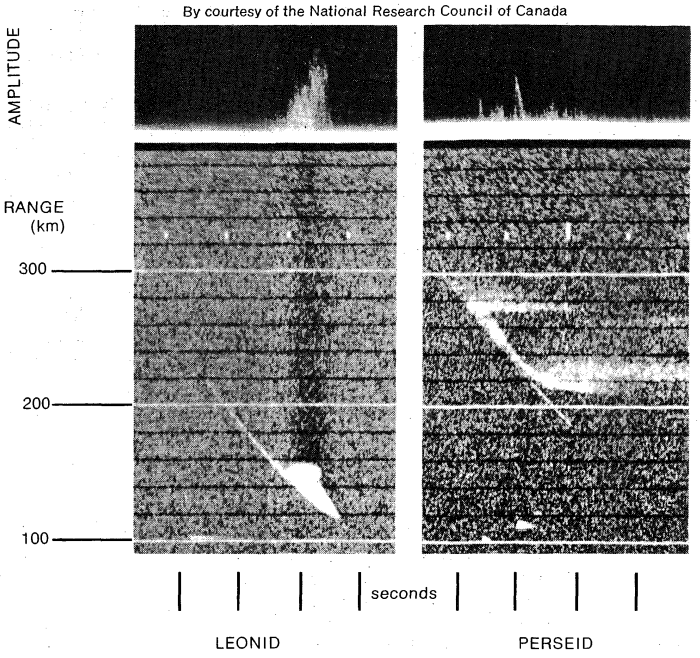

Figure 1: Radar records of two bright shower meteors, made in 1966 at Ottawa, Ontario.

Rates of occurrence. The frequency with which meteors enter the atmosphere has been the subject of much study but, until 1950, most of the data had been collected by visual observers, who recorded the number of meteors observed per hour. Such records, qualitatively useful, are difficult to reduce to quantitative values. A bright meteor will be seen if it appears anywhere in the general area of the sky the observer is facing. On the other hand, the faintest meteor visible will be recorded only if it is in a small area near the centre of the field of view. Slight changes in sky transparency alter the counts of faint meteors producing large random errors in the hourly rates. Even the best cameras do not record meteors down to the faint limit seen by the unaided eye. Radar observations have provided the best relative hourly rates throughout the year but these have not yet been accurately calibrated on the visual and photographic scales of brightness.

On an average clear dark night with no meteor shower, a single visual observer will generally see from five to ten meteors an hour, but unusual atmospheric transparency may double the number. A team of six observers will record between three and four times the number of meteors seen by an individual, and will make possible a better estimate of the total visible from one location. Meteors are relatively local in occurrence. In general, an observer at one location will not see the same meteors as a second observer at a location 500 or more kilometres (about 300 miles) away. More meteors are seen during the second half of the night, since in the early morning hours the rotation of the Earth carries the observer to the forward side of the planet in its orbit about the Sun. In the first half of the night, only those meteoroids fast enough to overtake the speeding Earth are seen as they plunge into the atmo-

sphere. The hourly rate during a meteor shower may increase by almost any amount; by factors of two to ten for the regular annual showers, up to factors as high as 10,000 to 100,000 for the really great showers.

Extrapolating from the counts for the area covered by a single observing station, the numbers of meteors encountered daily by the Earth during the entire 24 hours can be calculated. The count works out to be about 1,000,000 for objects as bright or brighter than the stars Vega, Arcturus, or Capella (zero magnitude in astronomical terms) and over 200,000,000 down to the limit of meteors visible to the naked eye. Still fainter objects can be seen in telescopes, and the number increases until meteors are included that are more than a million times fainter than the standard zero magnitude defined above. Somewhere in this size range the meteoroids no longer radiate visible light as they are slowed down in the upper air. These tiny particles, much less than a millimetre in diameter, are called micrometeoroids.

Heights. If a meteor is photographed from two stations separated by a reasonable distance—*e.g.*, 30 to 60 kilometres—its height above the Earth can be determined by triangulation. Average heights range from 70 to 110 kilometres, roughly 45–70 miles. As relatively few meteors are seen close to the zenith, the most common elevations above the horizon being from 20 to 70 degrees, it is obvious that the great majority of meteors are more than 90 kilometres from the observer when seen. In exceptional cases, usually slow, bright fireballs, the object when seen may be as close as 50 kilometres or as far away as 500 kilometres. The observation that a bright meteor has fallen to Earth "just beyond some trees" almost always may be discounted as incorrect. Normally, when a meteoroid does reach the ground as a meteorite it travels the final portion of its trajectory as a dark body; it is rarely luminous below heights of 10 to 20 kilometres.

Velocities. Even casual observers have noted the speed with which most meteors move across the sky. When this rapid angular motion is considered along with the distances noted above, it is clear that the real speed of meteors in the atmosphere is very high. The best determinations of meteor velocity are made by photography, using cameras equipped with shutters that block the lenses at a fixed frequency. This produces a series of breaks in the photographic trail, the number of breaks indicating the number of lens occultations and thus the duration of the meteor. The use of two such records from opposite ends of a base line makes possible the calculation of accurate velocities. Slightly less accurate values can be obtained by employing radio equipment. Most meteors slow down very little during the time they are visible, average decelerations amounting to not more than 1 or 2 percent.

Determining meteor velocity

The velocity at which meteoroids enter the atmosphere results primarily from two motions, that of the meteoroid in its orbit and that of the Earth (about 30 kilometres, or about 19 miles, per second) in its annual path about the Sun. The gravitational pull of the Earth on the particle increases the speed of the meteor by from 1 to 3 or more kilometres per second. The observed speeds of meteors range from a low near 15 kilometres per second, for the objects overtaking the Earth, to a high of over 70 kilometres per second for the particles that the Earth meets head on. A frequency plot of observed speeds shows a tendency to clump around two ranges, low-velocity meteors with speeds from 20 to 40 kilometres per second, and high-velocity meteors with speeds from 60 to 70 kilometres per second. The faster meteors are visible at greater heights. Those in the high-velocity group appear near 110 kilometres altitude and disappear near 95 kilometres. The corresponding values for the low-velocity group are 95 and 80 kilometres, respectively. Maximum luminosity normally occurs two-thirds of the way down the visible trajectory. The above heights are general averages only and there is considerable variation for individual meteors. Very bright objects, for example, will usually penetrate much lower in the atmosphere, by as much as 20 kilometres or more; the size of the original meteoroid and the inclination of its trajectory to the horizontal will also affect the height of the visible path.

Analysis of luminosity. A brilliant meteor is often described as looking like a magnesium flare, and this subjective impression happens to be quite close to the truth. Meteors, like flares and fireworks, have a large percentage of their luminosity produced by individual atoms radiating with their characteristic colours in an energized cloud of gas. Practically all of the visible light originates in a compact, gaseous cloud of atoms and molecules surrounding or closely trailing the meteoroid as it moves through the atmosphere. These atoms and molecules are a mixture of those evaporated or ablated from the meteoroid, together with others trapped from the upper atmosphere.

Meteor spectra

The nature of the light of meteors may be studied if a dispersing unit, such as a glass prism, or a diffraction grating, is used in conjunction with a camera. This produces a record of the meteor's spectrum. Low-energy radiations of the elements iron, oxygen, magnesium, sodium, nitrogen, and calcium are the most prominent in the spectra of meteors. This does not mean, necessarily, that these are the most abundant elements in the radiating source. Other atoms that are recorded frequently include hydrogen, silicon, manganese, and chromium, while the molecule of nitrogen is observed as a general background in the radiation. Whether a given element appears in a meteor spectrum depends not only on its presence in the meteoroid or the atmosphere but also on whether the atom or molecule has low-energy radiations in the wavelengths that can be photographed. The meteors that move through the atmosphere at higher speeds radiate light that requires higher energies for its production.

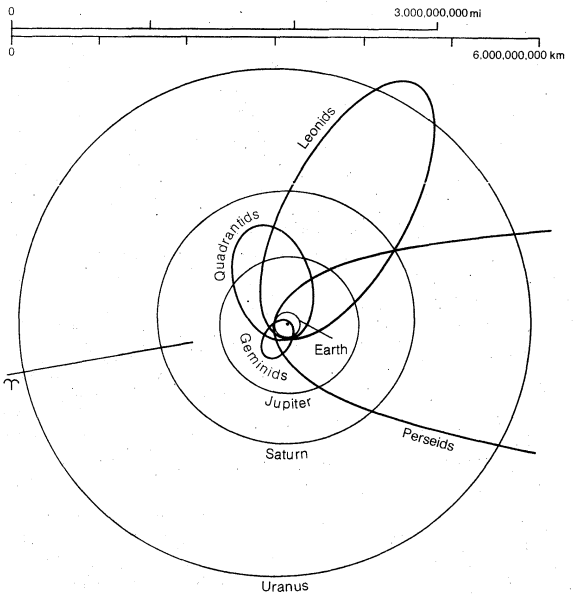

Figure 2: Orbits of four meteor showers plotted in relation to planetary orbits. Planes of meteor orbits deviate from those of planets. To illustrate their true shape, all meteor orbits have been plotted as if they were in the plane of the paper which represents the ecliptic, the plane of the Earth's orbit.

Meteor trains. The major portion of the light from a meteor is produced near the moving solid particle and is of very short duration, as is shown by the sharpness of the breaks produced in the photographed trail by an occulting shutter on the camera. In the case of bright meteors, particularly if they are fast, a residual luminosity called the train may be left behind the meteor head. That part of the train with a duration measured in small fractions of a second is called the wake, and the light is produced by some of the same types of atoms appearing in the head, but at a lower excitation. Another kind of train luminosity appears in the upper part of the meteor trajectory at heights from 100 to 115 kilometres, about 60–70 miles. It has a duration of one to two seconds and consists of the green radiation of the neutral oxygen atom, the strongest and commonest feature in most auroral displays. A third type of train luminosity may last up to 10 or 15 minutes as a faint

glow. This type has not yet been fully analyzed, but the light of the sodium and magnesium atoms and of the nitrogen molecule probably contributes to it.

The long-enduring trains of bright, fast meteors were the first phenomena to reveal the strong wind shears and jet streams common at heights between 80 and 100 kilometres. The train, initially a thin, straight line, rapidly diffuses and becomes twisted into complicated snakelike forms. This circumstance may well explain some rather bizarre accounts of things seen in the sky during great meteor showers of the past.

Orbits. Once the direction of motion of a meteor in the atmosphere and the corresponding speed along the trajectory have been accurately determined, it is possible to compute the orbit of the original meteoroid. Since the meteors that become visible either vaporize or fall to earth, only the orbits of meteoroids that have ceased to exist, as such, are known. It can be inferred that the observed orbits are typical of the others that are still active, but the Earth encounters only a very small fraction of the meteoroids in interplanetary space. These little objects are far too small to be detected until they become luminous in the upper air. Hence, only those meteoroid orbits can be studied that intersect the orbit of the Earth. Assumptions about meteoroids in other orbits depend on uncertain extrapolations.

The correspondence between shower meteoroid orbits and certain comet orbits has been noted already. As a class these orbits are elongated—that is, of high eccentricity—and objects moving in such orbits vary greatly in their distance from the Sun. The planes of the orbits tend to be fairly random and may deviate widely from the plane of the Earth's orbit, the ecliptic. This means that in some cases the meteoroid streams move about the Sun in the opposite direction to the planets, and the Earth meets the meteoroids almost head on. The Leonid shower is of this type; the Leonid meteors enter the Earth's atmosphere at a speed of over 70 kilometres (43 miles) per second, the fastest of any shower.

Orbits of sporadic meteors

The large numbers of meteors that do not belong to a recognized shower, often called the sporadic meteors, show a preference for direct motion; that is, they revolve around the Sun in the same direction as the planets. The planes of the orbits of sporadic meteors tend to be fairly near the ecliptic plane. The orbits for very bright, slow fireballs have planes that cluster still more closely near the ecliptic, and the shapes of these fireball orbits are more nearly circular, corresponding to those of the minor planets. Analysis of large numbers of faint-meteor orbits indicates that the density of small meteoroids in interplanetary space is high between the Earth's orbit and the Sun and decreases out toward the orbits of Mars and Jupiter.

In the early decades of this century good instrumentally determined orbits for meteors were nonexistent. It was concluded from indirect evidence that a significant percentage of the meteoroids were interstellar; that is, they came from outside the solar system. Such objects would have open-ended, hyperbolic orbits about the Sun and would move faster than objects in elliptical orbits. The use of radar techniques and of fast cameras has now proved that practically all observed meteoroids move in closed elliptical orbits, and it is difficult to find even a single example of a particle with an accurately determined hyperbolic orbit. Apparent exceptions to this rule generally prove to be particles recently accelerated into a hyperbolic orbit by a close approach to a large planet. Therefore the complex of meteoroids and meteoritic dust is part of the Sun's family, along with comets, planets, and satellites.

Masses. One of the major problems in the study of meteors is to determine the mass of the original meteoroid corresponding to any given meteor. Since the majority of meteoroids are vaporized high in the upper air, and since even the meteorites that land have lost a significant fraction of their mass in their passage through the atmosphere, all calculations of original mass must be made by indirect methods. Unfortunately, a complete physical theory to facilitate such calculations has not yet been worked out, though with the help of artificial meteors fired from rockets good progress is being made in determining the necessary constants for the theoretical equations.

It may be assumed that on the average a meteoroid that produces a zero-magnitude meteor weighs close to one gram. This can be thought of as a standard meteoroid and in one day the earth encounters about a million objects of this mass or heavier. The best recent knowledge concerning the relative numbers of meteoroids of various masses is based on radar studies. If a count is taken of particles down to a mass 0.01 gram, which will produce a meteor near the limit of visibility with the naked eye, the number will be 400 times the count down to the standard meteoroid of 1 gram. Following the same rule, a count down to masses of 0.0001 gram will give 160,000 times the number for the standard. For still smaller particles the ratio is not so well known, but other sources of evidence, such as the detection of nickel-iron particles in arctic snows and deep-sea drill cores, suggest that the Earth sweeps up several hundred tons of mass a day in the form of micrometeoroids or meteoritic dust. A simple calculation will show that, if the above figures for the numbers of visible meteors are of the right order of magnitude, the Earth collects far more mass in the form of dust and micrometeoroids than it does in the range of the larger particles.

Although the frequency of occurrence of specific masses in space is not yet known with high accuracy, the Pegasus satellite program of the U.S. has produced good values of penetration frequency. A sheet of aluminum one metre square and 0.01 centimetre thick, remaining in space in the vicinity of the Earth and Moon, will be penetrated once every 10 days on the average. Increasing the aluminum thickness 10 times decreases the frequency of penetration by a factor of nearly 200.

Meteorite

Though the term meteor, until the end of the 17th century, meant almost any atmospheric or supposedly atmospheric phenomenon—hail, rain, lightning, rainbows, etc. —the modern use of the term is restricted to what the 18th century called fiery meteors: shooting stars and those larger, more brilliant, but essentially similar objects usually called fireballs, or bolides. Meteorites may be defined as solid objects reaching the Earth's surface from interplanetary space. Strictly speaking, although any solid mass that manages to survive passage through the atmosphere and any dust arising from material melted or vaporized during passage would both fall under this definition, the term is usually restricted to the former.

The fall of a meteorite in this narrower sense is a striking phenomenon, involving a brilliant fireball and startling, thunderous noises. A very large meteorite—one weighing from about 200 tons up—explodes on impact with the ground (see METEORITE CRATERS), but, fortunately, such events are very rare. The solid mass itself is of great scientific interest, not only as the only extraterrestrial material available before the lunar landings took place but also because the analyses of the chemical and rock characteristics of meteorites carry clues to the early history of the solar system. The mean abundance of the

elements in a certain class of meteorites, the chondrites, is believed to approximate the abundance of elements in the solar system, excluding a few volatile ones. From study of the textures and internal structures of meteorites and of their content of various radioactive atoms (radionuclides) and the breakdown products of radionuclides, conclusions may be drawn about the early history of both meteorites and the solar system as a whole. It is widely accepted that meteorites originate from collisions between asteroids, probably 100 to 300 kilometres (roughly 60 to 190 miles) in diameter, which aggregated from fragmentary material about the same time as the Earth, some 4,500,000,000 years ago. A few astronomers, however, still champion a theory of an origin from the Moon or from Mars for at least some classes of meteorite.

Meteorites are named according to the place of discovery or fall, usually identified by the nearest named location, which may be a small farm, village, or other geographic place name. They are described as stones, irons, or stony irons, according to their composition (see below *Classification*).

Historical. Men have been aware at least since the dawn of civilization that stones and, more rarely, masses of iron sometimes fall from the sky. Nickeliferous iron beads found in predynastic graves at Gerzeh, Egypt, and fragments of iron found at Ur, in Mesopotamia, predate knowledge of iron smelting and are certainly of meteoritic origin. Such celestial objects were believed to have been sent by the gods. It was suggested as long ago as 1796 that cult objects found in classical times in a number of cities of Egypt and the Levant were meteorites, though the evidence is not conclusive. A black stone built into the sanctuary of the Ka'bah, in Mecca, has also been regarded as probably meteoritic.

Meteorite falls in ancient records

There are numerous records in ancient Chinese annals, in Greek and Latin literature, and in medieval annals of the fall of stones, but in many cases these reports may really refer to giant hailstones, and in others they are either insufficiently detailed or contain too many contradictions to be acceptable as conclusive evidence. Even reports of the fall of masses of iron (*e.g.*, Lucania, Italy, 56 BC; Meissen, Saxony, 1164; Naunhof, Saxony, about 1540) cannot be accepted as well established; and the tendency to embroider the details was and still is so strong that scientists are rarely prepared to accept any individual fall as proved unless material has been preserved and studied.

Although up to the early 18th century it was generally believed that stones do fall from the sky, there followed a period of almost a hundred years when this phenomenon was widely regarded as an impossibility. This view probably resulted from the mixture of inaccurate observation, misremembered detail, secondhand, misunderstood reporting, and preconceived notions of what was observed in the centuries preceding. The general philosophy of the mid-18th century was doubtless also an influence—it was a notion, largely unformulated, that Newtonian physics had explained the cosmos, leaving no room in the solar system for anything but the Sun, the major planets with their satellites, and a few wandering comets. An unconscious carry-over from the Ptolemaic cosmology, in which everything outside the orbit of the Moon was immutable, may also have been involved. The idea that the fall of stones from the sky is an absurdity was particularly strongly held in the Académie Française, and, under this influence, meteorites preserved from earlier times in several museums and collections of curiosities were thrown away. The U.S. president Thomas Jefferson refused to believe in the extraterrestrial origin of a meteorite that fell in Weston, Connecticut, in 1807. The oldest meteorite seen to fall and still preserved is the stone that fell at Ensisheim, Alsace, on November 16, 1492. Originally weighing about 127 kilograms (280 pounds), it was kept in the parish church for a long time, and the main mass is still treasured in the town hall of Ensisheim, though fragments have been distributed to museums in many parts of the world. Few other meteorites now preserved fell or were found earlier than 1790.

In 1766 an Italian scientist published a careful description of the Albareto (Italy) fall of that year; in 1769 the Lucé (France) fall of 1768 was described; and in 1794 a description of the Siena (Italy) fall of that year was published. In 1794 reports of iron masses for which an artificial origin seemed unlikely were collected and in 1796 reports of the fall of stones and irons were collected from older literature, chiefly through the efforts of the German physicist Ernst Chladni. To these were added notes on the Siena fall and a preliminary account of the Wold Cottage (Yorkshire) fall of 1795. This accumulated evidence, with reports of further falls at a rate of nearly one a year, shook the skeptics. When a shower of over 2,000 stones fell at L'Aigle, France, a commission was appointed to investigate, and its report, in 1804, firmly established the reality of falls of stones from outer space.

The sounds heard during the fall of a meteorite are very like thunder, and, before the nature of lightning was understood, it was reasonable to attribute damage from it to the fall of some solid object—a thunderbolt. The phrase a bolt from the blue indicates that a meteorite may fall from a cloudless sky. With this confusion of the two phenomena, it is not surprising that during the period of skepticism the Lucé meteorite that fell in 1768 was explained as a stone struck by lightning. In cases in which the actual impact of the meteorite had been witnessed, the scientific explanation was that these were stones thrown out by terrestrial volcanoes or, more reasonably, dust from volcanic eruptions carried by the winds for long distances and then fused and coagulated by lightning. The very light coloured and friable Pettiswood (Ireland) stone was attributed to sand from a nearby lake carried aloft by winds and there "coagulated and compacted."

Classification. The term meteorite, in the wide sense of any natural object arriving on the Earth's surface from outside the atmosphere, includes ablation material and micrometeorites (meteorites of microscopic size) and, possibly, some things not usually classed as meteoritic.

The kinetic energy (energy of motion) of any body entering the atmosphere is largely converted into heat, and much of the body's substance is melted or even vaporized to fall to the surface later as ablation dust; it is rarely possible to distinguish such material from volcanic dusts or certain industrial dusts (perhaps the best authentic example is that of the spherules of metallic iron and iron oxides found in association with the fall of iron meteorites in 1947 at Sikhote-Alin, northeast of Vladivostok, Russian S.F.S.R.), but the total amount of such material reaching the Earth's surface must greatly surpass the total of macroscopic, or large, meteorites. Calculations indicate that a small (less than about 0.01 millimetre) dust particle entering the Earth's atmosphere at cosmic velocity (9 to 40 kilometres [about 6 to 25 miles] per second) may lose heat by radiation as fast as it gains it by deceleration and so escape melting and slowly drift down to the surface. There can be little doubt that much material collected as cosmic dust was indeed of meteoritic origin, but for the most part it is almost impossible to distinguish such fine meteoric material from terrestrial dusts and, especially, from some industrial dusts.

Three main groups of meteorites

Excluding this dust, meteorites fall into three major groups: irons, or siderites; stones, or aerolites; and stony irons, or siderolites; each of which is further subdivided. An example of each major group is shown in Figure 1. For many purposes it is also useful to distinguish between falls (that is, meteorites whose falls were observed) and finds (meteorites discovered on or embedded in the ground but whose date of arrival on the earth is unknown); this distinction is important for detailed study of the chemical composition of meteorites, because a specimen that has lain on or in the Earth for an unknown time may well have undergone appreciable weathering or other alteration; but it must not be forgotten that individual specimens of an observed fall often were not picked up for months or even years and may also be appreciably altered.

Rates of meteorite weathering vary widely; a porous stony meteorite exposed to conditions of alternate wetting and drying and, especially, to frost action could be disintegrated in a few months, whereas estimates of age based on the rate of decay of the radioactive isotope

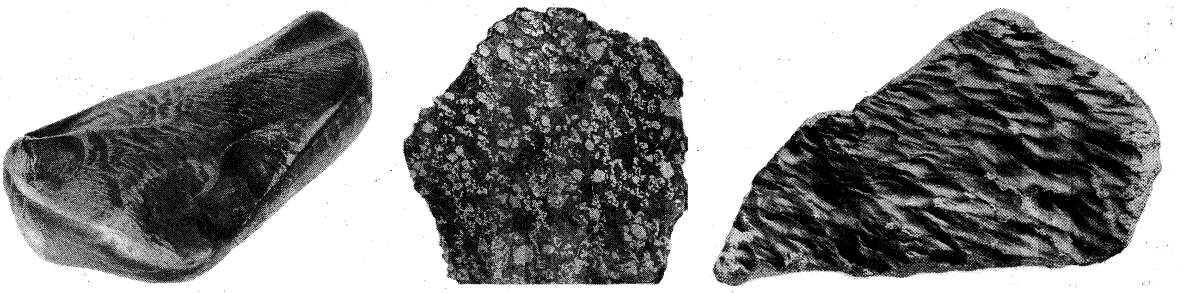

Figure 1: (Left) Iron meteorite: Nedagolla, an observed oriented fall showing the thin crust with bright metal in places and good oriented flow lines (approximately 30 percent of actual size). carbon-14 suggest that Potter, a compact stone that penetrated to the subsoil in southwest Nebraska, fell to the Earth some 20,000 years ago; and there is some evidence that under favourable conditions meteoritic irons may survive for 1,000,000 years. Probably an average life for a stony meteorite in all but arid climates is of the order of 100 years.

The course of weathering is fairly simple for iron meteorites; for most there is simply a gradually thickening crust of iron oxides—a mixture of goethite, hematite, and nickelian magnetite. Nickel is usually, but not always, partially leached out; *i.e.*, washed out by percolating water. Very rarely there is preferential oxidation of the nickel-poor component kamacite.

Weathering of stony irons and those stones that contain metal (the great majority) commences with rusting of the iron; this may be almost wholly oxidized before there is appreciable alteration of the sulfides and silicates, but ultimately the silicates undergo hydration (combination with water) and oxidation, and the final product will no longer be recognizable as of meteoritic origin.

Proof of origin

Strictly speaking, the final proof that an object is a meteorite is actual observation of its fall, but mistakes are common—any unfamiliar object may be picked up. A body of plausible evidence for extraterrestrial origin has gradually been built up. A freshly fallen stony meteorite will almost invariably be covered with a thin, glassy, black fusion crust produced during its passage through the atmosphere (in a few rare types of meteorite the crust is cream coloured owing to the absence of iron); most stony meteorites contain more or less metal, which is always a nickel–iron alloy with 5 to 30 percent nickel, and careful examination of most discloses rounded structures called chondri or chondrules unknown in any terrestrial rock; such meteorites are called chondrites. In all but a few rare classes, the chemical composition is different from that of any terrestrial rock; if there are types as yet unrecognized, the presence of a fusion crust will support direct evidence of fall, as it does for a few unusual types, such as calcium-rich achondrites (lacking chondrules) and carbonaceous meteorites.

For irons, the principal evidence is chemical and metallographic: no iron meteorite is known to contain less than 4 percent nickel, and only a few contain more than 20 percent; nearly all are extremely coarse grained, most medium-sized irons being basically single crystals; most irons with nickel contents in the range of 7 to 11 percent show a large-scale characteristic pattern of separation between crystals with different nickel contents, called the Widmanstätten structure, that cannot be developed in artificial alloys in any practicable cooling time. The presence of the Widmanstätten structure can therefore be used as conclusive evidence that a piece of iron is meteoritic in origin. In any case of doubt, a study of the amounts of the minor and trace elements present, especially gallium, germanium, iridium, copper, chromium, and vanadium, will usually confirm or disprove meteoritic origin.

Terrestrial native iron, which occurs in some basalts, usually has less than 3 percent nickel, though one analysis with 6.5 percent has been reported. There appeared to be no data available in the early 1970s for the trace elements in native iron. The alloying elements mainly used in artificial irons, apart from nickel, are very minor constituents of meteoritic iron.

Each of the three major classes of meteorites is subdivided, as shown in Table 1. The significance of these classes will become apparent when the composition and structure of meteorites are considered in more detail, but it is generally interesting and significant to note their numerical distribution as falls and finds among the various classes. It will be noted that, whereas, among finds, stones are far fewer than the more resistant irons, when observed falls are compared, it is clear that far more stones than irons arrive at the Earth's surface. The proportion of stones must be even greater in interplanetary space, for their greater mechanical weakness as compared to the irons would make for greater destruction in the atmosphere.

Within each of the three major groups, the unequal distribution among the several subdivisions is very noticeable. About a third of all irons are medium octahedrites; over half the stony irons are pallasites (see Table 1); over 80 percent of all stones are chondrites; and, of the chondrites, about 40 percent fall into each of the olivine–bronzite and olivine–hypersthene classes, which are often referred to jointly as common chondrites.

Phenomena of fall. Studies of meteor trajectories indicate that velocities up to 40 kilometres (about 25 miles) per second occur; the speed on entry for meteorites ranges from 13 to 21 kilometres per second. An object entering the upper atmosphere at such speeds rapidly collects a nose cap of ionized air, which can attain a large size and become brilliantly luminous; the forward surface of the object is intensely heated, melts, and is swept off as fine droplets, which condense to form a smoke trail that may persist for a considerable time. At night there may be a luminous trail, caused by slow recombination of ionized air. The fireball commonly becomes visible at a height of 150 to 120 kilometres (about 90 to 75 miles).

Fireballs and other flight phenomena

As the mass proceeds, the pressure in its gaseous nose cap builds up; most meteorites tumble over and over during flight, and, whenever there is a concave surface to the front, there will be a splitting moment tending to break up the mass. Most stony meteorites appear to break up in flight, and often the fragments break again. Some stones from the Richardton (North Dakota) fall preserve evidence of at least three fragmentations, in the shape of successive generations of fusion crust. Thus, well-documented observed falls are commonly multiple, and the number of individuals may run into many thousands, of all sizes down to fractions of a gram. Complete crusted stones of the Holbrook (Arizona) fall weighing no more than 18 milligrams (0.0063 ounce, avoirdupois) have been collected. Irons, because of their greater tensile strength, rarely fragment—the Sikhote-Alin (Siberia) fall of 1947 is a notable exception, but there the mass, a very coarse octahedrite, fractured along the taenite plates (taenite is an alloy of iron and nickel). Rarely, a meteorite has sufficient stability in flight, through symmetry or perhaps through sufficient rotational energy, to maintain one orientation; then, ablation tends to shape it into a

Table 1: Classification of Meteorites
(numbers as of December 1, 1965)

	falls	finds	"paired" and doubtful
Irons (Siderites)	43*	551*	67*

Coarsest octahedrites, kamacite lamellae over 2.5 mm wide	2	22	
Coarse octahedrites, kamacite lamellae 1.5 to 2.5 mm	4	87	7
Medium octahedrites, kamacite lamellae 0.5 to 1.5 mm	14	189	13
Fine octahedrites, kamacite lamellae 0.2 to 0.5 mm	4	62	1
Finest octahedrites, kamacite lamellae less than 0.2 mm		21	1
Nickel-rich ataxites, showing no structure on etching; Ni 9% to 60%	1	41	
Brecciated octahedrites, in which the Widmanstätten pattern only retains a given orientation over regions less than 10 cm^2; often with silicate inclusions	2	5	
Metabolites, in which the Widmanstätten pattern appears to have been destroyed by natural or terrestrial reheating		3	
Stony irons (Siderolites)	12	58	3‖
Pallasites, consisting of grains of olivine (Fe_2SiO_4 10–20 mole %) embedded in a matrix of nickel–iron (10%–20% Ni)	4	39	2
Siderophyres, bronzite (20 mole % $FeSiO_3$) and tridymite in nickel–iron		1	
Lodranite, olivine (13 mole % Fe_2SiO_4), bronzite (17 mole % $FeSiO_3$) with nickel–iron (9% Ni)	1		
Mesosiderites, a very miscellaneous group; the metal amounts to 40% or more but does not form a continuous network	7	18	
Stones (Aerolites)	725¶	404¶	72¶
Chondrites	624♀	380♀	25♀
subdivided into:			
Enstatite chondrites; dominant silicate enstatite, often almost iron-free; metal 20% to 35%, with Ni < 7% and often containing Si	11	6	
Olivine–bronzite chondrites♂, about equal amounts of bronzite and an olivine with 15 to 20 mole % Fe_2SiO_4; metal 16%–21%, with a nickel content of 7%–12%; total iron content ~26%	225	180	8
Olivine–hypersthene chondrites□, less pyroxene than olivine, which has 22% to 26% Fe_2SiO_4; metal < 10%, rich in Ni; total iron ~22%	273	170	12
Amphoterites◇, little pyroxene, olivine 28% to 32% Fe_2SiO_4; very little Ni-rich metal; total iron ~22%	39	10	
Olivine–pigeonite chondrites▲; iron-rich olivine (30–40 mole %) Fe_2SiO_4, little pyroxene, little or no metal; total iron 26%	15		
Carbonaceous chondrites, total iron 25%; characterized by the presence of 2% or more carbon, partly present as complex hydrocarbons, and of considerable hydrogen (hydroxyl groups and water);	20+		1
further divided into:			
Type I, in which sulfur is present as sulfates, largely water soluble; magnetic, iron being present mainly as nickelian magnetite, and silicates as amorphous hydrated magnesium silicate	5		
Type II, containing much elementary sulfur; nonmagnetic, iron being present mainly as a hydrated silicate related to the serpentines	13		
Achondrites	59§	9	1
divided into:			
Calcium-poor achondrites;	18	2	
subdivided into			
Enstatite achondrites (aubrites), composed of nearly pure enstatite with rare blebs of metal (kamacite) or oldhamite or both	7	1	
Hypersthene achondrites (diogenites), composed of hypersthene with 20–30 mole % $FeSiO_3$ with small amounts of accessory minerals	8		
Olivine achondrite (chassignite), over 95% olivine with 33 mole % Fe_2SiO_4	1		
Ureilites, consisting of grains of olivine and clinopyroxene, together with about 5% of metal, in a black matrix that appears to be severely shocked and contains about 1% of finely divided diamond	2	1	
Calcium-rich achondrites			
Nakhlites, containing 75% ferroan diopside and 15% olivine with about 66 mole % $FeSiO_4$, with a little feldspar and magnetite	1	1	
Augite achondrite (angrite), consisting of over 90% of a titanian augite with accessory olivine and troilite	1		
Eucrites consist of a plagioclase near An_{90} and pigeonite, with accessory chromite	26	3	1
Howardites differ from eucrites in containing hypersthene in place of augite, and rather less plagioclase	12	2	
Total, meteorites, all classes	785	1015	221

*Including 60 unclassified irons, 3 falls, 28 finds, 29 paired and doubtful. †Some authorities unite these two classes. ‡Including 39 octahedrites not further classified—6 falls, 31 finds, and 2 doubtful. §Including 3 unclassified achondrites. ‖Including one doubtful and unclassified stony iron. ¶Including 97 unclassified stones—39 falls, 15 finds, and 43 doubtful. ♀Including 59 unclassified chondrites—41 falls, 14 finds, and 4 doubtful. ♂Also referred to as H-group chondrites. □Also referred to as L-group chondrites; it should be noted that meteoriticists continue to place the boundary between bronzite and hypersthene at 20 mole % $FeSiO_3$. ◇Also referred to as LL-group chondrites. ▲Also referred to as carbonaceous chondrites, Type III, but not all members of the class are appreciably carbonaceous. +Including 2 not classed as Type I or Type II.
Source: B.H. Mason, *Meteorites* 1962.

blunt cone, and an oriented stone will usually escape fragmentation; the Middlesborough (Yorkshire) fall of 1881 is an excellent example. The fireball is often described as moving in a sinuous course; this motion is probably due to the breaking off of sizable fragments, sometimes described as "throwing off sparks," while a break into two or more pieces of comparable size is usually described as an explosion.

A meteorite may enter the upper atmosphere at any angle; should its fall be nearly vertical, the fireball will last only a short time, and it is perfectly possible for such a fall to pass unnoticed even in a fairly populous area; at the other extreme, a mass entering the atmosphere horizontally (that is, at grazing incidence) can give rise to a spectacular fireball visible over a long trajectory. In 1676 a fireball observed moving from the direction of the Adriatic passed over the whole width of northern Italy and fell into the sea off Leghorn; the fireball from which the Rochester (Indiana) meteorite of 1876 fell was visible over a course of 1,000 miles; and in 1913 a procession of between 30 and 60 fireballs was seen over a course from western Saskatchewan to southeast of Bermuda.

As the meteorite loses its initial kinetic energy to the fireball, it is slowed down and presently the fireball shrinks and is extinguished; for a mass of moderate size, the process usually occurs at about 17 to 25 kilometres (about 11 to 16 miles), and, from that point on, the meteorite falls as a dark body. If its atmospheric trajectory makes a small angle with the ground, the point of impact may be many kilometres from the point of extinction.

Over most of its path, the meteorite will be travelling at supersonic speed and will give rise to a typical shock wave, or sonic boom, which has been compared to the sounds of gunfire, of a heavy vehicle backfiring, or of a clap of thunder; there is commonly a series of echoes, as with a thunderclap. For distant observers, the boom and its echoes will naturally arrive some minutes after the fireball is seen; but in many cases whistling, whining, or hissing noises are reported to have been heard simultaneously with the sighting of the fireball or to have called the observer's attention to it, the typical boom being heard later. These sounds have not been fully explained, though it has been suggested that they are electrical in origin and are caused by the ionized mass of air; from their time of arrival, they cannot be normal sound waves.

As a rule, there is no further fragmentation once the fireball has extinguished, but the final breakup of the Barwell (Leicestershire, 1965) meteorite took place at a height of less than 10 kilometres (about 6 miles), and two fitting fragments without any trace of fusion crust were found about 600 metres (roughly 650 yards) apart.

Impact with the ground

The fragments from a multiple fall are usually distributed over a considerable area. The shape of the distribution pattern, an ellipse, depends principally on the entry angle and the fragmentation height; as a rule, larger, more massive pieces carry farther against air resistance, though there are rare exceptions (see Figure 2).

From B. Middlehurst and G. Kuiper (eds.), *The Moon, Meteorites and Comets;* University of Chicago Press (©1963)

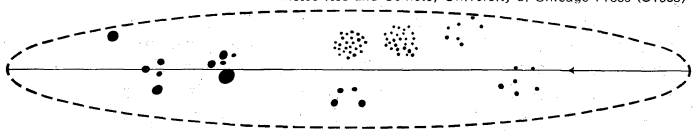

Figure 2: Distribution pattern of meteorite shower at Richardton, North Dakota. The arrow points from southwest to northeast.

The velocity of a meteorite at impact with the ground will, of course, depend on the angle of entry, the size and shape of the mass, and, in the case of a fragment, the height at which it became detached. Records indicate that, for masses of a few kilograms, very friable (easily crumbled) meteorites can land gently with little damage, while, at the other extreme, a 50-kilogram mass has been known to penetrate 1.25 metres into stiff clay, and one of 200 kilograms to nearly 3 metres, also in clay.

Since the kinetic energy increases as the cube of the equivalent diameter, but the air resistance increases only as its square, the buffering action of the air decreases rapidly as the mass increases, and a mass of 100 tons or more will have retained most of its entry velocity when it reaches the surface. Accordingly, while a moderate-sized mass will produce only a small impact pit, a mass arriving at the surface with a velocity of 0.5 to 2 kilometres per second will shatter, fragments of meteorite and soil or rock will fly in all directions, and an impact crater will form. The Sikhote-Alin shower produced some 200 craters of this type, and it appears that such craters can range from 9 to 100 metres in diameter.

When the mass is big enough to reach the ground at a speed above about 5 kilometres (3 miles) per second, the picture changes; with a meteorite having kinetic energy over 12,000 joules (a unit of energy, one watt being the rate of work equal to one joule per second) per gram, the shock waves on impact overcome the molecular cohesion of the meteorite and of the rock, so that an explosion crater results. Not only is the meteorite shattered but much is melted or vaporized and thrown out of the crater together with the solid fragments.

If the incoming mass breaks up in the atmosphere, the principal explosion crater may be accompanied by a number of impact craters in a typical scattering pattern, the principal crater being at the forward end of an ellipse; and complete masses may be found at the rear end of the ellipse. In the Henbury craters, central Australia, the scattering ellipse runs southwest to northeast.

Characteristics of a meteoritic crater

The primary characteristics of a meteoritic explosion crater include: a more or less circular form—though the marked jointing of the country rock (the bedrock) at the best known crater, Meteor Crater, Arizona, has resulted in a "bowed-square" outline; an upturned rim, the country rock all dipping outwards; and the presence within the crater of a breccia (sharp fragments embedded in a fine-grained matrix) of partly fused rock often containing high-pressure minerals formed by the shock wave, in particular, coesite and, in the regions of most intense shock, stishovite, both polymorphs of silica; below the partly fused breccia, there is a zone of shock-fractured but unmelted rock, passing downward and outward into unaltered country rock. In the case of ancient craters, this distribution of brecciation and fracturing, together with the absence of volcanic materials, is usually accepted as diagnostic of meteoritic origin. The peculiar structures known as shatter cones are widely, though not universally, regarded as shock-wave products and also diagnostic of meteoritic impact.

Chemical composition. Until 1969, when the first rock samples were brought back from the Moon, meteorites were the only extraterrestrial material man had to analyze in the laboratory, and their chemical and mineralogical composition was of great interest on that score alone. There are good reasons to believe that the relative abundance of the elements in the common chondritic meteorites approximates their relative abundance in the solar system as a whole, except for a number of the more volatile elements (hydrogen, nitrogen, and the noble gases, and, to a lesser degree oxygen, carbon, and sulfur). The relative abundances of the elements, excluding hydrogen, carbon, nitrogen, oxygen, and the noble gases, in the common chondrites, in the Sun (as deduced from spectroscopic data), and in the Earth's crust are to be found in Table 2.

The agreement between the meteoritic and solar abundances is for the most part within the probable errors of the determinations. The low solar lithium abundance is to be attributed to its consumption in nuclear reactions, but the relatively high iron figure for the common chondrites remains a subject of debate.

Comparison with the rocks of the Earth's crust

Compared with the common chondrites, the igneous rocks of the Earth's crust are markedly depleted in magnesium, chromium, manganese, iron, cobalt, nickel, germanium, and the platinum metals (all, except magnesium, siderophile elements; *i.e.*, those that would be concentrated in the metallic core usually assumed for the Earth) and enriched in the highly lithophile elements; *i.e.*, those that would tend to concentrate in Earth's crust. These include fluorine, aluminum, titanium, strontium, barium, zinc, thallium, and uranium. The meteorites appear to be depleted relatively to the crust and to the solar abundances in the more volatile elements rubidium, cesium, zinc, indium, tellurium, lead, and bismuth, and this depletion must be taken into account in any theory of the formation and cosmic history of the meteorites.

The above data are for the mean composition of the common chondrites, which are taken as a close approximation to the mean for all meteorites. Detailed studies,

Source: A.G.W. Cameron, "Abundances of the Elements," in S.P. Clark, *Handbook of Physical Constants* (1966; updated to the end of 1969).

however, show a marked uniformity in chemistry within each class of meteorite, accompanied by great divergence in some respects between the several classes.

Considering the irons first, there has long been noted a general tendency among the octahedrites (see Table 1) for the thickness of the kamacite crystals (kamacite is a characteristic meteoritic nickel–iron alloy with less than 7 percent nickel) in the Widmanstätten structure (see above *Classification*) to diminish as the nickel content increases, but it is not a very close correlation—there is a good deal of overlap in nickel content among the several groups. A more significant division is by the amounts of the trace elements gallium and germanium; over 80 percent of the siderites examined fall into one or other of six classes, each with quite narrow limits of gallium and germanium content, the remainder being widely scattered. The necessary chemical analyses have, to date, been made on only a relatively small number (about 150) of the known siderites.

Group I, with 80 to 100 parts per million (ppm) of gallium and 300 to 400 ppm germanium, consists of the 12 coarsest and coarse octahedrites.

Group II, with 40 to 65 ppm gallium and 130 to 230 ppm germanium, includes all the 19 hexahedrites and nickel-poor ataxites studied so far, together with seven coarsest to medium octahedrites, mostly with distinctly low nickel contents.

Group IIIA, with 15 to 24 ppm gallium, 32 to 55 ppm germanium, and 7.4 to 8.7 percent nickel, includes 37 coarse and medium octahedrites.

Group IIIB, with 13 to 23 ppm gallium, 27 to 50 ppm germanium, and 9.2 to 10.7 percent nickel, includes 29 medium and fine octahedrites.

Group IVA, with 1.7 to 2.2 ppm gallium and 0.09 to 0.2 ppm germanium, are all fine octahedrites, 15 in number, nickel 7.4 to 9.0 percent.

Group IVB, with less than 1 ppm gallium and less than 0.12 percent germanium, are all nickel-rich ataxites, eight in number.

The 20 percent or so of irons that do not fall into any of the above groups vary widely in structure and nickel content, and their trace-element contents show little if any correlation among themselves or with their nickel content.

The chemistry of the stony irons is summarized in Table 1; while the pallasites vary little, the mesosiderites should probably be subdivided into a class of true mesosiderites, with granular nickel–iron (about 7 percent nickel) irregularly distributed in a groundmass of hypersthene and plagioclase, and a miscellany, including falls such as that at Mount Egerton, Western Australia, in which enclaves of varied chemical and mineralogical composition are present, and Estherville (Iowa), with its one- to three-centimetre nodules of metal.

Among the stones, the achondrites can be conveniently considered first, in view of their simpler mineralogy and chemistry, largely summarized in Table 1. In each class there is little variation in chemical composition, and, if plotted on a diagram, with percentage of calcium oxide and the molecular ratio of ferrous oxide to the sum ferrous oxide–magnesium oxide as co-ordinates, the several groups form distinct fields; in particular, the eucrites and howardites, sometimes classed together as pyroxene–plagioclase achondrites, are seen to be distinct—howardites with 5% to 8% calcium oxide and the ratio of ferrous oxide to the sum of ferrous and magnesium oxides as 30% to 40%; eucrites with 8% to 14% calcium oxide and the ratio of ferrous oxide to the sum of ferrous and magnesium oxides as 48% to 66%. The one angrite has more calcium oxide (24%) and titanium dioxide (2.4%) than any other meteorite and is also high in alumina, 8.9%.

As a group, the achondrites have little in common; their lack of chondrules, rather coarse crystallization, and the rarity or absence of nickel–iron make most achondrites difficult to distinguish from certain terrestrial rocks once the characteristic fusion crust is lost.

In contrast, the chondrites show a remarkable similarity in much of their gross chemistry. Despite the great range in mineralogical composition, if typical analyses of the various chondrite groups are recalculated to give atom percentages (excluding hydrogen, oxygen, carbon, and sulfur), the between-group difference for most elements is less than the within-group differences; the exceptions are that the carbonaceous chondrites are much richer in those relatively volatile trace elements that are depleted in the common chondrites relative to their cosmic abundance and that the olivine–hypersthene chondrites and amphoterites appear to be uniformly about 4 to 5 percent poorer in iron than the olivine–bronzite, olivine–pigeonite, and carbonaceous chondrites. The enstatite chondrites, which vary considerably in iron percentage, fall into two groups; one, richer in total iron (32 to 35 percent) than any other group of stones, contains clinoenstatite and cristobalite but no feldspar and is relatively oxidized (1 to 2 percent ferrous oxide; phosphorus pentoxide partly as apatite; part of the titanium still in oxidized phases); the other, with a wide range of total iron (22 to 34 percent), contains enstatite and plagioclase and includes the most highly reduced stones (that is, stones containing the least oxygen) known.

Differences between groups of chondrites

Apart from the division into iron-rich and iron-poor series and the relative enrichment of the carbonaceous chondrites in volatile trace elements and in carbon and hydrogen, the essential difference between the groups of chondrites is a discontinuous difference in degree of oxidation, from the fully oxidized Type I carbonaceous chondrites, in which sulfur appears as sulfate, to the most reduced enstatite chondrites, in which the metal contains silicon, titanium is present in a sulfide phase, and phosphorus is present as phosphide. Apart from the carbonaceous chondrites, the degree of reduction is conveniently measured by the ratios given in Table 1. The estimates of the degree of oxidation depend on analysis of the amount of oxygen present in metallic phosphorus or sulfur compounds (phosphates to phosphides, etc.). While the proportion of oxygen combined with phosphorus ranges from maximum, as phosphate in the olivine–hypersthene chondrites and more oxidized groups, down to mainly phosphides (phosphorus only; no oxygen) in the enstatite chondrites, both phosphide and phosphate may be present in an olivine–bronzite chondrite. In each of the classes, there is appreciable variation in the proportions of iron and magnesium oxides, but there are definite gaps between classes; within the enstatite–chondrite group, decrease in the proportions of iron and magnesium oxides is correlated with an increase in the phosphide–phosphate ratio and a transfer of titanium from oxidized phases to sulfides.

Since the total iron, nickel, magnesium, and silicon contents do not vary greatly, and since nickel does not enter into the silicates to any appreciable extent (less than 50 parts per million), the increase in the ratio of ferrous to ferrous-plus-magnesium oxide from the enstatite chondrites to the olivine–pigeonite chondrites necessarily entails a decrease in the amount of pyroxene, an increase in the amount of olivine, a decrease in the amount of metal, and an increase in the nickel percentage in the metal. In some olivine–pigeonite chondrites there is so little iron in the nonoxidized phases that their sulfur appears as pentlandite, a compound of iron, nickel, and sulfur, and iron disulfide, or pyrite, instead of the nearly nickel-free troilite characteristic of the common chondrites.

Mineralogy. The principal mineral constituents of meteorites, other than carbonaceous chondrites, all occur as terrestrial minerals—olivine, ortho- and clino-pyroxene, feldspar, troilite, and the two nickel–iron alloys kamacite and taenite (terrestrial taenite is known as awaruite). There is, however, a wide range of minor constituents, many of which are not known to occur naturally on Earth; some of these can be formed only under extreme reducing conditions and are known only from enstatite chondrites, enstatite achondrites, a few bronzite chondrites, and a few peculiar siderites. Table 3 summarizes the meteoritic minerals.

Following the discovery of the so-called organized elements in carbonaceous chondrites—small spherical and ellipsoidal structures, many with an envelope of insoluble, complex hydrocarbon nature—and the assumption

Table 3: Meteoritic Minerals*

Elements and alloys:
Kamacite, (Fe,Ni), the body-centred α structure; Ni < 7%
Taenite, (Fe,Ni), the face-centred γ structure; Ni > 20%
Graphite
Sulfur†
Diamond‡
Lonsdaleite, a hexagonal polymorph of diamond‡
Copper
Gold (two doubtful records)

Halides:
Lawrencite§, $FeCl_2$

Oxides:
Chromite, $FeCr_2O_4$; often aluminian, magnesian, or vanadian
Magnetite‖, Fe_3O_4
Tridymite¶, SiO_2
Quartz♀, SiO_2
Cristobaliteδ, SiO_2
Ilmenite, $FeTiO_3$
Spinel□, $MgAl_2O_4$
Perovskite□, $CaTiO_3$

Carbides, phosphides, nitrides, and silicides:
Schreibersite, $(Fe,Ni)_3P$, tetragonal
Barringerite◇, $(Fe,Ni)_2P$, hexagonal
Cohenite, Fe_3C (cementite)
Osbornite▲, TiN
Sinoite✦, Si_2N_2O
Perryite, $Ni_5(Si,P)_2$
Moissanite⊕, SiC (carborundum)

Sulfides:
Troilite**, FeS
Pentlandite, $(Fe,Ni)_9S_8$
Daubréelite††, $FeCr_2S_4$
Oldhamite‡‡, CaS
*Niningerite*δ, (Mg,Fe,Mn)S
Blende (=sphalerite)δ, (Zn,Fe)S
Alabanditeδ, (Mn,Fe)S
*Djerfisherite*δ, $K(Cu,Na)(Fe,Ni)_{12}S_{14}$
Brezinaite, Cr_3S_4
Chalcopyrite, $CuFeS_2$
Chalcopyrrhotine, (Cu,Fe)S, cubic
Pyrite, FeS_2
Valleriite, sulfide of Cu and Fe (doubtful identification)

Silicates:
Olivine, $(Mg,Fe,Mn)_2SiO_4$
Orthopyroxene,§§ $(Mg,Fe)SiO_3$
Clinopyroxene‖‖, $(Mg,Fe,Ca)SiO_3$
Plagioclase, usually with an anorthite content between 5% and 10%
Serpentine; the principal constituent of Type II carbonaceous chondrites
Merrihueite, $(K,Na)_2(Fe,Mg)_5Si_{12}O_{30}$
Roedderite, $(Na,K)_2(Mg,Fe)_5Si_{12}O_{30}$
Yagiite, $(Na,K)_2(Mg,Fe,Al)_5(Si,Al)_{12}O_{30}$
Cosmochlore, $NaCrSi_2O_6$
Krinovite, $NaMg_2CrSi_3O_{10}$
Ringwoodite, $(Mg,Fe)_2SiO_4$ with spinel structure
Cordierite, $(Mg,Fe)_2Al_4Si_5O_{18}$

Hydrocarbons:
Much of the carbon of Type I carbonaceous chondrites is present as an insoluble complex hydrocarbon of very high molecular weight

Phosphates:
Chlorapatite, $Ca_5(PO_4)_3Cl$
Whitlockite, $(Ca,Mg)_3(PO_4)_2$
Farringtonite, $Mg_3(PO_4)_2$
Panethite, $(Na,Ca,K)(Mg,Fe,Mn)PO_4$
Brianite, $Na_2CaMg(PO_4)_2$
Stanfieldite, $Ca_4(Mg,Fe,Mn)_5(PO_4)_6$
Hydroxyapatite, $Ca_5(PO_4)_3OH$
Sarcopside, $(Fe,Mn,Ca)_7(PO_4)_4F_2$
Graftonite, $(Fe,Mn,Ca)_3(PO_4)_2$

Carbonates:
Calcite¶¶, $CaCO_3$
Dolomite♀♀, $CaMg(CO_3)_2$
Ferroan magnesite♀♀, $(Mg,Fe)CO_3$

Sulfates:
Epsomite♀♀, $MgSO_4{\cdot}7H_2O$; probably formed terrestrially from meteoritic kieserite, $MgSO_4{\cdot}H_2O$
Gypsum♀♀, $CaSO_4{\cdot}2H_2O$
Blödite♀♀, $Na_2Mg(SO_4)_2{\cdot}4H_2O$

*Those peculiar to meteorites are printed in *italics*. Within each group of minerals those commonest in meteorites are listed first. In accordance with the usual mineralogical nomenclature, a pair or more of elements replacing one another isomorphously are written in parentheses, in order of abundance, and separated by commas—*e.g.*, $(Mg,Fe,Mn)_2SiO_4$; minor and trace substituents are omitted from the formulas. †Recorded from Type II carbonaceous chondrites only. ‡Recorded from ureilites and severely shocked irons only. §Occurs in irons and stony irons, which are then very liable to rapid and destructive rusting. ‖Nickeliferous magnetite is a principal constituent of Type I carbonaceous chondrites and is an accessory in olivine–pigeonite chondrites. ¶A principal constituent of the stony iron Steinbach, and an accessory in some other stony irons and some Ca-rich achondrites and some enstatite chondrites. ♀Recorded from some Ca-rich achondrites and enstatite chondrites and from a few irons. δRecorded from enstatite achondrites only. □Recorded from some olivine–pigeonite chondrites. ◇Recorded to date (1970) only from the Ollague iron. ▲Recorded from enstatite achondrites and enstatite chondrites only. ✦Recorded from enstatite chondrites only. ⊕Doubtful; recorded from the Cañon Diablo iron only and not confirmed. **The ferrous sulfide of meteorites is normally the nonmagnetic, stoichiometric FeS, rare terrestrially, but in some metal-deficient meteorites the magnetic, metal-deficient pyrrhotine may occur. The troilite of enstatite chondrites carries nearly all the titanium of the meteorite; that of the common chondrites contains traces of titanium. ††Recorded from irons and from enstatite chondrites and achondrites. ‡‡Recorded from enstatite chondrites and achondrites only. §§Subdivided into enstatite, with $FeSiO_3$ < 12 mole %; bronzite, with $FeSiO_3$ 10 to 20 mole %; and hypersthene, with $FeSiO_3$ > 20 mole %. ‖‖A variety of clinopyroxenes occur in meteorites, including diopside, augite, pigeonite, and calcian members of the clinoenstatite–clinohypersthene series. ¶¶Recorded from carbonaceous chondrites and some achondrites. ♀♀Recorded from carbonaceous chondrites only.

Hydrocarbons in carbonaceous chondrites

that these were of biological origin and possibly fossil algae, a great deal of work has been done on carbon compounds in meteorites. The greater part of the carbon in both Type I and Type II carbonaceous chondrites is present as a compound of very high molecular weight, insoluble in all solvents and containing carbon, hydrogen, oxygen, and probably nitrogen; pyrolysis (breaking down by heat) yields a wide range of hydrocarbon compounds, both aliphatic and aromatic. Solvent extraction of the meteorite yields traces of carbon compounds of many classes, including aliphatic and aromatic hydrocarbons. The presence of these organic compounds has been advanced as evidence of extraterrestrial life, but it would appear that purely inorganic processes could have given rise to them all. Some of the organized elements have been shown to be pollen grains and other terrestrial contaminants, and many are simply mineral grains coated with the insoluble hydrocarbon mentioned above.

Structure. The nickel-poor irons, hexahedrites and nickel-poor ataxites, consist wholly (apart from small inclusions of troilite and schreibersite) of kamacite, and the hexahedrites are single crystals of this alloy. Etching a polished surface usually reveals numerous fine, closely parallel lines called Neumann lines—also termed glide-twin lamellae; glide-twinning is a type of slippage of internal structural planes. The lamellae are always parallel to some but not all of a particular set of 12 crystal planes of the metallic crystal and clearly arise from directed deformation, but whether the causal impact was extraterrestrial or was the impact with the atmosphere or the ground is unknown (see Figure 3).

Iron meteorites presumably crystallized from molten material, and at temperatures above 800° C would all have the so-called face-centred (taenite) structure; at a temperature depending on the nickel percentage the body-centred phase will segregate on cooling in plates parallel to planes of the parent taenite crystal. With few exceptions, the Widmanstätten pattern (consisting of these segregation plates; see above *Classification*) retains the same orientation in meteorites over distances up to a metre; cooling from the melt to the segregation temperature must have been slow to allow the growth of such large single crystals. This large-scale segregation pattern forms only if the composition is such that transformation begins above 650°–700° C; in nickel-rich meteorites, segregation is microscopic (resulting in the mineral plessite), as it also is in residual patches of nickel-rich alloy in interstices of the Widmanstätten pattern (see Figure 3).

The Widmanstätten pattern

The segregation process involves diffusion of nickel from the growing kamacite plates into the residual taenite, and as the temperature falls this process slows and fails to keep pace with recrystallization, so that the residual taenite lamellae develop relatively nickel-poor cores and nickel-rich rims. From microprobe studies of this profile and from the composition of residual taenite, cooling rates of the order of 1° to 10° C per 1,000,000 years have been deduced.

The structure in the stony irons called pallasites consists of five-millimetre crystals or large fragments of olivine, a common terrestrial mineral, embedded in nickel–iron; because the melting point of the olivine is well above that of the metal, these meteorites must have originated as a close-packed mass of olivine crystals floating in molten metal under a solid ceiling.

The achondrites are fairly coarsely crystallized, often brecciated, and their mineralogy and texture suggests igneous differentiation products, though the details remain obscure.

The Type I carbonaceous chondrites are not, in fact, chondritic but consist of an intimate mixture of fine-grained nickeliferous magnetite (an iron oxide) and a hydrated amorphous silicate, veined with sulfates; Type II contain variable amounts of chondrules, which are practically iron-free olivine or pyroxene (an igneous-rock-forming mineral). Some researchers believe that Type II are derived from Type I by crystallization; others that the reverse is the case, alteration by liquid water being responsible for the degradation.

The common chondrites and olivine–pigeonite chondrites vary markedly in texture: at one extreme, the chondrules are sharply bounded spherules, often readily detachable from their matrix; the pyroxene is mainly of the crystalline structure called monoclinic; little or no feldspar is present, the composition of the olivine and pyroxene varies from crystal to crystal, and clear primary glass is present; this type is referred to by some meteoriticists as unequilibrated and, later, by others as Type 3 and primitive and corresponds approximately to the spherical

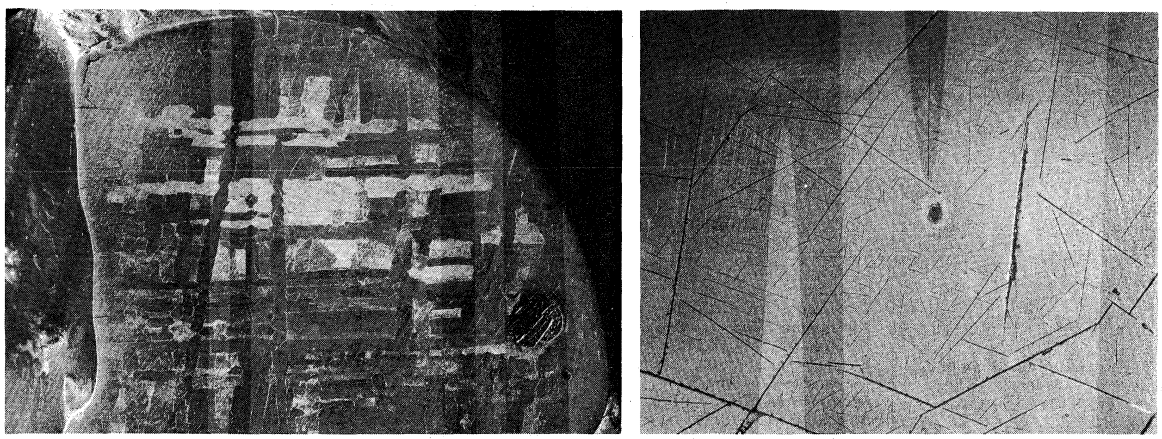

Figure 3: (Left) Widmanstätten pattern: The meteoritic iron Rowton, shown actual size, also has a heat-alteration zone near the surface. (Right) Neumann lines: Walker County; this hexahedrite has particularly well developed Neumann lines (approximately twice actual size).

chondrites of the old Brezina classification (see Figure 4); at the other extreme, the chondrules are poorly defined, the pyroxene is orthorhombic, feldspar (a silicate of aluminum, calcium, and sodium) is present and glass absent, and the olivine and pyroxene are uniform in composition; this is the equilibrated, or Type 6 (two intermediate types being recognized), or recrystallized, one transitional type being recognized. The petrologic types 1 and 2 correspond to Type I and Type II carbonaceous chondrites respectively. It appears probable that the recrystallized type was derived from material approaching the primitive type by metamorphism at some stage in its history.

The five types of meteorite age

Meteorite ages. The age of a meteorite must be qualified. It can refer to the time since it arrived on Earth (terrestrial age), the time since it was an interior part of a larger body (cosmic-ray age), the time since it was last too hot to retain helium or argon (gas-retention ages), or the time since it was molten. A fifth age, derived from measurements of the products of decay of short-lived radionuclides assumed to be present in the primitive solar nebula (iodine→xenon, plutonium→xenon, lead→tellurium, palladium→silver ages), refers to the period between nucleogenesis and the formation of meteorite parent bodies. Times of the order of 10^8 years for this fifth age have been deduced, but measurements are few and their interpretation difficult.

From the time a meteorite is broken off a larger body or otherwise reduced to a fragment of less than about five tons, it is strongly irradiated throughout most of its bulk by cosmic rays, which induce various nuclear reactions; some of the nuclides produced are stable, some radioactive. When the meteorite reaches the Earth's surface, it is shielded from cosmic rays by the atmosphere; the radioactive nuclides decay, and their decay can in principle be used to determine the terrestrial age. There are complications—the mass must have been in orbit long enough for a steady state to have been reached, and in this state the concentration of each product will vary with distance from the preatmospheric surface—but these complications can be evaded, and some useful results have been obtained.

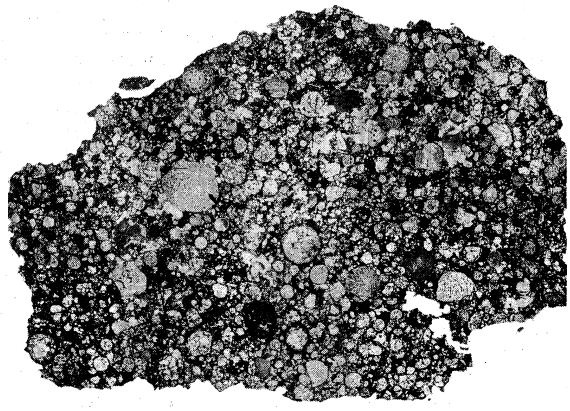

Figure 4: Chondrules in the stony meteorite Prairie Dog Creek (approximately 2¼ times actual size). The surface shown is a section through the meteorite.

Cosmic-ray ages. While a radioactive product will tend to attain a steady state under cosmic irradiation, a stable product will simply accumulate, and its amount can serve as a measure of the time during which irradiation has gone on; again there are complications, most of which can be overcome by making measurements both of a stable and of a suitable radioactive product nuclide. For chondrites, an age–frequency plot shows a very strong peak at 5×10^6 years, with a tail extending to about 40×10^6 years; for achondrites a generally similar curve, but with less pronounced peaks (at 5×10^6 and 11×10^6 years) has been obtained. For irons, much longer cosmic-ray ages have been found, with the hexahedrites, nickel-rich ataxites, and medium octahedrites forming distinct families at 10^8 to 2×10^8, 10^8 to 3×10^8, and 5×10^8 to 7×10^8 years, respectively.

Solidification ages. Solidification ages have been derived from the decay reactions of a rubidium isotope to strontium, of a rhenium isotope to osmium, or of two uranium isotopes to two isotopes of lead. Unfortunately, the chemical separation of parent and daughter nuclides, which is what the method really dates, tends to be very inefficient in meteorites, so that problems foreign to terrestrial geological dating arise. The subject cannot be briefly summarized, but its results are simple: all three methods agree in dating the solidification of both irons and stones at 4.4×10^9 to 4.6×10^9 years.

Gas-retention ages. At high temperatures, gases diffuse readily through silicate lattices; accordingly, the amount of radiogenic argon from the decay of potassium-40 or helium from uranium and thorium can furnish a measure of the time since the meteorite was last at a temperature at which gas leakage could occur. The results for irons appear to show ages much in excess of the solidification ages, but this is probably due to loss of potassium, which is readily leached out by water. For stones, both chondrites and achondrites, the ages from both methods tend to cluster around 4×10^9 to 4.5×10^9 years, indicating that cooling from solidification to gas retention was not very slow. There are, as were to be expected, many lower values, down to about 5×10^8 years, and, when the potassium–argon and uranium–helium ages do not agree, the latter is the lower—as is to be expected, since helium will be lost at a lower temperature than argon. The reheating is presumably due to collisions leading to the breakup of the parent body and to perihelion passages of the fragments.

Meteorite orbits. The only direct evidence available for the source or sources of the meteorites—Moon, minor planets, Mars, or outside the solar system—is the

orbit in which the object was travelling when it encountered the Earth. Unfortunately, observations of the atmospheric trajectories of meteorites are few and of low accuracy, especially the estimates of their velocities. For only one meteorite (Příbram, which fell in Czechoslovakia in 1959) have accurate data been obtained by photography from several observing stations, and this object had a highly elliptical orbit with perihelion (least distance from the Sun) at 0.8 astronomical unit (one astronomical unit is the mean distance between Earth and Sun, about 150,000,000 kilometres [93,000,000 miles]) and aphelion (greatest distance from the Sun) at about 4 astronomical units. Older calculations, based on very high velocities of entry, suggested hyperbolic (or open) orbits, but later studies indicate that orbits of all meteorites for which reasonable data are available are elliptical orbits of a similar general nature to that of Příbram. It also appears that most meteorites overtake the Earth and approach from directions not greatly inclined to the Earth's own motion.

Calculations of the probability of material broken off or ejected from the Moon, Mars, and the various families of comets and asteroids and of the average length of time such material may be expected to remain in orbit before being captured by the Earth have not been conclusive but tend to discount the Moon, Mars, or short-period comets as the parent body.

Origin of meteorites. For many years, meteorites and meteors (shooting stars) were taken to be essentially similar, differing only in size. Orbital evidence, however, suggests that the meteors are essentially cometary debris, while the meteorites almost certainly are not. (The fall of June 30, 1908, on the Tunguska River, Siberia, which was recorded on seismographs the world over but did not produce sizable craters, has been widely accepted as due to the head of a small comet, which exploded and disintegrated a few kilometres from the ground.) The age determinations show clearly that meteorites solidified at the same time or very shortly after the planets were formed and were broken off or ejected from a larger body relatively recently. The presence of diamond in the ureilites and some Canyon Diablo (Arizona) irons and certain details of the Widmanstätten structure have been adduced as evidence that the meteorites or some of them formed under high-pressure conditions in a body of lunar size or larger (the Moon and Mars have been favoured); but diamond can be formed by shock, and the effects of phosphorus on the iron–nickel system are rather similar to those of high pressure. On the other side, it is difficult to see how a body of lunar size could have cooled from a molten state in the time available.

Probable history of parent bodies

While there is no general consensus even on the size of the parent bodies and a wide divergence of opinion on details of these bodies' evolution, a coherent picture was beginning to emerge in the early 1970s, though it will doubtless undergo many modifications. The following scheme, one of many that cannot all be summarized here, appears satisfactory in many respects. The chondrules were formed in cool regions of the primitive solar nebula, probably by electrical discharges between dust aggregates, and cooled rapidly to a largely glassy state. The meteorite parent bodies, of medium asteroidal size, about 100–250 kilometres (about 60–150 miles) radius, aggregated cold from chondrules, metal and oxide grains, and carbonaceous material. Heat from the decay of short-lived radioactive nuclides melted a small core of the asteroid and heated a thicker zone short of complete melting; fractionation in the core produced achondrites, irons, and pallasites, while, farther out, thermal metamorphism produced the various petrological types of chondrite. A thin layer near the surface was altered by volatiles (carbon monoxide, water, and sulfur) distilled from the interior, to produce the carbonaceous chondrites, which also condensed such volatiles as zinc, cadmium, indium, mercury, tellurium, and lead distilled from the interior. These processes were virtually completed in about 10^8 years, about 4.5×10^9 years ago. Collisions between minor planets broke them up, and some of the fragments from each collision were attracted into Earth-crossing orbits. Because the life of a small body in such an orbit is fairly short, the sample of meteorites collected by the Earth shows a peak at material derived from one or more collisions about 5,000,000 years ago, material from older collisions being already largely lost. Heterogeneous meteorites such as Mount Egerton or Cumberland Falls (Kentucky) were probably

Table 4: A Selection of Historic and Other Notable Meteorites

meteorite	site	comments
Elbogen (Loket)	Bohemia	An iron of about 107 kg fell, probably about 1400; it was known for centuries as "the Bewitched Burgrave" and preserved at the castle; recognized as meteoritic 1811; medium octahedrite. 79 kg in Vienna.
Ensisheim	Alsace, France	A stone of about 127 kg fell November 16, 1492, 1130 hours; amphoterite. Specimens are in many museums and the main mass of 55¾ kg in the Rathaus, Ensisheim.
Hatford	Berkshire	At least 3 stones, totalling about 30 kg, fell April 9, 1628, 1700 hours. Though nothing is now preserved, the contemporary descriptions are so good its meteoritic nature is certain.
Krasnojarsk	Eniseisk, Siberia	A mass of about 700 kg was found about 1749; described by P.S. Pallas, 1772; pallasite. The etch pattern now known as the Widmanstätten pattern was first developed on a specimen by G. Thomson (W. Thomson, F.R.S.). Widely distributed; 515 kg in Moscow.
Lucé	Sarthe, France	A stone of 3½ kg fell September 13, 1768, 1630 hours; olivine–hypersthene chondrite. Discredited as "a stone struck by lightning," little has been preserved; 166 g in Vienna.
Siena	Tuscany, Italy	A shower of stones up to 3½ kg fell June 16, 1794, 1900 hours. Olivine–hypersthene chondrite. This fall stimulated interest in the problem of "stones from the sky." Widely distributed.
Wold Cottage	Yorkshire	A stone of about 25 kg fell October 13, 1795, 1530 hours. Olivine–hypersthene chondrite. This fall rallied English opinion to the reality of meteoritic falls. Main mass, 21 kg, in London (British Museum [Natural History]).
L'Aigle	Orne, France	A shower of stones, estimated to number 2,000–3,000 with an aggregate weight of about 37 kg, fell April 26, 1803, 1300 hours, and finally convinced the Paris Academy. Olivine–hypersthene chondrite. Widely distributed; 10½ kg in Paris.
Weston	Connecticut	A shower of several stones, together about 150 kg, fell December 14, 1807, 0630 hours; olivine–bronzite chondrite. The earliest American record. Little preserved; 15 kg in Yale University.
Cape York	West Greenland	Knives of meteoritic iron with bone handles were given to Capt. John Ross in 1818 by Eskimo. Three large masses were shown to Lieut. R.E. Peary in 1894 and transported to New York. Medium octahedrite. The mass of 31 tons in the American Museum of Natural History is the largest meteorite in any collection.
Oktibbeha County	Mississippi	A mass of 156 g found about 1854 in an Indian tumulus is the most nickel-rich meteorite known (60% Ni). Its meteoritic nature has been doubted but is established by a recent study by S.J.B. Reed.
Orgueil	Montauban, France	About 20 stones fell May 14, 1864, 2000 hours. Carbonaceous chondrite (Type I). The supposed microfossils and organic compounds in this meteorite have been the subject of extensive study and controversy. Main mass, 8.7 kg, in Paris.
Cañon Diablo	Arizona	Over 30 tons of pieces, from minute fragments to masses of 500 kg, have been collected since 1891 from around the crater now recognized as of meteoritic origin. Coarse octahedrite. Some pieces contain microscopic diamonds, probably produced by shock on impact.
Hoba	Grootfontein, South West Africa	A mass estimated at 60 tons was found in 1920; nickel-rich ataxite. The largest known meteorite. Preserved in situ.
Sikhote-Alin	Eastern Siberia	A shower of irons fell February 12, 1947, 1038 hours GMT, producing 106 small craters and impact holes; over 23 tons of material collected; coarsest octahedrite.
Norton County	Kansas	A shower of stones fell February 18, 1948, 1656 hours CST; over 100 have been recovered, including one of 1 ton—the largest known stony meteorite; enstatite achondrite. Main mass in Albuquerque, N.M.

formed by welding together of dissimilar fragments at the time of collision.

Objects formerly classified as meteorites. Tektites, small glassy fragments found in Czechoslovakia, Australia, Southeast Asia and the Malay Archipelago, West Africa, and the United States, were for a time regarded as glass meteorites, but this view is no longer tenable. There is a widely held opinion that they are formed from splashes of liquefied rock from major meteorite craters, but there are many difficulties with all present theories of origin (see further TEKTITE). The masses of nearly pure silica glass found on the surface in the eastern desert of Libya, near the Egyptian frontier, have also been supposed to be of meteoritic origin, but this is highly improbable, and their true origin also remains an enigma.

Meteorite collections. There are meteorite collections in many cities and universities, ranging from two or three specimens to large collections representing hundreds of falls. For many, catalogs have been published, and lists of such catalogs have been prepared. Some of the principal collections of the world are, with the number of falls represented at the last available count: British Museum (Natural History), London, 1,148 (1966); Field Museum of Natural History, Chicago, 835 (1946), but now probably more than 1,000; United States National Museum, Washington, D.C., 786 (1947), now probably more than 950; American Museum of Natural History, New York City, 850 (1964); Muséum d'Histoire Naturelle, Paris, 644 (1946); Naturhistorischen Hofmuseum, Vienna, 560 (1903); Arizona State University, Tempe (Nininger Collection), 536 (1950). A few of the most notable meteorites are listed in Table 4.

BIBLIOGRAPHY. Progress in the study of meteorites is so rapid that books are soon partly outdated, but the following are still useful: F. HEIDE, *Kleine Meteoritenkunde*, 2nd ed. (1957; Eng. trans., *Meteorites*, 1964); E.L. KRINOV, *Giant Meteorites* (Eng. trans. 1966); B.H. MASON, *Meteorites* (1962); B.M. MIDDLEHURST and G.P. KUIPER (eds.), *The Moon, Meteorites, and Comets* (1963); and J.A. WOOD, *Meteorites and the Origin of Planets* (1968). A good book for non-specialists, with excellent accounts of phenomena of fall, is by H.H. NININGER, *Out of the Sky* (1952). Scientific papers on meteorites are scattered through many journals, but two, *Meteoritika* (Russian) and *Meteoritics*, are devoted wholly to this subject. A record of known meteorites, with a summary of the principal literature on each fall, is provided by the *Catalogue of Meteorites*, published by the British Museum (Natural History), 3rd ed. rev. by M.H. HEY (1966).

(M.H.H.)

Meteorite Craters

Meteorite craters are depressions that result from the impact of a meteorite with any planetary body. Prior to the advent of space travel, meteorite craters were considered rare curiosities on Earth but were presumed to be commonplace on the Moon's surface. Some circular depressions associated with meteorites—such as Meteor Crater, Arizona; Odessa, Texas; four craters in Australia; Wabar in Arabia; Kaalijarv craters in Estonia; and the Campo del Cielo crater swarm in Argentina—were accepted as representative of occasional collisions between large iron meteorites and the Earth's surface. A few classic papers, known mainly to specialists, summarize the extent of scientific investigations up to the mid-1950s. Textbooks usually ignored the phenomenon of meteorite impact as a terrestrial process or treated it only briefly.

Since the launching of Sputnik in 1957, interest in and study of impacts between interplanetary materials (meteorites, micrometeorites, comets) and planetary surfaces have grown in proportion to the exploration of the planets made possible by the space probes. Ranger, Orbiter, Surveyor, and Apollo spacecraft have extended the estimate of the number of lunar craters from about 300,000 observable by telescope (at a 1.5-kilometre-diameter resolution) to roughly 3,000,000,000,000 with diameters greater than one metre. This includes those craters visible for the first time on the far side of the Moon. The space probe observations also allow the lunar craters to be classified by size and morphological characteristics and, at least inferentially, by modes of origin. Thus, most lunar scientists now recognize primary and secondary impact craters, volcanic calderas, maars, summit craters, and drainage or collapse craters as probable genetic types on the lunar surface.

The discovery of circular structures and actual depressions on the surface of Mars by Mariners 4, 6, and 7 suggests that cratering may be a universal natural process on terrestrial-like planetary bodies. Whether this conclusion can be extrapolated to impact cratering must await determination of the origin of Martian craters by later probes or direct landings; these may in fact be largely (or exclusively) volcanic or may be formed by still unspecified processes. It is reasonable, however, to assume that impacts occur frequently on all unprotected planetary surfaces in the solar system and, by extrapolation, on any similar bodies elsewhere in the universe. Therefore, Mercury is likely to display craters but Venus, with its gaseous envelope, would have few, if any, such structures. In general, the number of craters per unit of surface area correlates closely with the nature and density of the planetary atmosphere and its capability for erosion, as well as with the flux of bombarding particles over time in a planet's neighbourhood.

Most hypotheses for the origin of terrestrial (solid rock) planets assume a period of accretion of spherical and fragmented bodies of sizes varying from dust to planetesimals of multikilometre dimensions. It is probable, therefore, that collisions with energies sufficient to generate shock waves have occurred over much of the growth history of these planets. Many meteorites contain signs of shock damage, mostly inflicted during breakup of the parent body or during final impact with the Earth, but some aspects conceivably are related to the early accretionary process. It is impossible at present to state whether major, crater-producing impacts take place mainly after a planet approaches its final dimensions or as a continuing process while a protoplanet reaches a critical size capable of withstanding further large collisions. A partial answer may emerge when the relative ages of the cratered lunar surface are given more absolute values on the basis of radiometric dating of crustal rocks.

Numbers of craters on Earth and their recognition

Impact craters will necessarily be less frequent on the Earth than on the Moon. Friction from the Earth's atmosphere effectively burns up most of the smaller bodies entering it from outer space. Thus, any craters formed will tend to be larger than the average size of all entering meteorites. Over the last eon (1×10^9 years) meteorites large enough to survive the plunge through the air and then excavate big craters appear to have been too few to produce the expected population of impact structures on the continents. The combined effects of the hydrosphere and atmosphere in eroding the land surface since cooling of the crust and formation of oceans evidently have erased most meteorite craters between ten metres and about one to two kilometres. If such craters were more abundant in the first 2–3 $\times 10^9$ years of terrestrial history, owing to a greater meteorite flux in the early solar system, their traces have long since been removed by erosion, deposition, and metamorphism.

Since 1955, the list of definite and probable impact structures has tripled from the 20 to 27 proposed by investigators up until then. Another 50 structures that fall into the "suspicious" category have not been carefully checked in the field. The chief reasons for the sharp increase in numbers of identified craters have been formulation of the astrobleme concept, more intensive searching, and development of new criteria for recognizing impact structures.

The astrobleme was an important advance in the understanding of what to look for in relation to meteorite craters. An astrobleme (star wound) is, then, simply the scar of an impact crater—that is, any part of the structure that has survived erosion. Older structures may completely lack discernible crater rims but still retain some degree of circularity, have distinctive internal deformation features, or contain remnants of original rock fragments (breccia) shocked in the impact event. Thus, in the broader sense, a meteorite crater can be defined as any structure now at or near the surface containing evidence of a shock-producing impact in which the disturbance by deformation

and fragmentation of rock or soil is generally circular in outline (plan) and dies out rapidly in intensity upon reaching diameter-to-depth ratios of three to one or greater (Figure 1).

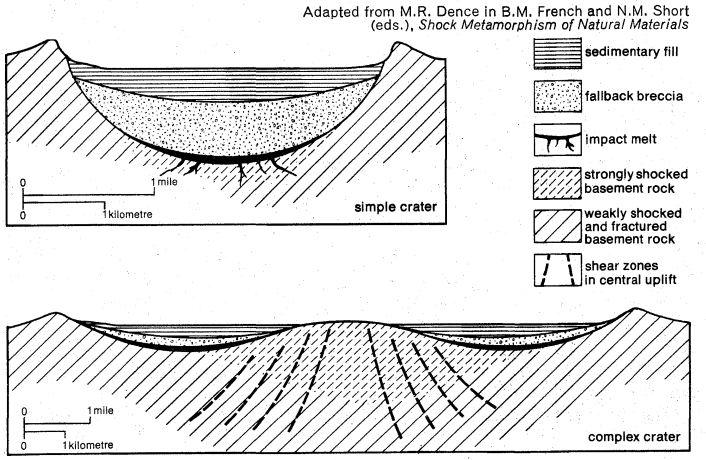

Figure 1: Major types of impact craters. Those larger than about six kilometres tend to be complex.

Once it was realized that astroblemes as well as actual crater depressions were clues to past meteorite impacts, the accelerated search given impetus by the space program could focus on any unusual structure meeting the general requirements of the above definition. A Canadian group at the Dominion Observatory in Ottawa led the way. These workers systematically examined aerial photos for circular features over all of Canada. The Precambrian shield of crystalline rocks, which outcrops over 50 percent of Canada, proved to be an excellent place to count impacts because of the improved probability of survival of larger structures in the shield terrane, where erosion rates have been low during the last 500,000,000 years (Figure 2). The group then applied geophysical methods, such as gravity and seismic surveys, to some of these structures. Several shallow-based disturbances were core drilled to provide samples of subsurface materials that exhibited evidence of shock pressure damage. Thus, from 1951, when the New Quebec (Chubb) Crater was first proposed as an impact crater, to the present, the number of probable meteorite craters in Canada has risen from 1 to 17. The Sudbury Basin can now be included among these; this structure, elongated by unrelated tectonic compression, is the source of over half the world's supply of nickel. Similar search techniques in other countries during the 1960s provided identification of many structural disturbances as rimmed impact craters (*e.g.*, Wolf Creek in Australia) and astroblemes (*e.g.*, Vredefort in South Africa).

Relation of numbers of craters and geological processes

The actual number of meteorite craters discovered on Earth is far below the numbers expected from calculations based on meteorite flux data and relations between meteorite mass and size of crater. Using data from several published estimates, there would be approximately 300 impact craters 2.5 kilometres and larger formed on the Canadian Shield in the last 10^9 years. The present value of 17 impact structures with diameters greater than 2.5 kilometres found to date affords a crude measure of the effectiveness of erosion in this ancient, stable area. Worldwide, the present land surface area would have been subjected to 130,000 impacts producing craters one kilometre or larger during the last 10^9 years. The gross discrepancy between that number and the 50–100 impact structures now known must be accounted for both by erosion and by the masking effect of younger sediments and metamorphism of older terranes.

Examination of meteorite craters in the field and studies of their rocks by laboratory techniques now provides new sets of criteria that serve as unique, unequivocal indicators of an impact event. Appropriate combinations of these criteria have never been found in craters or structures that are conclusively associated with volcanic or solution collapse origins. The criteria are direct and singular consequences of the impact process and thus are definitive in identifying meteorite craters as distinct from other crater types.

This article treats the processes associated with meteoritic impact, the characteristics of craters, and the effects of cratering on the Earth. For information on the nature and composition of meteorites, see METEORITE; for more detailed discussion of craters elsewhere in the solar system, see MOON, and MARS; for further information on shock processes and their effects on rocks, see WATER WAVES; ROCKS, PHYSICAL PROPERTIES OF; and GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES.

THE IMPACT CRATERING PROCESS

Another noteworthy advance in meteoritics since 1957 results from theoretical and experimental investigations of the cratering process. This includes field studies of nuclear and chemical explosions and of rocket missile impacts, laboratory-scale simulations of impacts using gun-impelled high-velocity projectiles, and the development of physical models of the sequence of crater formation using sophisticated computer codes. In addition, rocks and minerals can be subjected to shock effects under controlled conditions in crater explosions or laboratory experiments that reproduce most characteristics of shock metamorphism present in natural impact crater rocks.

A general model for impact cratering mechanics based

on studies of Meteor Crater, Arizona (Figure 3), requires a basic understanding of the nature of shock waves.

Nature of shock waves

A shock wave is a transient pulse, moving at velocities above that of elastic (seismic or sonic) waves in the same material or medium, which produces an almost instantaneous rise in pressure behind its advancing front. Ahead of this pressure rise, the medium is not yet affected in any way; behind it the medium is immediately compressed with a resultant decrease in volume (increase in density) until unloaded by decompression or rarefaction waves. Pressure magnitudes in shock waves exceed the dynamic elastic limits of the transmitting materials; for rocks, this limit falls between 20 and 100 kilobars (1,000 bars, or approximately 14,700 pounds per square inch, or 10^9 dynes per square centimetre). Nuclear explosions and impacts will generate pressure waves whose initial amplitudes can reach megabars in the materials undergoing shock. An important property of shock waves involves a possible change of phase upon meeting a free surface or another medium of differing density and wave propagating characteristics. Commonly, an initial compression wave (wave peaks are close together) will thus be converted to a rarefaction wave (farther apart), which, if reflected over the previous wave path, can unload the state of compression or place the medium into tension (stretching or tearing). As a shock wave diverges spherically from a point source, its expansion into an ever larger volume also reduces its magnitude so that the pressure at the moving front continually decreases with increasing radial distance from its source.

Hugoniot curves

Each material substance responds characteristically to shock waves of a given magnitude. This response is measured as a relative decrease in volume or increase in density. One specific change in volume or density results for each value of peak shock pressure. A plot of the different pressures attained and their corresponding changes in volume (density) produces a curve referred to as the Hugoniot. This represents an equation of state for the material under various shock loads, in which the total mass, momentum, and energy of the system are conserved during the shock event. These parameters, together with the velocities of the shock front and particles in motion behind it, are related by a series of conservation equations that allow calculation of pressures and volume changes if initial density and shock and particle velocities are experimentally measured. Once the Hugoniots are determined, one can calculate the partition of energy (appearing as heat, mechanical motion, etc.) in each material as shocks progress through interacting media.

Formation of Meteor Crater. According to E.M. Shoemaker's analysis of the formation of Meteor Crater, Arizona, an incoming iron meteorite (bolide) struck the layered rock units on the Colorado Plateau near Winslow, Arizona, some 15,000–40,000 years ago. The orbital velocity of this meteorite in space about the Sun could have been between 12–42 kilometres per second, to which the effect of Earth's velocity of 29.8 kilometres per second might be added if the meteorite were moving against it. Deceleration by the atmosphere reduced terminal velocity, but if it exceeded one to two kilometres per second an impact crater would result (a penetration crater is produced by meteorites reaching the surface in the range of one to two kilometres per second). In his calculations, Shoemaker used 15 kilometres per second as the terminal velocity.

Mass, energy, and impact of the meteorite

By assuming an equivalence between a shallow-buried nuclear explosion and the impact at Meteor Crater, the upward scaling of energy relations for nuclear cratering explosions to the dimensions of Meteor Crater (1.2 kilometres diameter) indicates that a total energy of 1.7 megatons (7.1×10^{22} ergs) was needed to excavate the volume of nearly 0.3 cubic kilometre at Meteor Crater (estimates as high as 17,500,000 megatons, or 7.2×10^{29} ergs, have been made for the 62-kilometre-wide Manicouagan structure in Quebec). From this, and from the assumed velocity of 15 kilometres per second, the kinetic energy of the meteorite can be calculated. This fixes its mass at 63,000 metric tons that, with a density of 7.85 grams per cubic centimetre for iron, would occupy a sphere of about 25 metres diameter. More recent estimates place the total energy as high as three to five megatons, which requires either a larger projectile or higher final velocity.

The sequence of events at Meteor Crater is depicted schematically in Figure 4. Immediately upon striking the ground, shock waves are imparted both to the rocks and the meteorite itself. The ground-traversing shock front outruns the penetrating meteorite and forms an expanding cavity. The rocks behind the front are strongly compressed and generally are set in radial motion outward from the region of penetration. Depending on the Hugoniots of the rocks present, varying fractions of this target material will be vaporized, melted, crushed, fragmented, or fractured; ultimately, different sections of the volume of rock actually excavated will be dispersed and mixed together. The shock generated in the meteorite at the interface with the ground moves back into it as a compression that, upon reaching boundary surfaces along the sides and rear, transforms to a rarefaction that reflects

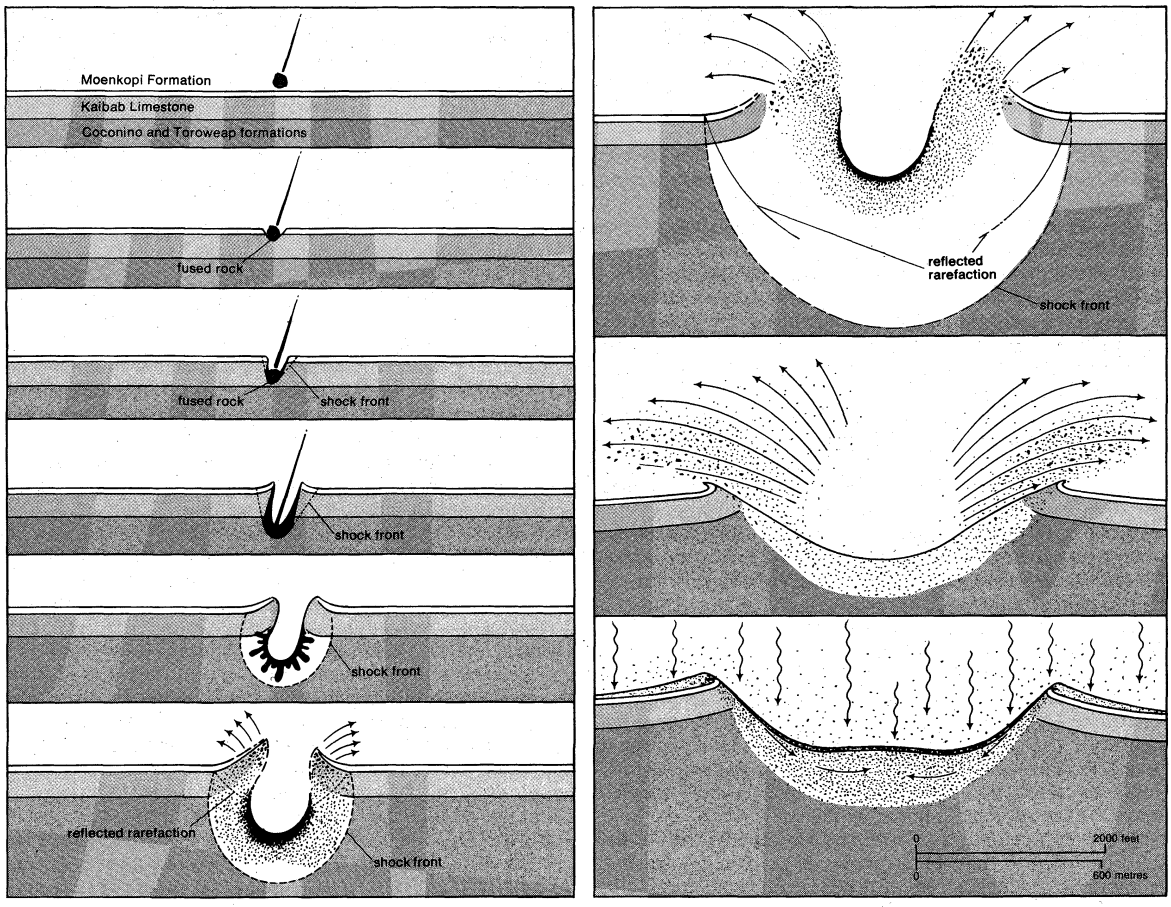

Figure 4: Stages in the formation of Meteor Crater, Arizona.
After E.M. Shoemaker in B.M. Middlehurst and G.P. Kuiper (eds.), *The Solar System*, vol. 4 (1963); University of Chicago Press

into the meteorite. Thus, some of the meteorite is vaporized, whereas other parts are melted or intensely heated and mechanically damaged as the entire body breaks up. A fraction of this meteorite is smeared along with the outward moving rock mass; much of the meteorite, however, ejects as fragments that escape the eventual crater.

The initially intense shock wave attenuates as it diverges outward. The net effect is that the degree of shock damage attributable to compression diminishes with increasing radial distance from the line of penetration. Only a small proportion of the total volume excavated undergoes strong to intense shock pressures; in contrast, the bulk of the rock experiences little or no permanent damage.

Excavation and brecciation of material

The actual excavation process requires rarefaction waves. These form as the advancing compression waves encounter free surfaces (ground–air interface) or discontinuities such as stratigraphic bedding surfaces, joints (rock fractures), or units with varying physical properties because of varying rock types. The rarefactions effectively place the rock medium under tension, resulting in a general disruption of the units. Because these now fragmented pieces were already in motion, they retain momentum sufficient to carry many of them forward and out of the developing crater as ejecta that follow trajectories established by their initial movements. Most such fragments move from the crater at low angles, and these are termed throwout deposits; at high angles the fragments fall back as crater-filling breccia deposits. Some, however, are carried downward without leaving to form fragmental debris that concentrates along the crater base. This base is defined by the boundary with the rupture zone, consisting of broken and displaced but not fragmented and ejected rock, that underlies the breccia fill. This boundary also represents the surface below which the compression and rarefaction waves become too weak to efficiently excavate material.

Within the rupture zone below the true crater floor and walls, the rocks can be folded, faulted, and intricately displaced. Especially in the rim, which marks the outer limit of surface excavation, layered units may be folded over completely to form structures that rival in complexity some of the great nappes (rock masses translated by thrust faulting) of the Alps. The overturning results when adjacent units below the uplifting free surface are peeled back as they go into motion in close succession. Massive rocks do not fold back but tend to uplift along joints, so that any pre-existing foliation is distorted. However, all crater-related deformation decreases abruptly away from the breccia-rupture zone contact, so that drilling beyond this contact would rapidly pass out of shocked or disturbed rock into ordinary, unmodified country rock.

For small craters, such as Meteor Crater, the entire formational process requires no more than a few seconds to completion. Craters that are tens of kilometres wide probably form in one to five minutes at most. The excavation caused by shock action occurs more rapidly than the later infilling process from fallback and slumping.

Conceptual crater model

Experimental studies. Experimental studies have added several details to the conceptual model. In the initial compression stage, materials behind the shock front experience pressures so high (many hundreds of kilobars) that their dynamic compressive strengths are greatly exceeded. Rocks behave under these conditions much like fluids (hydrodynamic state). The first rarefactions develop along the target-projectile interface and later the projectile itself. Decompression leads to the ejection of fluidized rock as a hot jet that, according to some workers, accounts for the glassy objects called tektites. As the spherical shock front advances outward, the compressed shell of material behind it mixes with the projectile (meteorite) and ejects steadily increasing amounts to begin the excavation stage. The complex geometric patterns of particle movements that follow progressive relaxation by rarefaction waves results in the lateral deflections of flowing materials from their earlier radial paths. Below the line of impact, particle movements still proceed mainly downward, but they deviate increasingly sideward until a tangential flow from the crater at low angles dominates the region of the ex-

panding rim. Ejection and crater growth is a continuous, orderly process involving a steady flow of materials along shear lines. Cratering ceases when stresses become too weak to break up materials or when momentum is insufficient to carry fragments beyond the excavation limits.

CRITERIA OF IMPACT ORIGIN

Crater geometry. The final shape of the crater depends on many factors. The depth to the visible crater floor (apparent crater boundary), relative to rim height, varies with the amount of material that backfills the crater as well as the degree of uplift or overturn of the rim. It has been suggested that the bulk of ejecta escape from the crater, but actual impact structures seemingly retain substantial fractions (up to 75 percent) of the initial excavated volume as breccia and melt deposits. Some of this is direct fallback or materials that fail to move out. A post-impact modification stage, however, begins even as cratering is being completed, and it continues for days to years afterward. Instability of steep crater walls leads to slumping and infill that, in effect, enlarges the rim-to-rim diameter. Erosion and inward drainage may bring some of the throw-out ejecta back into the crater. Isostatic adjustments, the regional response to reduction of crustal load at the crater site, can affect larger craters by pushing the entire structure upward.

Simple and complex craters

A simple crater is characterized by a well-defined lip, a bowl-shaped cross section, extensive fallback deposits that thicken toward the centre, and small to moderate amounts (1 to 2 percent) of impact melt concentrated along the central base. Its initial diameter to depth ratio is about five to one. When the crater diameter begins to exceed four to five kilometres, the rupture zone beneath the central base tends to uplift along shear lines. Large, complex craters have broad, domelike uplifts, which sometimes have topographic expression as central peaks. Rocks within this uplifted portion may be strongly shocked and intricately contorted. The mechanism of uplift is still conjectural: elastic rebound, isostatic adjustment, response to rarefaction waves reflected from deep crustal layers, and slump-induced rise of rubble are suggested mechanisms. Normally, in layered materials the uplift contains stratigraphic units from depths below the general level of the crater base, which indicates a real upward movement of rock. It has been proposed that large craters with diameter–depth ratios around ten to one and with central uplifts result from comet rather than meteorite impact. When a low-density cometary projectile strikes the ground, the dominant energy release remains near the surface; this causes lateral excavation to be more effective than is true of penetrating iron meteorites. Generally, complex craters develop poorly defined, relatively low rims and contain their breccia-melt deposits in an annular depression between rim and central peak.

Geophysical anomalies

Geophysical techniques are frequently applied to circular structures to determine their nature and origin. Commonly, impact craters and astroblemes show slight to strong negative gravity anomalies, because of brecciation and the creation of small cavities; but measurements of rock densities, compensation for possible infilling sediments, and topographic corrections are needed properly to assess the magnitudes and implications of such anomalies. Volcanic calderas, maars and diatremes, and even eroded volcanic necks and pipes may have comparable anomalies. Magnetic highs might suggest the presence of iron meteorite materials within the crater fill, but usually most of the projectile disperses outside the structure upon impact. Seismic reflection techniques can pick out the crater base contact and also may sense the local character of structural disturbance.

Shock metamorphism of rocks. Although shape, deformation, and geophysical anomalies are all useful criteria for locating meteorite craters, they do not, taken singly or together, comprise unambiguous proof of an impact origin. Some structures of nonimpact origin possess many features in common with meteorite craters. Astroblemes, in particular, may lack distinguishing surficial characteristics. The only truly definitive criteria so far advanced reside in the rocks themselves. Thus, rocks of any type are subject to remarkable changes during impact that, collectively, are described as shock metamorphism. The passage of transient pressure waves through rocks and their constituent minerals induces distinctive effects of very high pressures and temperatures and rapid strain rates that alter their composition and properties. These effects include the formation of high-pressure polymorphs (different forms of the same composition) that normally are not stable in the Earth's upper crust; fragmented, fractured and granulated rock masses; unusual intracrystalline markings; solid-state transformations from crystalline to glassy states; and selective melting and vesiculation of individual minerals. These changes are produced in microseconds to milliseconds by pressures ranging up to 500–750 kilobars (comparable to pressures at depths of 1,400–1,800 kilometres within the earth), temperatures that rise above 2,000° C (3,600° F), and strain rates millions of times faster than those operating during mountain building.

A clear picture of progressive shock metamorphism of rocks emerges from following the changes in granite, a common igneous rock containing quartz, feldspars and micas, as it undergoes increasing shock pressures. The effects of a nuclear explosion on granite surrounding the explosive device provide an example. In a contained (noncratering) explosion, pressures decrease systematically from the explosion centre as the waves diverge spherically. For a ten-kiloton explosion, maximum pressures 60 to 100 metres from the centre will be only five to two kilobars. No perceptible changes occur at these low pressures except where compressive waves encounter discontinuities that transform them into fracture-producing rarefactions. As peak pressures rise with ever-closer proximity to the explosion, microfractures generated in individual grains continue to increase in frequency and numbers per grain (Figure 5). At 20–30 kilobars, cleavage planes in mica start to bend and kink as though folded like layered strata; with higher pressures more individual mica crystals start to distort, and the intensity of deformation rises in all flakes thus affected. When the shock pressures in the passing waves exceed values of 50–75 kilobars (the dynamic elastic limit for many granitic rocks), changes not known even in equivalent rock types buried deep within the crust start to appear.

Shatter cones and mineral transformations

One such change is the development of shatter cones. These are peculiar external fracture surfaces in which close-spaced "grooves" seemingly radiate outward from the apex of a cone (horsetailing effect). Many such cones usually cluster together. Most have apices that point in a common direction that, when separate cone-bearing layers are rotated to their original position by later analysis, converge toward a single origin that appropriately coincides with the explosion centre or region of first impact.

In quartz grains, sets of lamellae-like planes form within crystalline zones over a pressure range from about 100 to 400 kilobars. These planar features are now known to be close-spaced bands (0.2–1.0 micrometre wide) of disordered crystalline material (the regular orientation of atomic units in a crystal lattice structure becomes distorted and bonds are bent and broken; the mineral substance is thus changed to the isotropic or glassy equivalent of the host grain). Planar feature sets tend to align along various atomic planes whose crystal indices are unusual or rare as crystal faces or mechanical slip zones in the corresponding unshocked mineral species. At higher pressures, as many as 5–15 distinct sets, following several different crystallographic orientations, appear to occupy all available space within a grain, although electron microscopy demonstrates some crystalline material to survive between planar discontinuities. Planar features presumably result from crushing or slipping of crystalline phases along preferred planes of weakness, as the grains are compressed rapidly into much smaller volumes.

In the higher pressure ranges over which quartz planar features are produced, coesite and stishovite, high-pressure forms of silica, will develop, presumably in association with the process of isotropization. Other shock-induced polymorphic transformations, such as diamond from other forms of carbon, have been discovered.

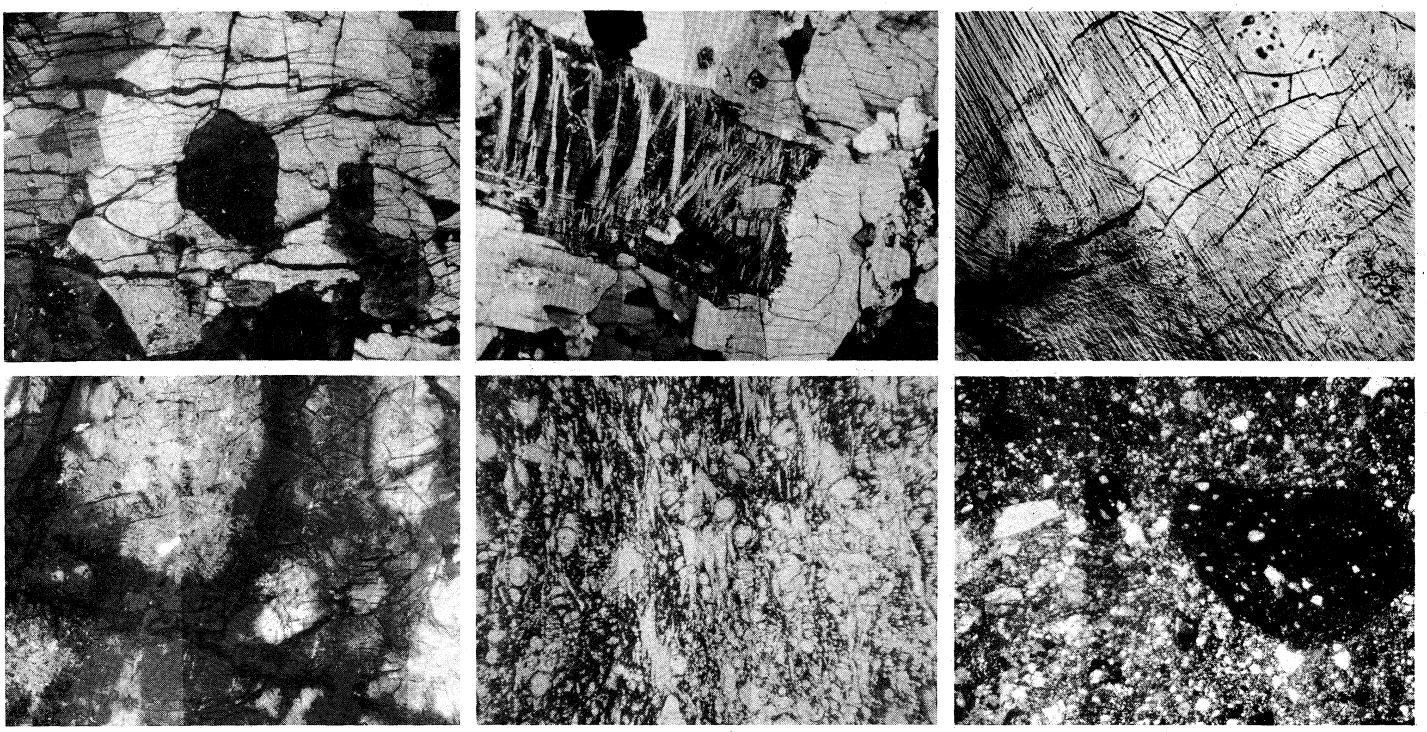

Figure 5: (Top left) Shock-induced fractures in a granite rock. (Top centre) Biotite mica flakes kinked by the action of shock waves. (Top right) Several sets of close-spaced planar features in a single grain of quartz in a shocked granite specimen. (Bottom left) Crystals of feldspar and perhaps quartz undergoing transformation from the crystalline state (white, light gray) to the disordered noncrystalline state (isotropic, dark gray) in a granite sample. (Bottom centre) Intensely shocked granite in which the rock has more or less melted (note some flow alignment) and is strongly vesiculated. (Bottom right) A "suevite" from the Brent impact structure, Canada; its texture is characterized by a mass of fragments broken by shock waves and containing various signs of shock metamorphism, mixed with glass (dark mass on right) and granulated material. Both feldspar and quartz within a shocked granite may contain planar features but some minerals have crystal structures that seemingly prevent formation of these discontinuities. At pressures around 350 kilobars (feldspar) and 425 kilobars (quartz), the density of planar features within grains reaches a maximum, and the grains become more or less completely isotropized. Thus, a grain may convert to a glassy state while retaining its original shape. These thetomorphs (Greek "adopted form") are unique to shocked rocks. Hand specimens containing thetomorphs may still display the original gross texture but will have noticeably reduced specific gravities.

Melting at high temperatures and pressures

At still higher pressures (450–600 kilobars), the effect of rapidly rising temperature from conversion of mechanical to thermal energy leads first to incipient melting of individual grains and then, eventually, to general melting and variable mixing of the whole rock material. The tectosilicates (quartz, feldspar) readily undergo such melting, accompanied by progressive vesiculation within individual grains. Mineral groups like olivines, pyroxenes, and micas (*qq.v.*) apparently degenerate structurally without actually melting until the remainder of the rock becomes superheated melt. Refractory minerals, like zircon and titanite, may partially decompose in the melt, trailing particles within the fluid.

When these shocked rocks are viewed in the microscope as thin sections, their distinctive character is immediately evident. The "suevite" texture, defined by rocks from the Ries Crater in Bavaria, consists of intensely shocked mineral and rock fragments mixed with moderately to imperceptibly shocked fragments held in a granulated matrix, often with blebs (small, irregular droplets) of melt. The identity of most constituents as nonvolcanic country rock (unless the impact happened in volcanics) distinguishes this impact material from most typical volcanic or tectonic breccias.

Other rock properties are drastically altered by shock. The indices of refraction of mineral components can be anomalously lowered, sometimes to values below those for any unshocked equivalents. X-ray analysis of individual grains may reveal that an apparently unstrained single crystal has been shattered to a fine aggregate, which produces a set of rings instead of spots in the diffraction pattern. Argon, derived from decay of radioactive potassium in feldspars or mica, can be driven off by the shock and attendant temperature rises, so that a rock may acquire a new age that reveals the time of impact.

If the deeply buried nuclear explosion in granite were replaced by a shallower explosion, the resulting crater should produce ejecta, showing a wide range of shock damage, which would mix on falling back to fill the excavated cavity. This crater would simulate, in many respects, the form, deformation style, and shock features that are the marks of an impact structure. Such an artificial crater, if recent, would differ mainly in the relative absence of postimpact alterations; natural impact craters generally contain tightly cemented breccia deposits characterized by notable geochemical changes.

Identification of circular structures. The various criteria for recognizing impact structures, as reviewed in this article, are as follows. On Earth, a circular ring, depression, or breccia zone is confirmed as a meteorite impact scar if it meets at least some of these definitive criteria. On the Moon and Mars, direct field investigation, including core drilling, is obviously still limited, so that proper identification of the literally billions of circular structures on these planets is presently impossible. Some of these structures are of one genetic type and differ mainly in their relative aging by erosive processes. Others appear to have nonimpact origins.

It is now clear from Orbiter, Surveyor, and Apollo investigations that volcanic rocks abound on the lunar surface. This implicitly suggests that volcanic cones, calderas, and maars should be interspersed with impact structures on the Moon. Two large circular structures in the inner ring of Mare Orientale, of apparently similar age, have been

proposed as the prototypes for impact and volcanic craters. The impact crater is defined by multiterraced walls, a rough floor, central peaks, a wide, hummocky surface beyond the rim, and ejecta rays extending out many crater radii. The volcanic caldera type shows a smoother floor, no central peaks (although this is possible), an unterraced inner wall, a smooth, relatively narrow ejecta (ash?) blanket, and no distinct large rays.

Ultimately, the question of origin of each lunar crater must rest on direct examination. If shocked rocks are collected *in situ* at a crater, its impact origin is substantiated. Shocked ejecta fragments should be prevalent over most of the lunar debris surface. Samples of breccias and regolith (soil-line rock debris covering the surfaces of both the maria and terrae or highlands) returned from all Apollo sites contain abundant signs of shock metamorphism. These materials evidently have participated in impact-crater-forming processes and tend to confirm the role of meteorites and comets in producing circular structures on the Moon. Repeated impacts over eons will sharply increase the proportion of more strongly shocked rock in the rubble.

A study of shock metamorphism of basalt, a prevailing lunar rock type, induced by a nuclear explosion in Nevada, indicates that the basalt is relatively resistant to shock damage below 300 kilobars. At higher pressures (~500 kilobars), feldspar constituents convert to thetomorphs and then melt with only localized fluid migration. Ferromagnesian minerals granulate, undergo variable decomposition, disperse within this molten feldspar, and then react with the melt to produce new mineral phases. Several crystal structure changes are recorded by optical and X-ray examination. In the extreme, dense basalt was converted by shock to a highly vesiculated, lightweight, partly glassy rock that resembles some volcanic cinders or dark pumice. Its true origin must be deciphered by confirming the shocked character of fragmental inclusions.

Meteorological Measurement

The behaviour of the atmospheric environment has long been a source of curiosity for mankind. Perception of warmth and cold, sunshine, winds, and precipitation must have been one of man's earliest sensations, yet it was many centuries before significant effort was expended on purposefully observing weather and on studying its causes.

The atmosphere as a fluid system. Only in the present century has the atmosphere been seen as a large fluid system, the behaviour of which is primarily determined by the need for a poleward transfer of heat. The weather (precipitation, wind, etc.) is primarily a result of a thermally driven, atmospheric, fluid motion on many time and space scales causing phase changes in the water substance—a small (4 percent) but vital component of the atmosphere. Thus clouds and precipitation (perhaps the two meteorological elements most frequently identified as "weather" by the layman) are a result of upward motion that favours cooling, and this in turn leads to condensation of water vapour into cloud droplets. Small-scale motion has important indirect effects on the growth of precipitation and even electrical activity within clouds. On a larger scale atmospheric motion is organized into planetary waves, cyclones, and anticyclones in the midlatitudes and into hurricanes and monsoons in lower latitudes. In all cases the distribution of resultant cloud cover is closely related to the configuration of motion in the system. The importance of cloud cover is not restricted to its ability to give precipitation: it also has a significant effect on the receipt of radiation by the Earth's surface. This effect is but one of the many mechanisms at work in the atmosphere and illustrates the complexity of a system with few, if any, simple, direct cause-and-effect processes.

Objectives of meteorological measurement. The basic object of meteorological measurement is to provide information on the behaviour of the complex atmospheric system in order to increase the understanding of the causes of weather and climate and to forecast their changes. But the scope of meteorological measurement has not always been so broad and yet, at the same time, so well defined. The fairly crude observations made prior to the 20th century were mostly the result of personal curiosity about the weather, and yet they were adequate to spawn the realization that the state of the atmosphere at a future time was, to some extent, predictable. This realization, together with the growth of aviation, has meant that weather forecasting holds prime place in the science of meteorology and, as such, has determined the pattern of meteorological measurement in this century. Most of the millions of meteorological measurements taken every day are for "operational" (routine) purposes—that is, to provide data for analysis that itself is the important first step in weather forecasting.

Since 1950 techniques of weather forecasting have undergone major changes. The forecasting problem in its widest sense has become the overall problem of meteorology—the elucidation of the workings of the general circulation of the atmosphere. A full understanding of the general circulation, including its component parts on many scales, will allow prediction of future states of its configuration—and this is the essence of forecasting.

This convergence of aims of routine and nonroutine observation means that meteorological measurement to-

Basic descriptive elements

day involves the description of the physical and dynamic state of the atmosphere on space scales ranging from millimetres to thousands of kilometres and time scales from seconds to years. The fluid state of the atmosphere suggests that five basic descriptive elements should be used: the gaseous constituents, density, pressure, temperature, and motion. Of these the first two (with the exception of water vapour) fluctuate very slowly, if at all, in time and, therefore, do not require frequent measurement. In contrast the last three are continuously variable in both space and time, and it is the variation of the elements themselves, their mutual interactions and their interactions with the water substance, that are observed. Continuous monitoring of the state of the atmosphere is of course impossible, so measurement largely involves the use of instruments (as opposed to visual estimation) in networks of varying density to take samples at different, yet internationally agreed times. The remainder of this article considers these methods in more detail.

HISTORY OF METEOROLOGICAL MEASUREMENT

True meteorological measurement, as opposed to simple perception of the vagaries of the atmosphere, began in the 17th century with the invention of the barometer and thermometer.

Barometers. Perhaps the most important discovery in meteorology was the principle of the barometer—the realization that changes in weather were related to fluctuations in the height of the mercury. The invention of the barometer in 1643 is attributed to Evangelista Torricelli, an associate of Galileo at Florence, who determined ". . . to make an instrument which might show the changes of the air, now heavier and coarser, now lighter and more subtle." By 1645 the idea had spread to France, and in 1663 the Royal Society of London had devised its own instruments using the same basic principle. A century later the principle of the aneroid barometer (see below *Atmospheric pressure*) was discovered, but not until 1843 was a satisfactory model produced.

Thermometers. Although the perception of heat and cold must have been more obvious to man than the weight of the air, the invention of the thermometer virtually coincided with that of the barometer. Early "thermoscopes" such as that devised by Galileo were defective in that they relied on the expansion of a gas, usually air, to indicate temperature change and had no scales. The barometer revealed the variability of the pressure of air and led to the adoption of the liquid-in-glass thermometer, which was being produced by Florentine glassblowers by mid-17th century. Of the many scales invented for the thermometer the most successful were those of D.G. Fahrenheit of Germany and Anders Celsius of Sweden.

Humidity measurements. One of the major stumbling blocks to the invention of the barometer was the widespread Aristotelian disbelief in the existence of vacuum. Water vapour also was slow in being recognized and accepted as fact. Once it was recognized that water vapour was a distinct substance, instruments to measure its amount in the atmosphere began to be invented.

The earliest humidity measuring instruments depended on the hygroscopic (moisture absorbing) properties of various substances. Changes in humidity affected either their weight or their volume. Sponge was frequently used in the 15th and 16th centuries—the principle being that changes in its weight in air gave a crude indication of the changes in humidity of the air. Although the first hygrometer was probably invented by Leonardo da Vinci, there is little doubt that he had access to the notes of Nicolas Cryfts, who in 1450 had suggested that a hygroscope could be made with the use of dried wool placed on scales. In the next three centuries many variations on this theme were conceived, culminating in the suggested use of seaweed in 1785. Hygrometers dependent on change of volume were similarly various. Wood was frequently used in the 17th century, and later it was found that gut, strings, and cords were good indicators of humidity changes. This eventually led to the discovery of the hair as a humidity sensor. Goldbeater's skin (ox gut) was probably first experimented with at the same time. It is still used today.

Humidity instruments dependent, on the one hand, on the formation of dew on artificially cooled surfaces (condensation hygrometers) and, on the other, on the amount of evaporation from a moist surface (psychrometers) were invented slightly later than the hygroscopic type. Ferdinand II of Tuscany probably discovered the condensation effect in 1655 and devised his own hygrometer working on this principle. A description of the cooling effect of evaporation was first recorded in the 17th century, but it was not until the late 18th century that the principle was used specifically to measure humidity. Theory and further development followed in the 19th century and continues today. Accurate measurement of humidity still challenges the makers of meteorological instruments.

Wind measurements. Wind direction was crudely recorded by the Greeks as early as 100 BC, but instruments to measure wind force as well as direction were only developed in the 17th century. The swinging-plate anemometer measured the deflection of a vertically hanging sheet of wood. This was an attempt to measure directly the dynamic pressure of moving air. The same basic principle is employed in the pressure-tube anemometer, conceived earlier but not constructed until the 1740s. The best known of this type is that invented in 1891 by the British meteorologist W.H. Dines, and still in use. The windmill effect, used in cup anemometers, was appreciated as early as AD 700 in Persia, but actual instruments were first constructed in France in the 17th century.

Swinging-plate anemometer

Rain gauges. Records of precipitation also have a long history. It is generally agreed that crude measurements were made with a container 18 inches wide in India about 400 BC, and that rain gauges were used in Korea in the 15th century. But the major developments again occurred in 17th-century western Europe, where self-recording gauges came into use.

Weather records and institutions. Whereas the 17th century saw the invention of the most important meteorological instruments for surface observation, the 18th century was a time of modification and usage to satisfy individual curiosity about the weather. The diaries of amateur observers provided invaluable information on changes in climate before the 19th-century establishment of national meteorological services. In Europe such institutions grew up in the period 1820–60 in Austria, Belgium, France, Greece, The Netherlands, and the United Kingdom. In the latter part of the 19th century, national organizations had been established in Japan, India, and Brazil.

At a very early date, the value of international cooperation was recognized. In 1853 a conference on maritime meteorology was held in Brussels to arrange the communication of meteorological data for the construction of the first weather maps. Nearly 20 years later a similar meeting laid down recommendations for the transmission of land-based data. By 1880 the directors of the national meteorological services had grouped themselves into the International Meteorological Organization (IMO). For over 70 years the IMO encouraged the improvement of observation and transmission of data for forecasting purposes. After World War II the IMO was reconstituted as the World Meteorological Organization (WMO), and in December 1951 the United Nations recognized the WMO as a specialized agency. Over 130 countries (virtually the entire world) are members of WMO and thus allow the free communication of standardized observations, mainly for forecasting purposes.

World Meteorological Organization

SURFACE MEASUREMENTS

Meteorological observations made at the Earth's surface are of two kinds: sensory observation—taken without the use of a measuring instrument and estimated by experience only; and instrumental observation—taken with the aid of measuring instruments and usually involving corrections and calculations to the actual readings. Three types of observing stations exist to record as fully as possible the state of the lower atmosphere. A synoptic station observes the following elements: present and past weather; wind direction and speed; amount, type, and height of base of cloud; visibility; air temperature; humidity; and atmospheric pressure. At certain synoptic stations

added observations are taken of pressure tendency; extreme temperatures; precipitation amount; state of ground; direction of cloud movement; and any special phenomena. Measurements of all these parameters are often taken at three-hour intervals, but at some stations certain measurements are taken every half hour. The other types of station are climatological and agricultural stations. At a principal climatological station, observations are usually made once per day of all or most of the following: weather, wind, clouds, visibility, temperature, humidity, pressure, precipitation, snow cover, sunshine, and soil temperature. Agrometeorological stations concentrate on air and soil temperatures, soil moisture, precipitation, sunshine, radiation, and evaporation amounts.

Cloud height: direction and speed of movement. Observations of clouds consist of visual estimations of their form and extent, instrumental measurement of their height above the ground, and visual estimations or instrumental measurements of their speed and direction of motion.

The identification of cloud forms is based on the specifications well illustrated in the WMO *International Cloud Atlas*. Ten basic forms constitute the basis of classification, but the infinite variety within these types means that recognition of an individual cloud-type requires some experience on the part of the observer. Cloud amount is also assessed visually, the amount of the visible dome over the observer that is cloud-covered being given in either eighths (*oktas*) or tenths.

The *International Cloud Atlas*

Although cloud-base height is often visually estimated by the experienced observer, it is possible, and preferable, to measure it (in metres) either with small pilot balloons or vertical light beams. The balloons, rising at a rate of about 130 metres per second, are tracked by binoculars or theodolite, and the duration of their visible ascent allows calculation of the cloud base. At night the measurement at one end of a base line of the angular elevation of the light spot produced on cloud base by a vertically pointed light at the other end of the base line provides a ready measure of cloud height. Instruments also exist to measure the speed and direction of cloud movement.

Sunlight duration. Although the WMO recognizes four main types of instrument for the measurement of sunshine duration, it recommends the use of the Campbell-Stokes recorder, which focusses the Sun's radiation to burn a trace on a chart. The length of the trace gives the duration of bright sunshine in hours. The instrument comprises a glass sphere about ten centimetres (four inches) in diameter mounted on a section of a spherical bowl such that the charts in the grooves of the bowl are scorched by the Sun's radiation. The sphere is mounted in differing positions, depending on whether it is in high, middle, or low latitudes, and three overlapping pairs of grooves are provided in the bowl to take cards suitable for different seasons of the year.

Visibility. The measurement of visibility is undertaken largely to meet aviation requirements, but the occurrence of ground fog has sufficient effect on man's other activities to justify its surface observation. As in the case of cloud observations, both visual and instrumental measurements of visibility can be made. The usual procedure is to record whether or not objects of a known distance (in kilometres and metres) from the observing station can be seen or not, but at night, visibility meters are useful. These instruments use photoelectric cells and are of two types, one measuring the attenuation coefficient of a long column of air, and the other measuring the scatter of light from a small volume of air.

Atmospheric pressure. The pressure of the atmosphere is the force it exerts per unit area on a given surface. This force is generally measured by either mercury or aneroid barometers, the units of measurement being millibars (1 millibar = 1,000 dynes/cm^2). A reading of pressure must be corrected for temperature and station altitude above mean sea level to make observations at different points comparable. The rise or fall of pressure in the previous three hours—the pressure tendency—is also recorded.

Barometer corrections

The mercury barometer works on the principle that the atmospheric pressure is balanced against the weight of a column of mercury. It is a sensitive, carefully calibrated instrument and once installed is not usually moved. The height of the mercury is read with the aid of a vernier scale (giving the pressure to a tenth of a millibar), and this reading is corrected with the aid of the attached thermometer reading and the knowledge of the height of the instrument above sea level. The number of readings per day ranges from one to 24 depending on the type of meteorological station.

Aneroid barometers are less accurate than mercury instruments but are particularly useful for their portability and their adaptability for use as barographs. An aneroid barometer has two basic parts: a closed, metal, evacuated chamber and a strong spring that prevents the chamber from collapsing. Variations in atmospheric pressure cause fluctuations in the size of the chamber. These fluctuations are recorded. If the recording is in the form of a pen trace on a chart, thus giving the variation of pressure with time, the instrument is known as a barograph.

Air temperature: maximum and minimum. A surface observation of air temperature refers to the shade temperature at 1.2 metres (four feet) above the ground. Only shade temperatures give the true air temperature: direct exposure of the thermometer to the sun's radiation would result in readings of the temperature of the glass of the thermometer rather than that of the surrounding air. To achieve this important objective, thermometers are housed in white, louvered screens (shelters) that allow adequate ventilation. The instruments themselves, used for actual, maximum, and minimum temperatures, are usually mercury-in-glass or alcohol-in-glass thermometers. The recommended scale is Celsius, but in some countries, notably the U.S., Fahrenheit is still used. Readings are estimated to a tenth of a degree. A maximum thermometer has a constriction in the bore below the lowest graduation. This constriction allows the mercury to expand freely up the bore but prevents its return when temperatures fall after the maximum is reached. The instrument is reset by gently shaking the mercury down through the constriction. A minimum thermometer usually has a dark index, about 2 centimetres (¾ inch) long, immersed in alcohol. As the temperature falls, the meniscus (curved surface) of the alcohol pulls down the index, which is left in the minimum reading position when the temperature rises.

Temporal variations in temperature are recorded on thermographs of which there are various types. They range from those dependent on the different expansion rates of two metals to those based on the variation with temperature of electrical resistance of fine wire elements. In all cases the changes in temperature are recorded by a pen arm on a chart wrapped around a rotating drum.

Earth temperature. Mercury-in-glass thermometers are used for both grass minimum readings and observations at depths of 5, 10, 20, 50, and 100 centimetres (2, 4, 8, 20, and 40 inches) in the soil. The grass minimum thermometer is simply a minimum thermometer exposed horizontally over short grass with its bulb just touching the tips of the blades of grass. The first three depths of soil are sampled by thermometers bent at right angles with their scales facing upward so that they can be read without being disturbed. At depths of 50 and 100 centimetres thermometers are usually suspended in tubes sunk into the earth.

Grass minimum thermometer

Precipitation. The estimation of precipitation amounts simply involves the exposure of a container for a given period, usually 24 hours, and the measurement of the depth of collected water (or liquid water equivalent of snow and hail). The most common rain gauge stands about 30 centimetres (12 inches) high and has an orifice of 13 centimetres (about 5 inches) diameter with a funnel leading to a glass jar, which itself stands in a metal can. Gauges designed for very wet areas usually have a greater capacity. The amount of rainfall in the 24-hour period is established with the use of a rain measure graduated in inches or millimetres, preferably the latter.

Autographic rain gauges provide two types of information on the variation of rainfall with time: first, the total amount of rain that has fallen since the time the record started and, second, the intensity of rainfall at any instant.

Very few gauges of the second type are in operational use. In the most common of the first type, the rain is led into a chamber containing a light float. The vertical movement of the float as the level of the water rises is recorded on the chart. When the chamber is full, a syphoning mechanism allows the whole operation to start again. A second type of rainfall recorder simply empties the known amount of water in the chamber by tipping and counts the number of tips.

Humidity. Water content of the air may be expressed in several ways: the vapour pressure (in millibars); the vapour density (in grams per cubic centimetre); the mixing ratio (in grams of water vapour per kilogram of dry air); and the more familiar relative humidity (in percent). Basically, the humidity of the air is related to the difference in the dry- and wet-bulb temperature readings. These readings are obtained by using a psychrometer, which has two thermometers mounted together, one with a wet cloth sleeve over its bulb. Reference to specially prepared tables gives relative humidity values. Changes in relative humidity are satisfactorily measured by the expansion or contraction of hairs and they are often used in the hygrograph—an instrument that provides a daily or weekly trace of temporal changes in relative humidity.

Wind speed and direction. Instruments for recording wind speed and direction are some of the most elaborate of the routine surface hardware. Wind direction (the direction from which the wind is blowing) is expressed in degrees, measured clockwise from geographical north, and assessed with the use of a freely turning wind vane. The wind speeds, corrected if necessary to the standard height of 10 metres (32.8 feet) are recorded in knots, and two types of instrument provide the relevant values: cup anemometers and pressure-tube anemometers. Cup anemometers work by using the wind to spin three hemispherical cups, driving a small electric generator; the resultant current is indicated on a meter, the scale of which is graduated in terms of wind speed. The pressure-tube anemometer uses a combination of pressure and suction forces to measure wind speed. Moving air enters an orifice, kept to the wind by a vane, and provides an upward push to a float in a chamber, while holes in the supporting vertical tube provide a suction force that pulls the float. A pen attached to the float gives a daily record of wind speed in knots on a chart.

Cup anemometers

Pollution and pollen count. The bases of measurement of smoke and pollen spores in the atmosphere are quite similar. In the case of smoke, a sample of air (usually about two cubic metres, or 70 cubic feet, per day) is passed through a filter paper, the smoke stain measured, and the reading converted into smoke concentrations of micrograms per cubic metre. The pollen count is measured by directing a continuous jet of air onto a stationary or moving slide that has an especially prepared surface. The pollen spores caught on the slide are counted for any desired time interval. Sulfur dioxide is perhaps the most dangerous of the routinely observed pollutants; it is usually measured simultaneously with smoke concentrations. The air that has just passed through the filter paper is passed through a chemical. The resultant acidity of the chemical gives an indication of sulfur dioxide concentration.

Radiation. Virtually all of the energy that drives the atmospheric circulation is received in the form of solar radiation. Three basic types of solar radiation are measured. Direct solar radiation is measured by a pyrheliometer; sky radiation and global (direct plus sky) radiation, by a pyranometer. But the Sun is not the only radiating body: both the Earth and the atmosphere emit thermal radiation (known as terrestrial radiation). Pyrradiometers measure both solar and terrestrial radiation, and a net pyrradiometer measures the net flux of downward and upward total (solar, terrestrial surface, and atmospheric) radiations through a horizontal surface.

As radiation is a process of continuous transfer of energy, it can be measured as a flux or as an amount received in a given time. Radiative flux per unit area is usually measured in milliwatts per square centimetre and radiation amount per unit area either in joules per square centimetre or milliwatt-hours per square centimetre. Many types of radiation instruments exist but most of them incorporate thermopiles (thermoelectric devices) as their sensitive elements and the outputs are measured as small electrical voltages. The exact nature of the equipment at any one station depends on observational requirements and these vary widely among national meteorological centres.

Evaporation. The measurement of water loss from the Earth's surface is of little value to routine weather forecasting but is vital to the elucidation of the water balance of the atmosphere. The term evaporation means water loss from a water surface; and the term evapotranspiration is used to cover the combined loss of water by evaporation and transpiration (water loss from leaf surfaces of plants that have taken up water from the ground). Both types of water loss are measured in millimetres of liquid water lost per unit time (an hour or a day) from a unit area.

Evapotranspiration

Evaporation is measured by observing the change of level of water in a pan or tank. The pan may be sunken, so that the water surface is nearly level with the ground; or above the ground to allow free air circulation; or floating in a lake to provide estimates of lake evaporation.

An evapotranspirometer is a container of soil and vegetation from which the water loss is measured by weighing or accounting for all incoming water at the surface and all outflow from the bottom of the container. Several designs exist, and research is still active in an attempt to devise instruments that will accurately measure water loss by the evapotranspiration process.

UPPER-AIR MEASUREMENT

For obvious reasons, information on conditions in the free atmosphere is far less complete (in both numbers of elements observed and density of observing networks) than on conditions at the surface. Routine upper-air observation by radiosonde (balloon-borne radio transmitter) is restricted to temperature, humidity, pressure, and wind speed and direction at selected levels between the surface and an altitude of about 18 kilometres (11 miles). Above that level rocket sondes are used. Data on other meteorological phenomena—particularly clouds—are available with the use of sferic equipment, radar, satellites, and aircraft.

Sferic measurements. When lightning flashes in a thunderstorm, electromagnetic waves are produced, which are known in meteorology as atmospherics or sferics. As these waves are fairly easily detectable for a distance of thousands of kilometres, sferics give a convenient way of locating thunderstorms.

The most common type of sferic equipment is the cathode-ray direction finder. This unit has two aerials at right angles. On receipt of the sferic, the direction from which the waves came is displayed on a cathode-ray tube. The information is either photographed or noted by the observer. A single direction is, of course, of little value, so a sferic network usually comprises from two to four stations 500–1,000 kilometres (about 300–600 miles) apart. The simultaneous recording of a lightning flash by these stations allows a "fix" on the storm to be made by simple intersection methods. In thundery weather the sferics stations usually operate for ten minutes before each hour and plot as many fixes as is possible.

Cathode-ray direction finder

Radar measurements. Radar can be used to "see" precipitation particles in the same way it can be used to "see" aircraft. The development of radar meteorology has provided information on the dynamics of clouds and upper air winds and has been most valuable in short-term forecasting.

Basically, a radar set comprises a transmitter of wave energy, a receiver of reflected energy, and a display system so arranged that the object under surveillance can be conveniently located. In meteorology the object under surveillance is most often a cloud or collection of clouds, and the energy is reflected by precipitation-sized raindrops or ice crystals in the cloud. For a given wavelength the amount of backscattered (reflected) energy is proportional to the sixth power of the drop or crystal diameter. For a given drop-diameter the reflected energy increases with a decreasing wavelength of the transmitted energy, but short wave-

length radars suffer from high attenuation—a weakening of outgoing and reflected wave by intervening clouds and raindrops—and are not used as widely as their properties would initially appear to warrant.

Radar observations of clouds (or strictly, the precipitation-sized particles in the clouds) are usually displayed in two basic ways on a cathode-ray tube. The horizontal location of "echoes" is shown by the plan position indicator (PPI), usually a full circle display with the radar station at the centre, with azimuth markings every 20°, and concentric range markers a constant distance apart. A variation is the constant-altitude plan position indicator (CAPPI): this provides PPI pictures of echoes at various altitudes other than the surface and has proved of great value in cloud physics research. The second basic type of display is the range–height indicator (RHI), which gives a section of precipitating clouds along a chosen direction. Both types of display may have a horizontal range over 150 kilometres (about 93 miles); the vertical range of the RHI is about 15 kilometres. Although most radar information is transmitted and stored in the form of either verbal descriptions or photographs, research is currently being directed toward the automatic numerical coding of echoes.

Plan position indicator (PPI)

Radar is also used to track targets attached to balloons. The slant range and direction of the target at different times provide a measure of the upper-air wind speed and direction.

Radiosonde measurements. Radiosondes are used to measure pressure (in millibars), temperature (in degrees Celsius), and humidity (in percent relative humidity) up to heights of 16 to 20 kilometres (10 to 12.5 miles)—occasionally to 30 kilometres (19 miles). The instrument comprises meteorological sensors, a radio transmitter, and a device to allow control of the transmitter from a distance. The whole is suspended beneath a large balloon that rises until it bursts; the sonde descends by parachute.

Sensors of radiosondes vary from country to country but certain types are most frequently used. For pressure, aneroid capsules are most satisfactory; for temperature, thermometers are usually of the bimetallic or resistance type; and for humidity, hair or goldbeater's skin is recommended. Of the four types of sonde listed by the WMO, that using the variable audio-frequency principle is most used. As the balloon rises with this instrument, the sensors sample the pressure, temperature, and humidity at height intervals of about 120 metres (390 feet) and activate inductors that vary the modulation frequency. The ground station receives the signal transmitted from the battery-powered sonde and compares its frequency (with the aid of an audio-frequency oscillator) with calibration curves to establish the conventional units. The calibration curves themselves are a result of subjecting the sensors to varying, but known, values of pressure, temperature, and humidity in the laboratory. Despite these efforts, it is recognized that quite large errors do occur in radiosonde measurements (particularly of humidity).

Often the radiosonde also provides useful information on upper winds. If the transmitted signal is sufficiently continuous with time to allow regular observations of direction and elevation of the instrument, upper wind speed and direction can be calculated.

Rocket soundings. Above the 30-kilometre (19-mile) level, rockets must be used to take instruments to the middle atmosphere (30–100 kilometres; 19–63 miles). Once there, the actual procedure of measurement of temperature and winds is very similar to that employed with balloon-borne sondes. The temperature element is basically similar to the radiosonde type and is ejected from the rocket at altitudes of about 70 kilometres (43 miles). When used by day, corrections of up to 20° C (36° F) must be made for solar radiation at a height of 65 kilometres (40 miles). To obviate this, many rocket soundings are made at night. Because the air density is so low at these altitudes (65 kilometres), the parachute and sensor fall at 200 metres (660 feet) per second, a speed that may cause dynamic heating of as much as 15° C (27° F). Such errors must, of course, be eliminated by correction procedures. The wind speed and direction are determined from radar observations of the partially metallized parachute. There is no pressure sensor on the sonde: pressures are calculated on the basis of the pressure at the 20-kilometre level. Another method of measuring the wind characteristics is to disperse fine wires from a rocket and track the resultant "cloud" by radar. This can give good wind measurements in the layer at a height of 65–90 kilometres.

Dynamic heating

The very small values of air density at high levels would, at first sight, appear to be of little meteorological importance. In fact, the measurement of density allows the calculation of temperature and pressure profiles and as such allows the useful upward extension of knowledge of the thermal and dynamic structure of the atmosphere. Radar tracking of small spheres falling at supersonic speeds in the 45–100-kilometre layer allows the calculation of drag on their surfaces and from this the density can be determined. A more explicit way of measuring temperature is to eject grenades into the high atmosphere, to record their explosion at vertical intervals of about five kilometres (about 16,400 feet) and to measure the travel time of the shock wave from each explosion to the ground. This travel time depends on mean air temperature and mean wind in the column between the ground and the grenade. The effects of temperature and wind can be separated and mean winds and mean temperatures separately determined.

Satellite observations. The advent of meteorological satellites in the 1950s and 1960s was perhaps the most spectacular development in the history of meteorological measurement. These satellites can provide efficient and economic global observation of different types of radiation emitted by the Earth and atmosphere, and recently strides have been made in the deduction from these radiation measurements of the vertical distribution of temperature and humidity in the atmosphere.

Perhaps the most striking results of satellite observations are the cloud photographs. The first pictures came from TIROS I in 1960, and since 1966 automatic picture transmission has made such pictures available to forecasters soon enough to be of value to a forecast. The quality of pictures has continually increased through to NIMBUS IV, launched April 8, 1970, and these show in great clarity the organization and structure of cloud systems ranging from large cyclonic vortices thousands of kilometres across to individual shower clouds only one kilometre across. Both NIMBUS satellites and Applied Technology Satellites (ATS) provide continuous surveillance of the globe: the former by having a polar orbit and by being Earth oriented and the latter by being geosynchronous (*i.e.*, the orbit is synchronized with the rotation of the Earth). A satisfactory global coverage of cloud pictures could probably be achieved by using a combination of three or four geosynchronous and one or two polar orbiting satellites, with the former relaying pictures received from the orbiting satellites to those points of the Earth not in direct view of the latter.

TIROS I

Both solar and terrestrial radiation amounts are measured by radiometers on satellites. Maps of Earth surface and cloud-top temperatures have been constructed from measurements of long-wave radiation. These measurements have provided useful estimates of the net amount of energy available to the Earth and atmosphere and some indication of the day-to-day changes in the heat balance of the system.

In 1969 a further important step was made in meteorological satellite observation. The Satellite Infra-Red Spectrometer (SIRS) on the NIMBUS III satellite permitted the calculation of the vertical temperature distribution through the atmosphere directly below the spacecraft. The results showed remarkable agreement with radiosonde soundings and already they are being used in the U.S. Weather Bureau's numerical weather analysis and forecasting programs. A later model on NIMBUS IV provided similarly encouraging results.

Aircraft observations. Aircraft observations can provide a valuable supplement to information gathered by conventional methods. An aircraft provides a moving observation platform to obtain information on temperature, humidity, pressure, altitude, wind direction, and speed

and, occasionally, ice accretion, turbulence, visibility, and cloud types, amounts, and heights. Usually aircraft observations are taken for a specific research purpose; *e.g.*, frontal structure and cloud dynamics, but in parts of the world where surface stations are few and far between, they fill a significant gap in operational networks.

MEASUREMENT TECHNIQUES IN MICROMETEOROLOGY AND MESOMETEOROLOGY

All measurements covered earlier are primarily relevant to large-scale atmospheric physical and dynamic processes. Micrometeorology and mesometeorology are concerned with atmospheric behaviour on space scales ranging from millimetres to tens of kilometres.

In micrometeorology interest is focussed on the distribution of temperature, humidity, water vapour pressure, wind speed, and evaporation with height above the ground surface up to a few decametres (under 100 feet). In this way the vertical transfers of heat, water, and momentum from ground to atmosphere and vice versa can be evaluated. The vertical profiles are established by attaching instruments to various levels of a tower and taking frequent, or occasionally continuous, observations. In choosing equipment for any project, it is important to assess what degree of instrument sensitivity is required. Most micrometeorological investigations employ fine temperature-sensing elements connected to suitable sensitive recorders, and with slight modifications they also allow the measurement of humidity. Wind speed may be measured by sensitive, small-cup anemometers or hot-wire anemometers. The latter works on the principle that moving air causes heat loss from a constantly heated wire, and changes in this heat loss are monitored on a gauge suitably calibrated to give the wind speed.

The instruments employed in mesometeorology are basically similar to those used in routine synoptic observations. But because mesoscale atmospheric systems have horizontal dimensions of about 150 kilometres and temporal dimensions of a few hours, most of the instruments are of the recording variety (occasionally of increased sensitivity) and they are deployed in networks of greater density than the routine synoptic grids. The organization of one major mesoscale research project exemplifies these points. In an area of 50 by 65 kilometres (31 by 40 miles) the following instruments were installed: 33 microbarographs, 10 hygrothermographs, 10 wind recorders, 165 rain gauges, and 165 hail gauges. Also, clouds were carefully photographed so they could be analyzed stereoscopically, and as a result of this observational onslaught, valuable new information and insight was provided on convective mesosystems.

High-density networks

WEATHER-STATION NETWORKS AND COMMUNICATIONS SYSTEMS

It is pertinent to consider how the stations employing the instruments described earlier are distributed in space and how frequently observations are made so that a coherent picture of atmospheric behaviour emerges.

Surface observations at synoptic stations are most widely taken every three hours from midnight Greenwich Mean Time (GMT). Nearly 8,000 stations supposedly conforming to this regulation are to be found on land areas and they are supplemented by over 4,000 weather, merchant, and passenger ships. Impressive as these numbers appear, there are huge gaps in the network, and their elimination is one of the major future tasks of meteorology.

Upper air observations by radiosonde are taken every 12 hours, again starting at midnight GMT. The network in the Northern Hemisphere, although not as complete as is desired, is quite impressive: it is in the Southern Hemisphere that knowledge of the free atmosphere suffers badly from a lack of data. The network of rocket-firing stations is the most sparse of all. This is, of course, due to the relatively recent innovation of this observation technique and the expense involved in each ascent. It is possible that further meteorological rocket development may be rendered unnecessary by the increasing capability of satellites.

The networks of radar sets are most dense in the U.S., western Europe, and Japan, partly because such stations are quite expensive to run. Although widely used on a routine basis, particularly in the United States, there are no international regulations for radar observations as there are for all surface and radiosonde measurements. Consequently the data tend to be treated as of an ephemeral nature and are not stored as carefully as more conventional recordings.

Once the conventional surface and upper-air measurements are made they are coded and transmitted to the local (often national) meteorological centre by telephone, radio, or teleprinter. Here they are decoded and analyzed and the resultant forecast in cartographic form is often transmitted back to outstations by facsimile machine. Much data and many satellite photographs are also transmitted internationally.

TRENDS IN METEOROLOGICAL MEASUREMENT

Perhaps the most heartening result of the rapid meteorological technological advance in the 1960s was the realization that observation of the whole atmosphere was possible. The continued development of remote sensing devices (a major trend in itself) will allow many of the large gaps in the observation network to be filled in the early 1970s. Such is the aim of the Global Atmospheric Research Program (GARP)—a massive international effort to increase understanding of the atmosphere.

Global Atmospheric Research Program

Major additions will be made to the radiosonde network —particularly in the tropics and Southern Hemisphere. Substantial increases will also be made in the numbers of commercial ships and aircraft capable of making meteorological observations. At the surface, it is hoped that automatic weather stations (on both land and sea) will consistently provide good quality synoptic data in those areas that at present have too sparse a network.

But it is the development of satellite observation capability that will provide the greatest amount of information. Much effort has been expended on developing the Global Horizontal Sounding Technique—a system whereby satellites track constant-altitude balloons as they are carried around the Southern Hemisphere. The technique is at present under review because of the short life of the balloons. More encouraging are the derivations of wind speeds from cloud movements recorded by geosynchronous satellites and of temperature profiles in the atmosphere below the vehicle. These developments are of paramount importance as they will allow the automatic and frequent observation of the parameters vital to the working of the most recent mathematical models of the atmosphere. Perhaps the time will soon come when a global model of the atmosphere will exist that is constantly being updated by a stream of data from an adequate observation system. When that time arrives a measure of true understanding of the behaviour of the atmosphere will exist.

HOWARD, *The Climate of London*, 3 vol., 2nd ed. (1803). A useful summary of the evolution of meteorology is contained in W.N. SHAW, *Manual of Meteorology*, vol. 1, *Meteorology in History* (1926).

The following books, published by the WORLD METEOROLOGICAL ORGANIZATION, Geneva, contain the international requirements for surface and upper-air observation practice: *International Cloud Atlas* (1956), *Guide to Climatological Practices* (1960), and *Guide to Meteorological Instrument and Observing Practices*, 3rd ed. (1969). More details on instruments are available in the following publications of the METEOROLOGICAL OFFICE, London: *Handbook of Meteorological Instruments* pt. 1, *Instruments for Surface Observations* (1956), and pt. 2, *Instruments for Upper-air Observations* (1961).

Radar usage is well covered in L.J. BATTAN, *Radar Meteorology* (1959); and "Use of Ground-Based Radar in Meteorology (Excluding Upper-Wind Measurements)," *Tech. Note Wld. Met. Org.* no. 78 (1966). High-altitude observations and satellite capabilities are treated in "Meteorological

soundings in the upper atmosphere," *Tech. Note Wld. Met. Org.* no. 60 (1964); E.C. BARRETT, *Viewing Weather from Space* (1967); L.F. HUBERT and P.E. LEHR, *Weather Satellites* (1967); and W.K. WIDGER, *Meteorological Satellites* (1966).

(B.W.A.)

Methodists

Methodist Christianity is a highly institutionalized example of a form of religious life and thought that has appeared from time to time during the history of the Christian Church.

Nature and significance. Methodism is marked by a warm acceptance of the doctrines of historic Christianity, without a stringent insistence on the need for doctrinal conformity or a great interest in theological speculation; by an emphasis on those doctrines that indicate the power of the Holy Spirit to confirm the faith of the believer and transform his personal life; by insistence that the heart of religion lies in personal relationship with God; by simplicity of worship; by the partnership of ordained ministers and laity in the worship and administration of the church; by a concern for the underprivileged and the betterment of social conditions; and (at least in its British form) by the formation of small groups for mutual encouragement and edification. Methodist churches of the two traditions—British and American—present considerable differences. Those in the British Isles and the British Commonwealth stand third in size to the churches of the Anglican Communion and the Roman Catholic Church. They are composed mostly of members of the middle class, though not of its most affluent section. They have affinities both to Anglicanism and to English Nonconformity (of which, nevertheless, they have rarely been an integral part). All are nonepiscopal. Those of the American tradition, spread over all those parts of the world where American influence is strong, are much larger in size than their British counterparts and receive considerable support from the wealthiest elements in society while remaining predominantly middle class. They are episcopally governed but in close relationship with the nonepiscopal representatives of American Protestantism.

For the last three-quarters of a century there have been determined efforts to bring the two traditions together, since they share the same doctrinal emphases, the same sort of connectional system of government (by which all ministers are "in connexion" with the central authority of the church, and the agencies of the church are centrally administered), and the same allegiance to John Wesley.

History. *Origins.* John Wesley, the founder of Methodism, was born in 1703. After ordination in the Church of England, he was elected a Fellow of Lincoln College at Oxford in 1726. In the following year he left Oxford temporarily to act as curate to his father, the rector of Epworth. Back in Oxford, to which his younger brother Charles had now come, he found himself a member and soon the leader of a group of earnest students pledged to frequent attendance at the Sacrament (Holy Communion), serious study of the Bible, and regular visitation of the filthy Oxford prisons. The members of this group received the sobriquet of Methodists and the group itself that of the Holy Club.

In 1735 both John and Charles Wesley set out for Georgia to be pastors to the colonists and missionaries (it was hoped) to the Indians, at the insistence of the founder of the colony, James Edward Oglethorpe. They were unsuccessful in their pastoral work and did no missionary work. The brothers returned to England conscious of their lack of genuine Christian faith. They looked for help from members of the Church of the Brethren, who were staying in England for a while before joining Moravian settlements in the American colonies; among these Peter Böhler was especially important. On May 24, 1738, John Wesley's *Journal* narrates that he "felt" his "heart strangely warmed" and continues, "I felt I did trust in Christ, Christ alone, for salvation; and an assurance was given me that He had taken away *my* sins, even *mine*, and saved *me* from the law of sin and death." Charles Wesley had reported a similar experience a few days previously.

Moravian influences

Some months later, John Wesley was invited by his friend George Whitefield, also an Anglican clergyman who had undergone a "conversion experience," to come to the city of Bristol and help to preach to the colliers of Kingswood Chase, just outside the city, where human conditions were at their lowest. Wesley came and found himself, much against his will, preaching in the open air. This enterprise among the outcasts of society was the beginning of the Methodist Revival. Whitefield and Wesley at first worked together, but later separated on doctrinal grounds: Whitefield believed in double predestination; Wesley regarded this as an erroneous doctrine and insisted that the love of God was universal.

Under the leadership at first of Whitefield and afterwards of Wesley, the movement rapidly gained ground among those who felt themselves neglected by the Church of England. Wesley differed from contemporary Anglicans not in doctrines but in emphases: he claimed to have reinstated the Biblical doctrines that a man may be assured of his salvation and that, by the power of the Holy Spirit, he is capable of attaining "perfect love" for God and his fellows in this life. Wesley's helpers included only a few ordained clergymen and notably his brother Charles, who wrote more than 6,000 hymns to express the message of the Revival and to assist both the public and private meetings of the Methodists. Many lay helpers were recruited.

The Methodists formed a "Society" within the Church of England, and Wesley never wished them to leave that church. But relations with Anglicans were often strained, and in 1784, when there was a shortage of ordained ministers in America after the Revolution, the Bishop of London refused to ordain a Methodist for America. Wesley, acting in an emergency and on biblical principles that allow (as he thought) a presbyter to ordain, consecrated Thomas Coke as superintendent and ordained two others as presbyters. In the same year, by a Deed of Declaration, he appointed a Conference of 100 men to govern the Society of Methodists after his death.

British Methodism from the death of Wesley to the present. The definite break with the Church of England came in 1795, four years after Wesley's death. After this, English Methodism, with vigorous outposts in Ireland, Scotland, and Wales, rapidly developed from a Society into a Church, with its system centred in the annual Conference, which controlled all its affairs. The country was divided into districts and the districts into circuits, or groups of congregations. The ministers were appointed to the circuits, and each circuit was led by a superintendent.

Organization of the Methodist Church

Much power remained in the hands of the local trustees, who sometimes opposed the wishes of the Conference. The sacraments were administered by the ordained ministers, but "local preachers"—laymen—conducted the majority of other services.

This tightly knit system enabled the Wesleyan Methodist Church to grow rapidly throughout the 19th century, at the end of which it counted 450,000 members. The growth was largest in the expanding industrial areas, where Methodism enabled men and women to overcome economic depression by spiritual means: and often, by its encouragement of thrift and simple living, raised their economic status as well.

These developments, combined with the autocratic habits of some leading Methodist ministers, alienated many of the more ardent and democratic spirits, and there was a series of schisms. The Methodist New Connexion broke off in 1797, the Primitive Methodists in 1811, the Bible Christians in 1815, and the United Methodist Free Churches in 1857.

The smaller Methodist groups were in closer contact with the working classes than the Wesleyans and provided the leadership in early trade unionism to an extent disproportionate to their size. The Wesleyans were at first conservative in politics but in the second half of the century identified themselves more and more with the liberalism of the foremost statesman of the century, William Gladstone.

A movement to reunite the Methodist groups began about the turn of the century and reached success in two stages. In 1907 the Methodist New Connexion, the Bible

Christians, and the United Methodist Free Churches joined to form the United Methodist Church; and in 1932 the Wesleyan Methodist Church, the Primitive Methodist Church, and the United Methodist Church came together to form the Methodist Church.

The Methodist Church has shared with the other English churches in the numerical decline that seems to have begun about 1910 and has affected both the lay membership and the ordained ministry. In 1969, 651,139 members and 3,149 ministers were reported. During the same period Methodists have not ceased, however, to exercise influence on national and local life and to plan fresh attempts at evangelism. But the chief development has been in the steady improvement of relations with the Church of England, culminating in a scheme for reunion in two stages. This was accepted in principle by both churches in 1965 and, in a slightly modified form, approved by the Methodist Conference in 1969 and 1971. Its implementation has been prevented by the failure of the governing body of the Church of England to register a sufficiently large vote in its favour.

Methodism in America. Methodism was brought to America by immigrants from Ireland converted by John Wesley. Wesley also sent preachers to strengthen the societies, and by far the most successful of these was Francis Asbury, a blacksmith, who arrived in 1771. He covered vast distances in his preaching journeys and organized the movement on Wesley's concepts, adapting them to the needs both of the settled communities and of the frontier. Wesley damaged the effect of his enterprise by taking the side of the English government at the time of the Revolution, but Asbury restored the situation by aligning himself with the new American republic. Wesley sent the men whom he had ordained as presbyters, with Thomas Coke as superintendent, to help Asbury. The Methodist Episcopal Church was constituted in 1784 and regarded itself as autonomous. Asbury and Coke, to Wesley's great displeasure, allowed themselves to be called bishops.

The next 50 years saw a remarkable advance led by the circuit riders who preached to the frontiersmen in simple terms and went with them to the furthest reaches of the American expansion, while colleges and schools were built in their wake. The advance was halted by the slavery issue, which bitterly divided the Methodists of the North and the South. In 1844 it split the Methodist Church into two churches: the Methodist Episcopal Church and the Methodist Episcopal Church, South (organized in 1845). After the Civil War both churches increased rapidly in numbers and in material resources. They became gradually assimilated to the general pattern of American Protestantism, and, when it was clear that the old issues no longer divided them, they began to move together. Certain antipathies had, however, outlived the issues that caused them, and it was not until 1939 that they came together to form The Methodist Church. The Methodist Protestant Church, a smaller group, joined in the same union. Their educational work, principally in the form of colleges and universities, has been widespread and influential; and their contribution to social service and to the enunciation of the "social gospel" has been considerable.

The church in the South lost its Negro members before and during the Civil War. At the time of the union, the Central Jurisdiction was formed embracing all of the Negro members wherever they lived, alongside the other jurisdictions that were determined by geography. The Central Jurisdiction was abolished in 1968; and black Methodists are now fully integrated in the higher departments of the church's life, though by no means in all the local congregations.

Merger with United Brethren

The Evangelical United Brethren Church, itself a union of the Church of the United Brethren in Christ and the Evangelical Church, was united with the Methodist Church in 1968 to form the United Methodist Church. Its origins lay in the work of German-speaking Protestant ministers who had been attracted to Methodist doctrines and church order in the early 19th century but had not been able to bring their people into the Methodist Church because of a Methodist rule that only the English language could be used in church services. With the disappearance of the language difficulty, the way to union was open, unimpeded by any doctrinal or liturgical difficulties. In 1970 the United Methodist Church had a membership of about 11,000,000.

Methodism in Canada. Most of the early Methodist preachers in Canada came from America, but the War of 1812 led to the coming of preachers from the British Wesleyan Church and the subsequent arrangement by which Upper Canada was subject to the General Conference of the U.S. and Lower Canada to the British Conference. In 1828 the church in Upper Canada became independent and in 1833 was united with the British Conference. The union was dissolved in 1840 and restored in 1847. A further union with the smaller Methodist bodies working in Canada was consummated in 1874, producing the autonomous Methodist Church of Canada.

Discussions with the other nonepiscopal churches with a view to union began in 1908, and in 1925 the United Church of Canada came into existence. Some Presbyterians remained outside, but in recent years the Episcopal Church has begun union talks with the United Church.

Missions and ecumenism. *Methodist world missions.* Thomas Coke initiated the missionary activities of British Methodism by his eloquence and ceaseless travels. The first area in which they took root was the West Indies; then followed Sierra Leone and southern Africa. The Gold Coast, French West Africa, and Nigeria received missionaries not much later, though the climate in many parts of Africa took a heavy toll of missionary lives.

Methodism in India

In India converts were very few until about 1880, when a mass movement swept many thousand low-caste Indians in the south into the Methodist and other churches. In China missionary work had a checkered career, though there were mass movements there also. The last English missionary left China in 1949. In Australia the Methodist Church began in 1815 and, like the Methodist Church in South Africa, became independent before the end of the 19th century. The movement toward autonomy became a flood after World War II; only a few small churches remain under the control of the Methodist Missionary Society. Most of the autonomous churches are negotiating for united churches in their countries; and the Church of South India, including Anglicans, Methodists, Congregationalists, and Presbyterians, has been in existence since 1947.

American Methodists have been equally enthusiastic for missionary activity, and their greater resources have carried them over still larger areas of the earth's surface. North India, Mexico and most of the other countries of Latin America, Cuba, Korea, Japan, Taiwan, and many parts of Africa not reached by the British possess Methodist churches of the American tradition. The movement toward autonomy was somewhat slower in starting in these areas than in the British sphere of influence, but is now well under way; and the General Conference of the United Methodist Church, which is responsible for them all, is formulating elaborate plans for combining fraternal relations among them with their newly found and highly valued independence.

There are minority Methodist churches in most European countries. The one in Italy is of English origin, that in Germany is of mixed English and American origin, though ordered in the American manner; the rest are all derived from American Methodism, though they exhibit many similarities in spirituality to the English type.

Methodism in the ecumenical movement. Methodists from all countries have played a full part in worldwide ecumenical activities, and the Methodist churches have joined in all union negotiations. In America the church responded to the call to discuss reunion contained in the Blake–Pike proposals of 1960, in which the Presbyterian leader Eugene Carson Blake called on the Methodists and other denominations to join the Episcopalians and United Presbyterians in planning a union of churches that was to be "truly Catholic and truly Reformed." The Methodist Church subsequently became involved in the Consultation on Church Union formed to accomplish this goal.

Teaching, practice, and organization. All Methodist churches profess allegiance to the Scriptures and to the

doctrines of the historic creeds and hold themselves to be in the tradition of the Protestant Reformation. They emphasize, though less now than in the past, the teaching about assurance and Christian perfection that is associated with John Wesley. Especially in America, there is a strong tendency to interpret this teaching as an insistence on the personal aspects of religion and as leading to its social application. The worship of both Methodist traditions is partly liturgical, partly spontaneous. In Britain many of the services in the Anglican *Book of Common Prayer*, more or less modified, have remained in use, especially the Order of Holy Communion. The *Book of Offices* (1936) marked a revision of liturgies in accordance with the liberalism then prevalent. Since then the Liturgical Movement has greatly affected all the churches, and all Methodist liturgies are again in processes of drastic revision. The majority of services, however, still follow the old pattern of interlaced hymn, prayer, lessons, and sermon, though experimental worship is on the increase. Wesley adapted *The Book of Common Prayer* for use in America as *The Sunday Service of the Methodists in North America*. This has been frequently revised, and the latest revision, *The Book of Worship for Church and Home* (1966), shows the influence of the Liturgical Movement. There is great freedom in nonliturgical services. Hymns are important in all branches of Methodism, and in Britain those of Charles Wesley are still dominant.

In all the churches of the British tradition the annual Conference is the supreme authority for doctrine, order, and practice. All ministers have parity of status, but special functions are exercised by the president and secretary of the Conference, the chairmen of districts, the secretaries of departments, theological tutors, and superintendents. District affairs are regulated by Synods, Circuits by Quarterly Meetings, local Societies by Leaders' Meetings. The American tradition is episcopal; the bishops are elected by the Jurisdictional Conferences, which, like the General Conference, meet every four years. Each diocese has an annual Conference and is divided into District Conferences, each with its superintendent. The dioceses are combined into five Jurisdictions that cover the nation. The circuit system is not developed as it is in England. Each local church has its Church Local Conference and various Boards. A minister is ordained first deacon, then elder.

In America the African Methodist Episcopal Zion Church and the African Methodist Episcopal Church (each about a million strong) antedate the explosion of the slavery question; the Colored (now "Christian") Methodist Episcopal Church was founded as a result of it. All three are exclusively Negro but follow the doctrine and organization of the United Methodist Church.

Metternich

The Austrian statesman Klemens Fürst von Metternich, the most resolute champion of conservative principles of his time, played a decisive role in bringing about the victorious alliance against Napoleon, took a leading part in the Congress of Vienna, and brought Austria to the front rank among the European powers. The descendant of an old Rhenish noble family, Metternich was born at Coblenz, in the electoral territory of Trier, on May 15, 1773, the son of Franz Georg Karl, Graf von Metternich-Winneburg and Countess Beatrix Kagenegg. His father was then the Austrian envoy to the Rhenish principalities of the empire, and Metternich spent his youth in the Rhine–Moselle region, for which he retained a lifelong affection.

Metternich, black and white chalk drawing by Anton Graff, *c.* 1803-05. In the Kupferstichkabinett, Dresden, East Germany.

Early years and first diplomatic position

In 1788 he entered the University of Strasbourg, where he studied diplomacy; but the spread of the French Revolution prompted him to leave Strasbourg in 1790 and enter the University of Mainz. Before the French revolutionary troops entered Mainz, he went to Brussels in the Austrian Netherlands, where his father was then chief minister. In 1794 he undertook a diplomatic mission to England, where he published a pamphlet calling for a general arming of the German people; but in October he rejoined his father, who had in the meantime fled to Vienna as the French invaded the Netherlands. In Vienna he occupied himself with natural, scientific, and medical studies, in which he always kept a lively interest and which he later did much to encourage.

In September 1795 Metternich married the countess Eleonore Kaunitz, heiress and granddaughter of the former Austrian state chancellor Wenzel Anton, Graf von Kaunitz. This marriage gave him the link with the high nobility of Austria and the access to high office he had long desired. After having represented the Catholic Westphalian counts of the empire at the end of the Congress of Rastatt (1797–99), which ratified compensation for the German princes ousted by the French from their possessions on the left bank of the Rhine, he was in 1801 appointed Austrian minister to the Saxon court at Dresden; and there he formed his friendship with Friedrich von Gentz, the German publicist and diplomat. Serving as Austrian minister in Berlin after 1803, Metternich failed to persuade Frederick William III of Prussia to join Austria in the war of 1805 against France but gained a profound insight into the internal brittleness of the

Prussian state, whose speedy ruin he predicted. While he was in Berlin, he attended lectures by Johann Gottlieb Fichte, the German philosopher, and the poet and critic August Wilhelm von Schlegel.

Ministry during the Napoleonic Wars. In 1806 Metternich served as Austrian minister to France. In contact with Napoleon's sister Caroline Murat and other ladies of Parisian society, he won a reputation for licentiousness; but nevertheless from those ladies and from his relations with the foreign minister Talleyrand and with the Russian envoy, he obtained excellent reports on the state of affairs in France. Although Metternich's successes in the negotiations leading up to the Franco-Austrian Treaty of Fontainebleau were insignificant, he used his time to acquire a deep insight into the emperor Napoleon I's character. Yet he overestimated the impact of the Spanish rising of 1808 on the Napoleonic system, and his optimistic reports did much to induce Austria to undertake the disastrous War of 1809 against France. After the Battle of Wagram, he tried to obtain favourable terms in the peace negotiations but was rebuffed by Napoleon.

Minister for foreign affairs

On October 8, 1809, the emperor Francis (at that time Francis I of Austria but no longer Holy Roman emperor) appointed Metternich minister of foreign affairs. Six days later the oppressive Treaty of Schönbrunn was signed with France. Austria was now in urgent need of a respite, which Metternich obtained by forming the project of a marriage between the archduchess Marie-Louise, a daughter of Francis I, and Napoleon, whose vanity Metternich cleverly exploited. It is not clear how far he expected that this marriage would restrain Napoleon from further campaigns of conquest, but at least he achieved a relationship between France and Austria loose enough to preserve Austria's freedom of action: Austria neither joined the Confederation of the Rhine, a league of German princes under Napoleon's protection, nor became one of the client states of the Napoleonic system. Utterly exhausted and debt ridden, Austria could hardly have resisted any further demands of Napoleon, but it was then no longer the main object of Napoleon's hostility.

As early as 1811, in order to promote Austria's internal development, Metternich wanted the state to be reorganized on federal lines instead of continuing under the centralized system that the emperor Joseph II had imposed. Yet Metternich could never overcome the objections of his strictly absolutist emperor. At the same time the enthusiasm for arming the nation and for a German national rising against Napoleon that he had felt as late as 1809 began to be superseded by a firm dislike for all popular movements. Agreeing with the Emperor on this, he now came to regard these manifestations as a menace to the multinational Habsburg state. He became the strictest exponent of the doctrine of the balance of power in Europe—a doctrine instilled into him originally by Koch, latterly by his diplomat friend Gentz.

When Napoleon launched his invasion of Russia in 1812, Metternich obtained the status of an independent contingent for the Austrian forces under Prince Karl Schwarzenberg that accompanied the French Army. The disaster that befell Napoleon's army came as a surprise to Metternich. On January 30, 1813, Schwarzenberg concluded an indefinite armistice with the Russians. But in view of the inadequacy of Austria's armaments, Metternich could not make up his mind to change over to war on Russia's side against Napoleon. Resisting all ill-considered projects, in particular those of the archduke John (who was put under house arrest for planning a premature anti-French rising in the Alps), Metternich firmly adhered to neutrality while Austria secretly rearmed. He even drew Saxony into the neutral camp for a time. When, later in 1813, Saxony's return to the French side and Napoleon's victory over the Russians and Prussians at Bautzen shook Metternich's will to make war and stiffened Napoleon's attitude, Metternich mediated an armistice between France, Russia, and Prussia. Even so, in the subsequent Treaty of Reichenbach, June 24, 1813, between Austria, Prussia, and Russia, Metternich undertook to bring Austria into the war against France if Napoleon rejected the peace terms that he was offering.

Metternich's middle course

By dominating the negotiations with the French during the summer of 1813, Metternich gained more time for rearming. At this point he was not interested in the annihilation of Napoleon's power, which the emperor Francis likewise, out of consideration for his daughter Marie-Louise, was unwilling to destroy altogether. Metternich also distrusted the Russian emperor Alexander I and feared that after the collapse of France, Europe would be at Russia's mercy. Napoleon's obstinacy frustrated the attempt at a settlement; but when in August Austria finally declared war on France, Metternich, by his superior conduct of negotiations, had won for his country the leadership both in the political and in the military field. In October 1813 the hereditary title of prince was bestowed on him by the Austrian emperor.

In opposition to the plans of the Prussian minister Karl, Freiherr vom Stein, and of the Russian emperor, Metternich promised the South German states of the Confederation of the Rhine that if they went over to the allies they would not forfeit the position they had achieved on Napoleon's side. This promise alone showed that while he was striving for a solution compatible with the interests of all parties, he also wanted to gain the South German states as allies against the Prussian–Russian designs of aggrandizement. After Napoleon's defeat at Waterloo and abdication, Metternich rejected as unrealistic the proposals of Baron Stein and others for the resuscitation of the Holy Roman Empire. The first Treaty of Paris (May 30, 1814) stipulated nothing more for Germany than a loose confederation of states.

Leadership of the Congress of Vienna. The Congress of Vienna (September 1814–June 1815) was the climax of Metternich's work of reconstruction. The very fact that it was held in Vienna was in itself a great success for him. He had precise ideas about the basis for a new order in Europe but knew from the start that he would have to modify them substantially if he was to salvage even a small part of his plans against the opposition of self-interested princes. He wanted to secure Austria's predominance by forming two confederations, one German and the other Italian, with Austria as the leading power in both. Within Germany, he proposed the creation of a hereditary German imperial title, and he thought that Austria and Prussia should share the task of protecting Germany's western frontier. Friendship with Prussia on the one hand and with Bavaria on the other thus seemed to him to be the prerequisite of success. Supported by the British foreign secretary Lord Castlereagh, Metternich sought to prevent the elimination of France, which he saw as a necessary counterweight against Russia. Likewise, he resisted the territorial aggrandizement of Russia and Prussia and objected in particular to Prussia's designs for annexing all of Saxony.

The congress became a splendid social event. By an unbroken chain of festivities Metternich kept the visiting monarchs in a mood that made them disinclined to interfere very persistently in the real work of the statesmen. Facile and not averse to amorous adventures, Metternich brilliantly mastered his dual role of social representation and political leadership.

Partial success of Metternich's policy

Yet Metternich only partly succeeded in his plans: the German imperial project came to nothing because Francis steadfastly refused to support it; the Italian confederation did not materialize; and the German confederation, when it at last did come into being in June 1815, was based only on a brief and noncommittal federal act derived from a Bavarian compromise proposal. In European affairs, however, Metternich was more successful: he achieved equality of status for France; he obtained a reduction of the Prussian demands on Saxony; and, in particular, he blocked the farther reaching demands of Russia. Both Russia and Prussia, in fact, were held in check by the common front of Austria, England, and France that Metternich had created.

Metternich's moderation produced a long-lasting European order. This, however, must be ascribed to his diplomatic capability rather than to his political foresight. Austria's status in the German confederation had been strengthened; but the Emperor's refusal of the German

crown meant that Prussia, with equal status in the confederation, would be able to counterbalance Austria.

Role in the German confederation. Not even within the Austrian Empire was Metternich able to prevail with the idea (already at the root of his plans of 1811) of overcoming the spirit of national revolution by revitalizing the old historical regions and the privileges they enjoyed in preabsolutist times. His attempt to organize the newly acquired Italian provinces according to historical principles was frustrated by the emperor Francis, who, though accepting Metternich's ideas, united two incompatible regions in a completely unhistorical "Lombardo-Venetian kingdom" and so destroyed Metternich's hopes of counteracting pan-Italian nationalism. Moreover, as Metternich had feared, the initially strong pro-Austrian mood turned into its opposite.

The reconstruction of Austria took shape entirely in the spirit of the emperor Joseph II, on centralist and absolutist lines, without regard to national differences and without the establishment of departmental ministries, which Metternich had demanded. After many futile remonstrances Metternich eventually yielded to the obstructionism of the Emperor, who detested innovation and stood jealously on his dignity. The re-establishment of the ancient diets of the estates of Tirol and Galicia complied to some extent with Metternich's idea of resurrecting the provincial diets in order to create a counterweight against the growing forces of liberal and nationalist opinion that was demanding a central parliament. He condemned, however, the repressive measures by which the police minister tried to achieve these aims.

The domestic affairs of Austria created difficulties for Metternich at the Frankfurt am Main Bundestag (federal assembly), which opened in 1816. He had originally intended to use this assembly to oppose revolutionary thought all over Germany. Pointing to the examples of Tirol and Galicia, he attempted in 1817–18 to encourage the German states to introduce constitutions resurrecting the historical provinces and to set up their own diets instead of a central parliament. In summer 1818, however, Bavaria and Baden promulgated constitutions that reflected not Metternich's ideas but those of limited monarchy similar to that outlined by the French charter of June 1814; and in 1819, when revolutionary activity culminated in the murder of the dramatist August von Kotzebue and when the opening sessions of the Bavarian and Baden assemblies proved stormy, Metternich decided to stifle these unmanageable liberal currents.

Failure of Metternich's constitutional ideas

He managed to convince the Prussian chancellor Prince Karl August von Hardenberg that his prescription for provincial diets was right. Then, assured that Prussia would not follow the South German example, he could quietly watch how parliaments created against his advice fulfilled his predictions and discouraged the liberal inclinations of German princes. Consequently, at the ministerial conferences of Carlsbad and Vienna in 1819–20, Metternich, to the surprise of the South German states, did not attempt to undo the new constitutions but simply curtailed the activity of the federal assembly, which had become an inconvenience to him. Reorienting his German policy, he began to rely not on the assembly but on the common interest of the princes whom he led to share his point of view by personal contact. Henceforth it was no longer the privileges of Austria as granted by the federal act, but Metternich's personality that guaranteed Austria's predominance in the German confederation.

Years of decline. Metternich had hoped that a system of congresses, at which the great powers would concert their actions, would maintain order and peace in Europe. At the congresses of Aix-la-Chapelle (1818), of Troppau (1820), of Laibach (1821), and of Verona (1822) his international reputation was at its zenith, but the disruption of the forum of great powers became evident when Great Britain abandoned the policy of intervention against revolutions in other countries: Viscount Castlereagh prepared the way for this change at Troppau, and George Canning, his successor as British foreign secretary, brought Metternich's influence on western Europe to an end by insisting on the right of national self-determination for the South American colonists in revolt against Spain and for the Greek insurgents against Turkey. With Alexander I's death (1825) it seemed likely that Metternich's influence on Russia would likewise come to an end; and Prussia's jealousy of Austria's dominance was causing further difficulties, when in 1830 the July Revolution in France, followed by insurrections in Belgium, in Poland, and in Germany, appeared to justify again Metternich's dismal prognoses and served to convince the three eastern powers, Austria, Prussia, and Russia, that they should stand together by his principles.

Effect of Britain's new policy of non-intervention

Metternich had been appointed Austrian state chancellor on May 25, 1821, but his influence in Austria was decisively restricted by the appointment of Franz Anton, Graf von Kolowrat, as minister of state and head of the cabinet conferences (1826). Kolowrat opposed an orderly governmental organization and won great ascendancy over the emperor Francis. Metternich, as his influence dwindled, yielded to an increasingly irritating vanity and to a passion for theorizing that caused his utterances to become increasingly prolix and, at times, to verge on the ridiculous. For the sake of legitimacy and despite general apprehensions, he gave Francis the disastrous advice to recognize his feebleminded eldest son, the archduke Ferdinand, as heir to the throne. In 1835, therefore, when Ferdinand succeeded his father, Metternich, at first together with the archduke Louis (Ludwig), took the chair at the "conference" or council of state that assumed the functions of a regency. In 1836 it seemed as if he would at last be able to carry out his idea of well-ordered government, but at the decisive moment Kolowrat managed to convert the archdukes John and Louis to his own theories. Thenceforth Metternich's authority was confined to external affairs. His vanity tempted him to disguise the waning of his influence by accepting responsibility for decrees that neither came from him nor accorded with his views. He thus became a hated symbol of repression and reaction and, eventually, on March 13, 1848, had to resign, as the first victim of the revolution. He made his way with difficulty into exile in England but returned to Vienna in 1851. Having taken no further direct part in politics, Metternich died in Vienna on June 11, 1859.

The marriages of Metternich

After his first wife's death in 1825, Metternich had married Baroness Antoinette Leykam in 1827. After her death in 1829, he had married Countess Melanie Zichy-Ferraris in 1831, who died in 1854. His son by his second marriage, Richard, Fürst von Metternich, was Austrian ambassador in Paris from 1859 to 1870 and one of the foremost diplomats of his time.

Assessment. Metternich's personality has long been the subject of dispute. His great merits cannot be denied. On the other hand, his failure to overhaul the government and administration of the Habsburg monarchy remained an omission that could never be compensated. He always went the way of least resistance and so allowed others to turn Austria into a prison in which free speech was impossible and any denunciation was enough to cut short a promising career. Although on several occasions he put before the Emperor projects that show his insight into the growing difficulties, he never drew the least consequence from the Emperor's rejection of his plans. Even in the regency council he was content to play the part of the philosopher. The complaisance associated with his predominantly diplomatic talents prevented him from playing the part of the great Austrian statesman.

The rapid decline of Austria's institutions from 1826 sapped Metternich's international standing, but his vanity would not let him see how hollow the foundations of his prestige and of his system had become. He considered himself the "father confessor of cabinets" and the "physician of sick governments in the entire world." The "Metternich system," which he himself so often cited and about which so much has been written, postulated the existence of eternally valid maxims of supreme wisdom in statesmanship, the most important of them being the European balance of power, sole guarantee of international peace. For Metternich, the old cultural and political order of Europe was a living organism that he wanted to preserve

against the destructive forces of revolution. His convictions were strengthened by the ease with which his statecraft could circumvent the liberals of the time, whose exaggerated manner of expressing themselves often had an air of dilettantism and whose political immaturity seemed to him to threaten the delicate mechanism of the balance of power. He therefore founded his system on restraint of all those imponderable forces that could not be reconciled with the old-established art of statesmanship: imponderables such as the coming-of-age of peoples, the awakening of nations, and the emergence of social problems.

The struggle against the spirit of the time and against the political aspirations of the bourgeoisie was for Metternich also a struggle against a rising tide of political dilettantism. He hoped that economic affluence would keep the bourgeoisie away from politics, and the return to preabsolutist conditions seemed to him the necessary basis for antirevolutionary action. Liberalism and the revolutionary spirit he merely regarded as a not entirely unjustified reaction against the absolutist anarchy for which the emperor Francis stood and which he, Metternich, condemned. In this absolutist anarchy he saw the root of all evil. It was his tragedy and also his fault that he never built a foundation on which his system could really develop and prove its worth. After the Revolution of 1848 Metternich asserted again and again that his influence on Austria's domestic policy had been insignificant. Although his statement is probably true, it cannot be conclusively confirmed; the records of the Austrian Council of State were lost in a fire in 1927.

Assessment

From the time of Joseph II there had been a discrepancy between the specific concerns of Austria and the old universalist tradition of the Holy Roman Empire; and the same discrepancy was evident between Austria's internal policy and Metternich's foreign policy, which was devised to assume responsibility for all of Europe. Whereas Francis and his entourage thought along narrow Austrian lines, Metternich stood entirely in the tradition of the universal monarchy—not so much from devotion to the past glory of the emperors as from the conviction that the revolutionary spirit was an international disease that could be fought successfully only by disregarding national frontiers. For ten years after Napoleon's downfall Metternich, by sheer force of personality, made the world think of Austria as a real power: his failure came when the feet of clay could no longer be hidden. For Germany, the fatal effect of his influence was loss of contact with the liberal and progressive West. In recent years, research on Metternich has mainly been pursued by United States historians, some of whom still consider Metternich an unmitigated reactionary. Whether he was or not can only be established with certainty by examination of the entire body of relevant documents in Vienna, in particular of Metternich's instructions to the Austrian ambassadors, in which he often freely expressed his thoughts.

BIBLIOGRAPHY. The standard biography is H. VON SRBIK, *Metternich der Staatsmann und der Mensch*, 3 vol. (1925–54); an opposing and unfavourable view of Metternich is given in V. BIBL, *Metternich, der Daemon Oesterreichs* (1936). The works by E.L. WOODWARD, *Three Studies in European Conservatism: Metternich, Guizot, the Catholic Church in the Nineteenth Century* (1929); A. MAY, *The Age of Metternich, 1814–1848* (1933); A. CECIL, *Metternich, 1773–1859* (1933); and E. LAUBER, *Metternichs Kampf um die europaeische Mitte: Struktur seiner Politik von 1809 bis 1815* (1939), have pursued lines of inquiry opened up by Srbik. More recent studies have offered various other views of Metternich. Among them are E.E. KRAEHE, *Metternich's German Policy*, vol. 1, *The Contest with Napoleon, 1799–1814* (1963); and G. DE BERTIER DE SAUVIGNY, *Metternich et la France après le Congrès de Vienne*, vol. 1, *De Napoléon à Decazes 1815–1820* (1968), vol. 2, *Les Grands Congrès—1820–1824* (1970). The dominant position of Metternich in Europe is treated in R.A. KANN, "Metternich: A Reappraisal of His Impact on International Relations," *Journal of Modern History*, 32:333–339 (1960); P.W. SCHROEDER, *Metternich's Diplomacy at Its Zenith, 1820–1823* (1962); H.F. SCHWARZ (ed.), *Metternich, the Coachman of Europe* (1962); D.E. EMERSON, *Metternich and the Political Police: Security and Subversion in the Habsburg Monarchy (1815–1830)* (1968); and A.G. HAAS, *Metternich, Reorganization and Nationality, 1813–1818* (1963), which describes a fundamental aspect of Metternich's plans for internal reform in Austria.

(K.O.v.A.)

Mexico

Mexico is a federal republic in North America. Officially known as the United Mexican States (in Spanish, Estados Unidos Mexicanos), it covers a total area of 761,600 square miles (1,972,544 square kilometres). It is bordered by the United States to the north, the Gulf of Mexico and the Caribbean Sea to the east, British Honduras and Guatemala to the southeast, and the Pacific Ocean to the south and west. Mexico in 1971 had a population of more than 50,000,000; its rate of population growth—about 3.5 percent a year—is one of the highest in the world.

This "land of great solitudes and the baroque," as it has been called, is geographically positioned in the Earth's great desert region. No major river crosses it, and water is scarce throughout most of its territory. Areas of benign, temperate climate are determined by altitude rather than latitude. One such area is the Mexican Plateau, the country's most densely populated region. Mexico City, the capital, with a population of about 8,600,000 (1970) is located here, in clear view of the peaks of Popocatépetl, rising 17,883 feet (5,452 metres), and Ixtaccihuatl, 17,338 feet (5,286 metres); it is the only megalopolis in the world without either direct access to the sea or an important river passing through it.

Cultural unification

Historians and sociologists are presently agreed that transculturation (the transmission of cultural characteristics from one cultural group to another) between the mestizos (of mixed Indian and European blood) and the criollos (Europeans born in America) has reached noteworthy proportions. The statement that "even though there may not be Indian blood in one's veins it is always present in one's spirit" is also true in the opposite direction, in that the Indian cannot escape absorbing European culture.

Cultural unification of the population has been aided by the existence of excellent air and land transport networks, connecting the 29 states, two territories, and the Federal District (Mexico City), which together make up the Mexican federal republic. Throughout the past four decades uninterrupted peace has permitted marked economic growth—calculated in 1970 to be occurring at a rate of 7.7 percent. Even though foreign investment is continuously growing, it has not dampened domestic saving, which has also greatly increased; a growing degree of industrialization is consequently taking place. This last factor, together with continuing governmental concern since the 1920s for the improvement of education, as well as a constant decrease in the degree of interference in national affairs by the church and the military since that time, have permitted consolidation of social and political stability (see MEXICO CITY; for associated physical features, see CARIBBEAN SEA; MEXICO, GULF OF; and RIO GRANDE; for historical aspects, see MEXICO, HISTORY OF).

THE LANDSCAPE

Mexico is a country of extraordinary physical variety. In many ways it is a bridge between the natural phenomena of the broad North American continent, characterized by vast ranges and plains and by climatic extremes, and the tropical features of Central America and the Caribbean region.

Mexico is widest in the north, where the frontier—running roughly northwest to southeast, from the Pacific to the Gulf of Mexico—covers a distance of about 1,300 miles. To the south, the width of the country diminishes until the Isthmus of Tehuantepec is reached; the isthmus is a neck of land about 140 miles wide, running from west to east and separating the Pacific to the south from the Gulf of Mexico to the north. To the east, the isthmus broadens toward the Guatemalan and British Honduran borders: Mexico's eastern extremity consists of the Yucatán Peninsula, which projects northeastward; it is about 200 miles wide and has a coastline 700 miles in length. One of the most striking features of Mexico is the Baja

California Peninsula. From Mexico's northwestern extremity, this long fringe of land, from 25 to 150 miles wide, runs parallel to the Pacific coast in a southeasterly direction for about 760 miles. It is separated from the mainland proper by the Gulf of California, a long arm of the sea.

About 300 miles to the south of the Baja California Peninsula and about 450 miles west of the coastal port of Manzanillo lie the Islas de Revillagigedo—a group of volcanic islands.

Relief features. With the exception of the Yucatán Peninsula and the eastern and northwestern coastal plains, which represent no more than 14 percent of its total area, Mexico is a country of broken relief composed of mountain ranges, tablelands or plateaus with bolsons (depressions or valleys having no outlet), and short depressions, canyons, and innumerable valleys. The average altitude exceeds about 3,300 feet, but almost 71 percent of the total area lies at about 1,600 feet above sea level.

Mountain ranges and plateaus. The Sierra Madre Occidental (Western Sierra Madre) and the Sierra Madre Oriental (Eastern Sierra Madre) extend along Mexico's coasts from north to south. In the isolated area between them lie two vast tablelands—the Mesa del Norte (Northern Plateau) and the Altiplanicie Mexicana (Mexican Plateau). These have enclosed basins in Chihuahua and Coahuila, north of the inland towns of Zacatecas and San Luis Potosí, followed to the south by wide valleys such as the Bajío de Guanajuato (Guanahuato Shoal) and the Michoacán.

The Sierra Volcánica Transversal

The Sierra Volcánica Transversal (Transversal Volcanic Mountain Range) is a range of volcanic mountains that extends from central Nayarit state in the west to central Veracruz state in the east. The nation's highest peaks belong to this range—Orizaba, rising to 18,700 feet (5,700 metres), and Popocatépetl, which reaches 17,883 feet (5,452 metres). Its numerous volcanoes enclose a belt of valleys, bolsons, plateaus, and lakes. On its southern slope the Neo-Volcánica Cordillera (New Volcanic Range) plunges abruptly in the direction of the valley of the great Río Balsas, traversing the states of Michoacán, Guerrero, and Morelos. Between the Río Balsas Valley and the Pacific Ocean, the Sierra Madre del Sur Range extends along the southern coast to the Isthmus of Tehuantepec, where it joins the complex mountain range of the Sierra Soconusco and the Chiapas Highlands.

The characteristics of north central Mexico are repeated in Chiapas: a central depression and plateau bounded by mountain ranges on either coast, which descend to the alluvial coastal plains.

The coastal plains. The coastal plain along the Gulf of Mexico is bounded inland by the Sierra Madre Oriental, the Sierra Madre del Sur, and the Chiapas Highlands. It is almost featureless along the Gulf but rises westward to foothills that are usually below 650 feet in elevation. Wide beaches, sandbars, swamps, and lagoons are common. There are no good natural harbours, although the Laguna Tamiahua shelters coastal craft.

The western coastal plain lies between the Sierra Madre Occidental and the Gulf of California and the Pacific Ocean. It is widest in the north, where its broad basins are separated by low hills and mountains. Here the coast is broken by numerous bays and lagoons. The southern portion of the Pacific coast is bordered inland by the Sierra Madre del Sur. It forms a narrow alluvial apron and contains good natural harbours such as those of Acapulco and Manzanillo.

The Yucatán Peninsula. The coastal lowlands attain their maximum width of about 275 miles in the limestone platform of the Yucatán Peninsula. The terrain is generally flat to rolling, and attains the greatest elevation in its centre. There is little surface drainage because precipitation penetrates the porous and soluble limestone. Subterranean erosion has produced caverns and sinkholes; the latter are formed when cavern roofs collapse.

The western and northern coasts of the peninsula are marked by lagoons and sandbars, but coral reefs dot the eastern coast. The islands of Cozumel and Mujeres lie off the peninsula's northeastern tip.

Drainage. Mexico has few important rivers. The humid northeast trade winds, as well as tropical hurricanes, blow onto the exterior slopes of the Sierra Madre ranges, causing great increases in the volume of the mountain rivers, which almost invariably flow through deep canyons into either the Pacific Ocean or the Gulf of Mexico.

The river systems

The central plateau region and the desert-like Baja California area suffer from a lack of large streams. The northern bolsons impede the development of a naturally flowing river network, and the scanty lakes of the plateau's interior watershed are subject to intense evaporation. The Río Conchos, the most important of the plateau's rivers, flows northward into the Rio Grande (*q.v.*; known to Mexicans as the Río Bravo del Norte), which forms part of the frontier between Mexico and the United States and empties into the Gulf of Mexico.

In the Salado area of northwest Mexico, the Chiapas Highlands, and the Sierra Madre Oriental, much moisture drains into the subsoil as a result of the terrain's limestone quality. This also occurs in the northern and central regions of the Yucatán Peninsula, a tropical land lacking fixed rivers.

On the Isthmus of Tehuantepec, however, the Grijalva-Usamacinta and the Papaloapan river systems account for almost 40 percent of the total volume of Mexico's rivers, flowing across the alluvial plain of the Gulf, where flood and swamp conditions prevail because of inefficient drainage. Another 15 percent crosses the valleys of the southern region, and 8 percent flows in the northwestern streams that irrigate the lower valleys of the Río Colorado. The major southern river, the Río Balsas, rises in Puebla state and flows in a generally westward direction across Guerrero state and between Guerrero and Michoacán states to its mouth on the Pacific.

Soils. Lateritic soils (soils with a high content of iron oxides and aluminum hydroxide) are found on the Yucatán Peninsula and on the Pacific coastal strip south of Cabo Corrientes. Yellow and red subtropical forest soils occur on the Gulf coast and on the west coast to the north of Cabo Corrientes. In the central plateau region, the soils gradually change in a northward direction from humid prairie soils to brown soils characteristic of the steppe (extensive and usually treeless plains), and to the gray and brown desert soils of the northwest.

The climate. *General climatic factors.* The Tropic of Cancer cuts Mexico almost in half. This factor permits polar air fronts to invade the north, east, and central regions, a phenomenon responsible for the great drops in temperature and increased rainfall associated with the *nortes,* or northern gales, that occur during the winter season. The northern regions belong to the desert belt of the hemisphere, and their climate is characterized by western anticyclones (systems of winds that rotate about a centre of high atmospheric pressure). Since, however, the country is practically surrounded by the waters of the Pacific, the Gulf of Mexico, and the Caribbean, most of the surface is subject to humid trade winds from the east between May and August and to tropical hurricanes originating in both oceans which may occur from August to October. These winds from the east, southeast, and south follow varied patterns but often cross the high Sierra Madre and deposit most of their moisture on the seaward mountain slopes. The extensive interior plateaus and lowlands thus receive minimal rainfall throughout the year.

Regional variations. Half of Mexico experiences a predominantly arid climate and receives less than 24 inches of precipitation annually. Continental climatic characteristics, such as hot springs and summers and relatively severe winters, are also in evidence. These characteristics are evident in such regions as the Mesa del Norte and Baja California. The degree of drought diminishes in the Mexican Plateau, but aridity is also apparent in the tropical coastal areas of the Balsas Lowlands, the Grijalva Uplands, and North Yucatán.

Except in Baja California, up to 75 percent of the rainfall occurs during the summer and early autumn, usually in the form of storms. The heaviest precipitation is registered on the southern seaward slope of the Sierra Madre

Oriental in north Oaxaca and Chiapas, in the Tuxtlas Massif, and in the Sierra de Soconusco near the Honduran border in the southwest, where the annual rainfall exceeds 100 inches and occasionally reaches 180 inches. The lowest precipitation—two to four inches—falls in the Baja California Peninsula.

Temperature patterns

Average high and low annual temperatures vary considerably between the coastal regions, the valleys at medium altitudes, and the plateaus. In Manzanillo, a port located on the hot, tropical Pacific Coast, the mean temperature is approximately 79° F (26° C), with annual variation fluctuating between 73° and 84° F (23° and 29° C). Tepic, at an altitude of 3,000 feet, has an average of 68° F (20° C) with a greater variation—from 57° to 82° F (14° to 28° C). In the northern continental climate of Chihuahua at 4,700 feet there is a strong contrast between mean temperatures of the months of June (79° F [26° C]) and of January (50° F [10° C]). The difference is less in the high Mexican Basin, at 7,500 feet, where the low reaches 52° F (11° C), the high 73° F (23° C), and the yearly average is 61° F (16° C). The low extremes reach several degrees below freezing in regions of continental climate, with frosts occurring in the plateau area, the arid northwest, and the high Sierra Madres.

Plant and animal life. In the arid northern, northwestern, and central regions, plants structurally adapted to a limited water supply predominate. These include cactus, agave, cassava, mesquite or scrub, and brush plants. In the south and east, in Yucatán, and on the western coasts, tropical vegetation such as dense deciduous or rain forests, savanna (grassy parkland) vegetation, grazing-land vegetation, and spiny plants are evident. The central mountains and the Sierra Madres, at altitudes of between 5,000 and 13,000 feet, support predominantly coniferous and mixed forests in which the holm, or German oak, is widespread. The mountain slopes contain regions of complex transition between different vegetation types; above the pine zones, cold pasture lands appear on the slopes of the large volcanoes. On the coasts, large mangrove swamps are common.

Cactus species are especially varied, particularly on the southern plateau and in Baja California. Great variety also characterizes the tropical forests, which contain valuable hardwoods, epiphytes (plants that derive their moisture and nutrients from the air and rain), and palms. From the southeast of Veracruz to the south of Yucatán, the plant life is unusually rich and varied.

Animal life includes examples from both the North and South American regions; the approximate dividing line between the two regions passes, at medium altitudes, along the seaward slopes of both the Sierra Volcánica Transversal, and the Sierra Madres. Species, however, are mixed in the Balsa Depression, the southern part of the Central Plateau, and in mountain areas.

Birds, reptiles, insects, and a variety of mammals—including rodents, monkeys, armadillos, tapirs, anteaters, pumas, and wolves—are plentiful. The nation's waters, especially the Gulf of California and the Pacific northwest, contain a wealth of fish and crustaceans.

Traditional regions. Various geographic, ethnic, and historic influences, together with a limited economic development, have resulted in the existence of a vast number of small natural, historic, and economic regions. Similarity of conditions permits the grouping of many of these small regions into larger ones. The "traditional" regions, which are enthroned in popular folklore, do not, however, possess clearly defined borders.

Baja California. A desert climate prevails, except in the high, temperate areas of the major mountain ranges of Sierra de Juárez and Sierra San Pedro Mártir and in the subtropical area of the far south. While the area, therefore, is not forested, those parts of it bordering the Pacific Ocean and the Gulf of California, as well as those parts watered by the Lower Colorado River or subterranean rivers, are rich in vegetation. Because the region borders the United States, it has a completely mixed population. The people are concentrated in oases; in agriculturally developed and irrigated areas, such as the Mexicali Valley and Santo Domingo; in the border belt with its tourism and trade centres, such as Tijuana and Ensenada; or in the numerous fishing ports along the coasts.

The northern regions. The northwest is an extensive area, stretching between the Sierra Madre Occidental to the east and the Gulf of California to the west and between the Desierto de Altar in the north and the tropical plain of Nayarit state in the south. High population densities occur in the highly productive irrigated valleys and in prosperous commercial and industrial border areas, such as Nogales–Cananea. Small Indian farming communities are located in the Yaquí, Mayo, and Fuerte valleys.

The nation's largest region, the north, is cut off from both coasts by the Sierra Madre ranges; it extends from the United States south through Zacatecas and northern San Luis Potosí states. It is an arid area, broken by bolsons and mountains. The plateau regions are virtually uninhabited, and population is concentrated in such irrigated areas as La Laguna, Delicias, and Juárez Valley; in the numerous mining areas from Parral and Durango to Nueva Rosita; and especially in such industrial cities as Monterrey.

The northeast is located between the Sierra Madre Oriental and the Gulf of Mexico and stretches from the United States border to Tampico. Population concentrations occur in valley regions; the agricultural, commercial, and oil-producing area of Bajo Bravo; the plantation areas of Montemorelos-Victoria; and the southern subtropical regions containing the industrial cities of Mante and Tampico. As in the north, the region is primarily inhabited by mestizos and criollos.

The western and central regions. In the western and central regions, where less arid conditions prevail and where black soil is often found at higher altitudes, there is a high rural population density in areas such as the Bajío, the Tarasca Plateau, central Jalisco state, and the southern part of the San Luis-Aguascalientes area. The rural landscape is being transformed, however, by the accelerated growth of such cities as Guadalajara, Léon, Salamanca, and Querétaro. Many rural migrants have been attracted to the volcanic regions of the high central valleys, where industry is located in or near Mexico City, Puebla, Toluca, and Sahagún. Although racial mixing has been intense, rural pockets of Indian groups may still be found in Michoacán, Mezquital, Puebla, and Toluca. As a result, there are great contrasts between the life-style of the rural inhabitants of the valleys and mountains and that of the urban populations.

The southern regions. The south is an extremely mountainous region that stretches along the Pacific Ocean from Jalisco state to the Isthmus of Tehuantepec and also extends inland to Puebla state. Arid tropical conditions predominate in the narrow valleys of Guerrero and southern Puebla states, while more humid conditions are found in the Sierra Madre del Sur (southern Sierra Madre), and in the state of Oaxaca. A land of both *minifundios* (small—often very small—farms) and commercial plantations, the south is primarily inhabited by Indians. There are only a few important cities, among which are the communications and tourist centre of Acapulco and the commercial centre of Oaxaca.

The Isthmus of Tehuantepec

The narrow Isthmus of Tehuantepec presents two different physical regions. Veracruz state, to the north, has a damp tropical climate and is populated mainly by mestizos. The state of Oaxaca has a semi-arid climate and an undeveloped agricultural economy and is marked by the cultural influence of the Zapotec Indians. It is sparsely populated; some communities, such as those in the Coatzacoalcos Mountains, are virtually isolated.

The Huastecas region covers territory in the states of San Luis Potosí, Veracruz, Puebla, Hildalgo, and Querétaro. It is composed both of the complicated mountain systems of the Sierra Madre Oriental and the flat coastal lands of Veracruz state. Its population is composed of Indians in remote areas and mestizos in developed areas, such as Valles, Tuxpan, Pánuco, and the oil fields of Naranjos-Pozo Rica and Ebano.

The east, or Gulf region, stretches along the Gulf of

Mexico coastal plain and extends inland to the foothills of the Sierra Madre Oriental. It is mainly composed of plains, hills, and the exterior slope of the Veracruz, Tabasco, and northern Oaxacan and Pueblan ranges, which have rainy tropical climates and dense forests or savannas of great potential wealth. Mestizos and small groups of Indians live in the rich alluvial valleys of the Papaloapan and the Grijalva-Usamacinta river systems, on the plantation lands of medium altitudes in Veracruz and Puebla states, and in the oil-field and manufacturing districts of Minatitlán, Coatzacoalcos, Ciudad Pemex, Orizaba-Córdoba, and Veracruz.

Except for its northern section, Chiapas state is relatively isolated from the rest of the country. Its physical regions include the tropical coastal area on the Pacific Ocean, the central Grijalva Depression, the almost uninhabited Lacandonia jungles, and the temperate and cold regions of the Sierra Madre ranges and the Mexican Plateau. In the Chiapas Highlands, around San Cristobál de Las Casas, there is a large concentration of Indians—the Tzeltales and Tzotziles—who are engaged in animal husbandry.

The southeast, which consists entirely of the Yucatán Peninsula, is a region containing the tropical forests of the territory of Quintana Roo and Campeche state in the south and communal farms (*ejidos*) and agave plantations in the north. Mérida, where agave is processed to yield the henequin fibre, is located in the northwest. The region is populated by Mayan peasants, the descendants of a people who, centuries ago, created a great civilization.

The landscape under human settlement. Mexico continues to be a predominantly agricultural nation, which at the same time is experiencing a rapid, and almost totally disproportionate, growth in its cities. The urbanization process, which began in about 1940, has changed the complexion of the country, although in 1970 about 50 percent of the population continued to live in localities of fewer than 10,000 inhabitants.

The origins of rural settlement

Rural life. Because the Spanish colonial economy was based primarily on mining and only secondarily on agriculture, western and central Mexico became the most densely populated regions. In the more arid areas, settlement took the form of missions, mining posts, and small towns. The Indians were divested of their lands in the valleys and were relegated to the mountains or the forests, where they settled in small poverty-ridden villages. During the presidency of Porfirio Díaz from 1877 to 1911, large haciendas, or ranches, based on the production of grain, were established in central Mexico, while cattle ranches were established in the north. The peons, or peasants, settled in the vicinity of the haciendas. After 1910, important changes were effected in regional population patterns. The haciendas were divided; large areas were irrigated in La Laguna, Bajo Bravo, and in the northwest, creating high rural population densities on what had previously been almost uninhabited plains.

The rural population is also dense in the oil-producing regions of the east, on the tropical plantations of Yucatán and other coastal areas, and in the traditionally Indian areas of the southern valleys. In general, rural communities are widely scattered. There are more than 90,000 settlements, the majority of which are ranches or hamlets with less than 500 inhabitants.

In irrigated regions where agriculture is mechanized and where productivity is high, rural life offers opportunities for the improvement of the peasants' standard of living. In contrast to this, in the areas of traditional peasant agriculture—the rainy areas of central Mexico and the western mountains, the tropical southern regions, and Yucatán—the dietary and housing conditions of the peasants, especially of the Indians, reflect their poverty, isolation, and abandonment.

Urban regions. The urban population is concentrated in the central regions, which extend across the country between the 19th and 22nd parallels north latitude. Large industrial and commercial centres have also developed in the north (Monterrey, Chihuahua, and Torreón), in the strip along the United States frontier (Tijuana, Juárez, and Nuevo Laredo), and in the irrigated valleys of the northwest (Hermosillo), where commercial agriculture is practiced. The oil centres of Tampico, Poza Rica, Minatitlán, and Coatzacoalcos; the large Yucatán metropolis of Mérida; and the tourist and commercial centre of Acapulco have developed independently. Since the 1950s, the great urban agglomerations of Mexico City, Guadalajara, Monterrey, León, and Puebla have accelerated their growth, as have other cities located in the central and lowland regions, in the northeast, and in Veracruz state.

Many cities in the northwest and in the border zone—among them Mexicali, Nogales, Obregón, Juárez, Piedras Negras, Tijuana, and Los Mochis—have developed since the 1950s and are new in appearance. This is also true of certain industrial centres, such as Sahagún, Poza Rica, Coatzacoalcos, Reinosa, and Monclova, whose growth has been stimulated by heavy government investment.

In contrast to the new cities, the colonial towns and cities contrive to preserve their original central plaza, from which radiates a network of streets. In the early 1970s these older towns and cities experienced enormous difficulties in expanding. Many of them, such as Guanajuato, Zacatecas, Pachuca, and Taxco, are old mining cities in a state of decay, which have retained only their cultural, commercial, or administrative importance.

The large cities

By 1970 the greater Mexico City area contained 18 percent of the total national population. It was the largest industrial centre, producing about 45 percent of the total value of gross national production in 1965 and was also the largest consumption centre in the country. An enormous, cosmopolitan city, Mexico City is the true economic, political, and cultural heart of the republic. Guadalajara in the west, with its 1,500,000 inhabitants, is a flourishing state capital experiencing rapid industrialization. Monterrey (population 1,200,000) is a steel centre and the financial capital of the north.

In the large cities, skyscrapers and deluxe housing developments are found beside poor and sordid slums. Rapid expansion and industrial concentration have caused serious problems of water and power supply, as well as traffic, housing, and cost-of-living problems; there is, moreover, a diminishing amount of "green space" for gardens and parks. There is also a problem of pollution, increased in Mexico City by the lack of rivers and by the partial or total drying up of old lakes, such as Texcoco, Zumpango, Xaltocan, Chalco, and Xochimilco.

PEOPLE AND POPULATION

Groups historically associated with contemporary Mexico. Spanish is the official national language and is spoken either as a first or second language by almost the entire population. Mexican Spanish is greatly influenced by the country's indigenous languages, which are spoken by about 8 percent of the population. About 1,000,000 people speak only their indigenous tongues. The highest concentrations of Indian language speakers are found in the states of Oaxaca, Puebla, Yucatán, Veracruz, Chiapas, México, Hidalgo, and Guerrero. The main Indian language families are Uto-Aztecan, Mayan, Hokaltecan, and Oto-Manguean.

Mestizos compose about 55 percent of the population. About 29 percent of the population is Indian and 15 percent is of European ancestry; of the latter, two-thirds are native-born and the remainder are aliens from Spain, the United States, China, France, and Guatemala.

About 96 percent of the population is Roman Catholic.

The constitution of 1917 established the separation of church and state, and the church lands are controlled by the government. The Protestant population numbers about 879,000 and there are about 49,000 Jews.

Demography. *Fertility and mortality rates.* Throughout the 20th century, Mexico's fertility rate has been one of the highest in the world. It has maintained itself at a constant level—approximately 45 births per 1,000 population. Yet fairly important changes in fertility rates among women of different age groups have occurred. The fertility rate of young women has dropped, whereas that for women over 35 has increased. The fertility of women living in urban centres is less than that of women who live in rural areas. There are, however, no indications of a decrease in the general fertility rates in the cities, despite the fact that the rate is decreasing among young women.

The rate of growth has produced a rejuvenation of the population. The proportion of persons under 14 rose from 41 percent in 1930 to 46 percent in 1970; this was the result of the maintenance of high fertility rates and of a greater decrease in the mortality rates of infants and young people than in those for adults and the aged.

The mortality rate

There has been a notable decrease in the mortality rate since the 1930s. From a gross mortality rate of 27 deaths per 1,000 population in 1930, the rate dropped to 9.9 per 1,000 in 1970. Average life expectancy correspondingly rose from approximately 37 years in 1930 to 61 years for men and 64 years for women in 1965–70. The drop in the mortality rate was due partly to better economic and social conditions in general but especially to advances in medicine.

Infant mortality declined about 69 percent between 1930 and 1965. Deaths resulting from infectious and parasitic diseases have been reduced, although these causes of death are still the most important. To an increasing extent, the lengthening of life will be subject to the control of "degenerative" diseases.

Migration. International immigration is relatively unimportant, as less than one-half of 1 percent of the population in 1970 was foreign-born. Of the 191,000 persons not born in Mexico, 35 percent were concentrated in the Federal District and 38 percent in the states of Baja California, Chihuahua, Jalisco, Nuevo León, and Tamaulipas—*i.e.*, in the states closest to the United States.

Most Mexicans who emigrate go to the United States. Between 1900 and 1950 approximately 1,000,000 Mexicans migrated north. From 1960 to 1970 an estimated 30,000 to 40,000 emigrants entered the United States.

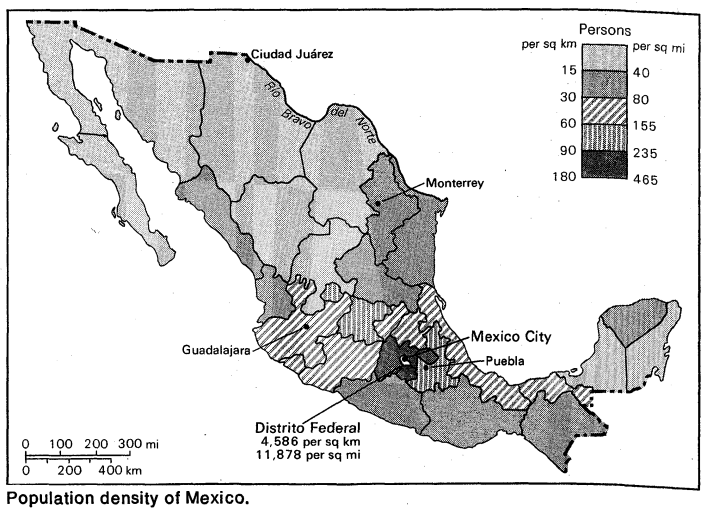
Internal migration between 1940 and 1970 was marked by three major characteristics—an increase in the number of persons residing in a state different from that of their birth; a heavy concentration of the migrant population in specific areas; and—from 1960 to 1970—a stabilization of the proportion of migrants to the total population. For every 1,000 inhabitants, 105 were residing outside their state of birth in 1930, 128 in 1950, 149 in 1960, and 145 in 1970. In 1970, there were, altogether, 7,000,000 persons living outside their state of origin.

In 1970, 74 percent of the migrant population was concentrated in the Federal District and in the states of Baja California, Tamaulipas, Veracruz, México, Nuevo León, Chihuahua, and Jalisco. The metropolitan area of Mexico City alone absorbed over 47 percent of the migrants. The migrants are predominantly young persons; among them, the proportion of women to men is slightly greater.

The attraction of the cities

Population distribution. The accelerated growth rate in the urban centres is a result of both migration and of the birth rate among the population. The average annual rate of population increase in communities of fewer than 2,500 persons is less than 2 percent annually, while in communities of 2,500 or more persons, the rate of increase had risen to more than 5 percent by 1970.

In 1970, more than 42 percent of the population lived in communities of less than 2,500 persons, 23 percent in those of 2,500 to 20,000; almost 10 percent in those of 20,000 to 75,000; 14 percent in those of 75,000 to 500,000; and 11 percent in cities of 500,000 persons or more.



Population density of Mexico.

Demographic trends. A decrease in fertility rates is foreseen in response to changing fertility patterns, higher levels of education, raised income levels, and an increase in the age of matrimony. Estimates have been made of a birth rate of 41 births per 1,000 population by 1980, with a decline to 33 per 1,000 by 2000. Estimates indicate a

life expectancy at birth of approximately 72 years of age by 2000. This would mean a population of approximately 135,000,000 in the year 2000. (P.G.C.)

THE NATIONAL ECONOMY

Nationalization of the economy

Mexico's most remarkable economic achievement has been the sharp reduction in the degree of foreign control exercised over key sectors of the economy, while maintaining overall national growth. The state has assumed control of telegraphic and electrical generation and distribution systems and has reduced the foreign interest in mining and in important manufacturing fields. State initiative has also resulted in the establishment of a motor-vehicle manufacturing industry based on local components. At the same time Mexico has recorded the most sustained pace of economic growth in Latin America; the gross national product (GNP) at 1950 prices more than doubled between 1950 and 1965, and in the period between 1965 and 1970 the real increase in GNP averaged 7 percent a year.

Such rapid development inevitably put a strain on the balance of payments. The heavy intake of foreign capital meant that the amount spent on servicing the public debt has been proportionately higher than in any other Latin American country except Argentina. Massive imports of raw materials and machinery, in spite of extensive import substitution, more than doubled the trade deficit between 1960 and 1970. The peso, however, has retained its value on world markets since 1954 and is used by the International Monetary Fund as one of the world's reserve currencies. Moreover, in spite of its economic nationalism, close ties with the United States still enable Mexico to attract public and private investment from abroad. The trading dependence of Mexico on the United States has, in fact, hardly declined, for the gradual diversification of export clients has been overshadowed by the massive annual influx of United States tourists.

Mexico has a wide variety of natural resources and has an enormous power potential in its petroleum, hydroelectric, and uranium reserves. It supplies almost one-fifth of the world's silver and is the world's largest producer of fluorite (the principal source of fluorine, used as a flux in metallurgy); it is the third largest producer of bismuth (a brittle metallic element used in the manufacture of fusible alloys and in medicine); the third largest of sulfur; the fourth largest of graphite; and the fifth largest of mercury. It is also an important producer of gold, lead, copper, zinc, manganese, cadmium (a white ductile metallic element resembling tin), and antimony (a brittle, lustrous, white metallic element used chiefly in alloys and in medicine). Its coal reserves, together with those of Colombia, are the only deposits in Latin America directly convertible into coke. Combined with its large iron deposits, Mexico has built up the second biggest steel industry in Latin America (after Brazil). The country has the largest petroleum and basic petrochemical industry in Latin America, as well as the highest glass output. It provides half the world's supply of hormones and is the world's largest exporter of natural honey.

The extent and distribution of resources. *Mineral resources.* The state of Chihuahua is responsible for approximately half the nation's lead and zinc production, about one-third of its gold, and most of its uranium. Sonora has dominated the copper industry because of its deposits at Cananea and La Caridad. In the early 1970s, known iron ore deposits were estimated at about 600,000,000 tons or more; they included the Las Truchas deposits on the Michoacán and Guerrero borders. Coal reserves are estimated at 2,200,000,000 tons in the state of Coahuila.

Silver and gold are largely produced as a by-product of lead, zinc, and copper. Other metals to be found include manganese, molybdenum (a metallic element used as an alloy with iron in making high-speed cutting tools), tungsten (a relatively uncommon metallic element used in some alloys), antimony, tin, bismuth, and cadmium. Sulfur, the major nonmetallic ore, is located in the Isthmus of Tehuantepec, although a small amount of sulfur of volcanic origin is obtainable in the state of San Luis Potosí. Fluorite is a major mining product, as is barite (the principal ore of the metallic element barium).

The petroleum industry is oriented toward supplying domestic fuel needs. About 90 percent of industry's energy needs are supplied by petroleum. Exploration and drilling are geared to guaranteeing supplies for 20 years in advance; the main hopes of exceeding this limit come from the offshore fields in the Gulf of Mexico off Tampico, where reserves are estimated to exceed 10,000,000,000 barrels. Two-thirds of the nation's crude oil comes from the state of Veracruz and the rest from Tabasco, which also produces approximately 45 percent of the country's natural gas.

Biological resources. Tropical hardwoods are an important biological resource. They include mahogany, cedar, logwood, primavera (white mahogany, used for making furniture), ceiba (kapok), and fustic (a tree of the mulberry family that yields a yellow dye). Hardwoods are exploited chiefly in the southeastern region of the Isthmus of Tehuantepec and on the Yucatán Peninsula. The sapodilla tree yields chicle, the chief ingredient of chewing gum.

The main fish reserves are found in the Gulf of California and the Gulf of Mexico. They include shrimp, oysters, tuna, sardines, and red snapper.

Hydroelectric resources. Water resources are unevenly distributed, but the Sierra Madre ranges give rise to sizeable rivers. Before the nationalization of the electrical industry in 1960, thermal (fuel-burning) plants supplied 57 percent of the total capacity. Since then, there has been a major shift to developing the country's hydroelectric potential. This has led to the construction of the Infiernillo project on the Michoacán–Guerrero border and of the Malpaso project in the state of Tabasco. The latter is the largest single source of power in Mexico. Power for the northern border is derived from geothermal sources, which tap live steam from beneath the Earth's crust. A geothermic plant is in operation near Mexicali.

Sources of national income. *Agriculture, forestry, and fishing.* The dependence of national growth on the agricultural sector has been considerably reduced since World War II. In 1970 agriculture, forestry, and fishing together provided only about 12 percent of the gross domestic product. The agricultural sector is the major source of employment and involves approximately 40 percent of the active population. The growth of agricultural output has been slow but remarkable in the context of Central and South America; livestock rearing, in particular, has shown steady growth.

The most dispersed agriculture is that of the scattered Indian communities, which maintain only minimal contact with the money economy. Nevertheless, they provide an important quantity of maize and in some areas are self-sufficient in many basic commodities.

Agricultural cooperatives

The ejidos are communal farms, created after 1910, that form the basis of the land-redistribution program; these communities have supplied labour to the more organized agricultural sectors.

Plantation agriculture produces the main export commodities, such as cotton, coffee, sugar, and henequen. Cattle rearing is also practiced on a large scale.

Because of fluctuations in world-commodity prices, the government has taken a large stake in the sugar industry and has assumed control of henequen processing. The production of coffee has grown steadily, but cotton has fallen drastically since the late 1960s. Tobacco production has held firm. The export of fruit and vegetables to the United States was becoming significant in the early 1970s.

Fishing cooperatives dominate the fishing industry, especially on the west coast. Mexico is the most important supplier of prawns (shrimplike crustaceans) to the United States market. Forestry is affected by ejido rights, which have limited expansion of the commercial forested area to 12,000,000 acres. The main product is hardwood timber.

Mining. Mining output has increased since the mid-1960s because of special incentives, the extension of ma-

jority ownership rule to all mining companies, and the upturn in world markets. Coal and iron ore cannot be exported, but mining still makes an important impact on exports. The rapid growth of manufacturing diverts approximately 60 percent of production away from the export markets, and local needs influence government policy.

Manufacturing. The manufacturing of chemicals, especially of basic petrochemicals, was the fastest growing industry in the early 1970s. The iron and steel industry is dominated by three basic producers of ingots and rolled products, and by one producer of tubing; the government has an interest in all but one of these companies. There is one basic aluminum producer, and a strong mechanical engineering sector has grown up around the automobile industry.

The glass industry is well developed. There are almost 50 basic producers of paper and about 20 producers of pulp, but considerable quantities of pulp and newsprint have to be imported. The textile industry has traditionally been a major source of manufacturing employment. In spite of some progress in the wool and cotton industry, locally produced man-made fibres are gaining in importance. A substantial industry in consumer durable goods (such as cars, radios, etc.) has grown up; production of television sets, for instance, amounted to more than 400,000 in 1969.

Public works accounted for half the construction activity, which represented more than 4 percent of the gross domestic product in 1970. The country was self-sufficient in cement in the early 1970s.

Industry is concentrated in the Mexico City area and to a lesser extent in the Monterrey and Guadalajara areas. Satellite industrial zones have been established around these centres; the largest of these are in Puebla, Querétaro, Cuernavaca, and Toluca.

Energy. The state petroleum monopoly, Petroleos Mexicanos (Pemex), is the largest Latin-American oil company. Productivity, however, is not high, as it employs only slightly more workers than the Italian oil company, Ente Nazionale Idrocarburi (ENI). No crude oil is exported.

The installed capacity of the electricity network run by the Comisión Federal de Electricidad (Federal Commission of Electricity) was 7,495,000 kilowatts in 1970. Electricity is also produced privately by industrial and mining concerns.

Financial services. The dual banking structure consists of government financial institutions and a number of private merchant, deposit, and mortgage banks—all closely linked with industrial and commercial groups. The stock exchange plays only a minor role in the provision of new capital, as most of the activity is in government bonds or banking securities.

The Banco de México (Bank of Mexico) follows the general monetary and financial policy laid down by the secretary of the treasury. It engages in open-market operations, sells gold to the public, fixes reserve requirements, enforces credit controls, and has the sole right of note issue. There are about 30 other state financial institutions, the most important of which, the Nacional Financiera (the National Merchant Bank), is one of the main channels of foreign funds into infrastructure projects such as road construction and water supply.

The Nacional Financiera has a direct stake in a number of industrial concerns, as does the smaller holding company, the Sociedad Mexicana de Crédito Industrial (Mexican Society of Industrial Credit). The other government banking institutions each specialize in one sphere of activity—such as providing credit to cooperatives, rural communities, public works, or foreign trade.

The private banking system is composed of deposit, merchant, and mortgage banks. The merchant banks overtook the deposit banks in the size of their combined resources in 1965 and have had the competitive edge since then. The secretary of the treasury controls prime interest rates, but both the cost and availability of credit vary according to the relationship of the lender to the borrower, since financial power is very concentrated. Three merchant banks control up to 40 percent of the lending power of this type of institution, and another seven merchant banks control about 33 percent. The leading merchant banks are linked with the major deposit banks, where resources are also concentrated—two banks control over one-half of the total of deposited bank funds and four others control one-third. The result of this concentration has been to restrict the volume and increase the cost of credit to companies outside these groups, particularly to companies involved in agriculture, low-cost housing, and similar nonmanufacturing activities. Investment in some sectors, such as agriculture, is therefore dependent on government institutions.

Foreign trade. Industrialization has reduced the need for imported consumer goods, but the need for capital equipment and production goods has led to a rapid rate of import growth. Exports, however, increased only slightly from 1965 to 1970, with the result that the trade gap has widened. The impact of the trade deficit has been moderated by the increase in tourism and expenditure by United States citizens in the northern border zone, which produces a gross foreign-exchange income greater than that earned by merchandise exports. At the same time, however, there has been a rapid rate of growth in travel abroad by Mexicans, as well as in profits sent abroad as a result of increased foreign investment.

The balance of trade

The main destinations for Mexico's major exports of cotton, sugar, coffee, and sulfur are the United States, Japan, Switzerland, and West Germany. The chief import sources are the United States, West Germany, Japan, the United Kingdom, and France. Major imports include machinery, motor vehicles, electrical equipment, chemical products, and iron and steel.

Management of the economy. *The private sector and the role of government.* The state controls electricity generation and distribution; petroleum production, refining, and distribution; the telegraphic and railway systems; and one of the two international airlines. The government also has exclusive rights to operate in basic petrochemicals and dominates the fertilizer market. It controls the Nacional Financiera and the Sociedad Mexicana de Crédito Industrial, as well as the major producers of steel, tubing, copper, iron ore, and motor vehicles.

The state affects the operation of private industry by various means, both formal and informal, including the system of import licenses, the production quotas and requirements for use of local materials applied to some industries, and the control of the retail prices of some consumer products. The private sector is also legally debarred from certain activities reserved for the state, including the manufacturing of basic petrochemicals.

An industrial incentive scheme operates through tax incentives and other concessions, and a special industrialization program is also in operation along the northern boundary with the United States. There is no national development plan, although a public-investment program and a plan for agricultural development were under consideration in the early 1970s.

The government also defines the spheres of activity of the foreign investor. Foreign capital is barred completely from a number of industries, including insurance, petroleum, and forestry, and is permitted only on a minority basis in activities such as mining, transport, radio and television broadcasting, fishing, advertising and publicity, soft drinks, rubber products, fertilizers, iron and steel, cement, glass, pulp, aluminum, and banking. Moreover, no incentives are granted to companies with a majority of foreign ownership; the government also has discretionary power to introduce minimum local ownership requirements.

Taxation. Income taxes provide about 47 percent of the government's revenue. Others include import and export duties and taxes on profits, industry, trade, the exploitation of natural resources, and public services.

Trade unions and employer associations. The right to strike is guaranteed, but only strikes that follow prescribed procedures are protected by law. Industrial peace is largely maintained through the close relations of the unions with the ruling Partido Revolucionario Institucion-

al (PRI). The Confederación de Trabajadores Mexicanos (Confederation of Mexican Workers), with an estimated membership of 2,000,000 and a wide net of affiliated regional unions, is the most important union.

Approximately half of the nonagricultural labour force, including civil servants, belongs to a union. Unions have generally succeeded in establishing closed shops in most major industries; dismissals are resisted by unions and are penalized by high severance payments. The national minimum wage level is adjusted every two years. The 1970 labour law laid emphasis on fringe benefits and on programs requiring that workers participate in the profits. Workers not covered by collective contracts are guaranteed the national minimum wage, but the system is widely disregarded in rural districts where it is difficult to enforce.

Industrial boards

Every individual employer or company is required to join an industrial board; these are grouped under either the Confederación de Camáras Industriales (Confederation of Industrial Boards) or the Confederación de Camáras Nacionales de Comercio (National Confederation of Industrial Boards). These and the private association of employers, the Confederación Patronal (Employers' Confederation), provide the focus for lobbying and public relations activities.

Contemporary economic policies. Economic policy is aimed at the achievement of economic growth and the dissemination of economic benefits to the public. Priority has been given to agricultural development and the elimination of the pockets of poverty existing in the countryside. Social security and public-health programs are to be improved and an attempt made to reduce the housing shortage. New industrial investment is to be directed outside the central area. This policy requires the strengthening of budgetary resources and the external-payments position. Taxes on luxury items have been increased, and the tax structure is oriented toward the provision of investment incentives, especially for the production of exports. Foreign trade is to be promoted by bodies that will coordinate and finance exports and smooth out the problems at ports. Development of tourism will continue, in order to moderate the outflow of capital resulting from the high trade deficit and foreign investment.

Problems and prospects. About one-third of the population have a substandard income and live in one-room dwellings. Most of the wealth is concentrated in the Mexico City area or in the major provincial capitals. With a high rate of population growth, prosperity cannot depend on traditional activities such as agriculture. Industrial growth, however, has passed the first stage of import substitution, so that growth now must come from the scale of operations made possible by the size of the home market. This, in turn, may lead to a greater export capability.

Inflation has not been a problem, but the close links of the financial and trading system with the United States makes the system vulnerable to any downturn in the economic fortunes of its northern neighbour. The most critical short term problem is likely to be the deficit in the balance of payments. Lack of controls on capital repatriation and on the sending of remittances abroad will continue to be required so as to attract foreign private capital investment, but curbs may be imposed on imports and on travel abroad by Mexican residents. (E.I.U.)

TRANSPORTATION

Overall patterns of transport. In 1965, over 90 percent of Mexico's passenger traffic was carried by automobiles, while the railways transported almost 50 percent of the total freight tonnage. The central and northern zones, where economic activity and population are most concentrated, have the most developed transport network.

The three transportation regions

There are three major transportation regions. In the northeast, Saltillo, Monterrey, and Ciudad Victoria are the principal convergence points for railway, highway, and air transport. Connections are made to the United States by way of Piedras Negras, Nuevo Laredo, Reinosa, and Matamoros or via Tampico on the Gulf of Mexico; numerous routes lead to the rest of the country. In the north central region, the main focusses of transportation are Chihuahua and Torreón. These are highway and rail connections to the northern border by way of Ojinaga and Ciudad Juárez and to the northwest by means of the Chihuahua-Pacific Railroad, which ends at the port of Topolobampo. In the northwest, the road and rail centres are Guaymas, Hermosillo, and Nogales. The Baja California Peninsula is linked with the coastal states of Sonora and Sinaloa by means of highways, railways, and trans-gulf ferries. A highway running down the entire length of the peninsula was under construction in the early 1970s.

In the south and southeast, the main focuses of transportation are the cities of Tapachula, Oaxaca, Acapulco, and Salina Cruz in the Pacific coastal area, and Veracruz, Villahermosa, and Mérida in the area of the Gulf of Mexico. Connections are made to Guatemala by way of El Talismán, Ciudad Hidalgo, and Ciudad Cuauhtémoc in Chiapas.

Component systems. *The highway network.* In 1970, highways totalled more than 46,000 miles. Tollways and federal highways—which extend throughout the country—represent almost half the total road mileage and form the trunk lines of the system. The remainder of the system consists of a growing network of rural and state roads; these promote the development of new regions and feed the principal highway and railway lines. The 1,250-mile (2,000-kilometre) Pan-American Highway runs from Ciudad Cuauhtémoc, on the border with Guatemala, to Ciudad Juárez, on the border with the United States, passing through Mexico City.

The railways. There are 15,000 miles of railway lines. The system was constructed in the late 19th century and rehabilitated after 1910. Since the 1950s, new railway construction has taken place in order to help service national markets. In addition to the lines that lead to the United States border and those that connect the central areas with the Gulf and Pacific ports, railways connecting the central plateau with Yucatán and Baja California have been completed. In 1961 the Chihuahua-Pacific line, between Ojinaga on the northern frontier and Topolobampo on the Gulf of California, was opened.

Maritime transport. Approximately 50 percent of all foreign commerce is carried by sea. There are 14 ports on the Gulf of Mexico and 16 on the Pacific. Major ports include Tampico, Veracruz, Salina Cruz, Acapulco, Ensenada, Guaymas, Manzanillo, and Coatzacoalcos. The merchant marine is relatively small, and port installations remained insufficient in the early 1970s. There is a considerable amount of coastal shipping.

Air services. In 1921 the first concession was granted for regular passenger, mail, and air-freight services between Mexico City and other Mexican cities and ports. By the early 1970s there were over 60 airports, not including small runways and rural airfields. Of these airports, 23 were equipped for international service. Scheduled flights connect Mexico with cities in North, Central, and South America, Europe, and Asia.

ADMINISTRATION AND SOCIAL CONDITIONS

The structure of government. *Constitutional framework.* The 1917 constitution of the United Mexican States (Estados Unidos Mexicanos) declares that Mexico is a representative, democratic, and federal republic. Executive, legislative, and judicial powers are divided, and provision is made for the direct election of the president and the legislators. In addition to guarantees of personal and civil liberties, the constitution establishes principles of an economic and political nature.

Constitutional guarantees

Supreme executive authority is vested in the president, who is elected to serve one six-year term. His power of appointment extends to the members of his cabinet and the attorney general, and to the territorial and federal district governors, diplomatic officials, the higher officers of the army, and ministers of the higher courts of justice. As the leader of the dominant political party, the president can effect constitutional amendments that then require approval by a two-thirds vote of a quorum in Congress and the support of a majority of the state legislatures. The chief executive may also establish basic rules

or *reglamentos*, which give effect to general statutes and have the force of law. The president has extensive control over foreign affairs. (P.G.C.)

A bicameral Congress is composed of the Chamber of Deputies and the Senate. Two senators from each state and from the Federal District are elected for six-year terms, concurrent with that of the president. The 178 deputies are elected every three years, one deputy representing 200,000 people. Each state has at least two deputies and each territory at least one. Congressmen may not be re-elected for the immediately succeeding term. Each house is the final judge of the election of its own members, an arrangement that has permitted the majority party to declare its own candidates elected, regardless of ballot results.

A permanent committee of 15 deputies and 14 senators serves during the congressional recess and approves certain presidential requests, the most important of which may be suspension of guarantees in times of emergency.

The legislative branch has declined in importance as compared with the executive. Annual changes in committee membership, low pay, infrequent meetings, and short sessions have discouraged the full development of congressional powers. The fact that the majority party leader in each house outranks the congressional president of each house (who is selected at monthly intervals) further restricts congressional autonomy. Potentially, however, the Chamber of Deputies could exercise great power over the executive through its functions of verifying the presidential electoral returns, passing the budget, and initiating tax bills. (M.B.T.)

Local and municipal government. Mexico is politically divided into 29 states, two territories, and one federal district, which is the seat of the federal government. The territorial division and political and administrative organization of the states are based on the concept of *municipio libre* (literally "free municipality). Each state is an autonomous unit governed by a constitution modelled on the national document. State governors are elected by popular vote every six years; deputies of the unicameral state legislatures are elected every three years and senators every four years. Each state may levy taxes and legislate under specified conditions; all powers not delegated to the federal government are reserved for the states.

The federal union of states

The federal district is governed by a *jefe* (chief), or *regente* (regent), who is appointed by the president of the country. The two territories of Quintana Roo in the Yucatán and Sur de Baja California are headed by governors, also appointed by the president. An amendment was approved in 1971 for the reinstitution of *municipio libre* in these entities.

The political process. The history of 20th-century Mexico has been eventful and rich in de facto and legal political movements. With the formation in 1929 of the Partido de la Revolución Mexicana (National Revolutionary Party), now the Partido Revolucionario Institucional (PRI, or Institutional Revolutionary Party), politics became more strongly and more significantly institutionalized.

All Mexicans over the age of 18 have the right to vote. The dominant feature of elections is the strength of the PRI. Since its foundation as the Partido Nacional Revolucionario, it has not lost a presidential, gubernatorial, or senatorial election. Presidential elections, which are the model for elections on other levels, have reaffirmed the dominant character of the party in power and have minimized the opposition's possibilities. Extreme violence has not occurred since the murder of President-elect Alvaro Obregón in 1928.

The PRI is the expression of the interests of the country's middle classes, with respect to its nominees; its managing cadres; its support of a policy of state intervention in economic, political, and cultural life; and its reconciliation of different social sectors.

In the early 1970s there were three other legally constituted national parties. The Partido Acción Nacional (PAN, National Action Party) is the most successful opposition party. It presents an image as the defender of popular causes but adopts an eminently individualistic policy toward matters of education and property. The Partido Popular Socialista (PPS, Socialist People's Party) is only minimally important; it is preoccupied with the demands of labour and has a Marxist orientation. The military is supported by the elitist Partido Auténtico de la Revolución Mexicana (PARM, Authentic Party of the Mexican Revolution).

Justice. The administration of justice, at the federal level, is the responsibility of the Supreme Court of Justice and of the circuit and district courts. In each state or federal unit, there is a Superior Court of Justice, as well as civil, criminal, and mixed peace courts (courts with civil and minor criminal jurisdiction).

The attorney offices of the Ministerio Público (Public Ministry) prosecute criminal cases in their respective jurisdictions: there is an attorney general for the republic and one attorney for each state and territory and for the federal district.

The federal constitution protects the accused and guarantees free trial and due process. No one may be imprisoned for a debt of a purely civil nature, and cruel or unusual punishments are forbidden. No criminal trial may go through more than two levels of appeal. Laws or acts of authority that violate constitutionally guaranteed rights of the individual may be contested before the federal courts by means of the Juicio de Amparo (Protection Proceeding); Amparo is also used in ruling on conflicting state and federal statutes.

The Juicio de Amparo

In its relations with the executive branch of government, the federal judiciary is independent and has the power to restrain the president. The Supreme Court, however, largely follows the policies of the executive and, in effect, serves to give it greater stability.

The armed forces. The Mexican Army does not play a preponderant role in the political life of the country. Since the 1920s, measures have been taken to achieve civil control of the military, through the agency of the PRI and the power of the president, who appoints the higher military officers.

The regular armed services are composed of almost 68,000 members, of whom 54,000 are in the army, 7,600 in the navy, 6,000 in the air force, and 900 in the marines. The navy is equipped with frigates, minesweepers and other craft, and the air force has jet-trainer fighter bombers among its aircraft. Given the absence of external conflicts, the army's function consists exclusively of maintaining internal order. Conscripts—18-year-olds who serve a compulsory year in the military—and the Rural Defense Corps (consisting of some 80,000 cavalry and 40,000 infantry) are also considered integral parts of the army.

Administration. *Educational services.* Education is free and compulsory. It provides for two years of pre-primary and six years of primary schooling and for three years of secondary training. On the primary level, three-fourths of the schools are public and are located in rural areas; the remainder are located in urban areas. Most of the rural establishments, however, provide only three, instead of six, years of primary instruction. The private primary schools are generally directed by religious orders.

Post-primary education is provided by professional, normal (teacher-training), secondary, preparatory, and subprofessional schools.

There are more than 35 universities. The two large institutions of higher education, both in Mexico City, are the Universidad Nacional Autónoma de México (Autonomous National University of Mexico) and the Instituto Politécnico Nacional (National Polytechnic Institute).

Health and welfare services. Social aid is furnished through three main institutions—the Secretariat of Health and Aid, the Mexican Institute of Social Insurance (IMSS), and the Institute of Social Services and Security of the Workers of the State (ISSSTE). The secretariat provides for more than 2,700 medical centres. The IMSS provides medical services, workmen's compensation, and retirement benefits to labourers and employees in the private and mixed-enterprise sector; it obtains funds through proportional assessments on their salaries.

Governmental social agencies

Most of the beneficiaries form part of the urban population and include the insured, the pensioned, and their families. The ISSSTE performs the same functions as the IMSS but provides benefits only to the bureaucracy.

Housing. The problem of housing is one of the most serious facing the country, particularly in the cities. In addition to a chronic housing shortage, a large proportion of the existing units are substandard or have insufficient water supplies, poor drainage, or other defects. By 1964 new housing was being built at a rate of 12,000 units per year. In the early 1970s, official policy was to construct large, multifamily units, which were to be sold as condominiums; it was estimated that it would be necessary to build some 300,000 housing units annually to satisfy the existing demand.

Police services. There are two federal police forces—the Judicial Police of the Federal District and Territories and the Federal Judicial Police.

The local police of Mexico City consist of grenadiers (riot police), mounted, transport, motorized and traffic police.

Social conditions. *Wages and cost of living.* The range of wages is extremely wide; it runs the gamut from high salaries earned by senior government officials and managers of private companies at one end of the scale, down to the precarious subsistence levels of the peons in the rural areas, at the other. The wages of workers and employees depend upon their qualifications and length of service, but there are appreciable differences according to the type and size of firm.

The minimum wage

Since 1934, there has been a law requiring owners to pay a minimum wage that is fixed every two years in accordance with the cost of living of each region. This law is not, however, fully observed. Workers are legally empowered to ask for biennial raises, but the increase in cost of living continues to parallel the raises granted.

Health conditions. Health conditions have markedly improved because of investment both in social assistance services and health services.

The greatest incidence of illness is caused by diseases of intestinal origin, either parasitic or infectious. As a result of bad diet, there is a high incidence of such ailments as rickets, vitamin deficiency, and anemia (deficiency of red blood cells). There is also a high incidence of diseases that are difficult to control, such as tonsillitis, influenza, and respiratory diseases.

Economic and social divisions. In the early 1970s, 40 percent of the economically active population were employed in agriculture, 23 percent in industry, and 32 percent in services.

There are three major agricultural groups—the *ejidatarios,* or communal farmers, the proprietors, and the agricultural workers. The *ejidatarios* are poor and are on about the same economic level as the least of the proprietors, those who own the *minifundios.* The small and medium-sized landowners form the rural middle class, whereas the large landowners form an agricultural elite. Possessing about 84 percent of all privately owned land, this elite receives close to half of the net national agricultural income and has managed to elude reforms aiming at redistribution of land. The rural proletariat is made up of 3,500,000 landless peasants who labour for landowners and communal farmers. They are employed during sowing and harvesting periods for an extremely low wage.

Blue-collar and white-collar workers form the bulk of the urban middle class. These two categories are subdivided by levels of income that are proportional to training and education. The urban higher income group is comprised of public officials as well as affluent groups of Mexican and foreign origin.

CULTURAL LIFE AND INSTITUTIONS

The cultural environment. A tendency toward cosmopolitanism, which paradoxically blends with a tendency toward a nationalistic culture, is perhaps the most characteristic aspect of Mexico's cultural environment. The old obsession for remaining in contact with "universal" culture persists, yet at the same time interest in Mexico's own cultural heritage continues.

The state of the arts. Culturally, the Mexican is concerned with his role in the wider, international community. In the field of philosophy, this concern was initiated by Samuel Ramos' speculations on man and culture in Mexico. Literature no longer deals with the revolution. Although the cares and sufferings of the Mexican peasant continue to be the subject of such writers as Juan Rulfo, there is now a universal literature with characters and themes that are universally applicable. Contemporary literature ranges from the fantasies of Juan José Arreola to the novels of Carlos Fuentes, portraying Mexican cosmopolites, to the poetry of Octavio Paz.

In music, Carlos Chávez, without renouncing the heritage of the past, has transformed it to create a music belonging to no specific country—a trend which has been amplified by those composers who have followed the Chávez tradition. Something similar has also taken place in the contemporary theatre, through the work of such figures as Rodolfo Usigli, who has taken material for his dramas from Mexican history.

Painting

The Mexican Muralist School of Painting, which sought its inspiration in the Combative period of the Mexican Revolution, has been followed by contemporary artists who have sought to express themes that transcend the national. Rufino Tamayo, who crystallized this trend and demonstrated its possibilities, was followed by Carlos Mérida and Juan Soriano. Painters such as José Luis Cuevas have sought only to express themselves, regardless of whether their artistic work might or might not be viewed as meeting any particular standard or as belonging to any particular school. The national art is no longer simply folkloric or popular, although popular art may be the point of departure for an apparently abstract art, which is also truly national.

Cultural institutions. The Instituto Nacional de Bellas Artes (National Fine Arts Institute) is devoted to the stimulation of creativity in the fine arts and to the dissemination of artistic work. Theatre, literature, dance, the plastic arts, and music are all objects of its attention. The Orquesta Sinfónica de México (National Symphony Orchestra) has been given notable government support, as have various ballet groups such as the Ballet Folklórico de México (Folkloric Ballet) and the Ballet Moderno y Clásico (Modern and Classical Ballet).

National University carries on extensive artistic activities, both within the University and extramurally. Theatre, dance, films, music, the humanities, and the sciences receive great stimulus in faculties, schools, centres and institutes. Original, classical, and contemporary works are presented to audiences through the use of the media and through university facilities.

Folklore and popular culture are promoted under the auspices of the Secretariat of Public Education. The Instituto Nacional de Antropología e Historia (Institute of Anthropology and History) includes the Museo de Antropología (Museum of Anthropology), the Museo de las Culturas (Cultural Museum), the Museo de Artes Populares (Museum of Popular Art), and the Instituto Nacional de Bellas Artes (National Fine Arts Institute). The Instituto Indigenista (Native Institute) encourages native crafts.

Other important cultural institutions include the Colegio de México (the College of Mexico), the Colegio Nacional (the National College), and the Seminario de Cultura (Cultural Seminar); there are also academies of the arts, languages, and history.

Press and broadcasting. A variety of cultural publications is issued by the Secretariat of Public Education. The National University publishes through its General Directorate the works of its professors, researchers, and artists. Among publishing firms, the Fondo de Cultura Económica (Foundation of Economic Culture) and the Editorial Siglo XXI (21st Century Publishers) produce works that reach every Spanish-speaking country.

Daily newspapers

In the late 1960s, there were more than 230 daily newspapers, of which 18 were located in Mexico City, the rest being spread throughout the country. They operate under the constitutional guarantee of freedom of the press, but conservative social pressures and a desire to make Mexi-

co attractive to tourists have resulted in low-key criticism of the government. The Mexico City morning daily *Excelsior* is often considered as the nation's best newspaper; moderately conservative, it is circulated throughout Mexico and has a wide impact on public opinion. Other influential dailies include *El Universal, Novedades, Diario de la Tarde,* and the English-language *News.* The morning daily *La Prensa* is the leading liberal newspaper; *El Nacional* supports government policies.

Radio plays an important role in linking rural areas to the cities. In the late 1960s there were almost 400 standard-band radio stations in operation throughout the country, as well as shortwave and FM transmitters. Two large radio networks owned about 130 stations, but most provincial stations were independent. Most broadcasts are in Spanish, with some in English, French, Italian, and German.

Mexico City acquired the first licensed television station in Latin America in 1950. In the early 1970s there were three commercial television stations in the capital; colour transmission was introduced in 1967. Latin America's first full-time educational television station began transmission in 1959. Television is also broadcast from 18 provincial cities and is received by a total of 38 channels.

PROSPECTS FOR THE FUTURE

In the early 1970s—more than 60 years after the revolution of 1910—Mexico had achieved many of the Revolution's objectives. Political advances included the ban on re-election of the governors and the president. Labour's position had improved markedly through constitutional provisions, and agricultural reform had been instituted. The nationalization of natural resources promised continued economic progress, and the secularization of public education reinforced a pattern of continuing social change.

Mexico finds itself, however, confronting the same problems as other nations engaged in industrialization. Economic problems include the necessities of establishing competitive prices, broadening domestic and foreign markets, and of lowering interest rates on loans. In the social area, the dissolution of family ties and the high crime rate present grave difficulties. To these problems must be added the serious demographic explosion, which will probably cause the population to double in 20 years. Mexico is also plagued by the lack of adequate technology, the restiveness of a politically aware youth, and particularly by the difficult situation in which the agrarian population finds itself placed.

BIBLIOGRAPHY

General works: DANIEL COSIO VILLEGAS, *Ensayos y notas* (1966), is a collection of essays on Mexican problems written by a notable historian. An important discussion of Mexico's industrialization is presented in SANFORD A. MOSK, *Industrial Revolution in Mexico* (1950). JORGE L. TAMAYO, *Geografía general de México* (1949), is an extensive geographic work; and FRANK TANNENBAUM, *Mexico: The Struggle for Peace and Bread* (1950), is important for its valuable observations.

Specific works: Natural resources and physical geography are discussed in ANGEL BASSOLS BATALLA, *Recursos naturales: Climas, agua, suelos,* 2nd ed. (1969); and P.E. JAMES, *Latin America,* 4th ed. (1969). H.G. GIERLOFF-EMDEN, *Mexico: Eine Landeskunde* (1970), is an excellent work on the geography of Mexico. MAXIMILIEN SORRE, *Le Méxique* (1928), is a classic work of great importance. For demographic information, see RAUL BENITEZ ZENTENO *et al., Dinámica de la población de México* (1970); ERIC WOLF, *Sons of the Shaking Earth* (1959); R. DE ZAYAS ENRIQUEZ, *Los Estados Unidos Mexicanos, sus condiciones naturales y sus elementos de prosperidad* (1893); and ALEXANDER VON HUMBOLDT, *Ensayo político sobre el reino de la Nueva-España,* 4 vol. (1822). Administration and social conditions are discussed in PABLO GONZALEZ CASANOVA, *La democracia en México* (1965); E.R. RUIZ, *Mexico: The Challenge of Poverty and Illiteracy* (1963); and JORGE ALBERTO LAZAYA, *El Ejército mexicano (1911–1965)* (1970). Cultural life and institutions are presented in JUSTINO FERNANDEZ, *Arte mexicano* (1958); JOSE MORENO VILLA, *Lo Mexicano en las artes plásticas* (1948); LEOPOLDO ZEA, *América como conciencia* (1953); and FONDO DE CULTURA ECONOMICA, MEXICO, *América en la historia* (1957).

(P.G.C.)

Mexico, Gulf of

The Gulf of Mexico is a partially landlocked body of water on the southeastern periphery of the North American continent. It is connected to the Atlantic Ocean by the Straits of Florida, running between the peninsula of Florida and the island of Cuba, and to the Caribbean Sea by the Yucatán Channel, which runs between the Yucatán Peninsula and Cuba. Both these channels are about 100 miles wide. It covers an area of more than 500,000 square miles (1,300,000 square kilometres). To the northwest, north, and northeast the Gulf is bounded by the southern coast of the United States, while to the west, south, and southeast it is bounded by the east coast of Mexico.

Area and boundaries

The various rivers flowing into the Gulf drain a total area of about 1,250,000 square miles. The Gulf, with a climate that varies from the tropical to the subtropical, is traversed by currents that become the Gulf Stream, entering through the Yucatán Channel and flowing in a clockwise direction to exit through the Straits of Florida. From June to October the Gulf is liable to become a spawning ground for hurricanes.

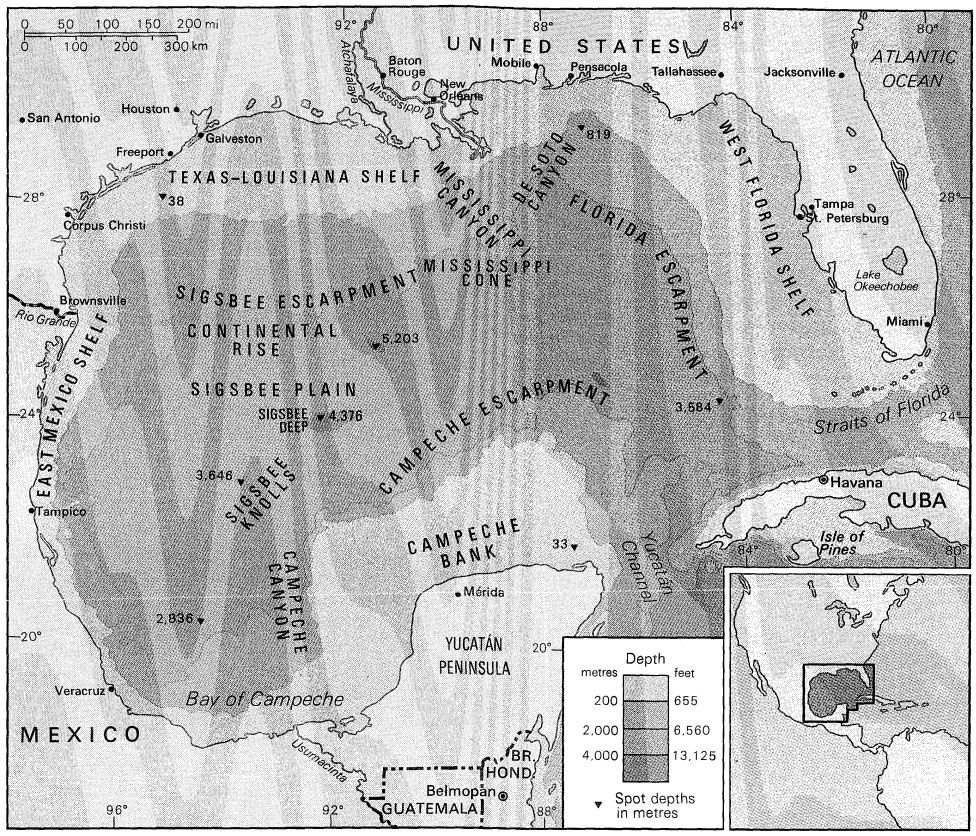
The Gulf has considerable economic resources, which include oil and gas, sulfur, and large quantities of fish; its coastal waters are also much used for recreation. To an increasing extent, however, the Gulf is becoming a receptacle for waste of all kinds, including pesticides and other pollutants, issuing particularly from the Mississippi. (For associated physical features, see CARIBBEAN SEA; MISSISSIPPI RIVER; and GULF STREAM.)

Physiography and geological history. The Gulf consists of several ecological and geological provinces, chief of which are the coastal zone, the continental shelf, the continental slope, and the abyssal plain. The coastal zone consists of tidal marshes, sandy beaches, mangrove-covered areas, and many bays, estuaries, and lagoons. The continental shelf forms an almost continuous terrace around the margin of the gulf; its width varies from a maximum of more than 200 miles (320 kilometres) to a minimum of about 25 miles (40 kilometres). Off the west coast of Florida as well as off the Yucatán Peninsula, the continental shelf consists of a broad area composed primarily of carbonate material (formed of salt or other chemical compounds). The remainder of the shelf consists of sand, silt, and clay sediments. On the shelf and on the slope that dips downward to the abyssal plain, buried salt domes occur at various depths; important oil and gas deposits are associated with them. The abyssal plain, which forms the floor of the Gulf, consists of a large triangular area near the centre, bounded by abrupt fault scarps toward Florida and Yucatán and by more gentle slopes to the north and west. The basin is unusually flat, having a gradient of only about one foot in every 8,000 feet. The deepest point is Sigsbee Deep, which is 17,070 feet (5,203 metres) below sea level. From the floor of the basin rise the Sigsbee Knolls, some of which attain heights of 1,300 feet; these are surface expressions of the buried salt domes.

Only since about 1950 have comprehensive and systematic oceanographic studies of the Gulf been begun. Much remains to be done before most of the scientific questions about it can be answered. There is, for example, considerable scientific speculation as to the geologic origin of the Gulf. Some contend it is a foundered continental crust that has been flooded by the ocean; others believe it to be an ocean basin that has been subjected to rifting. Proponents of the theory that the continents were once joined but drifted apart contend that, like the Mediterranean, the Gulf is an ancient sea that was in existence even when the various continental masses of the Earth formed a single landmass. Unfortunately, the scientific drilling of the sea floor of the Gulf during recent expeditions was not deep enough to obtain the definitive evidence needed to decide the question.

Oceanographic studies of area

Hydrology. *Currents.* The Gulf Stream is the principal current moving oceanic waters into the Gulf. It enters through the Yucatán Channel, the floor of which forms a sill at about 5,000 to 6,000 feet beneath the surface, and flows out via the Straits of Florida. Meandering masses of



The Gulf of Mexico.

water, known as loop currents, break off from the mainstream and move clockwise into the northeastern part of the Gulf. Both seasonal and annual variations occur in these loop currents. A less well-defined pattern exists in the western Gulf. Here, the currents are relatively weak, varying appreciably in intensity with season and location. There is extreme variability in both current direction and speed on the continental shelf and in the coastal waters of the Gulf, where currents are subjected not only to seasonal and annual variations caused by major circulation patterns but also by changes in the prevailing wind direction.

Salinity and temperature. The salinity of the Gulf is also subject to wide variations. In the open Gulf the salinity is comparable to that of the Atlantic Ocean, with about 36 parts of salt for every 1,000 parts of seawater by weight. This proportion varies markedly during the year, however, in coastal waters, particularly near the outflow of the broad delta region of the Mississippi. During periods when the volume of the Mississippi's flow is greatest, salinities as low as 14 to 20 parts of salt per 1,000 of water occur as far as 20 to 30 miles offshore.

Sea-surface temperatures in February vary between 64° F (18° C) in the northern Gulf and 76° F (24° C) off the Yucatán coast. In the summer, surface temperatures of about 90° F (32° C) have been measured, but the usual variation is between 65° to 75° F (18° to 24° C). Bottom-water temperatures of about 43° F (6° C) have been recorded near the northern part of the Yucatán Channel. The thickness of the isothermal layer (a surface layer of water of constant temperature) varies from a few feet to more than 500 feet, depending on seasonal and local conditions as well as on location. The tidal range is small, averaging less than two feet in most places; in general, only one high water and one low water occur during the lunar day.

Climate. The climate varies from tropical to subtropical. The hurricane season officially starts June 1 and ends November 1. Meteorological and oceanographic conditions are conducive during most of this period to the formation of hurricanes anywhere in the Gulf. Hurricanes spawned in the Caribbean and South Atlantic may also move through the Gulf at this time.

Fish and wildlife. Red snappers, flounder, shrimps, mullet, oysters, and crabs provide the basis for commercial fishing in the Gulf; tarpon and king mackerel are caught for sport. The shores of the Gulf are a major wintering area for waterfowl and whooping cranes, and substantial colonies of seabirds are located on the offshore islands. There is a marked absence of marine mammals.

Resources and their exploitation. Man makes extensive use of the Gulf as a major source of food, energy, and raw materials; he also uses it for recreation and, to an ever increasing extent, for waste disposal. The Gulf yields a rich harvest of fish and shellfish, which are sold for human consumption. In addition, a large tonnage of the fish caught are used to provide fish protein concentrate for raising cattle and poultry. About 1,400,000,000 pounds of fin fish were landed in 1970, and about 230,000,000 pounds of shrimp. The total value of these landings was about $167,000,000.

The Gulf is an important source of oil and gas, which is obtained from wells drilled on the continental shelf in water depths of as much as 500 feet and at distances of up to almost 100 miles offshore from Louisiana. Recent annual production of oil has exceeded 1,000,000 barrels per day. Oil reserves on the continental shelf alone are estimated to amount to about 2,400,000,000 barrels and gas reserves to about 34,000,000,000,000 cubic feet (960,000,000,000 cubic metres). Sulfur is also extracted from wells drilled on the continental shelf off Louisiana, with recent annual production amounting to several million tons. As much as 21,000,000 tons of oyster shells are obtained annually from the shallow waters of the Texas Gulf Coastal Plain, as well as from bays and estuaries. These are used in the chemical industry as a source of calcium carbonate and also provide material for building roads.

The coastal waters of the Gulf are used extensively for sport fishing, boating, sailing, swimming, and scuba diving. The estimated annual economic value of the recreational activities is more than $1,000,000,000.

Future prospects. The Gulf of Mexico is used with increasing frequency as a means of disposing of wastes—

Pollution of the waters

both directly by the discharge along the coast of sewage and industrial wastes and indirectly by the dissemination of pollutants carried by river waters draining into the Gulf. The Gulf thus becomes the final resting place of tremendous amounts of chemicals from pesticides, herbicides, and fertilizers used in agriculture in much of the United States. The introduction into the Gulf of large amounts of phosphates occasionally leads to the occurrence of red tides, so called partly because of the mass mortality caused among fish at various places along the shore from the tip of Florida to southwestern Texas and partly because of the large masses of red algae (Rhodophyta) that the phosphates cause to flourish. The true capacity of the Gulf as a receptacle for the wastes of a major portion of the United States remains to be determined, but it is certainly not infinite.

(R.A.G.)

Mexico, History of

Before the arrival of Europeans in the Americas, Mexico was the home of a number of advanced cultures (see MESO-AMERICAN CIVILIZATION, HISTORY OF). From the time of the Spanish conquest (1519–21) until it achieved independence in the early 19th century, it was part of the viceroyalty of New Spain, which, until *c.* 1700 embraced, in addition to Mexico, the Philippine Islands, the Spanish Caribbean islands, and Central America down to Panama. Its ill-defined northern frontiers included what are now Florida and parts of Georgia in the southeastern United States and much of the U.S. Southwest, including California. These sprawling, loosely connected jurisdictions were governed by the Habsburg monarchs of Spain through a series of interlocking and overlapping bureaucracies. In Spain itself the Council of the Indies administered the overseas realms in the name of the king, whose prime emissary was the viceroy in Mexico City, who headed numerous subordinate hierarchies. The basic jurisdictional unit was a county-sized area ruled by a so-called alcalde mayor, or corregidor, as the viceroy's local representative.

I. Colonial period after 1701

A fundamental shift in the governance of New Spain occurred as a result of the War of the Spanish Succession (1701–13), when Bourbons replaced Habsburgs on the Spanish throne. Ruling by divine right, the Bourbon kings were enlightened despots whose major interests lay in increasing the economic returns from the Spanish Empire; they introduced many French practices and ideas into overseas administration.

Among the notable administrative reforms undertaken by Charles III in 1784 was the creation of 18 intendancies. In place of the numerous *alcaldías mayores* and *corregimientos*, which were abolished, *partidos* of about the same size were created within each intendancy. Headed by the intendancy of Mexico, each intendant was given considerable autonomy in increasing economic production within his sphere, developing useful arts and sciences, and bettering education and social conditions, all of the latter less for altruistic than for economic reasons.

Fed by currents of rationalism from England and Europe, the Enlightenment in Spain and Mexico spurred the spread of new scientific knowledge and, especially, its application to mining and agriculture. Political liberalism became a factor when the American and French revolutions implied the denial of the divine right of kings. A later development was the proliferation of the military establishment under the impact of British and Russian pressures on the frontiers of New Spain. Having strung a series of mission-forts across northern Mexico, authorities in Madrid and Mexico augmented the few regular Spanish troops that could be spared from the Peninsula by fostering a local militia with special exemptions (*fueros*) granted to Creole (Mexican-born) officers. Thus, an explosive combination of new ideas, guns, and administrative confusion between the old Habsburg and the new Bourbon administrative system all made almost simultaneous appearances.

The turmoil of Napoleonic Europe was the immediate background of the move for Mexican independence. Napoleon Bonaparte occupied Spain in 1808, imprisoned King Ferdinand VII, and attempted unsuccessfully to impose his brother Joseph Bonaparte as monarch. Rebelling, the Spanish resurrected their long-defunct *Cortes* (representative assembly) to govern as regent in the absence of the legitimate king, and, with representation from the overseas realms, the *Cortes* in 1812 promulgated a liberal constitution in the king's name. The document provided for a constitutional monarch, popular suffrage, a representative government, and other features taken from the French and U.S. constitutions.

Continental events had a factionalizing effect in Mexico as contradictory commands were received from Spain. The viceregal establishment put down sporadic rebellions by those who professed loyalty to the imprisoned king but who demanded some form of self-government.

Factionalism and rebellion

The most important local revolt was sparked by Miguel Hidalgo y Costilla, a parish priest in Dolores, Michoacán, who had been the centre of a group of "enlightened" reformers. On September 16, 1810, Hidalgo issued the "Grito de Dolores" ("Cry of Dolores"), calling for the end of rule by Spanish peninsulars (*gachupínes*), for equality of races and for redistribution of land. Mexican Independence Day commemorates this event.

Warning that the Spaniards would deliver Mexico to the godless French, Hidalgo exhorted his followers to fight and die for the Mexican Virgin, Our Lady of Guadalupe. When Hidalgo left his tiny village, the tens of thousands who flocked to his banner followed him into Guanajuato, a major colonial mining centre, peopled by Spaniards and Creoles. There the leading citizens barricaded themselves in a warehouse that was captured by Hidalgo on September 28. Most of the Creole elite were massacred, and the town was pillaged.

The Guanajuato massacre swung moderate and undecided support behind the Viceroy's efforts to crush the Hidalgo rebellion, lest a full-scale caste war ensue. Royalist forces defeated Hidalgo at the Bridge of Calderón on January 18, 1811. On March 19 he was captured along with other major insurgent leaders. On July 31 Hidalgo was executed, ending the first of the political civil wars that were to wrack Mexico for three-quarters of a century.

The Hidalgo cause was taken up by his associate José María Morelos y Pavón, another parish priest, who won control of substantial sections of southern Mexico. The constituent congresses, which Morelos called at Chilpancingo in 1813, issued at Apatzingán in 1814 formal declarations of independence and drafted republican constitutions for the areas under his military control.

At about the same time Napoleonic troops were withdrawing from Spain, and in 1814 Ferdinand VII returned from involuntary exile. One of his first acts was to nullify Spain's 1812 constitution drawn up by the *Cortes*. The departure of the French freed Spanish troops needed to crush the Morelos revolution. Captured and defrocked, Morelos was shot as a heretic and revolutionary on December 22, 1815. Scattered but dwindling guerrilla bands kept alive the populist, republican, nationalist tradition of Hidalgo and Morelos.

Mexican independence came about almost by accident when constitutionalists in Spain led a rebellion that, in 1820, forced Ferdinand VII to reinstate the liberal constitution of 1812. Conservatives in Mexico, alarmed that anticlerical liberals would threaten their religious, economic, and social privileges, saw independence from Spain as a method of sparing New Spain from such

changes. They found a spokesman and able leader in Agustín Itúrbide, a first-generation Creole and the son of a moderately wealthy Spaniard. Itúrbide, who had served as a loyal royalist officer against Hidalgo and others, had been given command of royal troops with which he was to snuff out remnants of the republican movement, then headed by the future president Vicente Guerrero in southern Mexico.

But, while ostensibly fighting Guerrero, Itúrbide was in fact negotiating with him to join a new independence movement. In 1821 they issued the so-called Plan of Iguala, a conservative document the 23 articles of which declared that the Mexican nation was to be independent, that its religion was to be Roman Catholicism, and that its inhabitants were to be united, without distinction between Mexican and European. It stipulated further that Mexico would become a constitutional monarchy under Ferdinand VII, that he or some Spanish prince would occupy the throne in Mexico City, and that an interim junta would draw up regulations for the election of deputies to a congress, which would write a constitution for the monarchy.

The Plan of Iguala

United as the Army of the Three Guarantees (independence, union, preservation of Roman Catholicism), the combined troops of Itúrbide and Guerrero controlled most of Mexico by the time Juan O'Donojú, recently appointed Spanish captain general, arrived in the viceregal capital. Without money, provisions, or troops, O'Donojú felt himself compelled to sign the Treaty of Córdoba on August 24, 1821, thus officially ending New Spain's dependence on Old Spain. The convention provided that the Mexican nation, thenceforth to be styled the Mexican Empire, was to be recognized as independent. Under the treaty, the new Empire's congress was to elect an emperor if no suitable European prince could be found.

II. Mexico from independence to revolution (1821–1910)

INDEPENDENCE

Although Spain at first disavowed O'Donojú's actions as unauthorized, the date now recognized as that of separation of New Spain from Old Spain is in fact August 24, 1821.

The Mexican Empire, 1821–23. The first Mexican Empire spanned only a short transitional period from colony to republic. Independence had been the point on which republicans and conservatives alike could agree. The new constitutional monarchy shielded the conservatives from a Spanish government that had suppressed religious orders, tried clerical cases in civil courts, and decreed that the church could not acquire real property. Such a government was also palatable to the insurgents, whose major objective was independence.

Itúrbide became president of a council of regents, which convoked a Sovereign Constituent Congress. Deputies to the congress represented the intendancies, the name they retained during the empire. When representatives from the Central American intendancies decided that their areas did not wish to remain part of the Mexican Empire, they were allowed to withdraw and to organize their own independent governments.

On the evening of May 18, 1822, military groups proclaimed Itúrbide Emperor Agustín I, and on the next day a majority in congress ratified the "people's choice" and recommended that the monarchy be hereditary, not elective. Agustín I was crowned in a long ceremony on Sunday, July 21. The empire was recognized by the United States on December 12, 1822, when the Mexican minister was officially received in Washington. But even then Agustín's power and prestige were already ebbing, and conflict soon developed between the military hero Itúrbide and the primarily civilian congress. On October 31, 1822, the Emperor dismissed congress and ruled through an appointed 45-man junta. The act, which was condemned by many as arbitrary, provided discontented military men with a pretext to revolt. Among their leaders was Gen. Antonio López de Santa Anna, whom Agustín had first promoted for services in the Army of the Three Guarantees and later insulted in public. In Veracruz, Santa Anna proclaimed a Mexican Republic on December 2, 1823, and was supported by old guerrillas. Other military men had similar plans. Agustín was forced to reconvene congress and to abdicate. In 1824 he returned from European exile but was arrested and shot. This first epoch of independent Mexican national life thus foreshadowed many problems of the succeeding republic.

The early republic. When a republican constitution was adopted in 1824, the Mexican people had had little or no previous experience in self-government. Their economy was precarious; mining, a mainstay in colonial times, had declined, and widespread anti-Spanish feelings had caused an exodus of Spaniards, depleting both the nation's capital reserves and its pool of trained people. Political instability made borrowing abroad expensive, and nearly all public revenues had to come from customs receipts, which were pledged well in advance. As Mexico's national debt mounted, so did its problems. A vicious, seemingly unbreakable cycle marked the first half century of Mexican national life. Whenever public monies were insufficient to pay the army, its officers revolted, captured the government, and negotiated international loans. The high interest payments on such loans reduced available funds for education and other social and cultural improvements, which many Mexican leaders thought were urgent requirements.

Troubles of the new republic

The constitution of 1824 provided for a federal republic, consisting of 19 states, four territories, and a federal district; it also set a number of goals, toward which the nation subsequently inched its way. Although the monarchical idea survived for nearly half a century more, Mexico remained a democratic republic. The constitution abolished slavery, which was never a major issue, and enfranchised all inhabitants; Indians thus lost their special colonial status as wards of the government. Restrictive state legislation, however, excluded the great mass of peasantry from the political process; power rested in the hands of a small Creole and Mestizo (persons of mixed Spanish and Indian ancestry) elite.

Under various labels, two factions contended for control. Generally conservative, the Centralists favoured a strong central government in the viceregal tradition, a paid national army, Roman Catholicism as the exclusive religion, and minimal regional and state autonomy; they supported a union of church and state. Opposed to them were the Federalists, who favoured limited central government, local militia, and nearly autonomous states; they tended to be anticlerical and opposed the continuance of colonial *fueros*, which gave special status to ecclesiastics and the military and exempted them from various civil obligations.

The pendulum of power swung back and forth between the two groups. In 1824 Manuel Félix Fernández Guadalupe Victoria, a Federalist and a leader in the independence movement, was elected president. Centralists replaced Federalists in 1828. A Federalist revolt in 1829 put Vicente Guerrero in the presidential chair, but he was soon overthrown by the Centralists, who held power until 1832. In 1833 another change placed Federalists in power until 1836, when Centralists again regained control and held it for nearly a decade.

The age of Santa Anna: Texas and the Mexican War. After the downfall of Agustín Itúrbide, Mexican politics revolved for some time about the enigmatic personality of Antonio López de Santa Anna, a charismatic general with seemingly few fixed ideological or political beliefs.

Allied with the Federalists, Santa Anna was first chosen president in 1833, but, rather than serve, he placed the liberal vice president Valentín Gómez Farías at the head of the government until Farías and his group in 1834 attacked the privileges of the clergy. Then Santa Anna assumed his presidential post and nullified the anticlerical legislation.

Santa Anna was president when difficulties over Texas first began to mount. Under favourable terms, some 30,000 U.S. immigrants had populated that previously desolate area. Fearful that their growing numbers posed a threat, the Mexican government in 1830 closed the bor-

Problems over Texas

der to further immigration and imposed on the Texans oppressive restrictions that contravened the Mexican constitution. In March 1836 Texas declared itself an independent republic, and Santa Anna, the leading military figure of the day, gathered an army to crush the revolt. He met with initial success when he trapped a small Texas garrison at the Alamo and totally eliminated it, but he was defeated and captured by Texas forces in April 1836 and subsequently freed. Though Mexico made no further efforts to reconquer Texas, it refused to recognize its independence.

At that time a doctrine now known as Manifest Destiny was at its height in the United States. It expressed a belief that it was the destiny of the United States to occupy all the North American continent and perhaps all of Mexico. From Spain, in 1819, the United States had obtained Florida and New Spain's southeastern territory to the Mississippi; next it annexed the Republic of Texas in 1845, a move that caused the Mexican government to break off diplomatic relations. Santa Anna was overthrown for his apparent willingness to negotiate with the United States. The Centralists installed Mariano Paredes y Arrillaga.

Although the United States claimed that the southern boundary of Texas was the Rio Bravo del Norte, the fact is that before annexation Texans had not settled below the Nueces River. Shortly after his election in March 1845, United States Pres. James K. Polk tried to secure an agreement on the Rio Grande boundary and to purchase California, but the new Paredes government refused to discuss either matter. Polk then ordered United States troops to occupy the disputed territory between the rivers. When Mexican and United States patrols clashed in April 1846, Polk asserted that American blood had been shed on American soil—an outrage that required action. Less warlike politicians, such as the Illinois Congressman Abraham Lincoln, to no avail submitted resolutions asking Polk to point out the precise location of this outrage. Polk's congressional majority formally declared war on Mexico in April.

War with the United States

Without major difficulty, United States troops captured New Mexico and what the Mexicans called Upper California (now the state of California). Gen. Zachary Taylor led the main United States force to quick victories in northeastern Mexico. At that juncture the Paredes government was overthrown, and Santa Anna re-emerged as president in September 1846. Almost immediately, Santa Anna mobilized Mexican forces and marched northward, boasting that the superior numbers and courage of his men meant that he would sign a peace treaty in Washington. Although Taylor and Santa Anna fought a close battle at Buena Vista, Santa Anna was beaten and forced to retreat on February 23, 1847. Both sides sustained heavy losses.

A change in U.S. strategy left Taylor holding ground in northern Mexico; it was decided that Mexico could be beaten only by capturing Mexico City, via Veracruz. Gen. Winfield Scott was given command of that expedition. On April 18, 1847, he defeated Santa Anna in the critical battle at Cerro Gordo. Though Mexican resistance continued to be formidable, Scott captured Mexico City on September 14, 1847. Santa Anna went into voluntary exile, while a new Mexican government negotiated peace.

Dated February 2, 1848, the Treaty of Guadalupe Hidalgo terminated the war. Under its terms Mexico ceded all territory north of an irregular line of the Rio Grande and the Gila River across the Colorado to the Pacific. The United States paid Mexico $15,000,000 and assumed $3,000,000 in claims held by United States citizens against Mexico. At the time, the large area involved was lightly populated and economically unexploited.

After the war, Santa Anna figured in one more major episode before the political scene changed. In 1853 conservatives seized power and invited him to become dictator. Among other things, on December 16, 1853, Santa Anna decreed that the dictatorship should be prolonged indefinitely and that he should be addressed as "His Most Serene Highness." To raise funds for an expanded army, he sold the Mesilla Valley in southern Arizona to the United States for $10,000,000; this Gadsden Purchase, as it is now called, was the last significant boundary change of the Mexican Republic.

An era was ending. The death of Lucas Alamán on June 2, 1853, deprived the conservatives of their most important intellectual leader. On September 11 his distinguished colleague, José Mariáno y Mendivil Tornel, also died. These men, with other like-minded Mexicans, had sought to give their country a national culture and an economic independence that would free the nation from colonialism but retain the Spanish religious heritage. Though they played subordinate administrative roles, their collective impact on Mexico may have been more important than the antics of Santa Anna.

The reform. Since independence a new generation of Mexicans had been born; appalled at the easy victory the United States had won, the more thoughtful among them felt that Mexico's survival as an independent nation depended on fundamental reform. Among the new faces was Benito Juárez, a Zapotec Indian educated as a middle class liberal, who had moved to New Orleans and had discussed and planned Mexico's future with fellow expatriates. With no military force to implement their plans, they bided time until their opportunity came, in 1854, when Juan Álvarez, a surviving hero of independence, and Ignacio Comonfort, a political moderate, proclaimed a liberal rebellion against Santa Anna and forced him out of the presidency. (Santa Anna went to Colombia in exile in 1855; almost unknown, he returned to Mexico City before his death on June 21, 1867. Congress refused to pension his widow or to restore posthumously his military honours and titles.)

Neither Álvarez nor Comonfort, who followed him in the presidency, had any clearly defined program. The role of the returned expatriates was to act as a brain trust to carry out *La Reforma* ("The Reform"). Its aims were to abolish remnants of colonialism by removing special ecclesiastical and military privileges; to separate church and state by secularizing education, marriages, and burials; to reduce the economic power of the church by forcing it to sell its properties; to foster an economic development that envisaged Mexico as a country of yeoman farmers and small industrialists; and, above all, to establish a single standard of legal justice, based on laws passed by democratically elected representative assemblies.

Juárez was made minister of justice. Among his first reforms was the so-called Ley Juárez (November 23, 1855), which abolished *fueros* and the use of special military and ecclesiastical courts in civil cases. The minister of finance, Miguel Lerdo de Tejada, sponsored Ley Lerdo (June 25, 1856), which restricted the right of ecclesiastical corporations to own lands by decreeing that church lands not directly used for religious purposes must be sold and lands held in common by Indian communities (ejidos) be distributed to individual villagers.

Constitution of 1857

The reformers called a convention to revise the 1824 constitution, several provisions of which had been partially suspended or changed. A new constitution, which provided a legal base for the reform, was promulgated on February 12, 1857, but did not become effective until the following September 16. It prohibited slavery and abridgements of freedom of speech or press; it abolished special courts and prohibited civil and ecclesiastical corporations from owning property, except buildings in use; it eliminated monopolies; it prescribed that Mexico was to be a representative, democratic, republican nation; and it defined the states and their responsibilities. This constitution, which remained in force until it was modified in 1917, increased the power of the central executive.

Neither the religious nor the military accepted the 1857 constitution, and both inveighed against the reform, calling for retention of "religion and *fueros*." The church excommunicated all civil officials who swore to support the constitution. When civil war erupted, Comonfort went into exile after his efforts at compromise had failed; Juárez automatically succeeded him as constitutional president. The conservatives captured Mexico City and

set up a competing regime. Juárez and his government moved to Veracruz, where they controlled the customs receipts.

Foreign powers became involved in the Mexican struggle. On April 6, 1859, the United States recognized the Juárez government; Pres. James Buchanan permitted war material to be shipped to Juárez' forces. Americans were encouraged to serve the liberal cause as volunteers; Spain and France generally favoured the conservatives, as did Great Britain.

Juárez in July 1859 issued a series of decrees: all church property except buildings used for worship was to be confiscated without compensation; all marriages apart from civil were declared annulled; the formal separation of church and state was proclaimed; cemeteries were declared public property, and burial fees were abolished. Moneys from the sale of confiscated church property, though less than anticipated, speeded the end of the civil war. On December 22, 1860, the liberals won a critical battle, and, when the conservative president, Miguel Miramón fled, the conservative cause collapsed. The victorious liberal army of about 25,000 men entered Mexico City on New Year's Day, 1861. On his return (January 11) Juárez was greeted by an enthusiastic populace who welcomed the end of the long and devastating civil war and the re-establishment of government under the constitution of 1857.

French intervention. Exiled Mexican conservatives, who continued to intrigue, enlisted the help of a powerful ally, Napoleon III, the ruler of France who wanted to create a Latin league that would include the Mediterranean lands and the former possessions of Spain and Portugal in the New World as well. (The term Latin America dates from this time and concept.) With its strategic position and its economic potential, Mexico seemed especially attractive to the Napoleonic imperial scheme. A French bastion in Mexico would check the Manifest Destiny of the United States and provide a base from which Central and South American protectorates could be added. The fact that the United States was engaged in a civil war (1861–65) was a determining element. In 1861 Napoleon III was willing to believe the Mexican conservatives' assertions that the masses of Mexican people would support his intervention to restore religion and set up a monarchy.

Ambitions of Napoleon III

In Maximilian of Habsburg and his wife, Charlotte (Carlota), daughter of the king of Belgium, Napoleon found eager aspirants for the Mexican throne. With Napoleon's promise of support, Maximilian agreed to become emperor of Mexico if a plebescite showed that the Mexican people wanted him. Reluctantly, however, he renounced any future claim to Habsburg succession.

Meanwhile, France, Spain, and Great Britain prepared to send a punitive expedition to collect debts owed them in Mexico. Juárez in 1861 had suspended for two years all payments on a foreign debt of $80,000,000, a sum that excluded some questionable French bonds amounting to $15,000,000. The intervention was spearheaded by Spain, the forces of which landed at Veracruz on December 14, 1861 and were followed soon after by French and British contingents. When the allies fell into dispute over the $15,000,000 French claim for payment of the bonds, both Spain and Great Britain disengaged from the joint venture.

The French expeditionary force began its march toward Mexico City. When the Mexican army made a stand at Puebla on May 5, 1862, the French retreated to await reinforcements. Napoleon dispatched 30,000 more troops under the command of the French general Élie-Frédéric Forey. The Mexicans could not withstand French might, and on June 10, 1863, Forey rode as conqueror into Mexico City. The French rapidly secured much of central Mexico, forcing Juárez and his government to keep constantly on the move in the north.

French occupation forces set up an Assembly of Notables and a council of regents to govern Mexico. The assembly, as expected, offered the throne to Maximilian in the name of the Mexican people. Assured of Napoleon's continued military support and the economic backing of the British, Maximilian and Charlotte arrived in Veracruz on May 28, 1864, having passed through Rome to confer with the Pope before they embarked. On June 12 Emperor Maximilian was welcomed in Mexico City.

Emperor Maximilian

Maximilian attempted to follow a policy of national conciliation, hoping to unite Mexican factions and interests. But he proved too much a Habsburg to be an effective tool of Napoleon's schemes, too much a liberal to please the conservatives who had engineered his coronation, and too tainted by conservative sponsorship to win republican support.

Maximilian was perhaps less naive than he has been pictured. Not fully convinced that a majority of Mexicans welcomed him as emperor nor sure that he should place full reliance on French troops, he tried to create a Mexican rural guard and a separate imperial army around a nucleus of Austrian and Belgian volunteers. His proposal to reduce the number of regular Mexican army generals to 18 brought early disillusionment to the army, a mainstay of conservatism, which had expected Maximilian to be a puppet. The Mexican officers became further irritated when, with Maximilian's approval, French officers outranked them. At this time the Habsburg emperor and the French commander, Achille François Bazaine, were following conflicting army policies, Napoleon having ordered Bazaine to Mexicanize the army to cut time and costs of occupation.

At the same time, clerical groups, eager to reap rewards for their efforts on the Emperor's behalf, pressed him to reverse the reform. A papal nuncio from Rome arrived with a message asking that Maximilian revoke the anticlerical laws, establish Roman Catholicism as the exclusive religion, restore the religious orders, remove the church from its dependence on civil authorities, turn education over to ecclesiastics, and return properties confiscated and sold by the republicans. Replying that he, not outsiders, would decide such matters, Maximilian issued decrees establishing religious toleration, with Catholicism favoured but still dependent on the state. He confirmed that the previous sales of church property under the Reform laws were legal and that revenues the church had received from property Juárez had nationalized were to be ceded to the state. Thus, Maximilian's conservative support further dwindled because the clergy and their followers felt betrayed.

In September 1864 Maximilian took what amounted to a guided tour of the cities that supported his empire. The warm welcomes he received led him to conclude that a majority of Mexicans wanted peace and justice, which the activities of the republican guerrillas threatened. He therefore decreed on November 4 that, thenceforth, republicans would be considered bandits and brigands, subject to extreme penalties; this negated Maximilian's attempts to woo their supporters by inviting them into his council of state.

In 1865 French troops chased Juárez to, but not over, the United States border. Believing that the Mexican president had left national territory and that republicanism had therefore collapsed, Maximilian on October 2 issued a strong decree, ordering that all guerrillas be court-martialled and shot within 24 hours; the same penalties were to apply to persons who hid, aided, or otherwise helped them. Juárez had earlier issued a parallel decree (January 1862) against those who aided the French interventionists and imperialists.

French troops, though they were effective in keeping republicans on the outskirts of major productive areas, were also costly. Napoleon's Mexican adventure came under heavy press and parliamentary fire in France as costs in men and francs mounted without economic or political advantages to compensate for the expenditures. There was criticism from overseas as well; with its civil war ended, the United States turned to the international scene. William H. Seward, the United States secretary of state, brought mounting diplomatic pressure on Napoleon to withdraw French troops; in February 1866 Napoleon agreed to clear foreign troops from Mexico by November 1867. A United States request to the Austrian government to stop enrollment of volunteers for the

Withdrawal of foreign troops

Mexican imperial army also brought an affirmative response.

In liquidating his Mexican venture, Napoleon said that, since Maximilian had not carried out his part of the pact to bring peace and orderly government to Mexico, the French were relieved of their obligations for military and financial support. Stunned, Maximilian sought to have the decision reversed. The empress Charlotte tried without success to persuade the French ruler to honour his solemn pledge. From Paris she travelled to Rome to plead with the Pope; there she went mad and was taken to Belgium, where she lingered insane until her death in 1927. Bazaine, ordered to withdraw all French troops immediately, auctioned off military material not worth shipping to France—horses, saddles, etc.—and destroyed large supplies of powder and projectiles rather than turn them over to Maximilian. In February 1867 Bazaine left Mexico City, and by March 12 all 28,690 men had embarked. Napoleon made Bazaine the scapegoat of the Mexican fiasco, blaming its high costs and lack of results on his mismanagement, and implied personal dishonesty.

As French power withdrew, republican forces reconquered Mexico, and Maximilian was left with only a regiment of Austrian hussars, a battalion of infantry, and a small army of relatively untrained Mexican draftees. After first considering abdication, Maximilian decided to defend his imperial status and his honour as a Habsburg by making as strong a stand as possible, though planning, in the event of defeat, to negotiate an honourable exile. With these resolves he concentrated most of his troops—9,000 men—at Querétaro, a city loyal to the imperial cause. On May 5, 1867, the republican forces laid siege, initially with 32,000 men, later with an additional 10,000. By May 14 the starving imperialist force, reduced to about 5,000, had decided to withdraw and take a stand in the mountains. A disaffected imperial officer, in return for a promise that Maximilian be spared, placed republican soldiers, whom he passed off as relief troops, at strategic places in Querétaro. The siege ended the next day when Maximilian and his generals surrendered.

Under Juárez' decrees of 1862, Maximilian and his two leading generals were court-martialled and sentenced to death by firing squad. President Juárez refused to be swayed by the petitions for mercy that poured in from foreign governments. He wanted to demonstrate that Mexico could act independently; that, as the reform contended, all men were equal under law; and that foreign monarchical adventures in Mexico were futile. Maximilian and the generals were executed on June 19, 1867, terminating a bizarre interlude of Mexican history.

Emperor Maximilian left few permanent legacies. He did beautify and rehabilitate Mexico City, and his castle at Chapultepec Park became a national historical museum overlooking the broad avenue he planned—ironically named Paseo de la Reforma.

The restored republic. At least 50,000 persons lost their lives in the struggles between republic and empire, and when Juárez re-entered Mexico City on July 15, 1867, his immediate task was to abate the rancors of civil war. The vindicated Juárez regime took few major reprisals—principal imperialists were fined, some were imprisoned for short terms, and a few were exiled. One of Juárez' first acts was to start rebuilding the shattered economy. In an era of goodwill engendered by the sympathy and aid the United States had extended to the Mexican cause, the claims of the two countries against each other were settled by peaceful arbitration. Diplomatic relations were gradually re-established with Europe; new treaties were aimed at furthering trade.

Rebuilding the republic

In December 1867 Juárez was re-elected president. Apart from trying to foster political tranquillity, his main aims were to improve public education and to put the economy on a sound footing. To avoid the problems of dogma and religious opinion that had divided Mexicans, Juárez entrusted the development of a national educational system to Gabino Barreda, a follower of the French thinker Auguste Comte, who had said that the human mind and society passed through three successive stages—religious, metaphysical, and positive. Known as Positivists, Barreda and his followers contended that the reform, by displacing the church and militarism, had done away with the earlier two stages and that Mexico was in the third, or positivist, stage. The public-education law for the Federal District, which was to serve as the national model, stressed the secular state as the inculcator of scientific ethical norms, with "Liberty, Order, and Progress" as the means, base, and product of the system.

The chief architect of economic rehabilitation was Matías Romero, who had been Juárez' minister in Washington, and who believed that Mexico's development was dependent on three basic elements: immigration, communication networks, and the exploitation of natural resources. In 1867 and 1868 the government renewed concessions to British capitalists for the completion of the Veracruz–Mexico City railway and issued concessions for others; it authorized the opening of new roads and the extension of the telegraph system. Work was begun on reforming the tax systems and tariff schedules.

The re-election of Juárez in 1871 was contested more heatedly than that of 1867 had been. Thereafter, despite formidable opposition in congress, tariff reform was approved, as was Mexico's adoption of the metric system, which ended the chaotic colonial system of weights and measures.

After a short illness, Juárez died suddenly on July 18, 1872, his death closing one era and opening another. Behind him lay Mexico's long colonial history and its partial survivals through the early 19th century. The notion of a Mexican monarchy had been forever buried with Maximilian. Under Juárez, Mexicans had begun to modernize the economy and some of the social institutions, to expand rail, road, and telegraph networks, and to develop secular education.

Juárez' death also brought temporary political peace. Without incident, Sebastián Lerdo de Tejada, the president of the supreme court, and next in line of succession, was sworn in as acting president on July 19. Congress immediately began to lavish posthumous honours on Juárez, who by his innate abilities and great strength of character had led his people through unprecedented travail. He remains a major figure in the history of Mexico.

Temporary political peace

A national election placed Lerdo in the presidential chair in his own right on November 16, 1872. The course Juárez had charted remained unchanged. On New Year's Day, 1873, the Veracruz–Mexico City railway was inaugurated. Other works were commissioned. Congress and the executive branch of government continued to dole out railway and telegraph concessions. To safeguard the nation against future bloodshed, congress on May 31 added specific reform laws to the constitution of 1857—church and state were explicitly declared independent of one another; freedom of religion was proclaimed; church acquisition of real estate was abolished; religious oaths were banned in civil courts; forced labour was forbidden; and liberty of man in respect to labour, education, and religion was declared inviolable. The degree to which the reform had triumphed was evidenced by the fact that no national movement developed against these additions to the organic laws. The Lerdo government in 1874 renewed diplomatic relations with France, Spain, and Prussia.

The age of Porfirio Díaz. From 1876 until a political revolution unseated him in 1910, the personality of Porfirio Díaz dominated the history of his country. Like Juárez, Díaz was a poor Indian from Oaxaca but of Mixtec rather then Zapotec heritage. Educated locally, he had chosen a military career and had become an outstanding general in the republican cause against the French intervention and empire. Although he vied for the presidency against Juárez in 1867 and again in 1871, their ideological differences were not great. When in 1875 Lerdo ran for re-election, Díaz led a successful revolt and assumed the presidency in November 1876.

Díaz took the blueprint for Mexico's future that Juárez and Lerdo had elaborated and implemented it. While clearing out pockets of political resistance, he turned the presidency over to Manuel González, a companion in arms. Díaz won the election again in 1884 and was regu-

larly returned to that office through 1908. During his long regime he scrupulously kept democratic and constitutional forms intact, partly in the conviction that it was the president's duty to train the unready Mexican people to use them properly.

The *científicos*

Around him Díaz gathered many intellectuals (the *científicos*), who stressed the need for rational planning and development. The emphasis was on economic development to assure social progress. How such development was to be achieved was translated into one of Díaz' political slogans, "pan o palo" ("bread or the club"), meaning that acquiescence to official policies would insure livelihood, even wealth, but failure to agree would bring sure reprisals—harassment, imprisonment, death. Another slogan was "few politics, much administration." Liberty was dropped from the earlier positivist triad of liberty, order, and progress. It was the price the Mexican people were expected to pay for the benefits the *científicos* policies would provide.

Capital, though badly needed, could not be attracted until Mexico had tidied up its international and national fiscal affairs. Mexican finances were placed on a solid base, and a stable currency was established. With guarantees of political and social tranquility, foreign investment was encouraged and obtained. European and United States funds built some 15,000 miles of railways, provided electricity and streetcars for the cities, created industrial complexes, rehabilitated port facilities, and developed the mining of industrial metals. Early petroleum concessions to foreigners laid the groundwork for serious problems later, when world navies shifted from coal to oil and when automobiles were mass produced.

A complex mechanism in which all major and most minor decisions rested in the hands of the president evolved during the first two decades of the Díaz regime. The success of the practice rested on self-interest; Díaz made it worthwhile for everyone to support the system. For the most part, the small body of intellectuals was absorbed into the expanding bureaucracy or the subsidized press. The army and the church were made handmaidens of the regime, rather than its adversaries; generals were encouraged to become entrepreneurs. While retaining the reform laws on the books, Díaz was purposely conciliatory toward the church and allowed it to regain some of its former economic power without letting it develop significant political influence.

The regime also perfected instruments of repression and control, though for many years it used them sparingly. Forced military conscription lay in the hands of the president's appointees. Troublesome elements such as the Yaqui Indians were inducted en masse and shipped as cheap labour to the sisal plantations of Yucatan or the tobacco fields of Oaxaca. Governors were personal appointees of the president. Their actions were monitored by *jefes políticos* ("political chiefs"), who reported directly to the president and on his authorization intervened in municipal and state affairs. An elite constabulary, the *rurales*, like the Texas Rangers and Canadian Mounted police, created a myth of ubiquity that eliminated the brigandage and banditry characteristic of earlier 19th-century Mexican countrysides.

In an era in which material success was highly regarded, Díaz' accomplishments were praised, but his popularity began to decline, perhaps about 1895. Prosperity had been pre-empted by a relatively small group, many of whom were foreigners. The Mexican economic and social elite self-consciously aped European (especially French) modes of dress, education, and even language. Between the affluent and the growing urban and rural proletariat there was an expanding middle class body. Meanwhile, a new generation, which could recall none of the chaos of pre-Porfirio days, began to question the system. As criticism increased, so did repression. It was from this interaction that the Mexican Revolution resulted.

PRECURSORS OF THE REVOLUTION

From about 1900 a majority of Mexicans began to question the nation's apathetic acceptance of the Porfirian peace. The earliest and most vocal critics were Mexican radical groups, perhaps the most important of which called itself Regeneration. Its members were anarchists who adapted their dogmas to the Mexican scene. While always small in numbers and often ineffective in actions, this group had great influence. Many of the reforms and programs it advocated were embodied in the Mexican constitution of 1917.

The Regeneration group

The leader of the Regeneration group was Ricardo Flores Magón, who had been born in Oaxaca of an Indian mother and a Mestizo father and had been sent for further education to Mexico City, where he had turned to idealistic student activism. For leading a small demonstration against the re-election of Porfirio Díaz in 1892, he was jailed for the first of many times. The group's movement took form in 1900, when Camilo Arriaga, a well-to-do engineer in San Luis Potosí, organized first a club and then a small party to restore the liberalism of Juárez. Arriaga called a national meeting of liberal clubs in 1901, and a short time later most of the small band were jailed, and their newspaper, *Regeneration*, which Flores Magón edited, was suppressed. After they had served their prison sentences the young radicals fled to the United States and Canada, settling for a while in St. Louis, Missouri, where they formally organized the Mexican Liberal Party. Although its name suggests the earlier reform, in fact it was anarcho-syndicalist, dedicated to the overthrow of the Mexican government and the total renovation of Mexican society.

In 1906 the Regeneration group published a comprehensive program in the form of a manifesto that had wide, if clandestine, circulation in Mexico. It advocated a one-term presidency, guarantees of civil liberties, breaking the hold of the Catholic Church, vast expansion of free public education, and land reform. It asked that Mexican citizenship be a prerequisite to property ownership and that unused land be distributed to the landless. The manifesto proposed confiscation of the wealth that Díaz and the *científicos* had illegally acquired, the abolition of child labour, guaranteed minimum wages, and bettered working conditions for workers. In muted tones it criticized capitalism as a system of exploitation. The Regeneration group drew its main lines of thought from Mikhail Bakunin, a Russian revolutionary writer who believed that the power of any institution, including government that exercised controls over individuals, should be reduced.

Many charges by the Regeneration and similar groups were borne out when the Díaz troops, in bloody fashion, broke strikes in the textile region of Veracruz and the mining regions of the north. Several of these strikes had been fomented by Regeneration organizers at the same time that muckrakers in the United States were exposing the evils of corrupt government, big business, and other aspects of life in the United States and abroad. Possibly to refute their unfavourable reports, Díaz gave an interview in 1908 to a United States reporter that became a milestone in pre-revolutionary history. To blunt charges of one-man rule, Díaz very carefully but clearly said that in his view the time had come for Mexico to advance toward democracy, that he would welcome an opposition party in the 1910 presidential election, that he would be most happy to sustain and guide the opposition party, and that to inaugurate a democratic government in Mexico he would forget himself. This fell like a bombshell in Mexico, where most readers failed to note that he had not specified a time. It was widely believed that this implied he would not run for the presidency in 1910. Mexican newspapers not only reprinted the interview but also began openly to discuss Mexican political questions, long forbidden by the regime. Pamphlets and then books added to the political rumblings.

Political opposition to Díaz

Two main opposition groups soon emerged. One backed Gen. Bernardo Reyes as vice presidential candidate over Díaz's handpicked candidate. As an efficient and stringent governor, Reyes had transformed the state of Nuevo León into a prosperous, progressive model; he forthrightly opposed *científico* theories and practices and had initiated a state workman's compensation law.

The other main party, anti-re-electionist, had been cre-

ated largely through the efforts of Francisco I. Madero, then a political unknown, whose efforts elevated him to the highest place in the revolutionary pantheon as the "Apostle of Democracy." Born into one of the ten richest families in Mexico, whose agricultural enterprises spread over much of northern Mexico, Madero was educated in the United States and France. In his own right he became an enlightened entrepreneur and amassed a considerable personal fortune.

Madero became concerned with how badly Mexico was faring in comparison to the rest of the world. Mexican food prices were rising, and rural and urban standards of living were dropping. He attributed Mexico's retrograde position to the prolonged political dictatorship. He helped journalists to expose these matters and provided considerable early financial support to the Regeneration group, but he disassociated from them after about 1907, when it became clearer that they intended to destroy, not reform, the system.

Madero, setting about to organize a national party to compete in the 1910 elections, published *La Sucesión Presidencial en 1910* ("The Presidential Succession in 1910") as a campaign document, two-thirds of which dealt with the history of Mexico and the corrupting influences of absolute power and the rest with his program to revive the democratic usages that had atrophied for so long. The initial aim was to win the vice presidency.

Despite harassment, Madero carried on a vigorous and wearying campaign in the summer of 1909. During an interview with Díaz, he was surprised by the dictator's advanced old age and his remoteness from current issues. Díaz' condition and the enthusiasm of Madero's crowds led the Anti-Re-electionists to modify their goals. Rather than accept Díaz as the inevitable president in 1910, they decided to try for the presidency themselves.

On June 14 Madero was arrested and jailed and thus became the martyr and victim of the system he was trying peacefully to change. Since it was perfectly clear that Díaz was not going to permit free and honest elections, Madero and his followers decided that the only hope of improving Mexico was through armed revolt. On October 4, 1909, the Chamber of Deputies, which had assembled as the electoral college, declared that Díaz had been re-elected. On October 5 Madero managed to escape from San Luis Potosí jail. He arrived on October 7 in San Antonio, Texas, where with aides he prepared and issued, as of the day of his escape, the Plan of San Luis Potosí, which proclaimed the principles of "effective suffrage, no re-election." Madero declared that Díaz was illegally president of Mexico. Designating Sunday, November 20, as the day when citizens should take up arms against the government of Porfirio Díaz, he promised that a successful revolution would institute political reforms.

The Plan of San Luis Potosí

But on November 20, the official birthday of the Mexican Revolution, no mass uprisings took place. Small bands of guerrillas, most of them in northern Mexico, kept the rebellion alive while Madero used his family fortune to supply them with arms from Texas. When the guerrilla bands combined, they began to defeat Federalist forces, who held most of the strategic rail lines, especially those emanating from Ciudad Juárez, on the United States border, where the Federalists troops had consolidated. Until the revolutionists laid siege to that city, no more than 2,500 armed men were engaged in the Madero revolution.

III. Mexico since 1910

THE MEXICAN REVOLUTION AND ITS AFTERMATH, 1910–40

When armed outbreaks initiated the Mexican Revolution in 1910, their immediate object was to replace Díaz as president. What began as a relatively simple political movement broadened into a major economic and social upheaval that gave Mexico many unique characteristics. During the long struggle, the Mexican people developed a sense of identity and purpose, unmatched by any Latin American republic. Many reforms had been established by 1940, when the goals of the revolution were institutionalized as guidelines for future Mexican policies.

The military revolution. On February 14, 1911, Madero crossed into Mexico near Ciudad Juárez to head his forces. There they learned how debilitated the Díaz army had become; led by aged generals, the Federalist troops lacked discipline, cohesion, unity of command, and effectiveness. Under these circumstances, the revolution gained ground and momentum. On May 10 the Federal commander surrendered at Ciudad Juárez. That marked the beginning of the end. An agreement negotiated with the Díaz regime provided that Díaz would resign, that an interim president would call general elections, and that revolutionary forces would be discharged. On May 25 Díaz resigned and sailed for Paris, a bewildered former hero. Several revolutionary bands, including that of Emiliano Zapata, resisted being disarmed by the Federal army.

In the heated political atmosphere, congress on November 2 declared that Madero had won the presidency. The new government was able to withstand constant attacks from the right and left for only 15 months. A series of unsuccessful counterrevolutionary revolts culminated in a successful plot in February 1913. Following ten days of cannonading the heart of Mexico City, with high civilian casualties, Victoriano Huerta, commandant of government forces, betrayed Madero and arranged for his arrest and that of his vice president so that Huerta could assume the presidency himself. These plans were made with the knowledge, if not the connivance, of the United States ambassador, Henry Lane Wilson, who was thus defying Pres. William H. Taft's instructions to remain aloof from domestic Mexican politics.

Shortly thereafter, presumably on Huerta's orders, Madero was shot while being transferred from one prison to another. His death rekindled revolutionary fires. In northern Mexico, Venustiano Carranza, refusing to recognize Huerta as president, demanded that the office be elective, as specified in the constitution. Former chieftains such as Pancho Villa made loose alliances with Carranza. The revived revolution took on highly local and regional aspects.

The new president of the United States, Woodrow Wilson, was determined to oust Huerta and, on flimsy pretexts, landed United States troops at Veracruz and occupied it. All of the revolutionary leaders except Villa rejected this external intervention in a national struggle. The combined revolutionary forces unseated Huerta in 1914 but then split over who was to exercise presidential power. Zapata in Morelos and Villa in the north joined to fight the revolutionary groups under Carranza, the most important of which was headed by Gen. Alvaro Obregón, a former schoolteacher. Obregón won a decisive victory over Villa at Celaya in April 1915 but failed to bring the civil war to an immediate end.

Split among revolutionary groups

The Constitution of 1917. With most of central and southern Mexico under constitutionalist control, Carranza in 1916 convoked a constituent congress in Querétaro to revise and update the constitution of 1857. In the course of fighting, the economic and social demands of the radical precursors had become common slogans as contending revolutionary bands bid for popular support. The constitution of 1917 incorporated the aspirations of those groups involved in the revolution. A major concern of Zapata's followers was land reform. Carranza's advisors had prepared a draft document that included not only most of the revolutionary decrees about land reform but also the most advanced European social legislation.

The constitution of 1917 specifically incorporated the major features of the 1824 and 1857 charters regarding territorial organization, civil liberties, democratic forms, anticlerical and antimonopoly clauses, etc. To avoid abuses such as those that had occurred under Díaz, the office of vicepresident was suppressed, as was the system of *jefes políticos*. The constitution completely reversed the concept widely held in Mexico and elsewhere that government should take only a limited, passive role. Its philosophy was that the national government had an obligation to take an active role in promoting the social, economic, and cultural well-being of its citizens. Article 3

sketched a vast plan of secular, free, compulsory public education. Article 14 reaffirmed the sanctity of private property and contracts, but article 27 interjected concepts of social utility and national benefit to limit the untrammelled use of private property. The most important new concepts came in articles 27 and 123. The former reasserted national ownership of subsoil resources and outlined alternative land-reform and agrarian programs. The latter, the magna carta of labour and social welfare, was set apart to highlight its importance; in addition to guaranteeing minimum wages and the right to organize and strike, it gave labour social status and destroyed the concept of it as an economic commodity to be bought at the lowest rates to maximize profits. Article 123 also outlined a comprehensive system of social security, including public-health and welfare programs. Reflecting the nationalistic feelings of the revolutionaries, foreigners and foreign interests were placed under limitations. Article 33, for instance, permitted the president to deport foreigners at will.

The constitution of 1917, promulgated on February 5, thus set the goals toward which presidents were to work. As expected, Carranza was elected president and given de jure recognition by the United States. When Zapata was betrayed and killed in 1919, the last organized opposition to the Carranza-Obregón reorganization dissolved. Pancho Villa retired from active campaigning after his raids across the border, especially one in Columbus, New Mexico (March 9, 1916), had failed to embroil the United States in conflict with Carranza. Villa was ambushed and shot in 1923.

The northern dynasty: Obregón and Calles. When Carranza failed to move toward immediate social reforms, General Obregón enlisted two other powerful north Mexican chieftans, Plutarco Elías Calles and Adolfo de La Huerta, to join him in an almost bloodless coup; together they formed the northern dynasty. Carranza was killed as he fled from Mexico City, and Obregón took office as president December 1, 1920. The dynasty agreed that peace was needed to rehabilitate Mexico from the devastations of nearly a decade of civil upheaval. By bribery and minimum force, Obregón placated the horde of revolutionary generals and colonels.

Overthrow of Carranza

Under Obregón a start was made toward fulfilling the ideals set forth in the constitution. Administrative machinery was set up to distribute land to the landless and to restore communal holdings (ejidos) to villages. The government supported the Regional Confederation of Mexican Labour (CROM). José Vasconcelos, who was named minister of education, was to implement the program of rural education. He sponsored a cultural program that brought Mexico worldwide fame and importance. Radical mural painters such as Diego Rivera, José Clemente Orozco, and David Alfaro Siqueiros, who were commissioned to portray Mexican and especially revolutionary history on public buildings, exalted the Indian past, as did creative writers.

At the end of his term, Obregón stepped aside for Calles, after La Huerta's unsuccessful revolt in 1924 had eliminated him from the coalition. Calles' presidency followed the same general lines as had Obregón's. Land distribution was stepped up, an irrigation program was begun, and in 1925 renewed pressure was put on the petroleum companies to exchange for leases the titles they had obtained from Díaz or La Huerta. Problems with the Church developed when Calles instituted vigorously anticlerical measures; in retaliation, the church suspended all religious ceremonies and approved and possibly sponsored a rebellion in western Mexico known as the Cristeros. Mediation of the church–state controversy was unofficially accomplished by Dwight W. Morrow, the United States ambassador to Mexico, whose sympathetic and skillful diplomacy also eased tensions between the two countries.

In 1928 the presidential term was extended from four to six years, and the doctrine of "no re-election" was modified to mean "no successive re-election." Obregón was the successful presidential candidate, but, before he could take office, he was assassinated by a religious fanatic. With Calles unable to succeed himself, a peculiar, nearly unique Mexican single-party system came into being.

Single-party system

Calles formed the National Revolutionary Party, a coalition of regional and local military bosses and labour and peasant leaders. To safeguard the gains of the revolution, he excluded the church and other possible reactionary elements. With Calles as chief, the official party governed in the name of the revolution. A congress, drawn from party ranks, named successive, short-term presidents to fill out the Obregón term.

In the period 1928–34, a worldwide depression and increasing personal vested interests caused many of the older, now conservative revolutionaries, including Calles, to go slowly in implementing the reform mandates of the constitution. The ruling clique continued to be militantly anticlerical, but government support was withdrawn from the Regional Confederation of Mexican Labour, which disintegrated. On the positive side, the Calles years saw the beginnings of an irrigation and road-building program.

Resurgence under Cárdenas. Within the revolutionary family, Gen. Lázaro Cárdenas was a respected if not outstanding revolutionary. Having quietly and faithfully worked his way up the ladder of politico-military power during the Obregón and Calles years, he seemed a safe candidate in the 1934 elections. He was also acceptable to a powerful group within the party, who drafted a six-year plan incorporating extended revolutionary reforms. Although his election was a foregone conclusion, Cárdenas astonished everyone by waging a vigorous campaign, visiting even remote hamlets to bring the six-year plan to the people.

After his election Cárdenas strengthened the labour movement and took other steps that defied Calles. When the inevitable power test came, Cárdenas won, and Calles fled into temporary exile, after which Cárdenas renamed and reorganized the party on a functional national basis —the agrarians formed one sector; labour another; the military yet another; and bureaucrats, teachers, and miscellaneous groups made up the popular sector. The four sectors agreed to support the slate of candidates the party designated. The local, state, and national representatives made party policy and ratified the President's choice of candidates.

With massive popular support and with the power elites under control, Cárdenas tirelessly pushed toward revolutionary goals. He and his advisers elaborated the land-reform programs; using land expropriated from private owners, they created communal cooperatives and gave them ejido status. By the end of his term about 40 percent of the rural working force was under the ejido program. Cárdenas also nationalized railways and placed them under the management of labour.

Perhaps Cárdenas' single most spectacular action was the expropriation of foreign petroleum companies following a labour dispute in which unions demanded not only wage increases but also participation in what management considered its exclusive role. A series of court cases and special boards found in favour of the workers. When the companies refused to accept the decisions, declaring they could not and would not comply, Cárdenas on March 18, 1938, decreed expropriation of their holdings, thus nationalizing the petroleum industry. Petroleos Mexicanos (Pemex), then a small agency, was designated to administer the industry for the nation. The British government, whose nationals had a far larger stake than United States firms, immediately broke diplomatic relations. After a short delay the United States government, under Franklin D. Roosevelt, indicated that, if Mexico would make prompt and fair payments, he would not intervene diplomatically on behalf of the oil companies nor would he suspend purchases of Mexican silver, a main source of Mexican foreign exchange. This sympathetic reaction was based largely on the advice of the United States ambassador, Josephus Daniels, who as secretary of the navy had ordered the occupation of Veracruz in 1914 but who over the years had become a warm friend of the Mexican people.

Expropriation of foreign petroleum companies

Mexicans consider March 18, 1938, as the anniversary

of Mexican economic independence. Cárdenas, by taking this bold action, had not only restored an important resource to national patrimony but also showed that national honour and dignity could not be flouted by foreign entrepreneurs, however powerful. After engaging in propaganda campaigns, boycotts, blacklists, and other forms of economic warfare, the oil companies eventually were forced to settle their claims on essentially Mexican terms. Once the initial bungling was over, Pemex developed the capacity to fuel the industrial revolution that marked Mexico's next epoch.

Gen. Manuel Avila Camacho, whom Cárdenas supported, and Gen. Juan Andreu Almazán fought a close and bitter contest for the presidency in 1940. When Almazán lost, he sought United States backing for a revolution. But to emphasize the United States position toward Avila Camacho and Mexico, Roosevelt sent Vice President Henry A. Wallace to attend the inauguration. When Cárdenas stepped down from the presidency in November 1940, a major chapter of the Mexican Revolution had closed.

The Avila Camacho domestic policy was one of conciliation. While retaining earlier forms, he placated Catholic groups by announcing, "I am a believer." Under the doctrine of political unity and harmony, he brought back from exile various former presidents; with linked arms several of them, including Calles and Cárdenas, appeared on the National Palace balcony to greet a cheering crowd. Avila Camacho also mounted campaigns against illiteracy and other social deficiencies, but the overriding issues of the day were diplomatic and economic; the Cárdenas resurgence had increased Mexico's self-respect but had left its economy in a shambles.

WORLD WAR II (1941–45)

World War II brought profound changes to Mexico. Its basic economic structures were transformed, as to a lesser degree were its political, social, and cultural realms. Industrialization and urbanization were accelerated to meet wartime needs.

Industrialization and urbanization

The successes of Hitler's Fascist forces in Europe and the rising power of Japan in the Orient affected many of Mexico's national policies in 1939–40. While not yet an active belligerent, the United States saw itself as the arsenal of democracy and was gearing up its industrial plant for war. Many necessary raw materials came from Mexico.

For their mutual benefit, Mexico and the United States in November 1941 signed a General Agreement that liquidated most outstanding quarrels between the two countries. The old problem of United States agrarian claims was resolved; a reciprocal-trade treaty was outlined, and the Mexican peso was stabilized and supported to maintain a constant dollar ratio. The United States agreed to continue silver purchases at world prices and to provide long-term loans to buttress Mexico's economy. Separate agreements were reached on military aid, primarily to professionalize the Mexican army and its small air force; as a step in that direction the military sector was dropped from the official party, to eliminate the army as a bloc in politics, and officers and men were represented through the diversified popular sector.

The United States declared war on the Axis powers in December 1941. Mexico also became an active belligerent after Germany sank some of its tankers. A Mexican–North American joint defense committee planned cooperative operations to be carried out in case the Japanese attacked northern Mexico and the Pacific states. The former president Lázaro Cárdenas served on that committee and became secretary of defense when that post was created on January 23, 1944. A draft law requiring one year of military training provided trained reserves for the Mexican army, which was forced to modernize. A token Mexican air unit operated with the United States in the Philippines. But Mexico's major contribution to the war effort was to supply raw materials for the United States industrial plant. Mexico's railways had not been refurbished since the military phases of the revolution, and the frequency of wrecks highlighted the extent of deterioration under inept workers' administration. Joint planners rehabilitated the system, which remained nationalized under the direct management of the Mexican government.

With most of the free world producing war material, consumer goods were unavailable. To fill this vacuum, Mexican light industry developed, almost exclusively with Mexican capital. The new industrialists were nationalistic, patriotic, and able. They represented a new and growing interest in the old political equations.

As a recognized ally, Mexico took the lead in Latin America in preparing for the formation of the United Nations. It also supported the 1948 changes in the Organization of American States, the United Nation's regional body.

POSTWAR MEXICO (SINCE 1945)

From the end of World War II to 1970 Mexico's population about doubled; its cities continued to grow, and the nascent industrialism spawned by the war became a major element in the economy. The military increasingly faded into the background as arbiters of national policy, and Mexico had an unbroken line of civilian presidents, beginning with the election of Miguel Alemán in 1946. With him, the emphasis shifted from the Cárdenas approach of dividing Mexico's small agricultural land area among many hands to the development of new resources. Massive hydraulic projects were undertaken to furnish electric power, create high-yield irrigated lands, provide flood control, and become the nuclei of regional agricultural–industrial complexes. The nationalized oil industry changed from one aimed primarily at producing petroleum for export and processing abroad to a vast petrochemical enterprise geared to meet burgeoning domestic needs. Economic integration was accomplished by the extension of railroad, highway, and airline networks to nearly all regions of the republic. As the population increased, the domestic markets expanded.

Civilian presidents

Political changes. Postwar Mexico was marked by a continuity of basic policies unprecedented in Mexican history and by the peaceful constitutional transfer of presidential power from one civilian regime to the next. Presidents following Miguel Alemán were Adolfo Ruíz Cortines (1952–58), Adolfo López Mateos (1958–64), Gustavo Díaz Órdaz (1964–70), and Luis Echeverría Álvarez (1970–), all of whom had worked upward through party and bureaucratic ranks and most of whom had gone to the presidency from the ministry of interior. During the campaign periods before the July 1 elections, all followed the Cárdenas precedent of making extended national tours to confer with state and local leaders about their programs.

President Alemán was the major architect of new departures in the official party. Under him the name was changed from the Party of the Mexican Revolution to the Party of Institutionalized Revolution (PRI). This reflected Mexican thought that the task of the leaders was to make the institutions created by earlier revolutionaries produce the results they envisioned. Suffrage in Mexico was nearly doubled when Ruíz Cortines enfranchised women, who first voted in the national elections of 1958.

While opposition was not stifled, it simply had little to offer as an alternative to the well-oiled and responsive single party. For the same reason, the appeals of Soviet or Chinese Communism and Cuban Castroism elicited only token response. They were viewed as exotic foreign ideologies, suspect from the outset for being non-Mexican; most of their ultimate utopian goals had been stated in the 1917 Mexican constitution.

The economy. Mexico's economy combined private enterprise, state capitalism, and cooperative combinations of the two. Certain areas, such as mining, remained almost completely in the hands of the private sector, while such activities as transportation, communications, petrochemicals, and electric-power production were state owned and operated, usually by semiautonomous executive agencies. Private enterprise controlled most manufacturing, both heavy industry and consumer goods. A flexible government instrument, the Nacional Financiera, played an important role in furnishing capital for needed

Governmental and private ownership

Pres. Gustavo Díaz Ordaz of Mexico and Pres. Lyndon Johnson of the U.S. shake hands after completing legal steps necessary for relocating a section of the U.S.–Mexican border between El Paso, Texas, and Ciudad Juárez, Mexico, on October 28, 1967. industries, either by purchasing shares in the enterprises or by directly launching the desired activity and then transferring it to private investors. A number of international corporations expanded into Mexico under the general doctrine that they would supply expertise for Mexican management and not more than half the capital. Thus, automobile-assembly plants and even mass merchandising, such as Sears, Roebuck stores, were joint foreign–Mexican ventures.

The industrialization process had not been fully completed by 1970. Among Latin American nations, however, Mexico was a close second to Brazil in gross national product and in per capita gross national product was outranked only by Argentina, Chile, Panama, and Venezuela. Comparison on an international scale with countries of comparable population, however, indicated that Mexico was still relatively underdeveloped.

Urbanization. The lure of better wages in such industrial centres as Mexico City, Puebla, Guadalajara, and Monterrey sped the growth of towns to cities and cities to regional metropolises and made the metropolitan area of Mexico City, with perhaps 4,000,000 people, among the world's largest. Rapid urbanization imposed serious strains on housing facilities, social services, and transportation systems. A subway system, inaugurated in 1969 and extended in 1970, partially alleviated the mass-transit problem in Mexico City. Industrialization and urbanization increased atmospheric pollution, which became especially severe in the Mexico City area, where surrounding mountains trapped the smog.

Sociocultural policies. National outlays for education began to grow in 1921, when Obregón created the National Ministry of Education; military expenditures were reduced as those for education rose. Obregón had to spend nearly half the federal budget to control the military, whereas López Mateos allocated only 6 percent to military needs. The major change came under Alemán, after Avila Camacho had reduced and professionalized the army; the per capita outlay in pesos of 1950 value stabilized at about 14.5. Educational outlay in the early years took a proportionately significant share of expenditures, but, as government revenues were small, the per capita outlay was also limited. The highest percentage outlay came under Cárdenas. Subsequent governments spent about 10 percent for education, but increased public revenues raised the per capita figure to nearly twice that expended for the military. Outlays for education, both percentage and per capita, began to outstrip the military under Ruíz Cortines.

Educational gains

With each new administration, gains were made in equipping the nation with sufficient classrooms and adequate teaching staffs at all levels, but by the 1970s much still remained to be done. Perhaps half the eligible elementary school children lacked facilities to attend school at all, and fewer than half of those in school went beyond the second grade; fewer than 20 percent of the eligible pupils completed the six grades of primary education. Yet, compared to 30 or 60 years earlier, the positive accomplishments were significant.

International relations. Although it outranked France in population and nearly equalled the United Kingdom in the 1970s, Mexico was still considered to be and seemingly was content to be a small world power. It faithfully discharged its duties in such multilateral organizations as the United Nations and the Organization of American States, where it pursued a course independent of the United States and where its leadership was respected.

By 1970 Mexico maintained diplomatic relations with more than 60 countries, including Cuba. Its single most important diplomatic partner was the United States, whose long, unfortified border it shared and with whom, after 1940, when an era of good feeling set in, it was able to remove all major and nearly all minor points of friction through amicable negotiation. Mutual respect has formed the basis for numerous joint United States–Mexican enterprises, especially along the north Mexican border, where irrigation projects have made the population the fastest growing in the Mexican Republic. Tourism ranked above petroleum and agriculture as a source of national revenue; most tourists come from the United States.

When Mexico played host to the Olympic Games in October 1968, persons from all over the world saw its natural and social wonders at firsthand or on television. In addition to the usual array of athletic contests, Mexico simultaneously sponsored "artistic and cultural Olympics" in which friendly rivalry rather than intense competition prevailed.

Mexico in the 1970s. In his inaugural address on December 1, 1970, Pres. Luis Echeverría indicated that his government would continue to strengthen Mexican democratic institutions, guided by the goals of the 1917 constitution. He noted that grave gaps and injustices remained despite the fact that the continuing revolution "assured individual liberty, internal peace, uninterrupted growth, and our capacity for self-determination." He predicted that Mexico's population would reach 70,000,000 by the end of the decade and 100,000,000 within

20 years. Advanced planning was imperative to provide these new Mexicans with jobs and opportunities when they needed them. He welcomed foreign capital that would complement, not displace, Mexican, and he announced, "Technological progress is today the best ally of the Mexican Revolution." Technology was expected to create a good portion of the 500,000 new jobs needed annually for the expanding labour force. The advancement of science, therefore, was set as the national goal to modernize the society and the economy.

President Echeverría repeated a theme often enunciated by his predecessors—that the "Mexican Revolution was not imported, nor have we tried to export it." He strongly affirmed that Mexico would continue to reject all interference in its internal affairs, "under whatever ideological label it may be disguised." He noted that "The Mexican people were never daunted by the grave challenges of history," and he called on his people "to reaffirm the staunchness of their principles; to live to the full the rich philosophy of the Constitution of 1917."

BIBLIOGRAPHY. ROBERT A. POTASH, "The Historiography of Mexico Since 1821," *Hispanic American Historical Review*, 40:383–424 (1960), introduces the vast scholarly and popular literature; Mexican history sections in the *Handbook of Latin American Studies* (annual), supplement and update Potash. Despite a slanted viewpoint, HENRY B. PARKES, *A History of Mexico*, 3rd ed. (1960), remains a standard single-volume summary. H.H. BANCROFT, *History of Mexico*, vol. 4–6 (*Works*, vol. 12–14, 1883–88), is a large compendium of facts, 1804–1887. Details on independence and the first empire are found in WILLIAM S. ROBERTSON, *Iturbide of Mexico* (1952). WILFRID H. CALLCOTT probed that era and the following in his *Church and State in Mexico, 1822–1857* (1926), and *Liberalism in Mexico, 1857–1929* (1931). A discussion of the evolution of the Reform appears in CHARLES A. HALE, *Mexican Liberalism in the Age of Mora, 1821–1853* (1968), while ROBERT A. POTASH, *El banco de avío de México: el fomento de la industria, 1821–1846* (1959), deals with contemporaneous economic developments. The Juárez era is covered by RALPH ROEDER, *Juárez and His Mexico*, 2 vol. (1947); and by WALTER V. SCHOLES, *Mexican Politics During the Juarez Regime, 1855–1872* (1957), both to be read in conjunction with E.C. CORTI, *Maximilian and Charlotte of Mexico*, 2 vol. (1928); the late Juárez, Porfirian, and early revolutionary years are being explored in depth in the massive volumes published by El Colegio de Mexico under the editorship of DANIEL COSIO VILLEGAS, *Historia moderna de México*, 8 vol. (1955–). Despite its title, HOWARD F. CLINE, *The United States and Mexico*, rev. ed. (1963), emphasizes Mexican events from 1900 to 1952, expanded in his *Mexico: Revolution to Evolution, 1940–1960* (1962). Achievements and gaps of the Revolution are recorded in JAMES W. WILKIE, *The Mexican Revolution: Federal Expenditure and Social Change Since 1910*, rev. ed. (1970). JAMES D. COCKCROFT, *Intellectual Precursors of the Mexican Revolution, 1900–1913* (1968), is revisionist of STANLEY R. ROSS, *Francisco I. Madero: Apostle of Mexican Democracy* (1955), a scholarly biography, and CHARLES CUMBERLAND, *Mexican Revolution: Genesis Under Madero* (1952).

(H.F.C.)

Mexico City

Mexico City (Ciudad de México), the capital of the United Mexican States, is one of the oldest metropolises in the Western Hemisphere and one of the world's fastest growing cities as well. Located in the southern part of the Valley of Mexico, it occupies an ancient plain that was once a lake and is surrounded by mountains. The city proper covers an area of 147 square miles (380 square kilometres), but the greater metropolitan area, where some 8,600,000 people lived in the early 1970s, stretches over 779 square miles (2,018 square kilometres). The centre of the powerful Aztec Empire of the 14th and 15th centuries AD, its name is derived from the Aztec words *mexliapan* ("lake of the moon") and *xitli* ("center"), which literally mean "city in the centre of the lake of the moon."

Mexico City is both the political and economic centre of Mexico and has remained a focus of Latin American culture since the 16th century. It is a sprawling megalopolis, the continuous rapid growth of which has brought in its train problems of poor housing, pollution, and social tension. At the same time, however, it is also a city of great charm that contains notable examples of colonial and modern architecture, palaces, and gardens.

History. *Origins.* The Aztec Indians arrived in the Valley of Mexico in about 1221. According to tradition, they found in 1325, on a small island in the middle of Lake Mexliapan (Lake Texcoco), the site that had been indicated by their god Huitzilopóchtli for locating a city. Known as Tenochtitlán (Place of the High Priest Tenoch), the city began to spread out over the island's marshes and swamps, and it soon became a place of fountains and gardens. It was divided into *calpullis*, or self-governed districts, each with communal lands and schools. There were also two zoos that belonged to the Great Tlatoani (emperor).

The city of Tenochtitlán

When the Spanish, led by the explorer Hernán Cortés, arrived in 1519 from the Old World, there were about 500,000 persons living in Tenochtitlán. The small islands in the lake had been united through land reclamation to form one large oval island that was connected to the mainland by three causeways—Tepeyac to the north, Ixtapalapa to the south, and Tacuba to the west. The three causeways converged on the ceremonial city centre, where the main temple and the palace were located. This centre, or plaza, now called the Zócalo, or officially

Central Mexico City and (inset) its metropolitan area.

Plaza de la Constitución, remains the hub of Mexico City's life.

The viceregal city. Hernán Cortés, the conqueror of the Aztecs, razed Tenochtitlán and destroyed every element capable of reminding the Aztecs of their former institutions. To take advantage of the city's prestige as a former capital, however, he constructed a Spanish city on its ruins. He divided the central area among the conquerors and left the periphery to the defeated. The Aztecs intermingled with the Spaniards, making Mexico City the first mestizo city in history.

Mexico City received many privileges from the Spanish crown and in the 16th century became the most important capital in the Americas. The city was chartered, and its town council, or *cabildo*, was recognized in 1522; it was given leadership over the other *cabildos* of New Spain in 1535. Governed by colonial viceroys, it became the capital of Spanish America as far south as Panama.

Mexico City continued as a lakeside centre until constant floods necessitated the gradual filling of the lakes of the valley floor. During the 17th century it was essentially a well laid out assemblage of homes, public buildings, churches, and convents. In their execution of European designs, the Indians and the colonists created a Baroque architecture (*i.e.*, characterized by elaborate ornamentation) that employed *tezontle* (a light and porous volcanic rock) for facades. They used quarried stone for lintels. The 18th century was the golden age of architecture in New Spain, and after the Baroque manner reached its ultimate expression, Neoclassical ideas were introduced by Manuel Tolsá.

From independence to the revolution. After the fall of Emperor Agustín de Iturbide of Mexico, in 1824, the republican constitution created the Distrito Federal (Federal District) to centralize the new government in Mexico City. Invasions by the United States in the 1840s and by France in the 1860s as well as internal insurrections prevented a program of urban renewal. During the anticlerical reform movement of the 1850s, all the city's convents were either demolished or put to other uses. The city limits were expanded in 1865, when the Habsburg Archduke Maximilian—then emperor of Mexico—built the Paseo del Emperador (now Paseo de la Reforma) to connect his palace with the Castillo de Chapultepec (Castle of Chapultepec). At about this time the first *colonias*, or barrios (residential districts), appeared on the city's fringes to house the expanding population. During the rule of Porfirio Díaz, from 1876 to 1911, Mexico City was modernized on the lines of Baron Haussmann's Paris. European architectural styles were adopted in such buildings as the post office and the Palacio de Bellas Artes (Palace of Fine Arts). The drainage system was completed in 1907, and gas and electric lighting and streetcars were introduced.

The first urban expansion

The 20th century. During the civil wars of the Mexican Revolution, which lasted from 1910 to 1917, the city became a battlefield, for control of the nation without its capital was virtually meaningless, and disruption in rural areas resulted in an exodus from the countryside to the capital. In 1924, urban works were renewed with the construction of the 21-mile-long Avenida Insurgentes; French palaces were replaced with buildings designed in the style popular in the United States. In post-revolutionary Mexico City, however, luxurious districts, such as Lomas de Chapultepec (Chapultepec Hills), arose in sharp contrast to the working class *colonias* that were

inhabited by emigrant peasants. The first skyscrapers appeared in the 1930s and in the 1940s industrialization began to transform the city; large urban complexes were formed, and highways and a subway were constructed. The problem constituted by the belt of poverty that surrounded the city also grew more acute.

Rapid growth has continued, checked only by the encircling mountains. The metropolitan area spread beyond the original political limits of the Distrito Federal into the neighbouring State of Mexico. In effect, Mexico City in the 1970s was no longer a single city but an agglomeration of different and sometimes contrasting cities.

The contemporary city. *The city site.* Mexico City lies at an altitude of 7,350 feet (2,240 metres). It is walled in by the mountains of the Sierra de Pachuca, to the north; the Serranía del Ajusco, to the south; the Sierra de las Cruces, to the west; and the Sierra Nevada, with its two extinct volcanoes, Iztaccíhuatl (17,340 feet; 5,286 metres) and Popocatépetl (17,887 feet; 5,452 metres), to the east. In 1971 the city proper occupied 147 square miles. The 779-square-mile greater metropolitan area included all of the Distrito Federal—except for the rural area of Milpa Alta and its ten municipalities—and ten municipalities in the State of Mexico.

Although urban continuity is unbroken, it may broadly be said that the city proper extends to Tlatelolco—originally a twin city of Tenochtitlán—on the north, Avenida Río Churubusco on the south, Bosque de Chapultepec (Chapultepec Park) on the west, and the area of San Lázaro on the east. The present-day suburbs were once either isolated villages—such as Tlalpan, Coyoacán, and San Angel—or else cattle ranches and farms. The central section is located on a lacustrine plain the watery subsoil of which has caused the city to sink more than 20 feet since 1900.

The environment. The tropical, high-altitude climate lacks a winter season. The weather is cool and dry, except in the rainy season—from May through September. The annual median temperature is 64° F (18° C). The warmer months are July and August, when temperatures average about 70° F (21° C). Night frosts occur in December, and sudden temperature changes are usual.

Vegetation and animal life

The main agricultural product of the area is alfalfa, which is used as feed for livestock. Maize and beans are the staples of the human diet. A characteristic tree of the area is the *ahuehuete* (Montezuma cypress), which lives for as long as 2,000 years. City flowers include the *zempoazúchitl*, or flower of death (whose yellow colour was the colour of death for the Aztecs), and the poinsettia. The *charal* (a small edible fish), the *acocil* (a freshwater crustacean), and the *ajolote* (a vertebrate amphibian) are typical inhabitants of the valley's lakes.

Air pollution is a serious problem. The city's 800,000 vehicles, 4,500 industrial plants, and one oil refinery emit tons of contaminants daily. Deforestation and the drying up of the surrounding lakes' beds aggravate the problem of pollution by producing tons of dust laden with saltpetre (sodium nitrate).

The city plan and traditional neighbourhoods. At the centre of the original city of Tenochtitlán, the Spaniards created a planned town, placing the main public buildings around a square and utilizing former Indian sites. The great cathedral stands very nearly on the spot of the main temple of the Aztecs, and the viceroy's palace (now Palacio Nacional) was substituted for the palace of Montezuma. The conquered Aztec population was confined to areas in the north and east. The city gradually broadened and enveloped various new nuclei (*colonias*) from 1862 onward. Until Mexico City reached a population of more than 1,000,000, in 1930, its growth and development was haphazard and unplanned. Suppression of numerous municipalities and annexation of others in that year set the stage for a series of planning commissions to reorganize and reform the metropolis. Between 1930 and 1950, the city more than doubled its population.

Since the city was designed by Cortés in the 16th century, there has been no plan to regulate its growth. Although the area is overwhelmingly urban, there are places in the south that are agricultural or forested. The historic hub of the city is centered around the Plaza de la Constitución, where the Palacio Nacional (the original home of Cortés and the viceregal residence), the seat of the federal government, the Catedral Metropolitana, and the city hall are located.

Despite frantic destruction of the old parts of the city, plazas such as that of Santo Domingo preserve their original atmosphere. Numerous buildings of great artistic and historic value include the palaces of Iturbide, Buenavista, and Chapultepec, where more than 100 military rebellions have occurred.

In stark contrast to sites such as Netzahualcóyotl, where 90,000 persons live in conditions of extreme poverty, the area of Lomas de Chapultepec contains luxurious homes overlooking ravines. Huge mansions are integrated into the landscape of lava, rock, flowers, and water in the Jardines del Pedregal de San Angel. Xochimilco evokes a semblance of Tenochtitlán, while San Angel and Coyoacán resemble colonial Mexico.

Transportation. Mexico City is the hub of all national transportation lines. Four great highways lead from the capital to the United States; one connects the city to the Guatemalan frontier; four run to Atlantic ports; and five connect it with the Pacific coast. The national railways link the city with all of these points except Acapulco. The principal contact with other countries is by air, and more than 80 percent of the flights registered annually at the Aeropuerto Internacional are international.

Although foreign transport has improved markedly, overpopulation and excessive expansion have hampered the development of the domestic transport system. Traffic congestion is the rule in Mexico City; bus and taxi service is inadequate, and the bus lines are often symbolic targets of student protest. There is, however, a cheap service of collective taxis, known as *peseros*, along established routes, and the Metro, or subway, is highly efficient.

Population. In 1970 there were more than 2,907,000 persons living in the city proper and almost 8,600,000 in the greater metropolitan area. It is estimated that in addition to natural growth, 400,000 migrants from rural areas will become new residents each year. With a population density of 19,775 persons per square mile (7,650 persons per square kilometre), the greater metropolitan area of Mexico City holds almost 15 percent of the total population of the country; 62 percent are under 25 years of age and only 10 percent are over 50.

Most of the middle and high income groups live in newly developed suburbs, such as Ciudad Satélite (Satellite City), while low income families are segregated in the 450 slum districts called *ciudades perdidas*, or lost cities, in which many live in tin-roofed huts, and in the 5,000 *vecindades*, or neighbourhoods, of the capital.

Ethnically, the large majority of the population is mestizo (of mixed European and American Indian descent), professes Roman Catholicism, and lives in the poorer northern section. The middle income group is generally criollo (the term for Mexicans of European descent) or European. Its members live in the southern and western sections, speak English as a second tongue, and often send their children to European and U.S. schools.

The acute housing shortage

Housing. One of the most distressing problems facing Mexico City in the early 1970s was housing. All government efforts to resolve this problem had failed because of the population explosion and the high rate of internal migration. Hence, the Labour Law of 1970 required all companies that employ more than 100 workers to build housing for their employees. In 1970, 13,000 low-cost housing units were completed under that law, but there were 40,000 families waiting to occupy them. To contain the flood of migrants to the capital, the new city of Cuatitlán Izcalli was under construction north of the city in the early 1970s to house 1,600,000 persons. In addition, there was a continual program of rehabilitation of the *ciudades perdidas* and the *vecindades*.

Building types. Buildings include the cardboard and sheet metal huts of the "lost cities" and the deluxe mansions and modern condominiums of the well-to-do. A fascinating aspect is the contrast of old and new, of Spanish, Indian, and modern, and of homes with Moor-

ish-style interior patios and modern functional architecture.

The main architectural interest lies in the colonial buildings that largely date from the 18th century and that still stand in the city centre, as well as in San Angel and Coyoacán. These include the Catedral Metropolitana, the largest of the continent (begun in 1570; completed *c.* 1810), and other buildings around the Plaza de la Constitución, such as the municipal palace, or city hall, and the Palacio Nacional.

Economic life. The greater part of the nation's economic activity is concentrated in the capital, which generates 50 percent of all industrial production. It also accounts for 59 percent of the wages and 60 percent of the non-agricultural work force. Industry has located 31 percent of its plants in the city, where 40 percent of the gross national product is created.

Industry

The main industries deal with construction and the production of iron and steel, chemicals, plastics, cement, and yarns and textiles. More than 1,000,000 tourists are accommodated each year; 60 percent of the nation's commercial transactions are conducted in the capital; and there are more than 40 banking institutions (with 350 branch offices) in the metropolitan area. Finance, mortgage, and insurance companies have their home offices in Mexico City, which is also the seat of the nation's stock exchange. The Banco de México (Bank of Mexico) is the only institution that issues currency. Basically, the municipal budget depends on income, property, excise, and other taxes and tourism.

Political and governmental institutions. All the political parties have their headquarters in Mexico City, which is also the site of the Mexican Chamber of Deputies, the Senate, the Supreme Court, and the federal courts. The president of the republic administers the Distrito Federal through a regent (*jefe del departamento central*), who is appointed by him when the cabinet is named.

Public utilities. Water supply has been a constant problem for Mexico City. A Central Drainage Canal (El Gran Canal del Desagüe), which was built to move sewage waters, is inadequate; hence, three interceptor canals that will run the length of the city at depths of up to 720 feet were being built in the 1970s. Also, because local springs have run dry, drinking water must be supplied from increasingly remote areas.

The electric company (Compañía de Luz) operates 12 generating plants powered by hydraulic turbines and has a capacity of more than 647,000 kilowatts.

Health and safety. Mexico City has the oldest hospital in the Western Hemisphere—the Hospital de Jesús Nazareño, which was founded by Cortés in the early 16th century. Among the government-run institutions are the ISSSTE (Instituto de Seguridad y Servicios Sociales de los Trabajadores del Estado), which runs hospitals for government employees, in addition to social security hospitals, and the Centro Médico (Medical Centre), a conglomerate of specialized units. There are several private hospitals, including the American–British Cowdray Hospital. Although all of the barrios are serviced by general and maternity clinics and dispensaries, there is a shortage of available hospital beds.

The fire department, established in 1871, is outfitted with modern equipment and has demonstrated high levels of efficiency. The federal and city police number 20,000, an inadequate figure for a city of such dimensions.

Education. Although the government devotes 20 percent of its budget to education, the demand for buildings and personnel is still not met. In the early 1970s more than 90 percent of primary school age children attended classes; many, however, leave school at the secondary and university levels. There were more than 300 kindergartens, 2,000 primary schools, and almost 500 secondary schools in the city. The Universidad Nacional Autónoma de México (National Autonomous University of Mexico) is located south of the city on a campus known as Ciudad Universitaria, or University City. Its buildings are beautifully decorated with murals by the painter Diego Rivera and others. The enrollment in the early 1970s was over 100,000. The Instituto Politécnico Nacional (National Polytechnic Institute) has an enrollment of about 80,000 students. There are also several technical schools and private universities in the city. Classes are conducted in Spanish, but some institutions offer instruction in English during the summer sessions.

University City

Cultural life. The city retains its historic position as one of the greatest centres of Latin American culture. In addition to the research institutes of the National University, the most outstanding institutions of advanced learning are the Colegio de México and the Colegio Nacional. There are about 35 museums, including the magnificent Museo Nacional de Antropología, which opened in 1964 and contains collections of almost all the ancient cultures of Mexico.

The public libraries are poor, tradition being more in favour of vast private libraries. There are more than 50 active publishing houses and approximately 1,000 bookstores.

The media. Twenty newspapers are published daily, including *Excelsior*, considered one of the most important newspapers in the Spanish-speaking world. Several of the papers have nationwide circulation and are important factors in the formation of public opinion. There are numerous informative, literary, and other specialized magazines. Of Mexico's seven television channels, one is devoted exclusively to cultural broadcasts, and there are about 60 radio stations.

Recreation. Each neighbourhood has its own parks and gardens. Bosque de Chapultepec, the largest and most beautiful of these, encompasses almost 1,000 acres in the southwest. Its grounds contain museums, zoos, botanical gardens, an amusement park, lakes, and fountains. El Desierto de los Leones (Desert of the Lions), another park ten miles southwest of the city, occupies 4,695 acres of mountains, pine forests, springs, and aqueducts. The Alameda Central (Central Mall), west of the Zócalo, was created in 1592.

The most popular spectator sports are football (soccer) and bullfights. Soccer is played in the Azteca Stadium, in the stadium located in the Plaza Ciudad de los Deportes (Sports City), and in the Olympic Stadium of University City. There are two bull rings—México, which is the world's largest, and El Toreo. In addition, there are 50 sports centres and numerous swimming pools, as well as other facilities that were built to house the Olympic Games in 1968. The Ciudad Deportiva de la Magdalena Mixhuca (Magdalena Mixhuca Sports City) covers 565 acres and includes sports fields and a three-mile auto racing track. There are numerous cinemas and legitimate theatres, and free concerts and exhibits are held in the public parks.

BIBLIOGRAPHY. The best works on Mexico City, in English, are two minor 19th-century classics: FRANCES CALDERON DE LA BARCA, *Life in Mexico During a Residence of Two Years in That Country* (1843); and BRANTZ MAYER, *Mexico As It Was And As It Is* (1844). Numerous collections of photographs with brief comments include BOB SCHALKWIJK and J.M. COHEN, *Mexico City, México* (1967). SALVADOR NOVO, *Nueva Grandeza Mexicana* (1946; Eng. trans., *New Mexican Grandeur*, 1967), describes city life in the 1940s. The Spanish bibliography is, of course, extensive, although works on contemporary Mexico are scarce. The best summary is SALVADOR NOVO, *México* (1968). Historical works include HERNANDO CORTES, *Cartas de Relación* (Eng. trans. by FRANCIS A. MACNUTT, *Letters of Cortes*, 2nd ed., 2 vol., 1932); and BERNAL DIAZ DEL CASTILLO, *La Verdadera historia de la conquista de la Nueva España* (1632), on Tenochtitlán. On the colonial city, see FRANCISCO CERVANTES DE SALAZAR, *México en 1554* (1875; 3rd ed., 1964); and BERNARDO DE BALBUENA, *Grandeza Mexicana* (written 1604, first published 1829, reprinted 1941). On Mexico from the 17th to the 19th century, see LUIS GONZALEZ OBREGON, *México viejo*, new ed. (1900); JOSE M. MARROQUI, *La Ciudad de México*, 3 vol. (1901–03, reprinted 1969); and JESUS GALINDO Y VILLA, *Historia sumaria de la ciudad de México* (1925). The magazine *Artes de México* has published three volumes under the title *La ciudad de México* (1964), which have fine photographic illustrations. Regarding serious contemporary problems, the two volumes of *Memoria de la reunión para el estudio de los problemas del D.F.* (1971); and LUIS UNIKEL, *La dinámica del crecimiento de la ciudad de México* (1972), are indispensable.

(F.Be.)

Micas

The micas are an important group of common rock-forming minerals characterized by their highly perfect cleavage, or tendency to split along planes determined by crystal structure, yielding thin laminae. The name is from the Latin *mica* ("grain"). The principal members of the group are muscovite, biotite, and lepidolite. These are aluminosilicates with potassium, magnesium, iron, or lithium, and hydroxyl and fluorine. The micas as a group are highly variable in chemical composition, physical and optical properties, and mode of occurrence, but all are based on a relatively simple crystal-structure unit.

Importance and uses

Because some micas are poor electrical conductors, they are used in the construction of electrical equipment. Some micas are also poor heat conductors, transparent, and relatively resistant to water corrosion; these have been useful as stove windows and boiler gauge packings. Ground mica is commonly employed as a filler, lubricant, absorbant, dusting powder, and packing material. It is used in the manufacture of wallpaper, roofing paper, and paints. It is employed for special effects by decorators and toy manufacturers—for example, as "frosting" or Christmas tree "snow." Sheets of mica are used to make plates of precise thickness for use in the analysis of polarized light. Lepidolite is an important source of lithium and rubidium salts. Some of the synthetic micas are used as electrical insulators and in special delicate electronic instruments.

The common micas are rich in potassium and also contain some strontium and rubidium, which are essential elements involved in the age determination of minerals and rocks. The abundance of the elements involved in the decay of the isotope (isotopes are elements with the same atomic number but different atomic weights) potassium-40 to argon-40, and of rubidium-87 to strontium-87, in a mica can be measured with precision and the absolute age of the mineral calculated in millions of years. Metamorphism (alteration by heat and pressure) of the micas often affects the relative abundance of these elements, so that the micas usually record the last geological event or episode of metamorphism and not the date of their initial growth in the Earth (see further DATING, RELATIVE AND ABSOLUTE).

Occurrence of micas and their mining

The micas occur in all rock types—igneous (formed by the cooling and crystallization of molten silicate material), metamorphic, and sedimentary. They are absent in rocks so far recovered from the lunar surface, however. Members of the group are found under the entire range of pressures and temperatures that reflect geological conditions: thus, micas occur in lavas, schists, granites, marbles, soils and deep-sea sediments, mineralized veins, pegmatites (very coarse-grained igneous rocks), alteration zones, and in products of weathering of other minerals. Each particular mica type is limited in occurrence to a certain range of variables (such as composition, temperature, and pressure) of the geological environment, and some micas are found only in specific rock types. A characteristic occurrence is in granite (see Figure 1), in which biotite and muscovite usually form. Phlogopite is common both in ultrabasic rocks (those poor in silica) such as dunites and peridotites and in dolomitic marbles. Fine-grained white micas, or sericite, particularly muscovite, form in the early stages of metamorphism of sediments and are closely associated with biotite. During retrograde metamorphism (the occurrence of one episode of intense metamorphism followed by subsequent, less intense episodes) the aluminous silicates are altered to sericite; these silicate minerals include andalusite, kyanite, sillimanite, cordierite, and staurolite, as well as the feldspars. The illites, a group of clay minerals, are partly of mica and are a common constituent of soils and deep-sea sediments. Glauconite, another type of clay mineral, also occurs in marine deposits. Celadonite is an alteration product of some igneous rocks. Lepidolite is mainly found in veins and pegmatites, often in parallel growths with muscovite.

The mining of mica is difficult because the mica books (crystalline blocks that cleave or split readily into thin mica sheets) are readily damaged by rough handling. Methods of extraction are therefore primitive and necessarily wasteful; the veins and pegmatites are usually worked by quarrying, but underground excavation may be economical. The books are split and trimmed by hand; sorted according to size, transparency, colour, and freedom from spots or strains; and the scrap is ground. The production of mica sheets seldom exceeds 10 percent of the total mine output. Mining is conducted primarily in the United States (North Carolina, Idaho, South Dakota), India, the Republic of South Africa, the Soviet Union, Brazil, Argentina, Canada, and the Malagasy Republic.

This article treats the mineralogical properties, crystal structure, and chemical composition of the micas. It also includes discussion of the synthesis of micas and their stability limits in nature. For information on closely related mineral types see CLAY MINERALS and SILICATE MINERALS, and for further detail on the occurrence of micas in nature see IGNEOUS ROCKS; METAMORPHIC ROCKS; and SEDIMENTARY ROCKS. See also SHALES; MARINE SEDIMENTS; and GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES for related information.

PROPERTIES OF MICAS

Mineralogical characteristics. The different kinds of mica (see Table 1 for principal members) vary greatly in colour and are frequently zoned (*i.e.*, there are concentric colour bands). Muscovite is commonly colourless and may be gray, brown, light green, lavender, or ruby red. The biotites are commonly black, brown, green, yellow, and occasionally are colourless. High ferric iron content tends to make the crystals green, whereas high titanium oxide content gives a reddish brown colour. Intermediate proportions of titanium and ferric iron tend to produce colours of yellowish or greenish brown. Pink, violet, yellow, gray, red, brown, and green are the colours displayed by the lepidolites. Paragonite is colourless. The luster varies from pearly, as in muscovite, to submetallic, as in lepidomelane.

Table 1: Principal End-Members of the Mica Group*

	X	Y	Z	O_{10}	$(OH, F)_2$
Dioctahedral					
Muscovite	K	Al_2	$AlSi_3$	O_{10}	$(OH)_2$

*General formula is: $XY_{2-3}Z_4O_{10}(OH, F)_2$.

Most occurrences of the micas yield fine-grained crystals; the largest crystals are found in veins and pegmatites. The largest book of mica discovered was 4.3 metres (14 feet) in diameter and 10 metres (30 feet) long. Paragonite is especially fine-grained, occurring in massive scaly aggregates. Where colourless micas occur in two size ranges, the smaller size range can usually, but not always, be attributed to paragonite and the larger to muscovite.

Form and cleavage

When well formed, the crystals are usually tabular with hexagonal or pseudo-hexagonal outline; hence, six-sided prisms are common. The perfect basal cleavage yields thin laminae that are usually elastic. Some varieties, margarite for example, have brittle laminae. The perfect bas-

(Left) Joe J. Holdaway, (centre) B. M. Shaub, (right) Hatten S. Yoder, Jr.

al cleavage (perpendicular to the sides of the prism form) reflects the layered character of the internal crystal structure. The cleavage laminae are not equal in thickness throughout but may exhibit a series of steps. Each step is exactly equal to, or a multiple of, a crystal structure unit. These steps are also observed in the spiral growth of mica crystals.

When a cleavage flake is struck a sharp blow with a blunt needle point, a six-rayed star of cracks, or percussion figure, develops. A similar set of cracks develops 30 degrees from the percussion set when a blunt punch is pressed against crystal; these cracks, the pressure figure, coincide with secondary parting planes in the crystal. Such parting planes are inclined to the basal cleavage and often are mistaken for true crystal faces. The percussion figure is a useful aid in determining the orientation of the crystal symmetry in the absence of faces. Micas in the vicinity of a shear zone (zone of deformation in the Earth's crust) show kink banding. Kink bands are narrow, sharply bounded by plane surfaces inclined to the cleavage, and are parallel or subparallel. They indicate strong local deformation by translation gliding (slippage of crystal structure) whose precise nature is as yet undefined. Kink bands are displayed particularly well in micas in the sheared schists and cataclastic rocks (greatly deformed metamorphic rocks) of Scotland and Austria, and have been noted in mica-bearing rocks shocked by meteorite impact. Kink bands have been produced in laboratory studies of natural mica.

The hardness of the micas is anisotropic (that is, it varies with direction in the crystal) and ranges from 2.5 to 4.5 on the Mohs scale of mineralogical hardness (talc has a hardness of 1.0 and diamond a hardness of 10). The specific gravity ranges from 2.8 to 3.4, and the indexes of refraction (measure of light transmission) from 1.535 to 1.705. Bi-refringence (double refraction) is strong in the micas, meaning that the speed of light transmission varies greatly with crystal direction. The dark-coloured micas exhibit strong pleochroism; that is, different colours are exhibited in different directions. Inclusions are common in the micas and sometimes produce pleochroic halos (concentric colour bands). Dark spots in micas are often a result of radiation damage from included zircons, which contain radioactive chemical elements. The micas often enclose flattened crystals of garnet, tourmaline, quartz, and magnetite in thin plates between the sheets. Minute acicular (needlelike) inclusions arranged parallel to the rays of the percussion figure, particularly in phlogopite, give rise to asterism similar to that observed in rubies and sapphires.

Alteration and weathering

Muscovite and clintonite are relatively insoluble in acids, whereas biotite, lepidolite, and margarite are attacked by acids, leaving a residue of silica. Most micas yield water on ignition. The structure of muscovite can be completely destroyed by prolonged grinding in the laboratory and appears to be similarly affected to various degrees when the mineral is transported in streams and rivers. Alteration of muscovite usually results in a loss of alkalies and hydration, producing a mixed-layer mineral with montmorillonite (a clay mineral). Strong alteration may produce the clay minerals (*q.v.*) kaolinite or gibbsite with quartz. The farmer tends to restore most of the lost alkalies in the soil micas by using potash fertilizer; that potash is unavailable to the crop because it is taken up by the micas. The exchange of alkalies in micas is reversible, but some slight irreversible structural changes appear to occur. Muscovite, for example, can be converted to paragonite in solutions rich in sodium chloride, and paragonite can be converted to muscovite in solutions containing potassium chloride. The biotites on alteration are converted to chlorites. Potash feldspar, rutile, hematite, magnetite, or serpentine may also be produced. Weathering of biotite usually changes it to a soft brown or yellow mineral with a bronze luster, vermiculite.

Crystal structure. The fundamental unit of structure of the micas (see Figure 2) has been deduced by X-ray analysis of single crystals. It consists of two sheets of oxygen tetrahedra containing silicon and, usually, some aluminum. Each sheet consists of tetrahedra linked at each of three corners to form a hexagonal or pseudo-hexagonal array with all the bases parallel and all the vertexes pointing the same way. The two sheets are parallel and have opposing vertexes. These sheets are held together by magnesium or other ions (atoms that have gained or lost electrons and are thus charged), which are coordinated

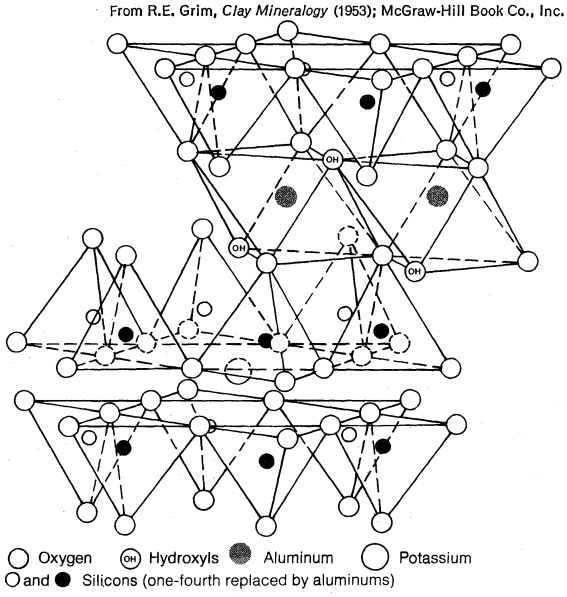

Figure 2: Structure of 1M muscovite (see text).

with two apical oxygens and one hydroxyl from one sheet and two apical oxygens and one hydroxyl from the opposite sheet, forming an octahedron. The hydroxyls occupy the centres of the hexagonal or pseudo-hexagonal arrays of apical oxygens. The structure is a succession of such double sheets with alkali atoms (*e.g.*, potassium) between them, the alkali atoms located between the hexagonal or pseudo-hexagonal arrays formed by the basal oxygens of the adjoining double sheets. The alkali atoms are thereby in twelvefold coordination, occupying the centre of a hexagonal prism formed by six basal oxygens from each of the adjoining sheets. The general structure may be

represented by the formula $XY_{2-3}\ Z_4O_{10}\ (OH,F)_2$, in which X in twelvefold coordination may be potassium, sodium, calcium, or barium; Y in sixfold coordination may be magnesium, ferric or ferrous iron, aluminum, lithium, manganese, and, rarely, chromium, vanadium, and titanium; and Z in fourfold coordination may be silicon and aluminum (see Table 1).

Polymorphism in micas

Minerals having the same chemical composition and different structures are called polymorphs. The simple structural unit described above has monoclinic symmetry; that is, it is related to three unequal crystal axes, two of which intersect obliquely and the third perpendicularly to the others. If successive units are stacked on top of each other with precisely the same orientation, the repeating unit of the mica is described as having a one-layer monoclinic structure (1M). If successive units are stacked with different orientations in a regular way, different structures (polymorphs) result. The symmetry of the surface of the unit restricts the number of ways in which succesive units may be stacked. The structures resulting from the various types of stacking may be described by the number of layers involved and the symmetry produced. The following structures have been observed in addition to the 1M: two-layer monoclinic, type one ($2M_1$); two-layer monoclinic, type two ($2M_2$); and two-layer orthorhombic (2O). Crystal symmetry in the orthorhombic system is related to three unequal and mutually perpendicular crystal axes: three-layer trigonal (3T)—a division of the hexagonal system in which crystal symmetry is related to three equal crystal axes that intersect at angles of 120 degrees and a fourth unequal axis that is perpendicular to these three; eight-layer triclinic (8TC)—crystal symmetry in the triclinic system is related to three unequal and mutually oblique crystal axes; twelve-layer monoclinic (12M); and eighteen-layer monoclinic (18M). Other more complex structures exist. A structure in which the units are randomly stacked also has been found. In addition, a six-layer hexagonal (6H) structure has been predicted but not found in nature. It should be emphasized that the structure of a ($2M_1$) mica, for example, is not exactly equivalent to two (1M) layers properly stacked. The internal strains and resulting distortions of the polyhedra produced by the various types of stacking yield new structures that, although very closely related, are not merely multiples of the simple structural unit as in polytypism. A single hand specimen may contain several polymorphs, but the biotites usually are (1M), the muscovites ($2M_1$), and the lepidolites ($2M_2$). Randomly stacked micas and mixed-layers with other layered minerals, such as montmorillonite, are common in sediments.

Chemical composition. The various species of the mica group may be described for the most part as consisting of variable proportions of ideal end-members (distinctive mineral species, between which gradual and continuous chemical variation occurs). Actual compositions are complex because of chemical substitutions. The group may be divided into those micas having two atoms in octahedral coordination (Y position), called the di-octahedral micas; those with three atoms in octahedral coordination, the tri-octahedral micas; and those containing between two and three atoms in octahedral coordination, the intermediate micas. The ideal end-members are listed in Table 1: the various atoms are arranged according to their structural position. Broadly speaking, the white micas, commonly referred to as sericite when fine grained, consist of muscovite, paragonite, or both. These form a limited series of solid solutions (a solid solution is a single crystalline phase that varies in composition between finite limits). Common glauconite consists of about two-thirds celadonite and one-third muscovite. It is not known whether glauconite is a true compound or a random mixed-layer structure, a structure consisting of discrete structural units of both muscovite and celadonite. Illite, a field designation for some sedimentary micas, is a mixed-layer mineral usually consisting of muscovite and montmorillonite. Common biotite is widely variable in composition and incorporates in solid solution various proportions of phlogopite, annite, eastonite, iron–eastonite, siderophyllite, and lepidomelane. The biotites do not form solid solutions with muscovite. Lepidolite consists mainly of polylithionite and trilithionite and forms limited solid solutions with muscovite and paragonite. There is no known complete series of solid solutions between a di-octahedral and a tri-octahedral mica. The rare micas include: a vanadium-rich mica (roscoelite), a chromium-rich mica (fuchsite), a manganese-bearing mica (manganophyllite), an aluminum-free mica (taeniolite), and a lithium–iron mica (zinnwaldite). Some mica samples yield more water on chemical analysis than that indicated by their formula. These are erroneously referred to as hydromica; in fact, they are mixtures or mixed-layered minerals of mica and a more hydrous mineral such as montmorillonite. A true hydromica, in which the hydronium ion, H_3O^+, replaces potassium, has not as yet been demonstrated in natural micas. The micas in some localities contain other volatile constituents such as ammonia and chloride in addition to hydroxl and fluoride.

Rare micas and hydromica

EXPERIMENTAL STUDY OF MICAS

Synthesis. Micas very closely approaching the properties of those found in nature have been synthesized in the laboratory; these include phlogopite, muscovite, paragonite, margarite, clintonite, annite, ferriannite, eastonite, siderophyllite, and celadonite. In addition, some end-member micas, possibly occurring as very minor solid solutions in other natural micas, have been made. Some of the fluorine end-members, such as fluorophlogopite, fluoromuscovite, fluoroparagonite, as well as polylithionite and trilithionite, have been synthesized. Na-phlogopite is another synthetic end-member. Other compounds having the mica structure, but not found in nature, have been prepared for special commercial applications. Examples of successful synthesis include fluorine (F) aluminosilicates that contain barium (Ba), magnesium (Mg), potassium (K), and nickel (Ni). The formulae of such compounds are: $BaMg_3Al_2Si_2O_{10}F_2$; $KNi_3AlSi_3O_{10}F_2$; and $KMg_2MnAlSi_3O_{10}F_2$. The hydrous micas are grown in steel pressure vessels capable of withstanding high water pressures, and the fluoromicas are grown from melts in platinum, graphite, or bonded silicon carbide crucibles at approximately atmospheric pressure. A few crystals in excess of 26 square centimetres (four square inches) and 0.3 centimetre (⅛ inch) in thickness have been produced from fluoride melts. Smaller synthetic fluoromica crystals have been bonded into large sheets and other forms.

Stability limits. The geological conditions under which a specific composition or polymorph of mica may be found are limited. Phlogopite ranges in occurrence from the relatively low temperature and pressure environment in which marbles are believed to have formed to the high temperature and pressure environment of some ultrabasic rocks. In fact, phlogopite will grow in hot silicate liquids (magma) and persist in the lava flows that appear at the surface of the Earth. Other micas such as lepidolite, however, are confined to the moderate temperatures and pressures of environment in which pegmatites are formed. The glauconites are confined almost exclusively to marine sediments and to low-temperature and low-pressure environments. These qualitative restrictions deduced from field observations do not fully describe the limits of stability of a mica because of the constraints imposed by the available compositions, temperatures, and pressures in the Earth. Quantitative measure of the limits of stability have been carried out in the laboratory, where composition, temperature, and pressure can be varied at will. Data are available on many of the pure end-member compositions listed in Table 1, as well as on compositions generated by mixtures of two or three end-members. The measured maximum stability limits in the pressure–temperature region studied for some micas are listed with their decomposition or breakdown products in Table 2. For reference, the pressure in the crust of the Earth increases with depth at an average rate of about one kilobar (the bar is a standard unit of atmospheric pressure; the pressure at sea level is 1,013 millibars) per 3.66 kilometres (273 bars per kilometre [434 atmo-

Environmental temperatures and pressures required for mica formation

Muscovite + quartz ⇄ sanidine + andalusite (or sillimanite) + H_2O		525	600	690		
Phlogopite + quartz ⇄ sanidine + enstatite + liquid + H_2O	820	820	820			

spheres per mile]). In general, the thermal stability of mica increases rapidly with pressure initially and then increases at a slow rate at pressures above about two kilobars. The stability of phlogopite at very high pressures is noteworthy; it is a mineral that is likely to be present in the Earth's mantle and is of particular interest because of its water and potassium content. The potassium content has great bearing on heat production in the mantle because it is a radioactive element, and water tends to lower the melting temperatures in the mantle and thus affect magma production.

The stability of a mica is also dependent on the presence of other minerals and the composition of the ambient fluid (mainly water). In Table 2 the results of studies on micas themselves, and when in the presence of quartz (SiO_2), are given. The muscovite + quartz reaction is important because it is prominent in the metamorphism of shales or clay-rich sediments. In addition, the stability of muscovite appears to be influenced by the potassium ion–hydrogen ion ratio in the fluid; and the magnesium–iron ratios, especially in biotite, are sensitive to the presence of sulfur. The presence of fluorine enlarges the thermal range of stability of the hydrous tri-octahedral micas.

Michael VIII Palaeologus

Most notable as the ruler who restored the Byzantine Empire to the Greeks after 57 years of Latin occupation, Michael VIII Palaeologus is the founder of the Palaeologan dynasty, the last and the longest lived of the Byzantine imperial houses (1261–1453).

A scion of several former imperial families (Ducas, Angelus, Comnenus), Michael was born probably in 1224 at Nicaea in Asia Minor, one of the several successor states established by the Greeks after the conquest of Constantinople by the Fourth Crusade (1204). After a rather uneventful boyhood, seemingly marked primarily by fantasies of himself recovering Constantinople from the Latins, he spent much of his youth living in the imperial palaces at Nicaea and Nicomedia.

His remarkable resourcefulness and talent for intrigue were revealed early. At the age of 21, he was charged by the emperor John III Vatatzes of Nicaea with treasonous conduct against the state, a charge from which he extricated himself by the force of his wit. Later, on the death of the emperor Theodore II Lascaris in 1258, Michael was chosen regent for Theodore's six-year-old son, John Lascaris. Gradually usurping more and more authority,

Seizure of the throne

Michael seized the throne and early in 1259 was crowned emperor after shunting aside and blinding the rightful heir, his charge, John. Faced with rebellion by Lascarid supporters in Asia Minor, Michael succeeded, in the eyes of many Greeks, in legitimatizing his rule by retaking Constantinople from the Latins. Whether as the result of Michael's carefully planned ruse or of accident, or both, the great city fell to his general in July 1261. Although the Greeks generally were exultant, a few realized that the centre of gravity had shifted from Asia Minor to Europe. In the long run this concern with Europe was to prove fateful; for, it led to the neglect of the frontiers in the East and with that neglect eventually to the conquest and settlement of all of Asia Minor by the Turks.

From the first, Michael's hold on the throne was precarious, surrounded as it was on all sides by Latins desirous of restoring Latin rule. Especially active was Baldwin II of Courtenay, the last Latin emperor of Constantinople. In his manoeuvres to recover his throne from Michael, Baldwin finally entered into a diplomatic and matrimonial alliance with a man who was the West's ablest diplomat —in his machinations almost the equal of Michael himself—Charles of Anjou, brother of St. Louis of France. At papal invitation, Charles had advanced into southern Italy, expelled the last representatives of the imperial house of Hohenstaufen, Manfred and Conradin, and then from Palermo and Naples almost at once fixed his gaze across the Balkans onto Constantinople. To quote a chronicler, "he aspired to the monarchy of the world, hoping thereby to recreate the great empire of Julius Caesar by joining East and West."

Threatened by this grand design was not only Michael but the papacy as well; should Charles succeed in the conquest of Constantinople, the pope would become a mere puppet of Charles in Italy. Hence development of an alliance between Michael and the papacy was logical, and it took shape in two decades of intricate negotiations for religious union between Rome and Constantinople. In exchange for the papal promise to restrain Charles from attacking Constantinople, Michael promised to bring about religious union of the Greek Church with Rome. That promise provoked the violent opposition of most of Michael's own people, who opposed union on doctrinal grounds; specifically they objected to such parts of the Latin liturgy as the *Filioque* (procession of the Holy Spirit from the Son and the Father) and the use of the azyme (unleavened bread). Perhaps more important,

Michael VIII Palaeologus, detail of a Greek manuscript, 14th century. In the Bavarian State Library, Munich (Codex Monacensis Graecus 442).

most of them refused to accept papal ecclesiastical supremacy, which they felt, however obscurely, would lead to restoration of Latin political domination and possibly even cultural assimilation to the Latins.

Union between Eastern and Latin churches

Despite all the obstacles, union was nevertheless finally pronounced at the second Council of Lyons in 1274. Though the Orthodox East was coerced into accepting union, immediately after Michael's death (1282) the Greek Church declared the union invalid and a fraud. The Greeks had objected to the council on the grounds that not all the Eastern patriarchs or their representatives had been present, that no discussion on problems separating the two churches had taken place, and that no subsequent council had declared that of Lyons ecumenical. Nevertheless, for political reasons, Michael had struggled to maintain the union. But when Charles of Anjou finally managed to enthrone his own candidate, Martin IV, as pope in 1281, Martin at once excommunicated Michael and at the same time pronounced Charles's projected expedition against Byzantium a "Holy Crusade" against the "schismatic" Greeks. Included in the vast network of alliances erected by Charles to conquer the Greek East were not only Sicily, parts of Italy, Greek Lascarid dissidents, various Slavs of the Balkans, Baldwin, France, and Venice but also the papacy. Venice's aim in particular was to recover the broad trading privileges it had exercised in the days of the Latin Empire and to oust its archfoe, the Genoese, from the lucrative Greek markets.

The diplomatic duel between Charles and Michael was intensified, with Charles striving unceasingly to prepare his troops and navy. He even launched an attack across the Adriatic on Berat (in modern Albania) under the French general Sully but was repulsed by Michael. What Michael had on his side—the result of his consummate diplomatic ability—was (for a time) the papal alliance, a secret agreement with the Hohenstaufen supporters in Sicily, the support of Genoa, and finally, most important, a secret alliance with the son-in-law of Manfred, King Peter III of Aragon. The denouement to this remarkable contest was the outbreak on March 30 or 31, 1282, of the famous Sicilian Vespers, the massacre of the French signalling the revolt against Charles. Byzantium was saved from a second occupation by the Latins.

Assessment of Michael's life

At his death, which occurred soon afterward (December 11, 1282), Michael thus left an intact empire to his son Andronicus II. But it cannot be denied that his policy of using ecclesiastical union to stave off Charles's attack on his capital and the deep opposition that policy provoked among the Byzantine population established a fateful precedent for later Byzantine history. Moreover, by focussing his attention too exclusively on Europe, his policy helped to lead to Ottoman occupation of all of Asia Minor and ultimately to the capture of Constantinople itself. Nevertheless, Michael's positive accomplishments cannot be overlooked. He gave Byzantium two centuries more of life, rebuilt the capital, and re-established the University of Constantinople. His sponsorship of a general revival of learning led to the important Byzantine "Renaissance" in the 14th and 15th centuries.

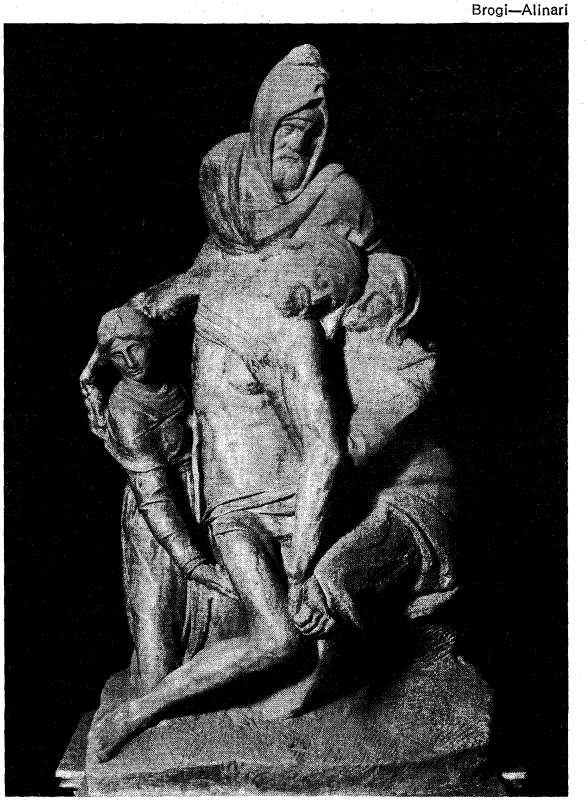
GEANAKOPLOS, *Emperor Michael Palaeologus and the West, 1258–1282: A Study in Byzantine-Latin Relations* (1959), with full bibliography. Also see C. CHAPMAN, *Michel Paléologue, restaurateur de l'empire byzantin* (1926), which contains extracts from Michael's so-called "autobiography." The most recent edition of the "autobiography" is by H. GREGOIRE, "Imperatoris Michaelis Palaeologi, 'De Vita Sua,'" *Byzantion*, 29–30: 447–476 (1959–60). For further references, see G. OSTROGORSKY, *Geschichte des Byzantinischen Staates* (1940, Eng. trans., *History of the Byzantine State*, 1956); and S. RUNCIMAN, *The Sicilian Vespers: A History of the Mediterranean World in the Later Thirteenth Century* (1958).

(D.Ge.)

Michelangelo

One of the major sculptors of all time, Michelangelo Buonarroti won incomparable recognition during the Renaissance for his paintings, architecture, and drawings. After the tardy appearance of his poetry in 1623, he slowly emerged as one of the most significant and personal poets of his age, his sonnets and madrigals appearing in almost all recent anthologies of Italian literature. So extraordinary was his influence on the history of art that the word Renaissance (Italian *rinascita*, "rebirth") was coined to characterize the saltation of the fine arts under Michelangelo and Raphael. According to the historian Giovanni Papini, the Reformation as well owes its very existence to Michelangelo. Papini reasons that Pope Julius II so increased the sale of indulgences to ensure the magnificence of his tomb, which Michelangelo was to execute, that Luther and others rebelled and split the church in two. Still a third definable age is occasionally credited to Michelangelo, who is often hailed as father of the Baroque for such tortuous and tense figures as the Haman of the Sistine ceiling. It is an overwhelming honour—if a debatable one—to be credited with the existence of the Renaissance, the Reformation, and the Baroque age, yet these claims at least suggest the influential role that Michelangelo played in the history of the fine arts.

Brogi—Alinari



"Pietà," marble sculpture by Michelangelo, *c.* 1550–56. In the Duomo, Florence.

Considering how few verifiable facts are known about William Shakespeare, who was born the year Michelangelo died, it is remarkable that the life of Michelangelo can be reconstructed almost month to month, if not week to week. This wealth of information derives largely from the 495 extant letters he wrote to others, the many written to him, the personal revelations in his poetry and artistic records, the biographies undertaken by his contemporaries (notably, Giorgio Vasari and Ascanio Condivi), conversations of his that were recorded by Donato Giannotti and Francisco de Hollanda, as well as from an abundance of direct and indirect testimony and comment by contemporaries who were aware that Michelangelo would outlive his age and be mirrored eventually in the glass of eternity.

CAREER

Early life and works. Michelangelo was born March 6, 1475, to Francesca and Lodovico di Lionardo Buonarroti Simoni in a small hill town near Arezzo called Caprese, now officially Caprese Michelangelo. Descend-

ed from two generations of Tuscan bankers, Lodovico was at the time nearing the end of his term as mayor of Caprese. Michelangelo's mother gave birth to five sons: her early death occurred December 6, 1481. All his life Michelangelo felt a strong bond with his father and brothers. The conscientious stream of letters to them and to his only nephew, Lionardo, from March 1497 to December 1563, pictures a Michelangelo unusually proud of his reported lineage from the counts of Canossa, eager to raise the status and fortunes of his family, interested in the health and welfare of each of the males who constituted that household, and hopeful for a brilliant survival of the Buonarroti Simoni line. The letters also reveal him as a son, brother, and uncle impatient with any relative's weaknesses or ingratitude, prodigal with complacent advice, and devoted to his kin in direct ratio to their willingness to stay away from him and let him work.

After Michelangelo's birth in 1475, the Buonarroti returned to Florence to share a crowded home in the Santa Croce neighbourhood with the family of Michelangelo's uncle Francesco. Michelangelo spent periods of his childhood on a family farm at Settignano, in the hills above Florence, where a wall drawing of his, a "Triton," can still be seen. On April 1, 1488, Michelangelo left the classroom of Francesco da Urbino to become an apprentice of the painter Domenico Ghirlandajo. His love of sculpture (he was to call it "the prime art") and a small stipend from the great Lorenzo de' Medici, the ruler of Florence, led to his leaving Ghirlandajo to study sculpture in the Medici garden (where Lorenzo had a collection of antique sculptures) under Bertoldo di Giovanni. This important step permitted him to know personally such Medici protégés as the philosopher Marsilio Ficino and the poet Politian, whose thought is reflected in his later art and poetry. At this time he executed his reliefs "Madonna of the Stairs" and the "Battle of the Centaurs." After this residence in the Medici household, he would be marked in Florence as a "Medici man," which, in the vicissitudes of Tuscan politics, could be either an advantage or a disadvantage. Indeed, after the death of Lorenzo in April 1492 and days before the expulsion of his son Piero in 1494 by the preacher and religious reformer Savonarola, Michelangelo prudently fled to Bologna. Housed by the nobleman Giovanni Francesco Aldrovandi in Bologna, he carved three small statues for the tomb of St. Domenic in the church bearing that saint's name. Having returned to Florence in 1495, he executed a sculptured "Sleeping Cupid" (now lost), making it appear as an antique. After it was resold as a work of antiquity to Cardinal Riario in Rome, Michelangelo offered to reimburse the money he had originally received for it. One important sculpture Michelangelo completed while still in Florence, probably before 1494, was a wooden "Crucifixion" (authenticated only in 1965), which he offered in gratitude to the church of S. Spirito for allowing him to study the anatomy of the corpses stored therein.

Apprenticeship with Ghirlandajo

Many reasons may have induced Michelangelo to leave Florence for Rome, where he arrived June 25, 1496: the discrediting of the Medici, Savonarola's burning of works of art, the invasion of Charles VIII of France, or perhaps, as Condivi suggests, his view of Rome as "a broad field in which a man may demonstrate his worth." From the first he was troubled by the bellicose and materialistic spirit of Rome, where, as he wrote, "Chalices become swords and Christ's blood is sold by the bucketful."

In Rome, as if mindful of one of Politian's Bacchic poems, he carved for the banker Jacopo Galli a marble "Bacchus," as pagan in spirit as the Greek fauns in the Capitoline Museum. In contrast, he turned in 1498 to the Christian themes that were to dominate his art henceforth; on a commission from Cardinal Jean Villiers de la Groslaye, he executed the marble "Pietà" that would later confront churchgoers entering St. Peter's basilica. Michelangelo explained that the youthful features of his Virgin were the result of her "never having entertained the slightest immodest thought which might have troubled her body." This "Pietà" was defaced in 1972 and subsequently restored.

Back in Florence in 1501, Michelangelo signed contracts for 15 figures for the Piccolomini altar in Siena, a commission only partially carried out, and for the marble "David," which he completed in April 1504. Immediately hailed by Florentines as "the Giant," it was viewed by the democratic Commune as an allegory of the moral strength of Florence. The Commune then requested a bronze statue of "David" to be commissioned as a diplomatic gesture to the Maréchal de Gié, the virtual ruler of France at the time. Completed with the help of Benedetto da Rovezzano in 1508, this work, last seen in the 16th century in the gardens of the Robertet Château in the Loire Valley, was apparently later moved to the Château de Villeroy near Mennecy, France. A marginal annotation penned alongside a sketch of Michelangelo's bronze "David"—"David with his sling and I with my bow"—permits the conclusion that the figures of David (two sculpted and two painted) in the artist's work represent Michelangelo's self-projections.

Late in August 1504 (possibly even in October) the secretary of the Commune, Piero Soderini, convinced Michelangelo to undertake a fresco of the "Battle of Cascina," fought in 1364 between Florentines and Pisans, for the Hall of the Five Hundred in the Palazzo Vecchio. This commission heightened the rivalry with his older competitor Leonardo da Vinci, who was painting the "Battle of Anghiari" on the wall opposite. This vast wall, later destroyed, illustrates Michelangelo's addiction to the tense, contorted male nude that reached its apogee in the vault of the Sistine Chapel and "The Last Judgment." His glorification of the male figure, in part a consequence of his long study of anatomy, he further justified by a Platonic assertion that it was the "veil" through which God revealed himself.

Mature life and works. Meanwhile Pope Julius II, aware of the absence of the young artist, recalled him to Rome, thereby initiating the temperamental, often bickering friendship that was to endure until the pontiff's death in February 1513. The Pope ordered Michelangelo to work on a vast sepulchre for him, containing over 40 lifesize figures, which was to be the eighth wonder of the world. The "tragedy of the Tomb," a tomb never completed, was to harass Michelangelo for years: problems of quarrying, inadequate assistants, niggardly financing, papal tantrums, and revisions of contract troubled the sculptor long after the Pope's death, when Julius' heirs threatened him with one lawsuit after another to bind him to complete the project. On April 17, 1506, Michelangelo fled Rome on horseback after an affront by the Pope. In Florence he entertained thoughts of accepting a commission from Bayazid, sultan of the Ottomans, to build a bridge between Constantinople and Pera. Piero Soderini urged him rather to effect a reconciliation with the Pope. So, on November 28, Michelangelo set off for Bologna to humiliate himself before the Pope, who was enjoying his military conquest of that city, and to agree to execute a bronze statue of Julius for the church of S. Petronio. This statue, installed in February 1508, was damaged by the vengeful Bolognese after restoration of the Bentivoglio regime and sent to Ferrara where Duke Alfonso d'Este had it melted down into a cannon in May 1512.

Recall to Rome by Pope Julius II

In May 1508 Michelangelo received the first payment from the Pope to begin the glorious expanse of the Sistine Chapel. Unhappy at being forced to paint rather than sculpt, he rigidly noted on the receipt that he, a sculptor, had received 500 ducats for the painting in the Sistine Chapel. A humorous, extended sonnet to his friend Giovanni da Pistoia at this time records the difficulties of this herculean task and complains that he "is not in the right place, nor is he a painter." (Many historians of his painting have commented, in fact, on its sculptural quality.) The panoramic vault, balancing pre-Christian prophets against the pagan sibyls, knitted together by nine histories and four spandrel (space between the exterior curve of an arch and an enclosing right angle) pictures from the Old Testament, fringed with the ancestors of Christ, and liberally decorated with nude youths that worried five popes, required his attention until October 31, 1512.

The Medici having returned to power in Florence in 1512, Michelangelo resided there intermittently between 1514 and 1534, after which date he lived in Rome until his death.

In May 1513 the sculptor was able to renegotiate the contract for Pope Julius' tomb with the pontiff's heirs and to work on the awesome "Moses" and two "Slaves" to adorn that sepulchre. In the meantime, two Medici popes, Leo X (the second son of Michelangelo's first patron, Lorenzo the Magnificent, who was elected pope in 1513) and Clement VII, were to keep him busy on their projects. In February 1518 Michelangelo designed a model for the facade of the Medici parish church of S. Lorenzo. Yet, after considerable work on the project, especially quarrying for marble at Carrara and Pietrasanta, he was transferred from it and in November 1520 signed a contract to plan a mortuary chapel in S. Lorenzo to contain tombs for the Medici family, starting with sepulchres for Giuliano, duke of Nemours, and Lorenzo, duke of Urbino, both recently deceased. From 1513 on, Michelangelo suffered under the contrary pressures of the Pope and the cardinal de'Medici, on the one hand, and the heirs of Julius II, on the other, each party demanding his undivided services. When this pressure began, Michelangelo wrote in a letter, "I am solicited so much that I cannot take time to eat."

Devotion to Dante

Michelangelo's great devotion to the Italian poet Dante, who had died in 1321, came to the fore in October 1519, when he approached the Pope with an unsuccessful offer to execute a tomb in Florence if the ashes of Dante could be returned from Ravenna. In a sonnet to the poet, Michaelangelo hailed him as a man "without peer." In another he wrote, "Would that I were he! Born to such a choice, I should give up the most felicitous state in the world for bitter exile, just to possess his virtue."

After Pope Leo's death in 1521, he was succeeded very briefly by Adrian VI, a patron with little interest in art. In November 1523 the artist's taskmaster Cardinal de' Medici became Pope Clement VII. The following year, he added to Michelangelo's chores in Florence the designing of the Laurentian Library. Even as Michelangelo worked on the New Sacristy and the Laurentian Library in 1526, he proceeded with the effigies of the two dukes. These two figures, detached from and set above their tombs in niches, dressed as placid captains of the church in diaphanous togas revealing their musculature, represented a new departure in mortuary design. Another departure was the idealized portrayal of the clean-shaven dukes, leading Florentines who had known them to complain that they did not resemble their bearded prototypes. Michelangelo, always interested in idealized representation, replied: "A thousand years from now no one could judge that they were otherwise." Four reclining marble statues of the times of day ("Dawn," "Day," "Dusk," "Night") represent the rapid passing of time, a constant motif in the artist's thought; in a prose poem, for example, Michelangelo regrets that the rapid course of night and day has brought Duke Giuliano to an early death.

The year 1529 brought a curious interruption to his busy schedule. Pessimistic about man in general, Michelangelo could only conclude that politics was an unattractive business to be shrugged off by an artist. He once wrote, "Artistic matters give me enough worries without politics." He was as emphatic in his condemnation of war: "He who wins by flight, let him quit the field." After the sack of Rome by the Spanish emperor in May 1527, the Pope and Emperor settled their differences and planned an attack against the Florentine Republic. In January 1529, Michelangelo was, despite himself, named magistrate of the Committee of Nine of the Florentine Militia and, in April, governor and procurator general of the city's fortifications. In July and August he visited the fortifications of Bologna, but in September he yielded to an impulse to "win by flight" and abandoned Florence for Ferrara and then Venice. In November he was declared a rebel by the City of Florence, only to return probably in December and continue fortifying the walls. In August 1530 the republic fell, and the Medici once more governed Florence. Michelangelo went into hiding and remained hidden until Pope Clement tacitly pardoned him for abandoning the Medici Chapel for the fortification of the city. While several of his friends went into exile in Rome and elsewhere, Michelangelo remained in Florence to complete the Medici Tombs (1534).

In 1531 Michelangelo's father, Lodovico, died, and his son wrote an affectionate eulogy in verse. The theme of the poem is that one is wrong to fear death, for the souls in heaven are emancipated, free of concerns and pressures, enviably exempt from hardships. Visiting Rome in July 1532, Michelangelo met a young nobleman, Tommaso Cavalieri, for whom he conceived a lasting Platonic love, a love he expressed in many sonnets and allegorized in many drawings (among them "Ganymede" [since lost], "Tityus" [Royal Collection, Windsor Castle], and "The Fall of Phaëton" [British Museum, London], according to Vasari). Their friendship endured until the artist's death, when the younger man sealed Michelangelo's eyes. Cavalieri and the widowed marchioness of Pescara, Vittoria Colonna, whom Michelangelo apparently met in 1536, were the two friends who penetrated most deeply Michelangelo's psychic sanctuary and gave the lie to his earlier (1509) claim: "I have no friends of any kind, nor do I wish any, for I have not so much time that I can afford to waste it." They form a contrast to the two young men, probably models, Gherardo Perini and Febo di Poggio, with whom Michelangelo probably had brief relationships of a homosexual nature.

On September 23, 1534, two days before the death of Clement VII, Michelangelo left Tuscany forever, returning to Rome, where the new pope, Paul III (Alessandro Farnese), appointed him official sculptor, painter, and architect of the Vatican. In May 1536 he was at work on "The Last Judgment" in the Sistine Chapel, a powerful fresco of the Day of Wrath inspired by the medieval hymn *Dies irae*, by his reading of Dante, and by his own fears of being judged unworthy at the Resurrection. His Christ-centred religiosity, often verging on mysticism, emerged both in verses composed concurrently with "The Last Judgment" and in the magnificent Christian poetic effusions of the 1550s, when the artist was "living on credit in the hostel of death" and fearful of salvation. His greatest anxiety, occasioned by the thought of the certainty of death, was his unworthiness to be judged on the Day of Wrath. His poems show him viewing death as a Gothic grim reaper, cutting down humanity like blades of hay. He was convinced that every passing day made a man less worthy of salvation: "he who lives least may hope more for pardon." From the unfurled banners of heaven at the top of the cosmic scene of "The Last Judgment" to the tumbling sinners condemned to hell at the bottom, the anger of the central figure of Christ the judge dominates the work. Whereas many theories of collective guilt have been elaborated to explain Christ's anger (for example, anger because of French military invasions into Italy), the Saviour's wrath and upraised arm are directed at individual sinners such as Michelangelo (clearly portrayed below the Saviour in the pelt of St. Bartholomew) who have disregarded Christian law. This personal meaning is borne out amply in the poetry of Michelangelo by such lines as "Hear not my fault with thy chaste ear, nor raise toward me thy righteous arm" and "Lord, in the last hours stretch toward me thy forgiving arms." "The Last Judgment" is clearly a testimonial to the artist's concern for his own soul.

Inspiration for "The Last Judgment"

A similar personal meaning is associated with his bust of "Brutus," which he offered in 1539 to his friend the historian Donato Giannotti. In a transcribed record of a conversation in Giannotti's home, Michelangelo speaks at length about the guilt of Brutus the tyrannicide. Michelangelo approved of Dante's placing Brutus in the lowest pit of hell (in the *Divine Comedy*), as slayer of a benefactor, and yet he felt obliged to admit to the Florentine exiles Giannotti and Luigi del Riccio that "he who kills a tyrant kills a beast." This final admission results from Michelangelo's disapproval of the Medici heirs then ruling Florence and of Duke Alessandro, murdered in 1537.

With "The Last Judgment" uncovered (October 31, All Saints Eve, 1541) and universally praised, Michelangelo turned for the last time to the tomb of Julius II. It was agreed with the Duke of Urbino that other masters would be brought into the project to relieve Michelangelo. In October 1542 the artist penned a plaintive letter about this project:

> I find myself having lost my youth and manhood tied down to this tomb, which I defended as much as possible with Popes Leo and Clement, and my excessive loyalty which no one has consented to acknowledge has ruined me. Thus my destiny wishes it.

The much reduced version of this "eighth wonder of the world," completed in February 1545, may be seen today in its modest chapel within the church of S. Pietro in Vincoli. Its chief attraction is the patriarchal "Moses," a prime display of *terribilità*, a quality Michelangelo acknowledged that his works possessed—and a quality that led the 19th-century English novelist William Makepeace Thackeray to remark that he would not wish to be left alone in a room with it. The curious horns that "Moses" wears are generally accepted as symbols of light rays derived from primitive statuary.

In November 1542 Michelangelo received payment to start the painting of the Cappella Paolina, a project completed in 1550. Two large frescoes depicting the "Conversion of St. Paul" and the "Crucifixion of St. Peter" were completed in 1545 and 1550. In July and August of 1544, Michelangelo was sufficiently ill that his friend Luigi del Riccio had him transferred to the Strozzi palace for care and recuperation, a transfer effected again in December 1545.

The bulk of Michelangelo's poetry having been written between 1530 and 1546, del Riccio collected the scattered poems and planned an edition of them. A rupture between the two friends (the cause is uncertain, but Michelangelo accused his friend of ingratitude) frustrated the project. The subsequent poems, the "trembling hand" verses, become more and more concerned with old age, approaching death, doubts, and renunciation. His fame as a poet gained ground when, in 1549, the Florentine humanist Benedetto Varchi published a textual exegesis of a sonnet embodying Michelangelo's Platonic view of art as something preordained by God and implanted within the marble or pigment to be "perceived" by the artist. Michelangelo wrote in return, "The sonnet comes from me all right, but the Commentary comes from heaven." The following year Giorgio Vasari published his biography of Michelangelo, and, in 1553, Condivi's life of the artist appeared.

Fame as a poet

In 1550 Michelangelo began work on his "Pietà" ("Deposition") to be placed in the Florence Cathedral. That it is less finished than other works does not lessen its emotional impact. For Michelangelo's theory of art as a preordained basic form allowed him to leave many of his sculptures consciously unfinished. To Michelangelo, the challenge offered to the artist is to capture the basic form that "grows" within the material, to "break the formula." The finishing process is a postlude and, indeed, could easily be entrusted to assistants. In the "Pietà," the group of Christ, Mary Magdalene, and Nicodemus is superbly done at focal points, with the finishing to have been undertaken by Tiberio Calcagni (who died in 1565 before doing so). The compassionate Nicodemus (a self-portrait of the artist) seems to be consoling the limp Christ with the words of Michelangelo's great hymn to the Redeemer, "Thou wast condemned to death that thou might with thy blood open the gates of heaven to man." Vasari wrote that Michelangelo intended this group to decorate his own tomb, even though he adds that Michelangelo at one point deliberately broke the stone "probably because it contained many flaws."

In March 1555, Pope Julius III died, to be succeeded by Marcellus II (Marcello Cervini), with whom Michelangelo had often disputed. The artist had ordered Cervini not to interfere with the activities in the Vatican workshop, to "keep the money coming in and keep it out of the hands of thieves, and as for the planning of the building, leave that to me!" This outburst is perhaps typical of Michelangelo's sometimes crotchety character, which created hostility among some of the assistants in the Vatican workshop. His rigidity is revealed in many self-assured phrases in his letters: "I am firm in my opinion," "I don't contradict myself," or "I'll abide with my original opinion." It was obvious that Marcellus II was going to side with the dissident workers who were loyal to the architect Sangallo. They had long complained that Michelangelo kept them ignorant of his plans. Fortunately for the artist, the pontiff's demise six weeks later turned the tide again in his favour. Marcellus' successor, the redoubtable Cardinal Carafa, who had been chiefly responsible for recent book burnings and the establishment of the *Index Librorum Prohibitorum*, was well disposed toward the octogenarian artist. As Pope Paul IV, he reconfirmed Michelangelo's title as architect of St. Peter's. Michelangelo was also protected by Bishop Beccadelli, a friend with whom he exchanged sonnets, against the workers' cabal.

In September 1556, Michelangelo's tendency toward panic flight before the threat of war overcame him one last time. With Rome threatened by the Spaniards under the Duke of Alba, Michelangelo took refuge at Spoleto. He whose art consistently disdained the portrayal of nature as landscape returned to Rome with the written declaration: "Less than half of me has returned to Rome. For truly one cannot find peace except in the woods."

In 1559, the Counter-Reformational zeal of Pope Paul led him to order Michelangelo's good friend the artist Daniele da Volterra to cover with loin cloths many of the nude figures in "The Last Judgment." Michelangelo's dismay could hardly have exceeded that of Volterra, who was given the mocking title of il Brachettone (the Breeches Maker) by the Roman populace. (It was Volterra, by the way, who executed the most accurate portrait bust of Michelangelo [in bronze] after casting a death mask of the deceased master.)

Late life and works. In his late years, Michelangelo's projects and commissions were mainly architectural, as though his tired arms needed respite from the hammer and chisel. These included the cornice of Palazzo Farnese (1547), the piazzale of the Capitoline Hill (1546), the designing of St. Peter's cupola (1557–58), the planning of the projected church of S. Giovanni dei Fiorentini (1559), designs and studies for the Porta Pia (1561), and the accommodation of the nave of the church of Sta. Maria degli Angeli into the precincts of the Baths of Diocletian (1561). Although familiar with the treatise on architecture by the Roman Vitruvius (1st century BC), Michelangelo typically declared to Pope Paul that he was no architect. Yet he did not hesitate to evaluate other architects (Bramante rated high, Antonio da Sangallo very low) and to boast of his plans for his S. Giovanni dei Fiorentini: "Neither Greeks nor Romans ever constructed such a thing among their temples." Criticized since mid-19th century for treating architectural details arbitrarily, for indifference to constructive efficiency, for the loss of conformity to constructive principle, Michelangelo has been praised by contemporary architects for having reacted to the ideal of static building during the High Renaissance.

Architectural projects

Yet, during his last days, he returned to "sweet sculpture," to the carving of the "Palestrina Pietà" (the authenticity of which is contested by only one historian), and the "Rondanini Pietà," on which the sculptor worked almost to his dying day. It was as though Michelangelo, fearful unto death of his unworthiness, had to carve one last time the pathos of the descent from the Cross and what he called the "mansuetude" (meekness or gentleness) of the Virgin Mary.

Michelangelo's Spartan habits and perhaps even his heavy work schedule toughened him for a long life in art. Of course he complained about his health, just as he sooner or later complained of much else in life. In a verbal self-portrait he claims to be plagued with diarrhea, coughs, catarrh, short-windedness, snoring, lumbago, hernia, exhaustion, dizziness, pain in his sides, weak teeth, and spotted eyes, weak hearing in one ear and a singing in the other—all this in addition to the painful gallstones for

which he sought relief from the waters of Viterbo. Yet his productivity is a testimony, if not to health, to his stamina and self-discipline. He who complained of his "imminent death" about 48 years before it took place managed to fulfill almost 89 years of life, the last of old Lodovico's sons to go. On February 14, 1564, he apparently suffered a stroke. Late in the afternoon of the 18th, Michelangelo died, Cardinal Salviati administering last rites and Daniele da Volterra, Tommaso Cavalieri, and a few other friends attending at the bedside. His last confession to Cardinal Salviati was worthy of the artist laureate of Christendom: "I regret that I have not done enough for the salvation of my soul and that I die just as I am beginning to learn the alphabet of my profession."

Although Michelangelo had been made an honorary citizen of Rome (in March 1546), he stated two days before death that he wished to be buried in Florence. Even after a state funeral in Rome's church of the SS. Apostoli, his nephew Lionardo managed to recover the body, have it baled in a packing box, and smuggle it to Florence. After more ambitious obsequies for their native son arranged by the Florentine Academy, Michelangelo's townsmen laid him to rest in Sta. Croce, where his sepulchre, designed by Vasari, may be seen next to the cenotaph of his lifelong hero Dante Alighieri.

CHARACTER AND ASSESSMENT

Michelangelo's poetry as a key to his character. The poetical works of Michelangelo, which have been correctly characterized as a "spiritual biography," consists of 343 sonnets, madrigals, *capitoli* (satirical pieces in tercet rhyme), quatrains, and fragments, unfinished pieces like much of his late art. Written without thought of publication, they provide a direct avenue to the artist's beliefs, thoughts, emotions, and moods. They were an intimate journal in which he could confide his thoughts on love, religion, friendship, politics, and even art, which he felt late in life had been a "false idol" and had pre-empted the years "granted him to meditate on God," as one sonnet complains. Some poems were shared with his few intimate friends, Luigi del Riccio, Tommaso Cavalieri, or Vittoria Colonna. A few served as verse epistles to his contemporaries: a gruff lecture to Pope Julius II, a request to Donato Giannotti to "adjust" a poem, a sonnet to Giorgio Vasari "to prove that he is in his second childhood," a gracious refusal to undertake a bust for Gandolfo Porrino, and so on. At one of the busiest times of his career, Michelangelo acceded to the request of Luigi del Riccio to compose 50 epitaphs on the death of the latter's adolescent nephew, epitaphs not always noble in quality and containing undertones homosexual in character. Never an activist in politics, he penned only a few poems that reflected either a direct or indirect condemnation of the Medici ravishers of the Florentine Republic.

Themes and moods of the poems

The lonely Michelangelo spent a great deal of time writing love poems. Just as symbols of love haunt his art (Venus and Cupid, Leda and the Swan, Samson and Dalilah, Tityus, Ganymede, for example), so the artist depicts himself as a figure assailed by love. He writes with consuming interest of the vagaries, suspense, power, renunciation, and even definition of love. He warns that "unbridled desire is lust and not love, and it kills the soul." Accordingly, his love poetry is usually spiritualized; but a few pieces wander away from the *amor onesto* ("true love"), and in his late poetry he regrets his indulgence in sensual pleasure. The poems fall into three classifications: generalities on love, poems to women (neither identified nor even authenticated, except for his chaste autumnal love, Vittoria Colonna), and poems to men (Cecchino Bracci named directly and Febo di Poggio indirectly).

The large corpus of confessional and mystical poetry of astonishing sincerity and revelation (discussed earlier) is valuable not only in itself but for the light it sheds on Michelangelo's art and the circumstances surrounding that art. The basic theme of the creation of day (light) and night (darkness) twice depicted on the Sistine ceiling is developed in several poems on the passage of time, especially in lines specifically alluding to the two creations on that vault:

> He who from nothing, and ere all things were, did time create, divided it in twain. To one he made the lofty sun a share, and to the other moonlight's dusky train.

Michelangelo continually deprecated his efforts as poet. He laughed off his poems as novelties and confections. To one poem he appended, "at Carnival time it seems legitimate for those not masked to commit some folly." Accompanying a sonnet sent to Vasari went the notation: "You will say that I am old and mad trying to make sonnets, but since many say I'm in my second babyhood, I've wished to play my part." Although he disclaimed its value, he was flattered and pleased at praise of his poetry. Yet he was hesitant to allow publication of them during his lifetime and frustrated the plan of Luigi del Riccio and Donato Giannotti to have them published. This heralded poet was to appear in print posthumously, when his great-nephew, the Florentine academician Michelangelo the Younger, brought out the first edition of the *Rime* in 1623. Unfortunately, this editor tampered with the Vatican and other texts and bowdlerized poems addressed to men, changing masculine pronouns to feminine. It was only in 1960 that a definitive edition was published.

First edition of the poems

A man of the Renaissance. Thanks to the long span of his lifetime and to the milieu in which that life was passed, Michelangelo was, despite himself, a man of the Renaissance, that Renaissance of which Vasari saw him the incarnation. As a product of the Humanistic age, Michelangelo's centrifugal interests brought him the breadth and universality to embrace and conciliate the polarities contained within the Italian Renaissance. Three such polarities seem particularly significant.

In the Middle Ages little art theory or criticism existed, leaving a gap between artistic self-consciousness and technical achievements. One of the chief characteristics of the High Renaissance was precisely this professional self-consciousness sensed by the artist, which led him inevitably to become both practitioner and theorist. In an age and country rich in treatises on art, Michelangelo himself planned a study to be entitled "Treatise on All Manners of Human Movements, Appearances, and Anatomy, with an Ingenious Theorick." Despite a reticence to talk about himself or even about art, he planned a treatise on painting as well. Although neither of these works of theory was ever written, Michelangelo left ample evidence of the nature of his speculation on art and artists in letters and conversations. Responding to the unremitting curiosity of his contemporaries, his many value judgments on artists were unusually clear and articulate. His immersion in art made it impossible for him to eschew the role common in the Renaissance of artist-theorist.

The greatest polarity to be reconciled in his lifetime resulted from the confrontation of pagan Humanism and Christian orthodoxy and authority. Here again, Michelangelo's thoughts and works served a unifying, conciliating purpose. His devotion to both Christianity and the Platonism of his friend Marsilio Ficino contributed to that accommodation. During his youth and manhood, creatures of Greco-Roman mythology, such as Cupid, Ganymede, Bacchus, Tityus, counterbalanced figures from the Christian theogony. The most conspicuous example of this accommodation is the juxtaposition of Old Testament prophets and pagan sibyls on the Sistine vault. His Neoplatonism was most noticeable in his poetry of the 1540s, the decade during which he executed the "Brutus." When the High Renaissance gave way to the Counter-Reformation, with Michelangelo being condemned at the Council of Trent by Gilio da Fabriano, the accommodation in which Michelangelo and the "Christian Humanists" had pioneered survived with some difficulty.

The third and last conciliation was the one that the artist effected among the three separate major arts. After his early, almost exclusive partiality to sculpture, Michelangelo was able to state in February 1546 that "everyone knows I am a sculptor, painter, and architect." It was not merely his increasing practice and success in all three arts, however, that led him to view them as parts of a

larger whole. It was rather the unifying embrace of Humanism, its unitarian drive, that led him to adopt as his personal emblem three circles interwoven, as he explained, to show the interdependence of each on the other two. Many of his comments shattered the rigid distinctions among the parallel arts. In an epistle to his academic friend Benedetto Varchi, Michelangelo declared "to no purpose" Benedetto's referendum on the relative art of painting and sculpture, since they are parts of the same phenomenon, are of equal nobility "philosophically speaking," serve the same purpose, and derive from the same experience and inspiration. Despite a personal preference for the practice of carving, he knew that, "philosophically speaking," the underlying unity of art was to be found in design (in Renaissance Italian the "fine" arts were then called the "arts of design"), and his insistence on the oneness of the arts issued from this knowledge. Design, draftsmanship, drawing—this was the basic talent he demanded of his colleagues and assistants. In the Roman dialogues transcribed by Francisco de Hollanda, Michelangelo views all arts as subservient to design. While others, such as Varchi and Leonardo da Vinci, were stressing the dissimilarities of the arts, Michelangelo held consistently to the unitarian view.

Interdependence of Michelangelo's arts

Thus, this unitarian tendency as a Renaissance thinker led the artist, so ungregarious and unaccommodating as an individual (Raphael called him "the hangman") to become conciliatory in the areas of aesthetics and philosophy, uniting artistic theory and practice, Christianity and paganism, and the three arts of design.

MAJOR WORKS

SCULPTURE: "Madonna of the Stairs" (*c.* 1492; Casa Buonarroti, Florence); "Battle of the Centaurs" (*c.* 1492; Casa Buonarroti); "Crucifixion" (before 1494; S. Spirito, Florence); "Bacchus" (1497; Bargello, Florence); "Pietà" (1499; St. Peter's, Rome); "David" (1501–04; Accademia, Florence); "Madonna and Child" (1501–04; Notre-Dame, Brugge); "The Madonna and Child with the Infant St. John" ("Taddei Tondo"; tondo, *c.* 1503; Royal Academy, London); "Madonna and Child" ("The Pitti Madonna"; tondo, *c.* 1503; Bargello); "Moses" (for Tomb of Pope Julius II, 1505–45; S. Pietro in Vincoli, Rome); "Christ Bearing the Cross" (1519–20; Sta. Maria Sopra Minerva, Rome); Medici Tombs ("Dawn," "Dusk," "Day," "Night"; 1520–34; S. Lorenzo, Florence); "David" ("Apollo"; *c.* 1530; Bargello); "Victory" (*c.* 1532–34; Palazzo Vecchio, Florence); "Pietà" ("Deposition"; 1550–56; Duomo, Florence); "Palestrina Pietà" (*c.* 1550; Accademia, Florence); "Rondanini Pietà" (1552–64; Castello Sforzesco, Milan).

DRAWINGS: Major collections: British Museum; Royal Library, Windsor; Ashmolean Museum, Oxford, England.

ARCHITECTURE: Chapel of Leo X (dedicated to SS. Cosmas and Damian; facade, 1514; Castel Sant'Angelo, Rome); Laurentian Library (1523–59; S. Lorenzo, Florence); Palazzo Farnese (facade completed 1547; Rome); St. Peter's dome designed 1557–58; Rome); Porta Pia (1561, Rome).

PAINTINGS: "Holy Family" ("Doni Madonna"; *c.* 1503–05; Uffizi); frescoes, Sistine Chapel ceiling (1508–12; Vatican); "The Last Judgment" (1533–41; Sistine Chapel, Vatican); "Conversion of St. Paul" (1542–45; Cappella Paolina, Vatican); "Crucifixion of St. Peter" (1542–50; Cappella Paolina, Vatican).

BIBLIOGRAPHY

Major published bibliographies: ERNST STEINMANN and RUDOLF WITTKOWER, *Michelangelo Bibliographie* (1927), covers the period 1510–1926; *Michelangelo im Spiegel seiner Zeit* (1930), covers the period 1927–30; P. CHERUBELLI, "Supplemento alla bibliografia michelangiolesca," in *Michelangelo Buonarroti del IV centenario del Giudizio Universale* (1942), covers the period 1931–42; *Zeitschrift für Kunstgeschichte*, brings bibliography from 1942 to the present.

Michelet, Jules

One of the first and greatest of the nationalist and romantic historians of France, Jules Michelet was born in Paris on August 21, 1798. His father, a modest printer, managed to give him an education. A brilliant and laborious student, Michelet at 29 was teaching history and philosophy at the École Normale Supérieure. He had already published various textbooks and a translation (1827) of Giambattista Vico's *Scienza nuova* ("New Science"). The French Revolution of 1830 confirmed Vico's influence on Michelet in stressing man's own part in the making of history, conceived as a continuous struggle of human freedom against fatality. This, the main theme of the *Introduction à l'histoire universelle* (1831), was to underlie all of Michelet's later writings.

After the *Histoire romaine* (2 vol., 1831), Michelet devoted himself to medieval and modern history; his appointment as head of the historical section of the Record Office in the same year provided him with unique resources for carrying out his monumental life's work, the *Histoire de France*. The first six volumes (1833-43) stop at the end of the Middle Ages; they include the "Tableau de la France," in which the emergence of France as a nation is seen as a victory over racial and geographical determinism; they also include his treatment of Joan of Arc as the very soul of France and the living symbol of his own patriotic and democratic ideals. Michelet deliberately threw his intimate self into his narrative, convinced that this was the way to achieve the historian's ultimate aim: the resurrection (or re-creation) of the past. Such a resurrection must be integral: all the elements of the past—artistic, religious, economic, as well as political—must be brought back, intertwined, as they once were, in a living synthesis. Arbitrary and overambitious as the undertaking seems, Michelet's compas-

Treatment of Joan of Arc

Giraudon

sionate genius and romantic imagination enabled him to conjure up an effective evocation, unsurpassed for poetic and dramatic power.

Toward the end of this period of life, which was marked by private crises reflected in his work (the death of his first wife, in 1839, and the death of his friend Mme Dumesnil, in 1842, cast their shadows over whole periods of his *History of France*), Michelet turned away from Christianity and began to profess a messianic belief in democratic progress. His increasing hostility to the church, expressed in his lectures at the Collège de France (where he had held the chair of history since 1838) and in *Duprêtre, de la femme et de la famille* (1845), brought him into conflict with the Jesuits and caused his lectures to be suspended in January 1848. A month later, the revolution that he had heralded in *Le Peuple* (1846) seemed to bring about the realization of his dreams. But they were soon shattered: in 1852 Michelet, having refused allegiance to the Second Empire, was deprived of his posts. In 1847 he had interrupted the sequence of the *Histoire de France* to write the *Histoire de la Revolution française* (7 vol., 1847–53). He visualized the French Revolution as a climax, as the triumph of *la Justice* over *la Grâce* (by which he meant both Christian dogma and the arbitrary power of the monarchy). These volumes, written at a feverish pace, are a vivid and impassioned chronicle.

Hatred of priests and kings

Michelet then resumed the *Histoire de France* from the Renaissance to the eve of the revolution (11 vol., 1855–67). Unfortunately, his hatred of priests and kings, his hasty or abusive treatment of documents, his mania for symbolic interpretation, continually distort these volumes into hallucinations or nightmares. Also thus distorted is *La Sorcière* (1862), an apology for witches considered as godforsaken souls, victims of the antinatural interdictions of the church. A new and happier inspiration produced a series of books on nature: *L'Oiseau* (1856); *L'Insecte* (1858); *La Mer* (1861); *La Montagne* (1868). They reflect the influence of his second marriage to Athénaïs Mialaret, 30 years his junior, in 1849; written in a lyrical vein, they contain some of the most beautiful pages of a supreme prose writer. *L'Amour* (1858) and *La Femme* (1860), written under the same influence, are erotic and didactic divagations. *La Bible de l'humanité* (1864) is the story of man's quest for God, a story immensely enriched by the 19th-century philological and archaeological discoveries in the Oriental field.

The Franco-German War of 1870 shattered Michelet's idealism and his illusions about Germany. He died at Hyères on February 9, 1874. His widow tampered with his diaries, and their publication as a whole was begun only in 1959 (*Journal*, vol. 1, 1959, vol. 2, 1962; *Écrits de jeunesse*, 1959). They record his travels through Europe, and, above all, they give a key to his personality and illuminate the relationship between his intimate experiences and his work.

BIBLIOGRAPHY. G.J.J. MONOD, *La Vie et la pensée de Jules Michelet, 1798–1852*, 2 vol. (1923), a classic biography that unfortunately does not go beyond 1852; G.P. GOOCH, *History and Historians in the Nineteenth Century*, 2nd ed., pp. 168–177 (1952), a short but excellent assessment, with an outdated bibliography; J. GUEHENNO, *L'Évangile éternel: Étude sur Michelet* (1927), a sympathetic view by a liberal critic; R. BARTHES (ed.), *Michelet par lui-même* (1954), an anthology with a brilliant essay on Michelet's obsessions; P. VIALLANEIX, *La Voie royale* (1959), a scholarly and valuable essay on Michelet's notion of "the people," with a full chronology and bibliography.

Michelson, A.A.

Albert Abraham Michelson, the first American to receive a Nobel Prize in science, is best known for his determination of the speed of light and the Michelson-Morley studies of the Earth's motion in relation to surrounding space, work that made an important contribution to Albert Einstein's theory of relativity.

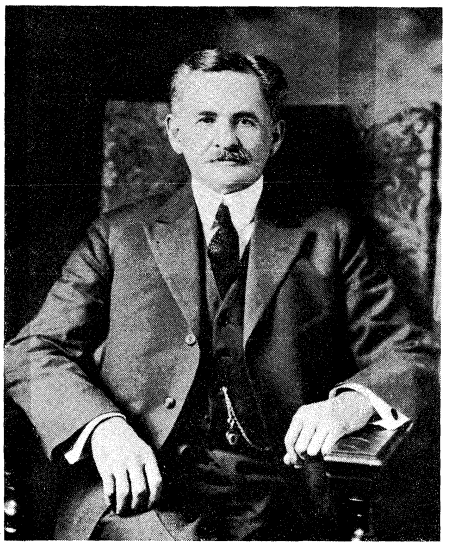
Michelson was born in Strelno, Prussia (now Strzelno, Poland), December 19, 1852. His parents brought him to the United States when he was two years old. From New York, the family made its way to Virginia City, Nevada, and San Francisco, where the elder Michelson prospered as a merchant.

At 17, Michelson entered the United States Naval Academy at Annapolis, Maryland, where he did well in science but was rather below average in seamanship. He was graduated in 1873, then served as science instructor at the academy from 1875 until 1879. In 1878 Michelson began work on what was to be the passion of his life, the accurate measurement of the speed of light. He was able to get useful values with homemade apparatus. Feeling the need to study optics before he could be qualified to make real progress, he travelled to Europe in 1880 and spent two years in Berlin, Heidelberg, and Paris, resigning from the navy in 1881. Upon his return to the United States, he determined the velocity of light to be 299,853 kilometres per second, a value that remained the best for a generation. When it was bettered, Michelson bettered it.

While in Europe, Michelson began constructing an interferometer, a device designed to split a beam of light in two, send the parts along perpendicular paths, then bring them back together. If the light waves had, in the interim, fallen out of step, interference fringes of alternating light and dark bands would be obtained. From the width and number of those fringes, unprecedently delicate measurements could be made, comparing the velocity of light rays travelling at right angles to each other.

It was Michelson's intention to use the interferometer to measure the Earth's velocity against the "ether" that was then thought to make up the basic substratum of the universe. If the Earth were travelling through the light-conducting ether, then the speed of the light travelling in the same direction would be expected to be equal to the velocity of light plus the velocity of the Earth, whereas the speed of light travelling at right angles to the Earth's path would be expected to travel only at the velocity of light. His earliest experiments in Berlin showed no interference fringes, however, which seemed to signify that there was no difference in the speed of the light rays, and, therefore, no Earth motion relative to the ether.

In 1883 he accepted a position as professor of physics at the Case School of Applied Science in Cleveland, Ohio, and there concentrated his efforts on improving the delicacy of his interferometer experiment. By 1887, with the



Michelson.

help of his colleague, American chemist Edward Williams Morley, he was ready to announce the results of what has since come to be called the Michelson-Morley experiment. Those results were still negative; there were no interference fringes and apparently no motion of the Earth relative to the ether.

Michelson-Morley experiment

It was perhaps the most significant negative experiment in the history of science. In terms of classical Newtonian physics, the results were paradoxical. Evidently, the speed of light plus any other added velocity was still equal only to the speed of light. To explain the result of the Michelson-Morley experiment, physics had to be recast on a new and more refined foundation, something that resulted, eventually, in Albert Einstein's formulation of the theory of relativity in 1905.

In 1892 Michelson, after serving as professor of physics at Clark University at Worcester, Massachusetts, from 1889, was appointed professor and the first head of the department of physics at the newly organized University of Chicago, a position he held until his retirement in 1929. From 1923 to 1927, he served as president of the National Academy of Sciences. In 1907 he became the first American ever to receive a Nobel Prize in the sciences, for his spectroscopic and meteorological investigations, the first of many honours he was to receive.

Michelson advocated using some particular wavelength of light as a standard of distance (a suggestion generally accepted in 1960) and, in 1893, measured the standard metre in terms of the red light emitted by heated cadmium. His interferometer made it possible for him to determine the width of heavenly objects by matching the light rays from the two sides and noting the interference fringes that resulted. In 1920, using a 20-foot interferometer attached to a 100-inch telescope, he succeeded in measuring the diameter of the star Betelgeuse (Alpha Orionis) as 240,000,000 miles (300 times the diameter of the Sun). This was the first substantially accurate determination of the size of a star.

In 1923 Michelson returned to the problem of the accurate measurement of the velocity of light. In the California mountains, he surveyed a 22-mile pathway between two mountain peaks, determining the distance to an accuracy of less than one inch. He made use of a special eight-sided revolving mirror and obtained a value of 299,798 kilometres per second for the velocity of light. To refine matters further, he made use of a long, evacuated tube through which a light beam was reflected back and forth until it had travelled 10 miles through a vacuum. Michelson died in Pasadena, California, on May 9, 1931, before the results of his final tests could be evaluated, but in 1933 the final figure was announced as 299,774 kilometres per second, a value less than 2 kilometres per second higher than the value accepted in the 1970s.

BIBLIOGRAPHY. The only full-length study of Michelson is BERNARD JAFFE, *Michelson and the Speed of Light* (1960).

(I.A.)

Michigan

Since its admission in 1837 as the 26th state of the Union and the fourth to be carved from the old Northwest Territory, Michigan has become a mainspring in the nation's economic life; the name of its largest city, Detroit, has become a byword throughout the world for the American automotive industry. The state also has retained its prominence in agriculture, and, because of its many inland lakes, its borders on four of the five Great Lakes, and its many wilderness tracts, has evolved into one of America's leading tourist regions. A young and rapidly increasing population, kept in the state by ample employment opportunities and wage scales well above the national average, has helped Michigan to become a symbol of the dynamic growth of the United States as a whole.

Michigan is the only one of the 49 continental states to be split into two large land segments: the sparsely populated but mineral-rich Upper Peninsula, which slices eastward from northern Wisconsin between Lakes Superior and Michigan, and the mitten-shaped Lower Peninsula, which reaches northward from Indiana and Ohio. The two landmasses have been joined since 1957 by "Big Mac," the five-mile-long Mackinac Bridge across the Straits of Mackinac, which separate Lake Michigan to the west from Lake Huron to the east. Between Lake Huron and Lake Erie, in the southeast, the Lower Peninsula is separated from the Canadian province of Ontario by Lake St. Clair and the St. Clair and Detroit rivers. The state's name is derived from a Chippewa Indian word meaning, approximately, "large lake." Though its 58,216 square miles (150,779 square kilometres) rank it only 23rd nationally in size, the inclusion of Great Lakes waters over which it has jurisdiction would raise the figure to 96,720 square miles (250,504 square kilometres), placing it 11th.

Nearly 75 percent of the 8,875,083 Michiganders counted in the census of 1970 are urbanized, heavily concentrated in the industrialized centres of the Lower Peninsula. This factor, together with a broad array of ethnic and national stocks among the people and a constant influx of lesser skilled workers attracted by the union-dominated labour scene, has created in many cities the typical marks of economic progress and poverty existing side by side and a sometimes tenuous social stability. The state government, in Lansing, coordinates a vast network of programs attempting to reduce these contrasts, and it has provided a system of public higher education that is among the most diversified and renowned in the nation. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; DETROIT; and GREAT LAKES.)

THE HISTORY OF MICHIGAN

In the 17th century, the Indian population of present-day Michigan was estimated at between 12,000 and 15,000. The majority, including the Ottawa, Chippewa (Ojibwa), Miami, and Potawatomi, belonged to the Algonkian linguistic group or family. A lesser number, primarily in southeastern Michigan were Hurons and Wyandots. The Ottawa and Chippewa, conditioned extensively by their Great Lakes environment, were of great assistance to the French in the development and expansion of the fur trade. The Ottawa, with their primitive commercial interests, had developed a type of canoe that was highly serviceable in the Great Lakes area. The Miami and Potawatomi were identified more with the culture of the woods. The Hurons were the most advanced in their agricultural practices. All of the Indians lived in small communities and lacked the concept of territorial boundaries.

French heritage

Settlement. Étienne Brulé, the first European to visit the area (1622), was the forerunner of numerous explorers, missionaries, and fur traders who paved the way for French control over Michigan. The oldest community in Michigan is Sault Ste. Marie, founded in 1668 at a site

where in 1641 missionaries held services for 2,000 Chippewas. In 1701 Antoine de la Mothe Cadillac established Detroit as a fur-trading centre and administrative post; it soon became the leading French community in the entire Great Lakes area.

In 1760 the French garrisons were surrendered to an English force, and by the Treaty of Paris, in 1763, England acquired jurisdiction over Canada and the French empire east of the Mississippi River except New Orleans. Under English rule, Michigan remained a part of Canada, and a handful of English-speaking traders helped to give Detroit and other communities a more English character. During the Revolution, Detroit was a major supply centre for British troops who raided the Kentucky country until 1779, when the British general Henry Hamilton was captured.

American territory. Though Michigan had been awarded to the United States in 1783, the British refused to leave Detroit and other major posts until 1796. In 1787 it was made a part of the newly created Northwest Territory. Indian opposition to American rule in the area was ended by the victory of Anthony Wayne at the Battle of Fallen Timbers, near present-day Toledo, Ohio. After 1796 the Americanizing of the regions was accomplished within a few years. Detroit became the capital of the Michigan Territory, which was separated in 1805 from Indiana. Although the first governor, William Hull, surrendered Detroit to the British early in the War of 1812, American rule was restored by the victory of Oliver Perry at the Battle of Lake Erie, late in 1813.

Process of Americanization

The real growth of Michigan Territory began soon after the war. The personality of the new governor, Lewis Cass, and the encouragement that he gave to settlement helped to promote its growth. New modes of transportation were even more significant. In 1818 steamship navigation linked Detroit and Buffalo, New York, inaugurating a new era in lake transportation. Cass's crude highway chain from Detroit to Chicago, Saginaw, and Port Huron helped to establish the patterns of settlement in the interior. Completion of the Erie Canal in 1825 made Detroit a leading distribution point for settlers seeking new homes in the Great Lakes area.

Statehood and growth. Michigan was anxious for statehood so that it might undertake a more ambitious program of internal improvements. The first constitution was drafted in 1835, but admission was delayed until 1837 by the Toledo War, a boundary dispute with Ohio. For relinquishing its claims to the mouth of the Maumee River, at Toledo, Michigan was awarded the western half of the Upper Peninsula as well as the eastern portion, which was historically part of the territory.

The state grew rapidly through the 1840s and 1850s. Thousands of prospective agricultural settlers, including many foreign-born, established new homes in the state. Detroit and other leading cities profited, and in the 1840s the rich iron and copper resources of the Upper Peninsula became known. Tension over the slavery issue resulted in the formation of the present-day Republican Party at Jackson in July 1854. The new party captured the Michigan delegation to Congress and immediately made impressive nationwide gains.

Throughout the Civil War, Michigan made major contributions, losing some 14,000 of its 90,000 men who served. A Negro regiment from Michigan included enlistees from many states and Ontario. Political life saw the Republican Party become dominant after the war, and in the 1890s Hazen Pingree implemented progressive legislation as mayor of Detroit and subsequently as governor.

The 20th century. Before 1900 all of Michigan's 83 counties had been settled. Agriculture, lumbering, mining, and manufacturing created a stirring economic tempo. Throughout the 20th century the economy has been modified greatly and often dominated by the automotive industry, which has contributed further to the rapid growth of Detroit, Flint, and other cities. During World War I, industrial production at all levels was intensified. The emergence of new problems connected with this urban–industrial growth was recognized by features of the new constitution approved in 1908.

Increasing economic tempo

The 1920s were characterized by more economic expansion and a new urban sophistication, as both state and nation continued to lose their rural character and values, and urban crime rates began to rise. The Depression was unusually severe in Michigan, the industrial products of which were not among the necessities of life. Unemployment and deflation were far above national averages: early in 1933, one-third of Detroit's labour force was unemployed.

In 1932 Michigan departed from the Republican fold, and thereafter it became one of the doubtful, or swing, states. Organized labour became a powerful political and economic factor during the 1930s. In 1937 the United Automobile Workers (UAW) became the bargaining agent for production workers at General Motors Corporation and by the outbreak of World War II it was the dominant union in all automotive plants. During the war, Detroit became known as the "Arsenal of Democracy," and industrial production continued at a peak afterward to restock the nation with new cars and other war-depleted consumer goods.

In Detroit the inner-city population reached its peak during the early 1950s. An influx of blacks to war plants created social tensions that brought on a major race riot in 1943, and in 1967 a major racial disturbance resulted largely in burning and looting. Other cities had less severe disorders in following years. Labour tension continued to be part of the Michigan scene, with large-scale UAW strikes invariably being felt throughout the national economy.

THE NATURAL AND HUMAN LANDSCAPE

The physical environment. The Great Lakes cool the hot winds of summer and warm the cold winds of winter, giving Michigan a milder climate than some other north central states. Though the Upper Peninsula is cooler, difference in temperature range between far northern and far southern cities is not excessive. Northern Sault Ste. Marie has average maximum temperatures of about 50° F (10° C) and average minimums of 30° F (−1° C). Detroit, in the southeast, has average maximums of about 58° F (14° C) and minimums of 42° F (6° C). The greatest amount of moisture is received in southern Michigan, with the state's average about 33 inches (838 millimetres). The central portion has less precipitation than does the Upper Peninsula, and the coastal strip along Lake Michigan receives an unusually large snowfall from westerly storm fronts moving across the lake. The growing season ranges from approximately three months in the Upper Peninsula to six months in the southern portions of the Lower Peninsula.

Climatic ranges

The mildly rolling country appealed to the early agricultural settlers. Even the elevations are not high. The highest point in the Lower Peninsula, near Cadillac, rises only about 1,200 feet (370 metres). Elevations approximate 2,000 feet (600 metres) only in the western Upper Peninsula.

Michigan's rivers, the majority of them in the southern portions of the Lower Peninsula, drain vast interior areas. With few exceptions, they are rather shallow and not wide. Their navigability and the ease of bridging them were factors that encouraged settlement. Several of the rivers, especially in the Upper Peninsula, have sufficient falls to serve as a basis for water power.

Rivers, lakes, and islands

Michigan's 11,000 inland lakes range from a few acres in size to the 19,000 acres (7,700 hectares) of Houghton Lake in the north central part of the Lower Peninsula. The shores of many lakes are ringed with summer cottages, as are the shores of the Great Lakes in many places.

About 500 islands dot the lakes and rivers. Belle Isle, a public recreation centre, and Grosse Ile, largely residential, are well-known features of the Detroit River. Mackinac Island became a resort on which motor vehicles are prohibited. Isle Royale, a virgin wilderness of nearly 850 square miles, is a national park in northern Lake Superior.

Several physical features of Michigan are unusually appealing to lovers of the scenic. The dunes on the Lake Michigan shore are used annually by thousands of vaca-

tioners, and the 3,000-odd state and local parks, containing more than 4,100,000 acres of wooded land, present varied landscapes that have helped Michigan to become a major tourist attraction of the Middle West.

Animals native to the area are numerous. Whitefish in abundance swim in the Great Lakes, and many streams contain various edible trout. The Conservation Department operates hatcheries and encourages tourism around the inland lakes, where carp and bass abound. The beaver was sought eagerly by early traders, and other fur-bearing mammals were also found in large numbers. Deer, as well as quail and ducks, remain numerous in many counties. Some 80 out of 83 Michigan counties were once heavily wooded, with genuine prairies or clearings found only in southwestern Michigan. Hardwood timbers included the hickory, ash, oak, and hemlock, though the white and Norway pine were the most common timber in the north.

Regions. Understandably, many Michiganders think of their state as divided into the Upper and Lower Peninsula, but the two physiographic divisions, the Superior Upland and the Central Lowland, follow this plan only in part. The Upland comprises only the rugged western region of the Upper Peninsula, where the abundance of copper and iron ores has made the area economically dependent on the extraction industries. Calumet, Hancock, Houghton, and Marquette are among the better known cities of the area. Agriculture has been of little significance, but tourist and recreational potentialities offer some hope of diversifying the economy.

Geographical divisions

Geographical as well as historical forces unite the eastern counties of the Upper Peninsula and the Lower Peninsula north of a Bay City–Muskegon corridor to create the popularly known "northern Michigan." Here the white-pine forests were ruthlessly exploited. Some agriculture is successful, for even the sandy soil, with adequate moisture, can produce an abundant yield of potatoes and grain. A fruit-growing region near Traverse City has succeeded because Lake Michigan's influence prevents early killing frosts. The towns serve as regional centres for tourists and farmers and often as headquarters for governmental services. Many of the larger communities have attracted small-scale manufacturing establishments. Thriving cities include Sault Ste. Marie, Petoskey, Ludington, Manistee, and Cadillac.

South of the Bay City–Muskegon corridor a fertile clay soil and a longer growing season permit a wider variety of crops, especially grains. The southern agricultural counties, resembling those of northern Ohio and Indiana, produce much of the state's agricultural wealth. The region also contains the great industrial concentrations, and large cities are numerous. As in Detroit, the fifth largest of America's cities, the automotive industry played an important role in the growth of Flint and Lansing. Grand Rapids attained prominence through its furniture industry, and Battle Creek is known nationally for its cereals. The majority of the cities, however, have more widely diversified industries than their reputations suggest.

THE PEOPLE OF MICHIGAN

The diverse backgrounds of Michigan's people, in nationality, religion, and ethnic stock, has been important in shaping the state's character. By the early 1970s, however, the percentage of foreign-born and first-generation citizens was small, even in Detroit.

National and ethnic groups. Germans, the most numerous of the early non-English-speaking immigrants, settled in both rural and urban areas. Detroit had a large German community by the mid-1830s, as did several rural counties by 1850. The large Irish population remained basically urban, although Irish farmers were found in southern Michigan and by 1860 in the Upper Peninsula. Other groups left an impact, though their numbers were not large. Dutch influences are still observable in western counties around Holland, where Dutch settlers pioneered successfully in 1847. Finns have been important in the economic and cultural life of the Upper Peninsula. Early Polish immigrants settled in rural areas until the 1890s, when a large number of Poles concentrated in Detroit. The city's present-day population has a large percentage of persons of Polish ancestry.

The most significant population phenomenon of the 20th century has been the growth of the black population from fewer than 16,000 in 1900 to just under 1,000,000 in 1970. Two-thirds live in Detroit, which had become nearly 45 percent black by 1970. Throughout the 1960s, blacks moved to suburbs that had long-established black neighbourhoods and substantial black populations. They also moved into older neighbourhoods where the prices of homes were not exceptionally high. The trend was similar to that in the central city, where blacks replaced whites. The majority of the newer Detroit suburbs, however, have very insignificant black populations, since much of the price of housing is above what many blacks could afford. Many Detroit blacks expressed a preference for the pattern of life that has evolved in the inner city. Among the Detroit suburbs with majority or large minority black populations were Highland Park and Inkster, 55 percent, and Pontiac, more than 25 percent. In other areas, Flint and Muskegon had sizable black communities, and the smaller city of Benton Harbor became nearly 60 percent black.

The growing black population

Religious affiliations. Michigan's religious history differs somewhat from that of many Middle Western states. Since the first European settlers in Detroit were Roman Catholic, many immigrants of that faith were attracted to the city even before the large Irish, Italian, and Polish immigrations of the 19th century. Detroit was created a diocese in 1833 and an archdiocese in 1937. Other dioceses were established at Marquette, Grand Rapids, Lansing, Saginaw, Gaylord, and Kalamazoo. Of the Protestant denominations, Lutheranism has had many German and Scandinavian adherents, while Methodism has been important in both rural and urban Michigan. The Baptist Church has a large membership throughout the state. The first Dutch settlers were members of the Christian Reformed Church, which was opposed to the state church of the Dutch. The Michigan group was highly independent and conservative in doctrine and social mores. Altogether, Michigan has almost 200 Protestant denominations, some with only small memberships. The first Jewish immigrants were of German background. In 1851 Detroit Jews founded a synagogue. Synagogues throughout the state today reflect all shades of Jewish theological persuasion.

Demography. The natural increase in population—the preponderance of births over deaths—has been important in Michigan's growth. Both birthrates and death rates declined during the 1960s, though they remained near national averages. The death rate among blacks is approximately 30 percent higher than among whites. All projections indicate continued population growth in future decades. The state's population is younger than the national average, suggesting a continuing preponderance of births, and the far greater immigration than emigration should also help to maintain the trend.

The major increases in population are indicated for the metropolitan areas. Some demographers suggest that by 2010 the population of the six-county Detroit area will reach 7,500,000. This urban growth has been continuous, from less than 8 percent of the state's population in 1850 to nearly 75 percent in 1970. As in most of the nation, suburbs have grown at the expense of the inner cities. The population of Detroit proper, 1,845,000 in 1950, had declined by 1970 to less than 1,575,000. Among Detroit's suburbs having unusual growth were Warren, which leaped from 727 in 1950 to nearly 180,000 in 1970, and Livonia, which grew from less than 18,000 to more than 110,000 in the same period.

Urban population growth

THE STATE'S ECONOMY

Economic overview. Manufacturing has been the continuing basis of Michigan's economic strength, ranking it sixth among the states in 1969 in value added by manufacturing. In that year nearly 1,200,000 persons were employed in manufacturing, about 970,000 of them in the production of durable goods. The high wages paid by the automotive industry help to explain the state's mag-

netic appeal in attracting workers from other states, for they have tended to increase wages for the 2,500,000 Michiganders employed in other areas of the economy.

Natural resources

With new methods of iron-ore processing, Michigan's huge mineral reserves should be exploitable through the 20th century. Some deposits of gypsum for cement have not been touched, and the continuing search for petroleum and natural gas promises rich new fields. The fertile soils will continue to make Michigan a major agricultural state. New power sites have added to the industrial potential, though in the early 1970s accommodation was being sought between conservationists and advocates of an extensive network of thermonuclear generating plants that might add to the growing evidences of air and water pollution in the Great Lakes as well as in the inland streams and lakes.

Michigan's tourist industry, which ranks as the state's second largest industry, is dependent largely upon these water resources threatened by pollution. Some 18,000,000 people take recreational trips in Michigan annually, spending about $1,300,000,000. Tourism employs about 155,000 persons, and another 400,000 receive indirect employment from it.

The future of Michigan's agriculture is dependent in part on prices. Its farms average 153 acres in size, in comparison with a national average of 378 in 1969. Many farmers work parttime in industry or for the government, supplementing their income and providing an important factor in the economy of many rural communities.

The automotive industry. Many reasons have been advanced for the rise of the automotive industry in Detroit. The city long had been noted for the manufacture of carriages, wagons, bicycles, and marine engines. The large number of skilled and semiskilled labourers was another important factor. Other cities, however, offered inducements equal to those of Detroit, and in fact, during the pioneering phase of the industry, Detroit had a number of rivals.

Unquestionably, personalities played a major role in making Detroit the world's automotive centre. The industry began with Ransom E. Olds of Lansing, whose father manufactured gasoline engines. Subcontractors found themselves pioneers in this new and profitable industry. Olds's success by 1901 focussed the attention of automotive people on Detroit. Henry Ford brought even greater fame. Organizing the Ford Motor Company in 1903, he was by 1908 confining production to the standard, low-priced Model T. He emphasized ease of repair, garage service, and the utility of his product. In that same year W.C. Durant of Flint recognized that the automobile would be purchased by persons who desired transportation rather than by faddist motorists. He hoped through the formation of a company with large-scale capital to speed up technological advances and thus capture a large portion of the untapped middle class market. The General Motors Corporation stands as a testimony to his thinking. The successful Michigan manufacturers succeeded because their models were designed for a national market, whereas many companies had models that could not be operated in mountainous country.

The industry paid high wages, and many automotive workers became members of the middle class. Because of the high wages, there was little interest in unionism until the Great Depression of the 1930s.

Government and industry. The state government encourages a climate favourable to economic expansion. Many sections of government maintain research divisions that offer assistance to various segments of the economy. The Department of Agriculture administers a division of animal health, a division of marketing, and a division of soil conservation. The state tax structure has been evaluated as one that attempts to avoid discrimination against the private sector of the economy. For the labour sector, Michigan has had a workmen's compensation law since 1912. Extensive programs of social legislation, including unemployment compensation, were undertaken even before World War II and have since been broadened.

Transportation. The first railroad in Michigan, the Erie and Kalamazoo, was completed between Toledo and Adrian in 1836, and by 1870 the state had more than 1,600 miles of rail. The peak of 9,000 miles in 1910 was reduced to 6,300 by the time the semipublic Amtrak system took over passenger service in 1971.

In turn, the gains in motor-vehicle ownership have been staggering, reaching more than 4,600,000 registrations in 1971. State and local governments have combined to give Michigan a modern system of state highways, county roads, and city streets. The interstate express system, built largely with federal assistance, will comprise 1,175 miles when the initial phases are completed.

Air services in Detroit

Air passenger service in Michigan began in 1926 with schedules between Detroit and Grand Rapids. In 1968 Detroit Metropolitan Wayne County Airport accounted for 80 percent of Michigan's 9,000,000 airline passengers, and there are 11 other major airports throughout the state and several small commuter air lines. Much of the air freight of metropolitan Detroit is handled at the Willow Run Airport, constructed as a bomber site during World War II.

The waterways, the sole basis of travel for the first pioneers, still carry tremendous tonnage, with many of the state's exports shipped from Detroit harbour. Ores and other bulk materials destined for the interstate trade are ordinarily sent by water.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of government. In 1967 Michigan had more than 2,900 local governmental units including counties, municipalities, townships, school districts, and such special districts as park authorities. The basis of this complex system is the new constitution of Michigan, ratified by the voters in 1963. The new document included a number of innovations designed to streamline the government and to make it more responsive to the problems of a modern industrial and urban society. Amendments may be submitted to the electorate by the legislature or by initiative petitions, but all amendments must be approved by a referendum of the voters.

Executive power is vested in the governor, who serves for four years. He is nominated by a primary election, but the lieutenant governor is chosen by party convention. The governor appoints a large number of administrative commissions that are responsible to him and several advisory commissions. The majority of the important governmental services are combined under 20 departments also responsible to the governor. A few of these bodies, such as the State Highway Commission, must be bipartisan.

The legislative branch comprises a Senate of 38 members elected for four-year terms and a House of Representatives of 110 members elected for two-year terms. The legislative districts are redefined by a special bipartisan commission after each federal census. The highest court is a seven-member state supreme court. The state also has a court of appeals, circuit court, probate court, and courts of limited jurisdiction that are specified by the legislature.

Local government

The organization of units of local government is very flexible. Though the majority of counties are governed by a board of supervisors, the home-rule privilege allows larger counties to entrust management to county commissioners. Extensive privileges of home rule are authorized for the cities as well. School districts are classified by population and enjoy differing privileges of government.

Politics. The precinct is the primary unit in the structure of political party organization, and the precinct delegates carry considerable importance in the annual party conventions. These conventions nominate the candidates for lieutenant governor, attorney general, and the members of the boards that govern the state system of higher education and the Board of Education. They also nominate justices of the supreme court, who, however, do not bear a partisan label on the ballot. The convention also selects delegates to national presidential conventions.

A new interest in politics has resulted from the civil rights movement and from the formation of coalitions among college students. The civil rights groups have been responsible for a new awareness of politics on the part of

the black voters. Blacks have been nominated for major state offices by both parties. Unions have been very active in Michigan politics, and the UAW has endorsed candidates at the municipal, state, and national levels.

Finance and social services. The state sales tax is the major source of revenue, though receipts from personal and corporate income taxes play major roles in assuring the financial structure. Gasoline and vehicle taxes are reserved exclusively for highways.

Michigan's annual budget of well over $1,500,000,000 reflects in its allocations the concern with the well-being of its citizens. A mental institution at Kalamazoo that received patients as early as 1859 was a forerunner of a number of other institutions caring for the unfortunate. Since 1936 many of the state welfare services have followed a federal formula in transmitting aid to units of local government. Payments to recipients of old-age assistance, for example, and aid to dependent children, the blind, and the disabled have required special personnel at the state level, though disbursal of most funds is done locally.

Education. Michigan's major governmental service lies in the field of education. Many of the legislature's major appropriation bills are for support of the numerous public institutions of higher learning and the many community colleges. Large sums, however, are returned to the local districts to enable public elementary and secondary schools to maintain a high standard. Many of these schools, both in the inner-city areas and in the suburbs, are under frequent study for the identification of problems, and experiments in improved methods of instruction are often conducted by educators and psychologists from the universities.

Higher education

The greatest of the monuments to Michigan's cultural heritage, combining the traditional and the popular, are its some 90 colleges and universities, both public and private. In 1817 Judge Augustus Woodward, one of the major figures in the state's early history, conceived of the idea of a "Catholepistemiad," an academy of universal knowledge. This was achieved in some measure in 1841, when the University of Michigan opened its doors in Ann Arbor. During the 20th century it has come to be widely regarded as one of the nation's, and perhaps the world's, finest universities, with programs on both the undergraduate and graduate levels. In 1852 a teacher-training institution began instruction at Ypsilanti, and in 1857 Michigan Agricultural College, now Michigan State University, was formally established in East Lansing. The latter shares much of the wide regard of its rival in Ann Arbor, having moved far beyond its early identification with agriculture in many areas of research and scholarship.

The several teacher-training institutions became state universities during the 20th century, as did the Michigan Technological University at Houghton. In 1956 the state acquired Wayne University, a Detroit municipal university, founded in 1868. As Wayne State University, it has fostered much educational experimentation, and in the 1960s its campus and physical plant have become landmarks in American educational architecture through the designs of the Japanese-American architect Minoru Yamasaki.

Michigan is also the home of widely recognized specialized schools. In 1927 the School of Music was founded in Interlochen, the forerunner of the National Music Camp that now offers instruction in music, dramatics, and related arts. The Cranbrook and Kingswood schools, in Bloomfield Hills, designed by the famous Finnish-born architect Eliel Saarinen, pioneered advanced art courses for students of high-school age.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu

Detroit dominated the cultural life of early Michigan. Many of its citizens had the leisure and wealth that allowed them to devote time to cultural pursuits, and the multifacetted backgrounds of its population gave it a more cosmopolitan atmosphere. It received the state's first travelling theatrical companies, and an opera house was erected before the Civil War. In 1819 the Young Men's Society was organized by Lewis Cass, who led many early civic endeavours, to promote debates, lectures, and general intellectual life.

The pioneer farmer, however, had little time for cultural pursuits. Often he respected only the more elementary aspects of cultural life that might have utilitarian value —the community dance that eased the strains of plowing or harvesting, the county fairs that provided a ritual summation of the year's achievements. Thus Michigan's culture, perhaps like that of the nation as a whole, tended to become broadly based in popular life, having many of the aspects of "mass culture." In the major parks the city of Detroit promoted band concerts and, later, symphony concerts to bring better music to thousands. The Detroit Institute of Arts, maintained municipally, has always emphasized exhibits that appeal to a broad public.

Cultural commemorations. With the emphasis upon popular culture, Michigan increasingly is commemorating its past. The Michigan Historical Commission has designated sites of historic importance, such as the location of battles and the first home of the Ford Motor Company. Many cities emphasize Homecoming Day, usually the anniversary date of the incorporation of the community. Local folk festivals have been given a greater emphasis. Holland's Tulip Festival, held each May, has become an event of more than local importance. The annual Bavarian Festival, in Frankenmuth, appeals to others besides those of German background. Traverse City sponsors a popular Cherry Festival, and the Lake Huron cities commemorate the lumbering era with their highly publicized Paul Bunyan Days. Many ethnic groups in Detroit and other cities sponsor folk festivals that recall their cultural ties to Europe. The International Afro-American Museum in Detroit is a continuing reminder to the black population of its distinguished heritage extending far back into pre-American centuries.

Folk and regional festivals

Museums and libraries. The Detroit Institute of Arts, which can be traced to a private museum established in 1889, holds one of the nation's major collections. In 1969 it was the recipient of the Robert Hudson Tannahill collection, which included five Picassos, two van Goghs, four Cézannes, three Renoirs, and two Degas, as well as works by Rouault, Modigliani, Rousseau, Manet, Chardin, and Corot. The institute also has noted Baroque, African, and German Impressionist collections. The Hackley Art Gallery in Muskegon was founded in 1911 by a wealthy philanthropist, and the Kalamazoo Institute of Arts and the Grand Rapids Art Museum are among other art museums that have won recognition. Lansing is the home of the Michigan Historical Museum, famous for its military and Indian collections, while many county museums commemorate local history.

The state library was founded in 1828. A state library board was created in 1936, but major public libraries are found only in the larger cities. Among the outstanding special libraries are the William L. Clements Library at the University of Michigan, a depository for records pertaining to the American Revolution, and the Burton Historical Collection of the Detroit Public Library, specializing in local history and genealogy.

Communications. Michigan's press dates from the one issue of *The Essay*, published by a priest in 1809, and from the weekly *Detroit Gazette* founded in 1817. Today's *Detroit Free Press* became the state's first daily in 1833 as the *Free Press and Intelligence*. Journalism was a wildly competitive activity by 1900, when both Kalamazoo and Grand Rapids had three daily newspapers. By the early 1970s, however, the *Detroit Free Press* was the only surviving morning daily in the state, along with about 50 evening dailies. Weeklies and semiweeklies number about 150, while neighbourhood and trade journals have increased in number. The foreign press has been important: in 1870 Detroit had two German dailies, but the majority of ethnic newspapers were weekly.

Broadcasting in Michigan began in 1920 with broadcasts of local Detroit news, and today there are about 190 AM and FM radio stations and about 20 commercial television stations. These are supplemented by several noncommercial radio and television outlets, usually sponsored by educational organizations.

PROSPECTS

Both immigration and the normal fertility of the young population seem to assure Michigan of a continued increase in population, especially in the metropolitan areas. The major bases for further economic expansion probably will lie in the service industries and in government employment. Increases in income and employment in tourist and recreational areas can be expected as well. Employment increases in manufacturing, however, will be nominal, and it is possible that employment in agriculture and in mining industries will register a slight decline.

The agricultural areas in Michigan are losing their distinctive character, with some 50,000 acres being swallowed up annually by suburban or exurban residential developments. The development of recreational areas in the north is also responsible for the decline of farming acreage, though the long-term results of this may prove positive.

Major social gains can be anticipated also from a state that has been in the vanguard in seeking the well-being of its citizens: public welfare programs and all levels of education will become increasingly important to Michiganders. Since such services are related to income, however, taxation will continue to be a major issue. Slight increases are anticipated from higher rates on liquor and racing, though the largest increases will come from the sales and personal- and corporate-income taxes.

Social progress may well be marred by further racial disturbances. The disorders of the larger cities have reached down to the smaller cities. Short-term disruptions reflecting these problems can be expected also in the schools. The electorate unquestionably will be called upon, through the referendum, to vote on numerous issues affecting the social and political life of the state.

BIBLIOGRAPHY. Good general histories include: F. CLEVER BALD, *Michigan in Four Centuries*, rev. ed. (1961); WILLIS F. DUNBAR, *Michigan: A History of the Wolverine State* (1971); and MILO M. QUAIFE and SIDNEY GLAZER, *Michigan: From Primitive Wilderness to Industrial Commonwealth* (1948). More specialized studies of state history are: FLOYD RUSSELL DAIN, *Education in the Wilderness* (1968); WILLIS F. DUNBAR, *All Aboard: A History of Railroading in Michigan* (1969); GEORGE N. FULLER, *Economic and Social Beginnings of Michigan: A Study of the Settlement of the Lower Peninsula During the Territorial Period, 1805–1837* (1916); CALVIN GOODRICH, *The First Michigan Frontier* (1940); and ANGUS MURDOCH, *Boom Copper* (1943), a history of the mining counties. Interesting studies of the Michiganders include: RICHARD M. DORSON (ed.), *Negro Folktales in Michigan* (1956); W. VERNON KINIETZ, *The Indians of the Western Great Lakes, 1615–1760* (1940); and C. WARREN VANDERHILL, *Settling the Great Lakes Frontier: Immigration to Michigan, 1837–1924* (1970).

(S.Gl.)

Microbiology

The 17th-century discovery that living forms exist that are invisible to the naked eye was a dramatic one in man's history, for, from the 13th century onward, it had been postulated that "invisible" organisms were responsible for decay and disease. The word microbe was coined in the latter quarter of the 19th century to describe these organisms, all of which were thought to be related. As microbiology eventually developed into a separate science, it was found that microbes comprise a very large group of extremely diverse organisms; thus, microbiology became subdivided into various disciplines—*e.g.*, bacteriology, protozoology, and virology. The diversity of microbes, or micro-organisms as they are now commonly called, has meant that it is almost impossible for one person to be knowledgeable in all of the disciplines grouped under microbiology.

Microbiology involves the identification of micro-organisms and the study of their structure and function. It encompasses the study of bacteria, rickettsiae, small fungi (*e.g.*, yeasts and molds), algae, and protozoans, as well as problematical forms of life such as viruses. Because of the difficulty of assigning plant or animal status to micro-organisms—some are plantlike, others animallike—they are sometimes considered a separate group called protists. Microbes can also be divided into procaryotes, which have a primitive and dispersed kind of nuclear material—*i.e.*, the blue-green algae, bacteria, and rickettsiae—and eucaryotes, which display a distinct nucleus bounded by a membrane. Such are small algae other than the blue-greens, yeasts and molds, and protozoans. (All higher organisms are eucaryotes.)

The biological status of micro-organisms

Man's daily life is interwoven inextricably with micro-organisms. They abound in the soil, in the seas, and in the air. Everywhere abundant, although usually unnoticed, micro-organisms provide ample evidence of their presence, sometimes unfavourably, as when they cause decay of objects valued by man or generate disease, and sometimes favourably, as when they ferment alcohol to wine and beer, raise bread, flavour cheeses, and create other dairy products from milk. Micro-organisms are of incalculable value in nature, causing the disintegration of animal and plant remains and converting them to gases and minerals that can be recycled in other organisms.

HISTORICAL BACKGROUND

Beginnings. Microbiology can be said to have begun with the development of the microscope. Although others may have seen microbes before him, Antonie van Leeuwenhoek, a Dutch draper whose hobby was lens grinding and microscope making, was the first to provide proper descriptions of his observations, which included protozoans from the guts of animals and bacteria from teeth scrapings. His descriptions and drawings were excellent because his lenses were of an exceptional quality. Leeuwenhoek conveyed his findings in a convincing and logical manner in a series of letters to the British Royal Society during the mid-1670s. Although his observations stimulated much interest, no one made a serious attempt either to repeat or to extend them. Leeuwenhoek's "animalcules," as he called them, thus remained mere oddities of nature to the scientists of his day, and enthusiasm for the study of microbes gained ground slowly. It was only later, during the 18th-century revival of a long-standing controversy about whether or not life can develop out of nonliving material, that the significance of micro-organisms in the scheme of nature and in the health and welfare of man became evident.

The early Greeks believed that living things could originate from nonliving matter; their goddess Gea was credited with creating life from stones. Although Aristotle discarded this notion, he still held that animals could arise spontaneously from other unlike organisms or from soil. His influence regarding this concept of spontaneous generation was still felt as late as the 17th century. Toward the end of the 17th century, a chain of observations, experiments, and arguments began that dealt a deathblow to the idea that life could be generated from nonlife. It was an involved series of events, with the forces of personality and strong wills often obscuring the facts.

Although Francesco Redi, an Italian naturalist, disproved that higher forms of life could originate spontaneously, proponents of the concept claimed that microbes were different and did indeed arise in this way. Such illustrious names as John Needham, Lazzaro Spallanzani, Franz Schultze, and Theodor Schwann, among numerous others, figured in the debates.

It remained for Louis Pasteur to settle the matter. He proved in a series of masterful experiments that only pre-existing microbes could give rise to other microbes —at least under current earthly conditions (see also LIFE; that life arose spontaneously from nonlife at some earlier time, under appropriate physical and chemical conditions, is an undisputed postulate of chemical evolution; see EVOLUTION).

Microbes and disease

Regarding microbes and disease, Girolamo Fracastoro, an Italian scholar, advanced the notion as early as the mid-1500s that contagion is an infection that passes from one thing to another. The "thing" that is passed along eluded discovery until the late 1800s, when the work of many scientists, Pasteur foremost among them, determined the role of bacteria in fermentation and disease. Robert Koch, a German physician, defined the procedure for proving that a specific organism causes a specific disease.

The age of discovery. The foundation of microbiology was securely laid during the period from about 1880 to 1900. The students of Pasteur, Koch, and others discovered in rapid succession a host of bacteria capable of causing specific diseases (pathogens) and elaborated an extensive armamentarium of techniques and laboratory procedures for revealing the ubiquity, diversity, and power of microbes.

All of these developments occurred in Europe. Not until the early 1900s did microbiology become established in America. Many of the microbiologists who worked in America at this time either had studied under Koch or at the Pasteur Institute, in Paris. All microbiologists of the early 20th century, however, were influenced by such men as Koch. Once established in America, microbiology flourished, especially with regard to such related disciplines as biochemistry and genetics.

Contemporary advances. Since the 1940s, microbiology has experienced an extremely productive period, during which many disease-causing microbes have been identified and methods to control them have been developed. Micro-organisms have also been effectively utilized in industry; their activities have been channelled so that valuable products of commerce and agricultural benefits result.

The study of micro-organisms has also advanced man's knowledge of living things. Microbes provide easy-to-work with material for studying the complex processes of life; *e.g.*, metabolism. Correlated with the intensive probing into the functions of microbes have been numerous, and often unexpected, dividends that can be applied to solving existing problems. Knowledge of the basic metabolism of a pathogenic bacterium, for example, often leads to a means for controlling the pathogen. Nutritional requirements of bacteria thus may be of value in combatting an infection.

THE SCOPE OF MICROBIOLOGY

The study of bacteria, which were among the first objects of microbiological study, is called bacteriology. Various subdisciplines deal exclusively with particular micro-organisms.

From another standpoint microbiology can be subdivided into theoretical, or pure, microbiology, and practical, or applied, microbiology. The latter can be further subdivided according to specialties, such as medical, industrial, agricultural, food, and dairy microbiology (see below *Applied microbiology*).

Interdisciplinary nature. The science of microbiology has been influenced by, and in turn has influenced, other sciences. Micro-organisms are no longer the exclusive concern of microbiologists. Biochemists, geneticists, cytologists, and molecular biologists have discovered the value of microbes as experimental tools in the study of such fundamental biological processes as metabolism, photosynthesis, enzyme action, gene action, and population dynamics. Micro-organisms are well suited to such uses; they represent a vast range of metabolic types, and genetic changes are correlated with their rapid proliferation. In addition, they can subsist on relatively simple inorganic nutrients and, because they multiply rapidly, are available in extremely large numbers in a relatively short period of time. They are also relatively easy to maintain and handle under laboratory conditions.

The content of microbiology. *Bacteriology.* Modern and accurate knowledge of the forms of bacteria dates from the researches of the German botanist F.J. Cohn, the chief results of which were published at various periods between 1853 and 1892. Cohn's classification of bacteria, published in 1872 and extended in 1875, dominated the study of these organisms thereafter. While various observers added to the knowledge of the structure of bacteria, others laid the foundation of what is known about the relations of bacteria to fermentation and disease. When Pasteur showed in 1857 that lactic acid fermentation depends upon the presence of an organism, it was already known that fermentation and putrefaction are intimately connected with the presence of organisms in the air. In 1862 Pasteur placed beyond reasonable doubt the fact that production of ammonia by the fermentation of urea is caused by the action of a minute bacterium, named in 1874 *Micrococcus ureae.*

Isolation of disease-causing bacteria

After the introduction of bacteriological techniques (see below *The study of microbiology: Cultivation of micro-organisms*) came the isolation of many bacteria. It was discovered in 1882, for example, that a bacillus (a rod-shaped bacterium) is the cause of glanders, a disease of horses. In 1883 Koch isolated the organism of Asiatic cholera, and the same year that of diphtheria was found. In 1885 the tetanus bacillus was observed in pus produced in mice and rabbits inoculated with soil; only in 1889, however, did the Japanese bacteriologist S. Kitasato discover the way in which the organisms could be cultivated (they grow only in the absence of oxygen). W.D. Miller, a U.S. dentist, studied the micro-organisms of the human mouth in the 1880s, noting their possible relationship to the decay of teeth.

Pasteur and his associates found that animals vaccinated with a specially cultivated anthrax bacillus showed immunity to disease when reinoculated with the deadly wild form. These findings were destined to lead to a study of the principles of immunity, which underlie the prevention and treatment of disease by vaccines and immune serum. Questions relating to causes and to the nature of changes occurring both in the bacteria and in the host, as well as the development of immunity in the latter, continue to be subjects of great interest and importance.

While investigations on infectious diseases and immunity were under way, it became apparent that other activities of bacteria also are of importance to man. In 1878, only two years after Koch announced the discovery of the anthrax bacillus, the U.S. botanist T.J. Burrill discovered the bacterial cause of fire blight in pears, thereby establishing that certain plant diseases are caused by bacteria. The importance of some bacteria in soil and their contribution to soil fertility was recognized in the 1880s and 1890s. The significance of bacterial activities in many aspects of the dairy industry was recognized at about the same time.

The further application of bacterial activities to industrial processes, other than early studies on alcoholic and lactic acid fermentations, began later. Thus, within the span of a few decades the study of bacteria had progressed enormously, and by the early 20th century it was recognized that the activities of bacteria bear an intimate relation to many aspects of human activity.

The original interest of bacteriologists centred upon what bacteria do. This interest has broadened to include the study of the bacteria themselves: what they are, their relationships to each other, and their relationships to other organisms.

Protozoology and others. The name Protozoa is derived from the Greek words meaning "first animal," and, indeed, protozoans are sometimes considered the most simple of all animals. First observed by Leeuwenhoek in the 17th century, protozoans are almost as ubiquitous as bacteria. The study of protozoans at one time centred on the parasites that cause malaria and sleeping sickness, thereby stimulating research in tropical medicine. Improved laboratory techniques for cultivating this diverse group of organisms have made them valuable tools in many types of investigations—from physiological studies, such as cytoplasmic motion in *Amoeba*, to ecological studies involving their role in the food chain of the oceans.

The term fungi, Latin for "mushroom," applies not only to mushrooms but to all of the large and diverse group of plantlike organisms to which the mushrooms belong. The fungi of most interest in microbiology are the yeasts and molds. Many molds are studied because of their economic importance. *Mucor*, for example, not only causes spoilage of foods such as vegetables and fruits but also is used to manufacture some cheeses.

Lichens and slime molds

Some molds form unique relationships with other organisms; lichens, for instance, are composed of both algae and fungi. The unusual nature of lichens was not discovered until after the invention of the microscope. The name lichen appeared long before, however, in the

writings of Theophrastus, a disciple of Aristotle, about the 4th century BC. At that time, and for many centuries thereafter, lichens were confused with mosses and the hepatics. Early students thought that the green cells, now known to be an alga, were specialized fungal structures. Not until 1867 were the green cells in lichens indentified as algae; at the same time it was announced that the fungal cells were parasitic upon them. The introduction of pure culture techniques permitted the lichen constituents to be isolated and grown apart from each other. In 1873 the German botanist H.A. De Bary suggested the name symbiosis to describe the mutual benefit between the components of lichens.

Once objects of interest for their curious form, slime molds—as their individual nutritional, environmental, and genetic characteristics have become better understood—have become objects useful in teaching and research. The creeping sheet (plasmodium), or vegetative stage of a slime mold, has the characteristics of a primitive animal and resembles a primitive amoeba. The reproductive stage (sporangium) has the characteristics of a mold. The double life of these organisms is reflected in the name Mycetozoa, meaning fungus animals, which was coined by De Bary in 1858.

Algae, a heterogeneous group of primitive organisms, are of great interest to all biologists because they are capable of photosynthesis and are of evolutionary interest as well. Intensive research is currently directed toward the small forms making up much of the free-floating microscopic life in water (phytoplankton) because they provide food for aquatic animals and thus are of great importance. Many freshwater algae produce undesirable tastes and odours, and studies have been aimed at eliminating them from domestic water supplies. Although algae occasionally form mats on water surfaces, sometimes causing suffocation of aquatic life, heavy growth of certain species also has been found to reduce water hardness and to remove the salts found in brackish water, thereby making the water more suitable for human consumption. Algae are also being studied for their potential value as a food source for man.

Virology and others. Viruses comprise a heterogeneous assemblage of self-reproducing agents, smaller than the microscopically visible bacteria, that multiply only within living susceptible cells. Certain diseases caused by viruses have been known since the late 1700s, when the British physician Edward Jenner developed a vaccine from material isolated from cowpox lesions. He did not see the causative agent. Pasteur, in the mid-1850s, developed an attenuated strain (*i.e.*, one made less virulent) of the virus that causes rabies, but he was not then aware of the viral nature of the disease. An associate of Pasteur, Charles Chamberland, discovered that bacteria would not pass through a porcelain filter but that the causative agent of rabies did. The term filter-passing, or filterable, virus was used to describe these agents.

The Russian bacteriologist D. Ivanovski in 1892 found that a filtrate of sap from tobacco plants infected with mosaic disease could be used to transfer infection to healthy plants; the Dutch microbiologist M.W. Beirjerinck later confirmed the work. The further finding in 1902 that the agent of foot-and-mouth disease of cattle is also filterable made clear the fact that the agents cause disease in animals as well as plants. By 1930 the term filterable had been dropped, and virus is routinely used by microbiologists as a name for these agents.

Nobel Prize winner Max Theiler found in 1951 a method for attenuating virulent yellow fever virus; the technique has since been modified to produce vaccines against other viral diseases. Thus, viruses have been studied intensively in recent years not only because they provide important information about life processes but also because vaccines against them are constantly sought.

The study of viruses

The study of rickettsiae, which resemble very small bacteria but grow only in susceptible cells, is intimately associated with those forms causing human disease. Elucidation of the microbes causing such diseases as epidemic typhus, Rocky Mountain spotted fever, and scrub typhus began in 1906 with the work of Howard Taylor Ricketts, for whom the organisms are named; he described the organism of spotted fever. In 1910 Ricketts and an associate described the organism of typhus fever, which in 1916, was named *Rickettsia prowazekii* in honour of Ricketts and Stanislas von Prowazek, both of whom died of the disease. Research continues as better methods for prevention, control, and treatment of rickettsial diseases are sought.

Subjects of current interest. One of the more current studies involving micro-organisms is their possible occurrence in outer space and on planets other than Earth. A branch of exobiology, space microbiology, includes the investigation of microbes as providers of food and oxygen in the closed environment of spaceships.

A less positive development of microbiology has been biological warfare—the selection and cultivation of microbes as weapons of war, to cause disease or injury to domestic plants, animals, and man.

Although most of the subdisciplines of microbiology are directed at the occurrence of microbes in specific environments, the study of gnotobiotics is concerned with the exclusion of microbes except those involved in any given experiment. Such germfree organisms are important research tools in investigating parasitic diseases, immunological processes, nutrition, stress, shock, and aging (see GERMFREE LIFE).

THE STUDY OF MICROBIOLOGY

The study of microbiology is channelled in two major directions. Pure microbiology—that is, the study of a particular group of micro-organisms in order to learn about their morphology, physiology, taxonomy, occurrence, variation, heredity, and evolution—seeks to understand the nature of microbes. Applied microbiology, on the other hand, is motivated by the desire to exploit the effects of micro-organisms that are of benefit to man and to control the activities of those that are harmful.

Bacteriology as a synonym for microbiology

The methods used to study bacteria have been widely adapted to the study of other micro-organisms; indeed, the techniques employed in the microbiological sciences probably have more in common than do the origin and evolution of the organisms themselves. For this reason, the term microbiology is often considered to be synonymous with bacteriology. Similarly, the term micro-organism no longer refers only to microscopic organisms. With the adoption of bacteriological methods for the study of many types of organisms, the meaning of the term micro-organism has gradually been extended to include any organism that can grow and be studied using the methods originally developed for bacteria. The study of microbiology, therefore, encompasses many organisms that are not microscopic (*e.g.*, molds) but usually does not include some that are (*e.g.*, rotifers).

Microscopy. That invisibly small organisms exist was believed from early times. Lucretius, who expressed an atomic view of matter, wrote about AD 75 that even the plague must be caused by a kind of atom. He considered the atoms, or seeds, as lifeless, however. The writings of Lucretius influenced 16th-century scientists, but the means for actually observing micro-organisms—a magnifying lens—was not developed until the 17th century by Galileo.

The convex lens of Leeuwenhoek allowed a greatly enlarged image to be seen, enabling him to see protozoans, filamentous fungi, and yeasts. In 1676, using his simple lens, which was capable of magnifying 280 times, he first saw bacteria. A few years before Leeuwenhoek's observation of bacteria, Robert Hooke, the father of the cell theory, had observed filamentous fungi (1667) through a compound microscope—one with two lenses, which gives a larger image than that given by a simple lens.

By 1786 various micro-organisms, including bacteria, had been viewed through the compound microscope. The compound microscope of today is widely used; it differs from those of the 18th century mainly in the addition of a device, called a condenser, for lighting the object being viewed with a wide cone of light. A condenser is necessary to provide sufficient light when large magnifications are used.

Types of light microscopy used in microbiology

Of the types of microscopy now used in microbiology, most utilize light microscopes; magnification is obtained by a system of optical lenses. The types of light microscopes include the commonly used bright field, in which the background is brightly lighted, the objects studied are dark, and the power of magnification is about 1,000; the dark field, in which the background is dark and the objects studied are bright, a phenomenon particularly useful for examining unstained organisms suspended in fluid; the ultraviolet, the greatest advantage of which is that magnifications two to three times greater than those obtained with the light microscope can be achieved because ultraviolet light has a shorter wavelength than visible light; and phase contrast, in which controlled illumination is obtained by the use of special equipment that enables the refraction, or bending, of light passing from one material to another to be seen, thereby revealing differences in cells not discernible with other microscopic methods. Fluorescence microscopy utilizes the ultraviolet microscope; a chemical substance with the property to absorb ultraviolet waves and emit visible ones is used with a mixture of micro-organisms, some of which take up the substance, and thus can be distinguished from those that do not. Still another type of microscopy, electron microscopy, allows very great magnification; waves of electrons (negatively charged particles), rather than light, and magnetic fields, rather than lenses, are used to achieve an image. Although electron microscopy has the advantage of great magnification, it also has several limitations, most important of which is that the material must be dry. This not only eliminates the possibility of studying living specimens but also raises the possibility that the drying process may alter the characteristics of the specimen.

Cultivation of micro-organisms. *Sterile culture.* Micro-organisms growing on a nutrient medium are referred to as a culture. Early experiments (1776) by Spallanzani, begun as the result of the previously mentioned controversy over whether or not life could develop out of lifeless matter, laid the foundation for the technique of sterile culture. This involves first freeing a suitable medium of micro-organisms by heating and, second, keeping the medium sterile—*i.e.*, keeping micro-organisms out of the medium. In his experiments, Spallanzani boiled various kinds of seeds in a flask and stoppered it. After a few days, many organisms could be found in the flask; Spallanzani distinguished the larger ones, which were destroyed by boiling for one-half minute, and microbes, which survived boiling and developed even after the flask had been sealed. Eventually, he discovered that, after boiling sealed flasks for as long as 45 minutes, no micro-organisms developed.

The objection then voiced to Spallanzani's work—that the quality of the air in the flasks had, by heating, been rendered unable to support life—was overcome later (1836) when air was passed into the flask after having been slowly drawn through solutions containing sulfuric acid. The meat extract in the flask remained uncontaminated because the micro-organisms in the air were killed by its passage through the solutions. In 1853 it was discovered that flasks did not have to be sealed after boiling but could be closed with a plug of cotton, which effectively filtered the incoming air; this procedure is still used. Because many micro-organisms can produce bodies (spores) that are extremely heat-resistant, mediums for the growth of micro-organisms are usually sterilized by heating under pressure to 120° C (250° F) for 15 or 20 minutes.

Simplification of the method for sealing flasks

Dilution method and pure culture techniques. The Scottish surgeon Joseph Lister contributed to culture methods in microbiology with the introduction in 1878 of the dilution method. During studies probably concerning the souring of milk, he used sterile water to dilute a small amount of milk, then diluted some of this mixture with more sterile water. He continued the dilution process until a sample of the milk and sterile water mixture no longer caused the milk to sour. The last dilution that resulted in souring thus contained a minimum number of organisms, and Lister considered it a pure culture—that is, containing only one species of organism. The dilution method has become an essential part of pure-culture methods.

The dilution method was modified in 1896 by a Danish microbiologist, Emil Hansen, who studied yeasts. He added one drop of a yeast culture to the first of a series of small drops of sterile water, then removed a drop of the culture and added it to the second drop of water. Eventually, he obtained a drop containing just one yeast cell.

Koch also made a significant contribution to culture techniques with his development of a simple method for obtaining pure cultures of bacteria. He added a solidifying agent (gelatin) to a nutrient medium. After the medium had been heat sterilized and partially cooled, he added some micro-organisms. By cooling the solution further and spreading the organisms before the gelatin solidified, he was able to isolate the micro-organisms from each other, with the result that each organism gave rise to a separate colony, or crop of cells.

The introduction of agar-agar

In 1883 a woman in Koch's laboratory, Frau Hesse, further improved the technique by substituting agar-agar for the gelatin. Unlike gelatin, agar-agar can be liquefied by only a few micro-organisms and does not provide a food source, thus allowing better control of the nutrient content of the medium. Silica gel has also been used as a solidifying agent.

Enrichment cultures. One final advance in culture technique was developed in the 1890s by the Dutch microbiologist M.W. Beirjerinck and by the Russian microbiologist Serge Winogradsky. They selected a medium that favours the growth of one organism over another. If an organism, one from the soil, for example, is capable of utilizing a certain substance (*e.g.*, a specific sugar), growth of the organism can be induced by using the substance in the medium. Only the organisms capable of attacking the substance will grow in great numbers. Successive transfers of a relatively small number of organisms (inoculum) to a fresh medium will eventually result in a culture strongly enriched with the organism that utilizes the desired substance.

The maintenance of pure cultures. After a species of micro-organism has been obtained as a pure culture, it is necessary to maintain it alive and as a pure culture. Microbiology laboratories in schools, universities, and industry usually maintain collections of pure cultures of the particular species they use. Various organizations throughout the world maintain pure cultures of micro-organisms; such collections are important in that they make available pure cultures of species when needed.

The Kral Collection in Prague, established in 1900, was the first known culture collection. The names and locations of a few of the other collections are: the American Type Culture Collection (Rockville, Maryland), the Japanese Type Culture Collection (Tokyo), and the (British) National Collection of Type Cultures (London). Other collections also exist worldwide to serve particular needs. A section on culture collections was established in 1966 by the International Association of Microbiological Societies in order to promote the exchange of information among culture collections.

Whenever a microbiologist proposes a new species, he provides one or more of the national culture collections with a pure culture of the species.

Staining techniques. Until the latter third of the 19th century, micro-organisms were observed only in the natural state; the similarity of their refractive index to water and their small size, however, made them difficult to see when viewed through a microscope. Thus, the discovery of a method that would allow them to be seen more easily was an important development.

In 1875 the German pathologist Carl Weigert, using techniques developed more than a decade earlier for staining animal tissues with dyes, found that dead ("fixed") bacteria would become heavily stained with the dye picrocarmine. Other dyes were then introduced—*e.g.*, methylene blue, fuchsin, and crystal violet. Hans Christian Gram, a Danish bacteriologist, discovered in 1884 a simple procedure for placing bacteria into either a gram-negative class or a gram-positive class, depending

on whether or not the organisms retained crystal violet when treated in a specific way. Although the gram stain is used mostly with bacteria, other micro-organisms also show a reaction. Yeasts and actinomycetes, for example, are gram-positive; rickettsiae are gram-negative. Stained preparations now are used particularly to observe structural features of micro-organisms.

Other methods. Twentieth-century developments in microbiological methods have depended largely upon the techniques of other disciplines—namely, biochemistry, physiology, organic chemistry, and physics.

The gas exchange of respiring micro-organisms, called the respiratory quotient (the ratio of carbon dioxide produced to oxygen consumed), is measured by following the pressure change of respiring organisms in a closed vessel. Other processes—*e.g.*, fermentation—can also be studied using this method.

The transfer of hydrogen ions (positively charged atoms) in micro-organisms has been studied by adding to the organisms or extracts prepared from them a substance (*e.g.*, the dye methylene blue) the colour of which changes when hydrogenated. Many other dyes behave in this way.

Techniques for breaking apart micro-organisms

The techniques used to break up micro-organisms include such biochemical techniques as alternate freezing and thawing, prolonged grinding, vigorous shaking with glass beads, and exposure to supersonic vibration; certain micro-organisms (*e.g.*, yeast) are especially difficult to disrupt because of their resistant cell walls.

The apparatus of modern physics has greatly aided the advance of virology. Around 1930 the steady development of new technical methods for studying the physical, chemical, and biological properties of micro-organisms completely changed the outlook of biologists toward viruses. An important advance in this new approach was the development of graded filter membranes of known pore size. This created for the first time the opportunity to assess the actual size of virus particles.

Another important advance of the 1930s was the growth of the virus of fowl pox in the tissues of a developing chick embryo. Methods for the growth in the laboratory of rickettsiae are similar in that living host cells are necessary. In 1949, tissue culture methods, long used in half-hearted fashion for the cultivation of viruses, were shown to be suitable for the growth of poliomyelitis viruses. This not only opened the way to immunization against polio but supplied a method by which many new types of virus could be isolated (see also TISSUE CULTURE).

APPLIED MICROBIOLOGY

Practical applications of microbiology began to develop soon after the first sterile cultures were prepared. In the 18th century, a Parisian cook applied Spallanzani's technique of sealing and heating flasks to jars containing fruits and vegetables. His discovery that they were preserved indefinitely not only made him wealthy but prepared the way for the canning industry.

Applications in industry and medicine. *Industrial microbiology.* Many substances are produced by micro-organisms on a large scale. Bacteria, for example, are used in the commercial production of lactic acid, derivatives of which are used as solvents and to treat calcium deficiency and anemia. Vinegar is formed by bacteria, as are amino acids, the latter being used as supplements for foodstuffs.

The ethyl alcohol produced by yeasts from carbohydrates is important to brewers of malt beverages, wine makers, distillers, and others; and yeasts were used in baking even before Roman times. Attempts have been made to cultivate many types of micro-organisms as food; yeasts are attractive because they are easy to grow and have a high nutritive value. Research is active in this area because yeasts can be grown as by-products of industry—*e.g.*, in sulfite liquor resulting from paper manufacture and in dairy wastes—thus reducing the problems associated with waste disposal and pollution.

Molds are used in the production of industrial chemicals; for example, citric acid, which is used in medicines, flavourings, extracts, foods, dyeing, and the manufacture of ink. Molds are also used to produce antibiotics, such as penicillin, which was the first one to be produced commercially, and enzymes. (For detailed discussions of these processes see BAKING AND BAKERY PRODUCTS; BREWING; WINE MAKING; PHARMACEUTICALS, PRODUCTION OF.)

Food microbiology. The preservation of food is an important aspect of applied microbiology. Foods consumed by man are largely perishable—that is, they provide nutrient sources for the growth of many micro-organisms; *e.g.*, bacteria, yeasts, molds. Some of these organisms cause chemical changes in food that make it unsuitable for human consumption; others can cause poisoning if the contaminated food is eaten.

Undesirable changes caused by micro-organisms in food

In ancient times, salting, drying, and smoking were practiced to preserve food. Modern techniques of food preservation involve refinements of the primitive methods and the utilization of newer ones: heating, low temperature, dehydration, and treatment with chemicals and radiation. Such techniques either prevent or remove contamination, prevent microbial growth or metabolism, or kill micro-organisms. (For details of methods of food preservation see FOOD PRESERVATION.)

Dairy microbiology. Milk, which has been called the "most nearly perfect" food, not only provides great nutritional value for man but also is an excellent medium for the growth of many micro-organisms. In fact, sterile skim milk is commonly used as a growth medium for many bacteria.

Milk from the cow, although essentially free of micro-organisms, is usually contaminated as it is processed. The pasteurization process—the heating of milk at a specific temperature for a specific amount of time—greatly reduces the number of bacteria in milk. If milk is not properly stored, micro-organisms can affect it by producing acid and gases such as carbon dioxide and hydrogen; by causing the texture to become viscous; and by causing curdling, abnormal flavours, odours, and colours.

Micro-organisms are of great value in the dairy industry, however. Fermented milks (*e.g.*, buttermilk), butter, and cheeses are produced as a result of microbial activity (see DAIRYING AND DAIRY PRODUCTS).

Medical microbiology. Many micro-organisms, especially species of bacteria, protozoans, and viruses, cause infections in man, other animals, and plants. The control of disease-causing organisms is thus of great importance, regarding both economic losses and the well-being of plant and animal life.

Commonly used methods of combatting plant diseases include the breeding of disease-resistant plants, sterilization of the soil, and crop rotation. Certain infectious diseases of animals, called zoonoses, are of special importance because they can be spread from infected animals to man. Some methods used to control animal diseases are similar to those used to control human diseases—*e.g.*, immunization, adequate diet and sanitation, and prevention of transmission by quarantine of infected animals (see DISEASES OF ANIMALS; DISEASES OF PLANTS; INFECTIOUS DISEASES).

Microbiology of water, soil, and air. Since 1854, when waters polluted with man's domestic and industrial wastes (sewage) were proved to have caused an epidemic of cholera, bacteriological studies of water have been concerned with detecting, identifying, controlling, and eliminating disease-causing species. Although water-purification systems have been very effective in protecting man against polluted waters, pollution problems have increased as the human population has grown (see SEWAGE SYSTEMS). Another aspect of water microbiology involves the microbes that occur in natural bodies of water—*e.g.*, ponds, lakes, rivers, and oceans; their enormous importance in the economy of nature is increasingly recognized.

Microbes mediate the conversion of organic matter in the soil to nutrients that can be utilized by plants. The condition of soil in a given area is therefore of great significance in agriculture.

Micro-organisms do not grow in air, but the particulate matter in air—*e.g.*, dust and water droplets—may be laden with them, the numbers and types being determined by

the contaminating source. The control of airborne pathogens is of great significance not only in the spread of disease but also in circumstances in which sterile conditions are required, such as in certain industrial processes.

MICROBIOLOGICAL SOCIETIES AND PUBLICATIONS

Certain microbiological societies publish several journals related to specific aspects of microbiology. The American Society for Microbiology, for example, publishes *Journal of Bacteriology; Bacteriological Reviews; Journal of Virology; Applied Microbiology;* and *Antimicrobial Agents and Chemotherapy*.

Some societies publish journals of a general nature—*e.g.*, the Society for General Microbiology in Great Britain publishes the *Journal of General Microbiology*. Societies that publish journals relating to a specific group of micro-organisms include the Mycological Society of America (*Mycologia*); the British Mycological Society (*British Mycological Society Transactions*); and the Society of Protozoologists (*Journal of Protozoology*).

Other publications relating to microbiology include the *Japanese Journal of Microbiology*, published by the Japanese Bacteriological Society and the Society of Japanese Virologists and the *Canadian Journal of Microbiology*. *Mikrobiologiya* is published in the U.S.S.R.; the *Institut Pasteur Bulletin* is published in France; and *Acta Pathologica et Microbiologica Scandinavica* is published in Denmark. *The Journal of General and Applied Microbiology* is also published in Japan.

(Ed.)

Microclimates

Though "climate" normally refers to the general, large-scale conditions of the atmosphere, it is often important to consider quite small areas and to distinguish between sharply contrasting climates at points close together. The term microclimate is used to describe this finer structure. In particular, within a very few feet above and below the earth's surface and within the canopies of vegetation, the temperature, humidity, and wind undergo much stronger gradients and stronger patterns of cyclical behaviour and variability than anywhere else. Within the height of a man, temperature differences of 10° C or more are commonplace; horizontally finding such climatic differences may involve a journey of continental dimensions.

Microclimate is strongly influenced by soil and vegetation, by slope and orientation, and by exposure. On a somewhat larger scale (the effects, for instance, of a small range of hills on the temperature and wind fields around them), the term mesoclimate is employed. Climate in general is described as macroclimate. Various other terms are also used, but their definitions are not universal.

An insect that chooses to live on the underside of a boulder or a cabbage leaf thus identifies its microhabitat. All of the different microhabitats encompassed by a given crop and soil type, including the variety of conditions within the soil itself, constitute the micro-environment. The complex of microclimatic factors as they involve individual plants or animals, including modifications due to the presence of those plants or animals, constitutes the bioclimate or proprioclimate.

Marine and terrestrial microclimates

Although any small species may tolerate only a limited range of bioclimate, the close proximity of strongly contrasting microclimates provides a total environment within which different animal and plant species can coexist and interact. The complexities of microclimate, therefore, constitute a requirement for the variety of life forms. The greater variety of terrestrial life, as compared with marine forms, follows not so much from the greater equability of the marine climate, although this is important, as it does from the greater variability of land surfaces and, hence, far wider range of microclimatic contrasts. These overlap the main climatic variations in space and time, though the overall tendencies remain; microclimates, for example, are generally coldest in winter and high latitudes. Furthermore, there is strong correlation between the type of macroclimate and the range of microclimates within its compass. Clear skies and dry conditions, as in desert climates, engender the strongest microclimatic contrasts in temperature. In permanently moist and overcast conditions, these contrasts may almost disappear.

Plants occupy their preferred microhabitats through processes of natural selection. The majority of animals seek theirs out by movement, although many forms do achieve marked modification of microclimates by nests, shelters, and other artifices. In all cases, the preferred conditions may vary with season and with the maturity of the plant or animal. Chief of the modifiers is man, who lacks great microclimatic tolerances and thus adjusts his shade and shelter and his house and clothing to suit his comfort, convenience, and efficiency.

MICROCLIMATIC CONDITIONS

Temperature and moisture. The interface between the air and the ground is heated by short-wave radiation received from the sun and scattered from the sky. The interface emits radiation, as do the gases of the atmosphere, in the long or terrestrial wavelengths. The time pattern of radiation processes is dominated by annual and diurnal cycles. In both cycles, the extremes of temperature are found at or very close to the surface, at or shortly after the times of extreme (net) radiation.

Heating and cooling propagate upward and downward from the interface. The wave amplitude is progressively attenuated, and the times of occurrence of maxima and minima become progressively later, with increasing height and depth. The rate of decrease of air temperature with height is known as the lapse rate; when the air temperature increases with height, it is termed an inversion.

Temperature ranges

The profiles in Figure 1 illustrate typical temperature ranges in air and soil on a clear summer day in middle latitudes. The daily range at the ground–air interface may compare with and even exceed the annual macroclimatic range so that surface-dwelling insects can experience a year's extremes in a single day. The attenuation of the two cycles with depth is, however, very different, the annual penetrating about 20 times as deep as the diurnal so that significant annual variations of temperature in most soils will be found up to depths of about ten metres. The maximum variation is delayed about one month at one metre and by three or four months at five-metre depth. The minimum will be delayed similarly, but the delay will be longer at the smaller depths in climatic zones where snow is prevalent.

The penetration of the annual wave into the atmosphere is under macroclimatic rather than microclimatic control. For reduction in daily amplitude to 10 percent of surface value, 300 metres is a characteristic height, but this depends on wind and weather. The maximum surface temperature occurs soon after noon, some two hours later at one-metre height, three to five hours at 100 metres. By night the cooling is slow, but it continues until sunrise; thereafter the surface temperature may rise rapidly, and the warming will spread upward relatively quickly. Thus, there is a strong asymmetry in the diurnal march of temperature.

It is clear that strong temperature gradients will be found near the interface in both media. Generally the atmospheric temperature gradient decreases approximately in inverse proportion to the distance from the surface. The

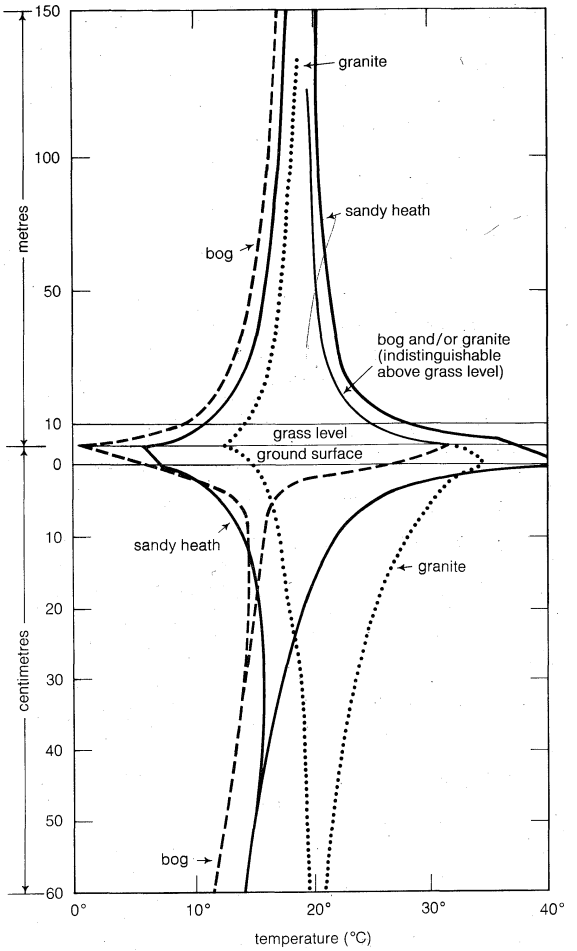

Figure 1: Maximum and minimum temperature curves, or heating and cooling paths, above and within the ground for different kinds of ground material.
From R. Geiger, *The Climate Near the Ground* (1965); Harvard University Press

change per unit distance in soil is much stronger, but the pattern of behaviour is harder to categorize.

The humidity (weight of water vapour per unit volume of air) behaves in much the same manner as temperature. Both the absolute value and the gradient decrease with height by day and increase at night. General statements about diurnal and annual moisture distributions in soil tend to be unreliable because recent rainfall and evaporation history exert a governing influence. Strong moisture gradients are found in partially wet soil, and moisture then migrates only slowly, mainly through distillation from warmer toward colder. Bare soils, once they have started to dry out, are thus defended against further daytime evaporation, but vegetation circumvents this defense by drawing water from depth and transpiring directly to the atmosphere.

Wind and turbulence. Friction reduces the wind to zero at a solid boundary and almost to zero where surface drift can occur, as on water surfaces. Near the ground, the average speed increases with height at a rate varying inversely with the height. Low-level winds tend to be stronger by day than by night.

Even a steady wind will show irregularities in strength and direction down to periods of seconds or less with corresponding fluctuations in temperature and other variables. This turbulence plays a vital role in microclimate. It controls the diffusion of heat and moisture in the air, the dispersal of seeds and spores, and of atmospheric pollutants.

Turbulence, especially in lighter winds, varies markedly with time of day and state of sky. By day, under clear skies, the air is heated from below, and the lighter air underlying heavier air is unstable and more turbulent. Nocturnal temperature inversions represent stable stratifications; heavier air underlies lighter air, and turbulence may virtually disappear. Very strong and irregular layering effects can then develop with marked layered contrasts of temperature, smoke content, etc. continuing throughout the night with layers sliding over each other with very little intermixing.

Dew and frost. When the surface temperature falls below the saturation level (temperature at which no additional moisture can be held), dew is deposited. This may represent true dewfall, a deposit from the vapour diffusing down through the air, or it may result from water diffusing upward through soil or plants and condensed at the coldest point. When this occurs at temperature below freezing, the result is a white frost or hoar frost. Black frost, by contrast, occurs when the water in the surface layers freezes *in situ*.

Dew and frost formation interrupt the cooling on clear nights because of the latent heat released as the water condenses or freezes. As the air warms up again, heat is required to evaporate or condense. The overall effect of this process is always to moderate the temperature and retard its changes.

Heat balance and evaporation. The temperature and moisture behaviour is dominantly controlled by the heat or energy budget at the interface. The interface possesses no heat capacity, and, as it absorbs daytime radiational energy, it must dispose of it by its own radiation, by conduction and convection, and by using energy for evaporation. Similarly, the heat radiated away at night must be conveyed to the surface. The daily radiation amounts are governed by macroclimate; that is, by latitude, season, and cloudiness. The temperature response is then conditioned by the heat capacity and effective conductivity of air and underlying medium.

Approximate quantitative rules may be given in terms of a combination of physical properties known as the admittance or conductive capacity of the medium. Table 1 illustrates the conductive properties of various soils and corresponding effective values of air and ocean. These latter may exhibit considerable variation because the effective conductivity is really dependent upon the degree of turbulence.

Surface absorption of heat

Heat absorbed at the surface will be shared between the atmosphere and the underlying medium in proportion to their conductive capacities. The magnitude of the temperature response will vary inversely as the sum of the two conductive capacities. Accordingly, the lapse rate is unstable by day and more heat will go into the air than into the ground. But on still nights, with stable stratification, most of the heat radiated is supplied by the ground. The difference between various underlying surfaces also is indicated by Table 1. The depth of penetration of surface temperature variations, whether periodic or irregular, varies as the square root of the conductivity. The more conductive the underlying material, the greater and more rapid the penetration and the smaller the temperature response.

The other major factor in the heat balance is evaporation. With soil saturated or vegetated with live growth, or over open water, energy is used in evaporating water at the interface. This often consumes the major fraction of the radiation energy available. By so reducing the energy available for heating, evaporation decreases the daily range in temperature. Over land, the daily march of evaporation follows closely the net radiation.

Over water, radiation is absorbed appreciably below the interface so that the heat balance is more complicated. Another important difference is that water, by virtue of its mobility, is effectively a much better conductor of heat than any soil. Thus, the daily cycles of temperature, and the temperature gradient, are much weaker in maritime than in continental environments. The same holds true for the annual cycle and the irregular variations from day to day.

FACTORS AFFECTING MICROCLIMATES

Soils and surfaces. The effects of different soil types and conditions on temperature and heat balance may be understood from the values in Table 1 and the principles of the preceding section. Sandy soils and other coarse,

Table 1: Conductive Properties of Air, Soils, and Other Media
(CGS units)

medium	new snow	dry sand	sandy clay	wet sand	ice	water*		air near ground*	
						stable, moderate currents	strong currents	stable	unstable
Conductivity (thermometric)	0.006	0.0013	0.004	0.01	0.1	0.1	100	10^3	10^5
Conductive capacity	0.002	0.011	0.04	0.04	0.05	0.3	10	0.01	0.1

*For water and air, these are effective values that allow for degrees of turbulence.

loose, and dry soils are subject to high maximum and low minimum surface temperatures with relatively little penetration. Compacted and wet soils, and clays, are better conductors and exhibit more equable surface temperatures and deeper penetration of daily and seasonal variations. For bare soils, the surface reflection characteristics are also important; darker soils reflect less and respond more to the daily heating. Experiments have shown that a 10° C reduction in surface temperature can be achieved by sprinkling white powder over a dark soil. Specimen reflection coefficients (albedo) for various natural surfaces are given in Table 2.

Table 2: Approximate Values of Albedo
(percentage)

Fresh snow	85
Old snow	50
Salt flats, sand dunes	45
Clean ice	40
Desert	25
Green trees	20
Cultivated soil	
Light	20
Dark	10
Green fields	15
Built-up areas	15
Pine forest	10
Water	
High sun	5
Sun at 5° elevation	25

A surface layer of material of low-conductive capacity tends to insulate the soil below from effects of the daily cycle and from longer spells of abnormal temperature. Thus, freshly fallen snow will protect against a subsequent frost. Snow following frost is only harmful when the frost has already been prolonged, otherwise there will be conduction of heat upward from greater depths. Other soil characteristics that are important to the microclimate include the ability to accept and retain moisture and the tendency to cake and crack. These depend on the composition of the soil itself and its use.

Local variability of soils results in adjacent pockets of quite strongly contrasting microclimates. Large-scale irregularities and the presence of stones and boulders all go to diversify the microhabitats.

Vegetative cover and forest canopies. Vegetation is another insulator, and dense low cover reduces the temperature variability in the soil below. The exposed parts become the radiational interface and the site of the strongest temperature change. Most plants exposed to strong radiation fields require evaporation to prevent damage by overheating. Only typical desert species are adapted both to conserve moisture and to withstand the consequent high temperatures.

Plants and plant communities grow in different configurations and result in an indefinite variety of heat-balance and temperature-distribution situations. A special case is the forest, where canopy and ground are separated effectively by an airspace. Vertical temperature gradients within the airspace are reversed from those in the atmosphere above, with inversions by day and stable, calm conditions providing insulation from the daytime heat. At night the canopy cooling destabilizes the air and causes drafts that bring colder air down in pockets. The airspace is warmer than it would be without a canopy, but the distribution is patchy. Evaporation occurs mainly from the leafy canopy but also from the ground wherever sunlight penetrates. At night, distillation occurs with water evaporated from warmer and condensing on colder spots. These conditions bring about a high humidity during the day and night, a feeling of clamminess in the air, and the accumulation of copious water droplets on the cooling forest litter.

Topography. Air expands and cools when pressures decrease. Elevated places experience low pressures, low temperatures, and high relative humidities. Air ascending a mountain range releases rain and snow; the condensation reduces its rate of cooling, and the warming in its subsequent descent occurs much faster. As a consequence, hot, dry, enervating winds are common in the lee of mountain ranges. These are called fohn winds and also carry local names like the chinook, east of the Rocky Mountains, and the zonda of Argentina.

Topography therefore affects the microclimate by affecting macroclimate, but there are also many direct topographic influences. Figure 2 illustrates the amounts of solar radiation that normally are incident on south-facing slopes of different angles, calculated for the New York area using observed cloud amounts. The great benefit gained by steeper south-facing slopes in winter is evident; even the small summer loss can be turned to advantage by growing crops that do not benefit from excessive heat. The very steep and vertical slopes that are included in the diagram have relevance to architecture.

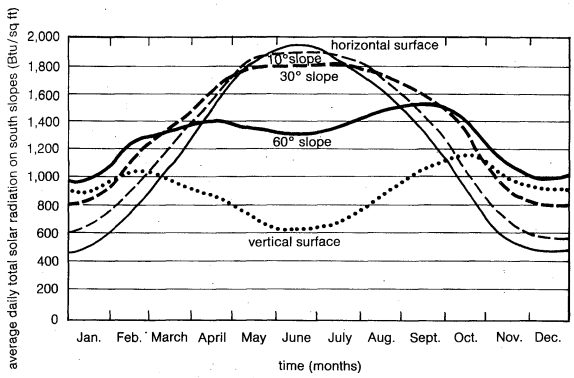

Figure 2: Daily solar radiation on south-facing slopes of varying declivity and the monthly distribution of radiation.

Undulating country also achieves microclimatic variety through air motions generated by differences in density. Nocturnal radiation from a slope creates a lowest layer of cold air that then flows downhill as a wind, which is termed the katabatic wind. The strength and vertical extent of the katabatic wind depend on both the angle and length of the slope. On the vast unbroken slopes of Greenland and Antarctica, it becomes a permanent feature of the winter night, capable of speeds of more than 100 miles an hour and depths of several hundred metres. More commonly, a katabatic is shallow and gentle and drains the cold air, accumulating it in cutoff depressions, or frost pockets, with night temperatures up to 20° below that of the surrounding country. The converse, anabatic wind, flowing uphill by day on slopes that are preferentially heated, lacks the same tenacity because the warm air breaks away from the surface and is more readily mixed. In steep-sided valleys, oriented north–south,

The katabatic wind

rotary motions can result, down the east and up the west side in early morning and oppositely at dusk. Similar circulations due to unequal heating or cooling underlie the familiar phenomena of land and sea breezes.

From R. Geiger, *The Climate Near the Ground* (1965); Harvard University Press

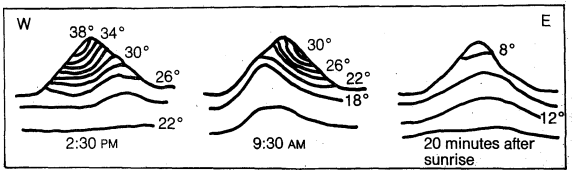

Figure 3: Surface temperatures (in degrees Celsius) on a hill at three times a day.

Mountain and valley winds are a complex of these thermal and gravitational influences on various scales coupled to channelling effects. A steep-sided valley will channel a wind that otherwise would cut across at an angle. On exposed ridges across a prevailing wind, the maximum speed is at the crest or else just below on the windward shoulder, which affords a preferred site for generation of wind power.

Shelter and roughness. Abrupt downslopes and the lee of obstacles gain significant shelter from wind. A good rule of thumb is that a barrier across wind will reduce the speed appreciably for a distance of some 20 times its height. A solid wall or fence provides good shelter for animals but can produce strong lee eddies that buffet crops. More open shelters, like hedges, reduce rather than stop the wind but avoid the damaging lee eddy. Drifting sand or snow accumulates in the sheltered zone behind a windbreak, and this effect commonly is exploited in setting protective fences some distance to the side of exposed sections of traffic routes.

A succession of shelters spaced across country will reduce the overall wind speed near ground level. Any scattered or continuous irregular surface cover constitutes such a succession of shelters. In this way, the low-level wind is reduced by surface roughness. To illustrate magnitudes of the roughness effect, Table 3 presents wind speeds at a height of one metre above some different type of surfaces, expressed as percentages of the speed in the free atmosphere. The importance of these differences is emphasized by the fact that wind force on structures varies as the square of its speed, and the power of windmills as the cube.

Table 3: Relative Wind Speeds at One Metre above Various Surfaces

Smooth mud flats or sea without ripples	52%
Bare soil, very short lawn, cropped pasture, sea in moderate winds	43%
Scrubland, rough cultivated land with row crops	26%
Uniform young orchard in full leaf	19%

Advection. Advection is the conveyance to an identified place of a property different from that currently obtaining there. The strongest advection phenomena occur at sharply contrasting boundaries, such as coastlines. Thus a sea breeze will represent the advection of cooler and moister air to the land. Advection is generally accompanied by a progressive microclimatic adjustment, modifying the properties of the air toward those of its new surroundings, as in the warming of the sea breeze as it moves inland. A small desert lake or oasis will evaporate more rapidly because of the dryness of the wind, drawing on advected energy in excess of that available locally from radiation. Evaporation will be strongest at the upwind edge and progressively decrease downwind as the air grows moister. For this reason, one lake with twice the downwind extent of another will evaporate less than twice as much. This is called the blanketing effect, and it applies equally to heat transfer when cold or warm air invades a surface at different temperature.

While the adjustment process following advection is essentially microclimatic, its effects extend strongly into weather phenomena on larger scales; for example, most rainfall over land occurs in air of maritime origin. Cooling due to advection results in fogs and dews in favourable locations, whereas heating causes convection and cloud and rain showers, and in other ways enhances temperature fluctuations and local differences in moisture. Thermal and moisture gradients of almost any magnitude can derive from advection if the contrasts in the underlying medium are sufficiently sharp.

RELATION OF MICROCLIMATES AND MACROCLIMATES

Macroclimatic influences. In terms of average moisture and temperature, the microclimate of a region is strongly bound to the climate, latitude, elevation, and the season. But the diversification of microclimates, the degree to which conditions vary between adjacent locations or within the daily cycle, is controlled by more special factors. Wet climates have less temperature diversity, both in space and time, than dry ones, partly because of the increase in soil conductivity and partly because the energy that is involved in evaporation and condensation would otherwise appear in the form of temperature changes. Wind and cloudiness are other elements that moderate the microclimates, although each has also one diversifying influence. The greater turbulence of stronger winds increases the air's effective conductivity; this reduces the intensity of temperature changes, but wind diversifies through advection. Cloudiness lowers the net incoming radiation by day and the outgoing radiation by night; however, it diversifies through its patchiness, in the magnitude of temperature change from sunshine to shadow.

The highest temperatures and the strongest daily variations are found not in the tropics but in the high pressure belt of latitudes 20° to 35° where dry, clear, calm conditions prevail. The extreme microclimatic cold is found on high polar plateaus, in places where the cooling of continuous winter night is magnified by clear skies, a poorly conducting undersurface, and locally by the frost-pocket effect (small pockets of cold air in depressions).

Effects of macroclimate on soils

Freezing and thawing in soils are other moderating influences, although less so than evaporation–condensation because of the sevenfold smaller latent heat involved. Because they occur at a single temperature, however, their moderating and retarding effects are sharply concentrated at 0° C. Thus, temperatures close to 0° C occur with relatively high frequency, and microclimatic winter may persist well into climatic summer wherever snow cover remains on sheltered and shaded slopes. An extreme effect known as permafrost (*q.v.*) extends over Antarctica and much of northern America and Eurasia. The ground is permanently frozen, in places for hundreds of metres, and is overlain in less severe parts by an active layer that thaws in summer down to a few metres, permitting growth of mosses and some trees. Deep drainage of the active layer is impossible, so the low-lying parts are waterlogged. The depth of the layer depends on slope, vegetation, and snow, which deepens it through winter insulation. Mosses act in the opposite way by insulating from the summer heat. The prevailing view is that permafrost in many places is a retardation effect from earlier colder periods and that its extent has declined during this century. Large areas with active layers could be more productively developed, although there are problems in construction, maintenance of roads, buildings, underground pipes, etc.

Microclimatic influences on weather and climates. Many influences of microclimate on climate are brought about through variations in surface characteristics. These characteristics determine how the solar radiation is apportioned between the different forms of energy (terrestrial radiation, convection, conduction, and evaporation) into which it is transformed.

Evaporation, for example, accounts for much of the continental–maritime contrast in climate, but it also exerts within the former a sharp cutoff effect on the daily maximum temperature. When water is available, maxima of 32° and 33° C are commonplace but above 34° C almost unknown except through dry-air advection. With dry soils, maxima are widely distributed from 30° to 45° C and even beyond.

The temperature contrasts between air masses are a prime cause of the development of cyclonic depressions. Because an air mass modifies its temperature through contact with the underlying medium, the conductive properties of that medium are vital. Cyclonic development occurs preferentially over certain oceanic regions, coastlines, and over major inland or semi-enclosed bodies of water, but not in seasons when these are frozen. The contrast in effective conductive capacity between water and land or ice testifies to the microclimatic nature of the control.

Effects of abnormal weather

Dramatic effects occur when an unusual weather condition modifies the surface in ways that operate to sustain or amplify the condition. Abnormal runs of weather and certain climatic trends are widely believed to have their roots in such feedback microclimatic processes rather than in external influences. Once more, evaporation enters as a major factor. Wet ground promotes evaporation and increases atmospheric moisture. Conversely, the drying of bare soil creates a crust with an adverse temperature gradient that inhibits upward diffusion of water, and the dry atmosphere persists. Moreover, ensuing dusty conditions create more condensation nuclei, and clouds that then form are colloidally more stable and less likely to give rain. Smoke particles from bush fires or burning of sugarcane, etc., may also reduce rainfall by the overproduction of nuclei.

Another feedback process derives from early winter snowfall in North America and Europe. A storm travelling a southerly track leaves a carpet of snow that increases the albedo; thereafter, less solar energy is retained. This tends to influence ensuing storms also to follow a southerly course. Thus, snow begets snow is one of many weather saws well rooted in scientific fact.

Similar trigger actions may underlie the occurrence of glacial epochs in climate. A sequence of severe winters decreases the fraction of open water in higher latitudes. For this reason, more solar energy is reflected away, less is conducted and stored, and still more ice forms, and an unstable sequence is initiated. This instability may be seen in miniature in small ponds. Once freezing starts, it extends quite rapidly despite the high latent heat, which, as already seen, at any other level than the interface exerts a retarding rather than a destabilizing influence.

THE IMPORTANCE OF MICROCLIMATES

In the hydrologic cycle. Microclimate controls evaporation from surfaces, and it influences precipitation. Both are principal factors in the hydrologic cycle.

Water vapour is transpired into the atmosphere by plants, is evaporated from open water or from bare soil, and is diffused upward from the water table. Over land, provided water is freely available, the total rate is regulated by the local energy supply or net radiation; all surfaces of the same reflectivity, which are uniform for sufficient distance to remove advective effects, will evaporate equally. This provides the concept of potential evaporation, the rate at which the least reflecting moist surface will evaporate. The potential evaporation thus depends solely on weather conditions, among which general temperature level (high temperature, strong evaporation) and sunshine are most important. With heterogeneous surfaces, wind speed also becomes important and evaporation will vary with position. It is strongest over wet areas in drier surroundings (the oasis effect) and where the surface protrudes (the clothesline effect). Where such advective influences prevail, potential evaporation loses significance. Given sufficient contrast, there is no limit to the evaporation rate at the upwind edge of a preferred area. Proceeding downwind, the local rate progressively declines through the blanketing effect of advection until the potential evaporation rate obtains.

Over extensive bodies of water, the local rate of energy supply is no longer a limiting factor because the water itself can store and transport energy in abundance. Limitation resides in the atmosphere's diffusing power, and this depends on turbulence and hence on wind strength near the surface. The evaporation rate E is commonly expressed by the formula

$$E = Cu\,(e_s - e_a)$$

in which u is wind speed, e_a the atmospheric vapour pressure, and e_s the saturation vapour pressure at the surface temperature. C is a quasi-constant whose value is known except for very strong winds, in which accurate experiments have so far proved impossible. Hence evaporation is proportional to the difference between the saturation vapour pressure and the atmospheric vapour pressure. Evaporation and its estimation are important in water-conservation schemes. Losses can exceed 100 inches per year. Research aims at reducing losses by reducing the effective value of e_s in the above formula, for example, by spreading monomolecular films of suitable substances like cetyl alcohol.

Rain and snow

Rain and snow fall from clouds formed by condensation on appropriate nuclei, whose nature and concentration determine the subsequent development of the distribution of drop sizes; this controls stability and, hence, the readiness to precipitate. Nuclei originate as sea salt from evaporated spray, as dust whirled up from exposed soil, or from combustion or other pollution. Thus, surface processes influence the precipitation, though details of cause and effect are often hard to identify.

Once formed, the heaviest rain is little influenced by the ground beneath, but driven rain and snow are subject to local currents that influence the moisture of microhabitats through both precipitation and evaporation. Some minor forms of precipitation are specially sensitive to surface characteristics and can prove decisive in marginal regimes. Dew falls most unevenly, being attracted to tips of leaves and other protuberances that are coldest because of poor conduction. This principle was exploited by ancient Mediterranean civilizations, who erected loose stone cairns to attract and retain copious deposits. Similarly, dew ponds result from attraction by a poor conductor, aided by topography to sustain a katabatic flow of cooled air past or into the sink. Without advection, dew deposit per unit of horizontal area is minute, but it may yet be significant in sustaining some desert species whose tendency to grow in clumps achieves the attraction of dew from surrounding bare areas. In deserts, emergency drinking water is obtainable by digging a hole, filling it with fresh shrubbery, and then covering with clear plastic on to which solar heat will distill soil and plant moisture. Collection of drippings will yield one to three pints of water per day from a hole three feet square.

Another marginal effect occurs when cloud or drifting fog is frequent at the canopy level of vegetation, as in the redwood forests of California. With clouds of small droplets that would otherwise not precipitate, the vegetation can act as a comb against whose teeth the droplets impinge, so collecting into larger drops that drip or trickle to the ground. The ancient Cedars of Lebanon were reputedly so nourished, but once cut down, the precipitation was lost and they could not regenerate.

Rock weathering and soil formation. Fracture of the harder rocks is initiated by rapid heating and cooling and by freezing of water trapped in the porous parts. This is particularly so in clear, calmer macroclimates and at high elevations where microclimatic extremes are greatest. Microclimate accounts only for this initial fragmentation, and the final weathering (*q.v.*) of hard rock into the clay and mineral-particle constituents of soils (*q.v.*) is largely a chemical process. Even here, however, warmth and moisture control the pace and degree; soils in cold, clear climates tend to remain thin and rocky. In stormier climates, and everywhere with softer rocks, the prolonged mechanical action of wind and rain is another soil-forming process. There are indirect influences of microclimate also through plant growth, which accelerates weathering by ionic exchanges (addition or subtraction of charged particles) through the roots, increasing the proneness to subsequent chemical decomposition. The ionic exchange is strongest for lichens and other more primitive plant forms, and so the nutrition of the plant is an inseparable part of weathering.

In agriculture. Agricultural practices are aimed at achieving the best possible arrangement of chemical, biochemical, and physical factors in the micro-environment

of plants and animals. Man strives to manipulate the temperature, moisture, and wind exposure to suit each crop according to its stage of maturity, combatting the constraints imposed by macroclimate, soil, and topography. He is specially concerned to avoid microclimatic disasters such as frost or gale damage, scorching, wilting, and soil erosion.

Proper study of siting and exposure and contingent decisions of cropping practice come first and may outweigh in importance the subsequent tillage of the land. Sun-facing slopes accommodate the heat-loving species, whereas poleward-facing slopes harbour the hardier plants. Exposed sites must be avoided or shelter provided for fragile crops, and attention must be given to soil and air drainage according to the projected crop. Hedges across slopes dam up cold air, producing frost-prone strips wherein all sensitive buds or young fruit may be killed up to hedgetop level; gaps for air drainage are effective but will increase the severity of frost pockets further downhill.

The choice of crop follows study of siting. Any but the most adverse microclimates can grow some crop, so the agriculturalist's task is to optimize; in continuous exercise of judgment and experience, understanding and application of microclimatology become virtually instinctive.

General principles of temperature and moisture control through cultivation have already been explained, but generalizations about optimum conditions and practices must be treated with care because of variations between species. The germination of seeds in cold ground in spring depends on the conduction of sufficient heat to the seed. Shallow-sown seeds will prefer a dry, loose soil, deeper ones a firmer and more conducting soil. Later, the supply of water and nutrients in the root zone becomes significant. As soon as the seedling emerges, surface moisture is required to protect the tender tips from extreme heat and cold. Thereafter, its total growth will depend on a complicated factor of accumulated temperature or of accumulated temperature above some threshold (5° C) below which growth is negligibly slow. Moisture then acts mainly as a passive part of the transpiration-growth process and as a protection against high temperatures and wilting. For many crops, success depends not on total growth but on some special property of flower, fruit, or leaf that responds to a somewhat different combination of heat units, moisture, and timing.

Seed germination

Agricultural practice must vary accordingly. Aside from controlling the physical properties of the soil by tilling and mulching, there is scope for changing its geometry by row cultivation, hilling, etc., with considerable impact on low-growing and root crops. Two examples described by Rudolf Geiger, the German microclimatologist, are illustrated in Figure 4. Young trees in a nursery threatened

From R. Geiger, *The Climate Near the Ground* (1965); Harvard University Press

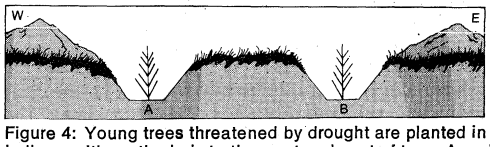

Figure 4: Young trees threatened by drought are planted in hollows with earth clods to the west and east of trees A and B as shown. Trees in hollow B thrived relative to those in A because they were shaded from the morning sun and had a few more hours of evening dew and humidity.

with drought were planted in hollows, with displaced clods left around the hollows. Plants B, with clods to the eastward, were shaded in the morning and had a few more hours of night dew and humidity. These thrived relative to plants A, which dried out early without any compensating benefit from the afternoon shade. The lower part of the Figure shows the temperature distribution at three different times of day, in unplanted drills running north–south at a height of about 15 centimetres and 30 centimetres apart.

Scorching and wilting are best avoided by watering, but frost prevention may take many forms. Smudge fires in orchards heat the air directly and achieve additional benefits by elevating the effective level of the outgoing radiation. Water sprays producing a glazed frost around buds and fruit protect them from falling below 0° C. Soil water, weeding, rolling, and frost fans achieve protection by increasing the effective conductivity of soil or air. Combinations of these methods can achieve benefits of more than 5° C in radiation frosts on calm, clear nights but are ineffective during prolonged freezes when day temperatures remain below 0° C. But even here some benefit is possible in marginal cases in which the surface is manipulated to retain more sensible heat, as by adding a covering of sand to the cranberry marshes in Wisconsin.

Soil erosion is the most permanent of all microclimatic disasters. Gully and other forms of water erosion are avoided or reduced by contour ploughing and by vegetation or artificial holding devices. Dust-bowl conditions leading to wind erosion are more insidious because of their progressive spreading if unchecked by means of water, shelter, and holding vegetation.

In air pollution. The dispersal of local pollutants is governed by turbulence and its variation with height. This may be observed from characteristic patterns of behaviour (coning, looping, fanning, lofting, fumigation) of smoke plumes from chimneys. The variation in turbulence through the diurnal cycle, and its dependence on weather conditions, thereby exerts a dominant influence on the time and space variations of air pollution in urban environments, thus creating urban climates (*q.v.*).

The interaction between microclimate and topography is another vital consideration, as evidenced by the katabatic accumulation of smog in low areas. Steep-sided valleys are specially prone to organized fumigations in which a concentrated stack effluent, accumulating clear of the ground by night, is brought to the surface by thermal circulation set up after sunrise. This may occur far downstream, as in fumigations in the U.S. from the smelter in Trail, British Columbia. Where chimneys are badly sited, their emission may have to be governed according to micrometeorological criteria.

Smog effects

In optical and radio transmission. Differences in optical refractive index accompany differences in temperature and density of the atmosphere. Shimmering on hot days and the lack of clear outline of distant objects results from disorganized refraction variations due to turbulence. Systematic layering of density causes more organized effects known as mirages. If the line of sight is near horizontal, images are displaced from their true position. The displacement is downward by day in the inferior mirage, when lighter air lies below heavier air and the rays are convex downward. The image of the sky, looking like water in the surface, has proved the despair of desert travellers. The superior mirage is convex upward and results from temperature inversions. These are most prevalent at sea with warm air overrunning colder water. Under special conditions, the ray may be trapped in a relatively shallow layer. Where this occurs, or when the curvature of the ray is close enough to that of the earth, very distant objects are seen well beyond the horizon and may appear deceptively close. Lateral mirages can appear over hilly country, where the density distribution conforms to the topography. Significant corrections for all systematic refractive effects are required in surveying, visual navigation, and astronomy.

These phenomena are paralleled in radio transmission, with the difference that the refractive index depends more on humidity than temperature. Because humidity decreases with altitude, near-horizontal rays bend back toward the earth (the superior mirage); the radio line of sight commonly extends well past the true horizon. Thus, anomalous propagation, in which waves travel large horizontal distances with little loss of energy, occurs more frequently in radio than in the optical wavelengths. If temperature decreases with height along with humidity, the resulting turbulence will tend to break up the regular stratification. The most extreme condition occurs, therefore, when dry air, as of a fohn wind, flows over cool water. Radar reflections can be obtained from humidity discontinuities in perfectly clear air, and other more complicated propagation effects are observed under special conditions.

Sound waves are similarly influenced by the density distribution in the air. Distant sounds are heard much more clearly at night, or with warm air over cold sea, when the bending is downward and the muffling effects of turbulence are absent.

SPECIAL AND ARTIFICIAL MICROCLIMATES

Artificial microclimates for crops. Whereas man in agriculture manipulates an essentially natural microclimate, his cropping and storage practices extend to the creation of artificial and radically new environments. Historically, the art was first practiced in the construction of walled gardens that provided shelter and directed the receipt and disposal of solar radiation.

Greenhouses

Glass has made possible the fullest concentration and exploitation of nature's heat sources. Short-wave radiation penetrates glass to warm soil and plants, and the convection plums, which in the open would rise high, can be trapped to heat a much smaller depth of air. Long-wave radiation from the glass makes a further contribution to the warming. Combinations of sheltering and the greenhouse effect are exploited in less ambitious structures (cloches, cucumber frames, plastic covers, etc.) for protecting sensitive crops or growth of valuable products at unseasonable times or in marginal climates. If sunshine is available, almost any degree of temperature increase is possible with devices no more complex than concave mirrors or blackened receptors; and these are in use in appropriate climates for cooking, water heating, and other purposes. With modern aids of air conditioning and artificial sunlight, supergreenhouses known as phytotrons are used to study plant growth and responses over the complete range of temperature, humidity, airspeed, and effective day length, though fully realistic modelling of the gradients of the variables that surround and affect a plant in nature have yet to be achieved.

Storage of crops presents different microclimatic problems. In many countries, winter supplies of root vegetables and fruit are stored outdoors in clamps, insulated by straw and earth to keep the temperature at about 3° C and ventilated to avoid excessive heat from fermentation. The great depths and pressures involved in silo storage of grain magnify this danger; moisture will migrate as in soils from the warm core to the colder parts and there cause molding. Suitable cooling by aeration will check this migration and, by keeping temperatures low enough, will inhibit breeding insects (which must otherwise be controlled by chemical methods).

The habitat of man. Although man feels comfortable at temperatures between 18° and 32° C, he has extended his habitat into climates ranging from −75° to +60° C. Clothing is a prime insulator against cold and excessive strength of sun. The microclimate of enclosed dwelling spaces (cryptoclimate) is today fully controllable by air conditioning, but there is much diversification where control is incomplete. An extensive bibliography of conditions in houses, cellars, tents, and other places has been compiled. Heat inside automobiles may be extreme because of exposure and poor insulation: temperatures 20° C higher than outside have been measured in a black sedan under certain conditions; excesses are halved by light colouring and further reduced by motion and ventilation.

The external climate and microclimate of cities differs from their natural surroundings because of different surface material, the changed effective roughness or shelter complex, and artificial alteration to heat and water budgets. Dust, smoke, and fumes affect the radiation balance, and the heat supplied by artificial fuels in winter may greatly exceed the receipt from the sun. The degree of modification depends so much on these factors and on topography that generalizations are difficult. An overall warming of 1° C is common, much more on cold, clear nights and in low-lying parts. Artificial convection in winter may be sufficient to increase rainfall over parts or all of the city.

Microclimate of caves. Caves and cave systems (*q.v.*) provide nature's cryptoclimates. Cold air seeps preferentially into the entrance, the average temperature of which is below that outside. Elsewhere, conditions depend strongly on the configuration. In static (single entrance) caves, downslopes admit only cold air, and the coldest seeps downward and stagnates. Rising caves are warmer, and the temperature increases inward and upward. Bats, insects, and other animals, therefore, are more numerous. Temperatures may be almost constant. Plant life occurs only near the entrance, where there is light for photosynthesis. Transit or dynamic (multiple entrance) caves are ventilated by air currents that arise because of temperature differences at the entrances. The current velocities can reach several metres per second at constrictions. The direction of circulation may vary with season or even diurnally if the entrances are differently exposed. Artificial caves, such as mines or railway tunnels, are normally ventilated or air-conditioned to avoid these adverse effects.

The marine and littoral microclimate. In oceans and seas (*q.v.*), microclimate is almost uniquely determined by macroclimate; and, with macroclimate more equable, microclimate has far less scope for diversity. Surface temperatures range from 30° C to freezing and vary only slowly with time, except at convergences or on the borders of strong meandering currents. Daily variation at the surface is about ¼° C. The bottom temperature of all deep oceans is generally between 0° and 2° C. The main vertical contrast is concentrated in the thermocline, extending through a few hundred metres from close to the surface. The increase in pressure with depth strongly influences life forms, but the most important physical variable controlling the habitat is light intensity. One percent of incident energy would penetrate to depths of several hundred metres in pure seawater, but more representative magnitudes for real oceans are 100 metres for the clearest waters, ten metres in coastal waters, and one metre in very turbid water near river mouths. One hundred metres is about the limit for plant growth.

Contrastingly, the intertidal zone of the shoreline provides unique and strongly time-dependent microclimates. Shallow rock pools in strong sun may rise to 40° C before the tide returns, and bare-rock surfaces become even hotter. Rock fauna, seaweeds, and animals that dwell among them must tolerate extremes of temperature, regular inundations of saltwater, and occasional inflows of freshwater from storms. The duration of exposure to microclimatic contrasts decreases from the high-water to the low-water mark. At neap tides, some shore is left uncovered for days on end. The strong microclimatic contrast results in zonations of plants and animals throughout the intertidal zone. Under stones and small rocks there exists another unique microhabitat; it is uniformly moist, saline, and without plants. Mangrove swamps, whose interlacing trunks and roots accumulate a permanently shaded mud layer, provide yet another unique microclimate and animal population.

HABITATS AND RESPONSES OF ORGANISMS

Heat budgets and animal modification. Just as the heat budget controls the microclimates at and near the ground–air interface, so the heat budget of the individual plant or animal governs its own proprioclimate and its own climatic responses. Energy is absorbed as radiation from the external field or is created by metabolism within. This must be balanced by long-wave radiation, convection, conduction of the ground, or evaporation (plants use only about 1 percent of their available energy in photosynthesis). Plants, and animals that sweat or pant, use principally evaporation; if this is inadequate, the surface temperature will rise until other processes can take over. Generally, only specially adapted desert plants can conserve moisture and withstand the consequent high temperatures without collapse. Animals are more versatile; the relative efficiencies of the various heat-disposal mechanisms will depend on size, shape, and exposure and on external factors such as wind speed.

Limitations on animal size

Animal size is related to the various heat quantities by the following rough rules. Metabolic heat production varies as the volume (for a given degree of activity); absorbed and emitted radiation varies as the projected area; and

free and forced convection varies less rapidly than the area because of the blanketing effect described earlier. That most members of the Negroid races of man have long slender limbs as compared with those of most of the short, squat Eskimo reflects their relative efficiencies in heat disposal and heat retention (large and small surface areas), respectively. Warm-blooded animals in cold climates require insulation, as do the larger animals exposed to strong sun unless they have evaporative cooling. Wool insulates the sheep; the temperature at the ends of its fleece may rise to 90° C before long-wave radiation can dispose of the heat intercepted: much smaller animals require no insulation from sun because smaller areas yield a higher convection-to-interception ratio and heat balance is reached at a lower surface temperature. For insects in flight, metabolic heat represents the major load, and this is shed by forced convection.

Such self-regulating systems imply adaptability to microclimatic changes. Organisms with little adaptability must achieve their narrower tolerance range; plants accomplish this by selective survival, and animals, generally, by locomotion. The habitat may even accompany the animal. In heat, snails and winkles retire to the recesses of their shells to avoid desiccation. Birds' nests, ant heaps, and animal burrows are made for comfort and protection of young and old and show attention to microclimatic positioning and complexity of structure that compare with man's own artifices. Notable are mound-building birds such as the Australian mallee fowl. The male's beak is temperature sensitive, and he daily tends the mound, adjusting soil insulation to the conditions of the day and season and to the heat of fermentation of its vegetable content.

Life forms in special environments. The broad divisions of macroclimate and environment generally determine the first-order distinction between larger species. Smaller species depend on microclimate, but because its ranges overlap the macroclimatic zones, smaller species have often the wider geographic distribution.

The great variety of microclimates engenders enormous diversification of species, and in practice only two criteria appear ultimately limiting to live growth: temperatures too extreme to sustain any liquid in vital tissues and, for plants, insufficient light. Animals are not restricted by the latter, for food may be brought to them by water, wind, or gravitational settling.

Unique micro-environments produce unique populations: earthworms and mud crabs, caterpillars at selected locations in plants, echinoderms on the sea floor, prawns and squids with luminescent organs in the depths. From Antarctica to tropical rain forests, the interface is populated by organisms of varyingly adapted species. Beach worms and clams, in densities of thousands per cubic foot, characterize the intertidal environment and its fecundity. Cave species show genetic adaptation to darkness and to the absence of rhythm and change in their subterranean environment. The microclimatic correlation is generally understood only qualitatively because the fine instrumentation for quantitative studies is of relatively recent development.

Variability effects on populations. Macroclimate controls the migrations of birds and fish, and its vicissitudes influence their abundance. In the same way, microclimate reacts on the daily behaviour of all life forms and their variations in space and time. Again, the marine environment presents an inherently more simple picture than does the land. Light confines anchored plant growth to shallow waters. Animal plankton rise at dusk and descend in the morning, seeking constant light intensity. Fish follow their food supply. The thermocline inhibits these daily migrations, but where major vertical circulations exist, the population density is profoundly influenced. Vast aggregations of life are found, for example, off Antarctica and in other nutrient-rich upwelling waters.

On land, the abundance of life is strongly correlated with temperature and moisture. The limits of the area that any particular species inhabits is a boundary zone in which the species is found to exist in pockets. Moisture especially exerts a buffering influence in regions otherwise subject to strong temperature gradients and rapid changes. Given adequate nourishment, enormous concentrations of smaller insects and microbial forms inhabit soil layers that remain moist but not waterlogged. The same applies to the permanently moist patches under stones and rocks in the intertidal zone, sometimes crowded with life to the point of suffocation.

Massing of populations in air is, by its nature, more spasmodic, and the causes are several. With birds, as with larger land animals, grouping is socially motivated, and only the composite movements of the flock are climatically regulated. Smaller flying insects mass from instincts that are microclimatically oriented, be it to seek shelter from wind buffetings or a favourable temperature in and around canopies in the morning. Massing of locusts in upcurrents appears a largely inert response, although it is motivated toward finding a good wind for transport.

Daily behaviour patterns of all animals relate to cycles of temperature and light, but in an almost infinitely varied manner. Speed of movement of smaller cold-blooded species is directly responsive to temperature. Snails, caterpillars, and crickets migrate up and down plants to suit their heat and moisture balance according to time of day. Some animals and plants vary their orientation to maintain maximum interception of radiation (see also PERIODICITY, BIOLOGICAL).

MEASUREMENT OF MICROCLIMATES

Where quantitative understanding of the microclimate is sought, the most important single measurement frequently is net radiation, which governs the heat balance. It can be measured directly by a thermopile with sets of junctions in contact with two opposed-plane blackened surfaces. These are so adjusted that the sensitivity to solar and terrestrial wavelengths is the same. Surface temperatures are also best measured by a suitable radiometer. Both instruments can be miniaturized to about one centimetre for study of spatial variations on this scale.

Soil temperatures can be recorded by any standard method or read from thermometers with long stems. Soil moisture *in situ* is determined indirectly from moisture tension or by electrical or thermal methods that determine moisture-dependent properties such as capacitance or conductivity. Temperature and humidity determinations of the air and within plant canopies frequently call for precision, and the strong gradients involve small sensing elements and sensitivity to rapid fluctuations. Probes are constructed as single thermojunctions, fine resistance wires, etc.; and when wrapped with a fine wick, they yield wet-bulb temperature and humidity. Small instruments avoid the need for special housing or aspiration. They can be used to measure temperature or humidity of individual eddies and, linked with a correspondingly fine measurement of air motion, can yield the rate of heat convection or evaporation by the eddy flux, an absolute method. The airflow instrument is most appropriately a hot wire anemometer or very light vane or propeller. Heat flux into the ground may be determined from temperature difference across a thin plate, whose conductivity is close to soil conductivity so that the heat flow is undistorted.

For measuring average conditions over periods of several minutes, and how these vary with height, etc., masts that hold arrays of more robust instruments are used. For mean wind speed, sensitive, rotating cup anemometers are commonly employed.

For evaporation, direct weighing of soil blocks is an alternative to the eddy flux as an absolute method, provided no disparity with surrounding terrain and surface cover is introduced. Various evaporation pans and devices similar to the Piche evaporimeter are also widely used. By interfering with the natural surface, however, they introduce advection errors, and their values must be corrected or restricted to comparative uses. This also applies to most dew gauges, in which a collector attracts the dew and the amount of deposit is determined. The use of a net radiometer and application of energy-balance principles will help to detect and avoid this sort of error.

Micronesian Cultures

The name Micronesia is derived from two Greek words meaning small islands. It is generally considered to include the Caroline Islands from the Palau Islands in the west to Kusaie in the east, the Mariana Islands to the north of the western Carolines, the Marshall Islands to the east of the Carolines, the Gilbert Islands to the south of the Marshalls, and the isolated island of Nauru west of the Gilberts and south of the eastern Carolines. The islands of Micronesia are scattered over an area of the tropical western Pacific, mostly north of the Equator, for an east–west distance of about 3,000 miles (5,000 kilometres) and a north–south distance ranging up to more than 1,000 miles, but the total land area of all the islands combined is only about 1,100 square miles (2,800 square kilometres), of which 207 square miles are found in the island of Guam and about 130 square miles each in the two next largest islands, Babelthuap in the Palaus (western Carolines) and Ponape (eastern Carolines). Many of the permanently inhabited atolls contain less than one square mile of land. The inhabitants of the Ellice Islands to the south of the Gilberts and the isolated atolls of Nukuoro and Kapingamarangi west of Nauru and south of the eastern Carolines speak Polynesian languages and by culture and physical type are properly classed as Polynesians rather than Micronesians (see map in OCEANIC PEOPLES AND CULTURES).

Nearly all the islands of Micronesia can be conveniently classified as high or low islands according to their physical relief. The high islands are typically volcanic; they support fairly large populations, and their soil sustains a greater variety of wild and cultivated plants than does that of the low islands. The high islands have traditionally served as ports of call for the inhabitants of nearby low islands.

THE TRADITIONAL CULTURAL SETTING

Seven major high-island cultures can be distinguished in Micronesia: those of the Chamorros, inhabiting the Marianas, principally the four southern islands; the Palauans; the Yapese; the Trukese, inhabiting about 12 high islands of varying size in the large Truk Lagoon; the Ponapeans; the Kusaieans; and the inhabitants of the isolated island of Nauru, which is geologically a raised atoll (without exposed volcanic rock).

Diversity of the Micronesian peoples

The inhabitants of most of the low islands in Micronesia are culturally distinct from the high islanders, though in contact with them. In the east are found two culturally distinctive groups of atolls, the Marshalls and the Gilberts, ranging from the northwest to the southeast over about 1,400 miles. The culture of Ocean Island, or Banaba, a raised atoll, is quite similar to that of the Gilberts and will be treated herein as a variant of Gilbertese culture. Three atolls within sailing distance of Ponape—Mokil, Pingelap, and Ngatik—show closer cultural relationships to the people of Ponape than to any other large population but are clearly distinct from them. The Hall Islands, atolls to the north of Truk, and the Mortlock (Nomoi) Islands, atolls to the south, are culturally closest to Truk. The remaining low islands to the west of Truk also show linguistic and cultural relationships to Truk, with the differences becoming increasingly marked the farther west one goes. The low islands between Namonuito and Yap were once part of a ceremonial exchange system called by anthropologists the Yap Empire. Linguistically and culturally, however, these low-island people were closer to the Trukese than to the Yapese.

The cultural diversity of Micronesia is indicated by the number of mutually unintelligible languages in the area. The following all have mutually unintelligible languages: Nauru, the Gilberts, the Marshalls, Kusaie, Pingelap, Mokil, Ponape, Ngatik, the Mortlocks, Truk, the Puluwat area, the Woleai area, Yap, the Palaus, and the Marianas (Chamorro language). The languages of the islands from the Marshalls through the Woleai area in the above list appear to be somewhat more closely related to each other than to the remaining languages and have been referred to as Nuclear Micronesian. The languages of Yap and the Gilberts may also be more closely related to this group than to any other Pacific languages. The languages of the Palaus and the Marianas are relatively distinct from each other and from other Micronesian languages, although they are clearly Austronesian (formerly called Malayo-Polynesian) in their general affiliation. The Chamorro language, spoken in the Marianas, has undergone much influence from Spanish and probably also from the Philippine Tagalog language after more than four centuries of Western contact.

Traditional Micronesian cultures were characterized by a belief in the stability of society and culture, perhaps even more so than most other nonliterate cultures. Man suffered occasional natural disasters, such as typhoons or droughts, but his goal after encountering one of these was to reconstitute the previous state of affairs. Wars occurred in most areas from time to time but often resulted in few casualties and no changes in land ownership.

Living in small communities on small territories, Micronesians learned to adjust to their neighbours and remain on good terms with most of them most of the time and to develop techniques of reconciliation when fights did break out. In general, Micronesians valued good manners. Even today, Micronesian adults and children are likely to impress the outsider as unusually quiet, polite people.

Local loyalties

Micronesians traditionally depended on the cultivation of plant crops and on fishing in shallow reef waters. Since both arable land and reef were in short supply for the relatively dense population, the Micronesian had a strong practical basis for his attachment to his locality and lands. Land rights were usually held through some sort of lineage or extended family group, often backed up by traditions of ancestral origins on the land.

The strong local loyalties of the Micronesians may also be partly explained by the difficulty of travelling to any place very far from home, especially for the high islanders who lacked ocean-going canoes. Of the high-island peoples, only the Yapese practiced very much navigation in the open seas at the time of their discovery by Europeans, sailing to Palau and to some of the atolls in the central Carolines. The remaining high-island peoples mostly sailed around their home islands without losing sight of land, although they were visited from time to time by low islanders. The low islanders had reason to visit the high islands, with their more fertile soil and greater elevation; they could obtain food products not found on their home islands or seek refuge after a typhoon or drought. Low islanders also had reason to visit other low islands in search of mates outside the limits of the incest taboo and for help after typhoons. Some of the low islanders, especially in the storm-swept central Carolines area between Truk and Yap and in the Marshalls, were skilled navigators of oceangoing canoes.

The populations of the Micronesian islands appear to have been in good balance with the natural resources at the time of their discovery by the Europeans. Since the climate is equable and varies little during the year, moderate amounts of labour were sufficient for comfortable survival, and much leisure was available for activities such as dancing, feasting, romantic affairs, and visiting

friends and relatives. Some kinds of subsistence activities, especially fishing, were regarded as something like play. The period of youth was often prolonged, since the older people could afford to indulge their children. This positive attitude toward the enjoyment of leisure was especially characteristic of the high islanders, with their more fertile soil and more secure life.

MICRONESIAN SOCIETY

Political units

Throughout most of Micronesia the maximum independent autonomous political unit was the high island or atoll, often subdivided into more than one unit. Satawan atoll in the Mortlocks had four separate communities aboriginally, each with its own chief; sometimes they fought each other. The Palaus had two confederations of villages or districts aboriginally, each independent of the other, and the villages themselves had considerable autonomy. Ponape had five petty states at the time it was discovered, although there were traditions of a unified rule for the whole island at an earlier period. Truk was extremely fragmented politically, with several independent communities on each of the six larger high islands. The Marshalls and the Gilberts had larger political units, integrating groups of separate atolls under a high chief, although the fullest development of these conquest states was achieved after the introduction of firearms by Europeans.

The low islands between Truk and Yap have been described as belonging to the Yap Empire. The so-called empire consisted mainly of a chain of trading and ceremonial relationships with one of the petty states of Yap. The Yapese exerted no military force against the low islanders but did claim the ability to punish them by magically sending typhoons, disease, and famine if they should fail to fulfill their obligations. According to widely accepted myths, the low islanders originated from the Yapese, although they are culturally and linguistically closer to the Trukese.

In most of the area from the Palaus in the west to the Marshalls in the east, the community was considered to be owned in some sense by a clan, the head of which was also the chief of the community. Other clans had land rights by their relation to former chiefs or to the men of the ranking clan: their women had married men of the chiefly clan, or their men had rendered the chiefly clan service in the past. The chiefly clans in some cases claimed their position by virtue of ancient military conquest and in others by virtue of being the first human beings to occupy the land. The aboriginal pattern of political and community organization in the Marianas has been obscured by the early Spanish conquest, which exterminated most of the population and concentrated the remainder under close Spanish military and religious control. Chieftainship in the Gilberts was variable and in some cases patrilineal.

Family and kinship patterns. The majority of Micronesians before European contact lived in some form of extended-family group. In most areas the organization of this group probably had considerable flexibility, some newlywed couples living with the husband's family, others with the wife's relatives. Major determinants in the choice of residence were the relative availability of agricultural land and the need for additional labourers on one or the other side of the family. In much of the area the wife's family was considered the ideal place of residence; but frequently exceptions were allowed in practice, and children often had rights to use land on their father's mother's side. In Yap, on the other hand, patrilocal residence and patrilineal inheritance of land were considered ideal.

As in other parts of Oceania, the adoption of children of relatives was frequent. This was, in part, a way of caring for illegitimate and orphaned children; in part, a way of relieving young adults of the chores of child care and providing old people with young children to do minor work for them; in part, a way of insuring more equitable distribution of land rights; and, in part, a way of providing heirs for specialized knowledge when the proper natural heir was lacking or unsatisfactory.

Where matrilineages existed in Micronesia, they were traditionally exogamous—*i.e.*, members did not marry within the same lineage. While matrilineage membership was considered basically unalterable in some communities, there was probably some flexibility everywhere. If a lineage grew too large, it tended to split into two parts, one of which would adopt a new name and no longer observe exogamy with the other. If outsiders came into a community, they would often be taken into an existing lineage as honorary or fictive members and eventually might merge with the patron group and observe rules of exogamy with them.

Marriage

Marriage in Micronesia varied in formality. In the west, in Palau and Yap, marriages were marked by formal payments from the groom's family to the bride's. In the area from the central Carolinian atolls to the Marshalls, marital relationships were usually rather loose and informal for most people, although people of high rank may have had public ceremonies with some exchange of wealth. In this area considerable premarital and extramarital sex was traditionally expected; marriage for ordinary people consisted simply of openly living together and being spoken of by the community as spouses. Apparently, there was more formality to marriage and more control of premarital sex in the Gilberts.

Polygyny was generally permitted to some extent in Micronesian societies, although it was not very common. It was more likely to be practiced by high-ranking men, and in eastern Micronesia it may have been restricted to chiefs.

Birth order is widely important in Micronesian societies. The seniority of the eldest child is recognized in representing the family or lineage in public and in inheriting political office. The eldest child generally directs the use of lineage or family lands. Younger siblings generally exhibit formal respect to older siblings.

Brother–sister avoidance relationships are well developed in parts of Micronesia, perhaps most strongly in the central Carolines from Truk through the atolls to the west. In this area women were traditionally expected to avoid speaking to their brothers, to crouch in their presence, etc. In Ponape, farther to the east, a similar relationship existed between a man and his next younger sister but did not extend with the same force to other sisters.

Social stratification. A certain amount of hereditary social stratification was found universally in Micronesia, but its degree varied considerably from some of the smaller Carolinian atolls, which had nominal hereditary chiefs with little special power or wealth, to the high island of Yap, which had several ranked endogamous castes. Other cultures that showed relatively marked social stratification were Palau, Ponape, Kusaie, the Marshalls, and the Gilberts. It seems likely that the Marianas may have also had distinct social classes before the Spanish conquest. In all the above areas there appear to have been some chiefs who were supported principally by tribute from their subjects; who were the object of considerable deference; who could punish offenses (especially against themselves and their own relatives) by fines, destruction of property, or death; and whose principal wives were chosen mostly from other high-ranking families. In these areas the high chiefs also had subordinate chiefs and officials.

Egalitarian tendencies

At the same time, there were limitations on the development of the hierarchical principle in most of these societies. The notion of crime to be punished by the state was weakly developed. Palau and Ponape had an abundance of nominal political titles, the principal significance of which might be called recreational and dramatic. In both these societies there was considerable opportunity for individuals to rise above their initial hereditary status through personal achievement, thus introducing much flexibility into the system of social stratification. The principle of birth order worked at cross purposes with the principle of hereditary rank of clans and lineages; a child of low birth order in a high-ranking lineage would not necessarily receive much advantage from his relationship to the chief.

On the high islands of Truk and on many of the low islands, especially those in the central Carolines and the smaller communities in the Marshalls and Gilberts, social relationships were quite egalitarian. The local chief was expected to work for his living like anyone else. He received occasional ceremonial deference but traditionally had little power to order people to do anything or punish them for offenses. His principal function was to preside at meetings and to try to define and state the community consensus as it developed. He had a wide choice as to whom he might marry.

Socialization and education. Micronesians are indulgent with infants. Because of the extended family, someone is usually available to amuse the baby and take care of its needs. Babies are generally exempt from physical punishment. In the tropical climate, toilet training is mainly a matter of teaching the baby to go outside the house for elimination when it is able to walk.

Children were inducted into adult life gradually through observation and participation; there was little in the way of formal schooling or initiation ceremonies in most of the Micronesian societies. Several forms of bodily ornamentation by mutilation were practiced, mostly performed around puberty or in early adulthood. The most widespread of these was tattooing, practiced by both sexes. This and other forms of bodily mutilation were generally done on individual initiative, to demonstrate bravery and increase a person's attractiveness to the opposite sex.

Training in cultural specialties, such as medicine, magic, esoteric mythology, canoe and house building, and navigation, was often delayed until young adulthood or middle age. It was usually given by an older relative, although sometimes outsiders could receive it by payment of food and goods. The most formal training in esoteric knowledge appears to have been given by the specialists known as *itang* (in Truk). Each *itang* had himself been trained under an older expert adept in traditional history, oratory, war strategy and tactics, and magic. At the end of his training he was formally awarded the title or degree of *itang* and thenceforth could serve as an orator, ambassador, counsellor, and executive officer for a chief. An *itang* sometimes trained a group of several young men at a time, receiving prescribed payments from them.

Settlement patterns. Micronesians preferred to live in dispersed, extended-family homesteads, in contrast to some Melanesians and Polynesians. In atolls the inhabitants generally preferred the lagoon side of the larger islands for ease in launching canoes and for protection from typhoons. On the high islands, people again wanted access to the lagoon, although easily defensible sites were sometimes also preferred, such as the top of a steep, cleared slope.

The "Venice" of Ponape

One ancient "city" in Micronesia is the archaeological site of Nan Matol or Metalanim on Ponape. This is a sort of tiny Venice, containing about 100 artificial islands, separated by shallow canals, covering one-third of a square mile in all, including water. The islands were used for residence and for ritual, and the total population may have been several hundred to 1,000. There is a similar site at Lelu (Lele) in Kusaie.

The typical Micronesian community had one or more meetinghouses. These served both as social gathering places and as places to plan community affairs. The number and elaborateness of the meetinghouses is greatest in Yap and Palau. Palauan meetinghouses were built by the men's clubs. In Palau, Yap, and the western atolls, meetinghouses were used mostly by men, while farther east, women and children also entered them freely much of the time.

Houses in most areas were built on slightly raised platforms made of coral rock and gravel on the low islands and volcanic rock and dirt on the high islands. They generally had thatched roofs with low eaves and poor ventilation. The smoke from a small hearth may have been a way of controlling mosquitoes, although plaited mosquito sleeping bags were also used at times. This form of construction may have also provided good protection against heavy rainstorms. Some of the houses in the Marianas appear to have been constructed on stone pillars. The *latte* stones of this area—double rows of stone pillars with capstones—are now thought to have been piles for raised houses, perhaps for chiefs and wealthy men, since the *latte* sites are relatively few for the reported population. Other houses may have been built on wooden piles that have since disappeared.

Canoe houses were another important form of building throughout Micronesia. Those big enough to store the larger canoes were on the scale of meetinghouses and often used as such in some areas.

Small buildings for the isolation of menstruating women existed in the western Carolines and continued in use in Yap until recent times.

ECONOMY

Production and technology. The islands were probably first settled by small groups of immigrants with few technical specialists among them. The prehistoric Micronesians had basically a subsistence technology with a few part-time specialists producing luxury items, such as personal ornaments and the shell and stone valuables used, mostly in the western Carolines, for ceremonial payments.

Subsistence everywhere was based primarily on horticulture and fishing, with fishing somewhat more important in the low islands and horticulture more important in the high islands. Domestic animals were limited to dogs and chickens, found only in some areas.

Food crops

Rice was grown in the Marianas but later was largely replaced by maize, introduced from Mexico by the Spanish conquerors. Coconuts were used everywhere, both as food and for other purposes, such as thatch, lumber, and cordage. Some form of taro, either the true taro (*Colocasia*) or the giant swamp taro (*Cyrtosperma*), was probably cultivated everywhere except on some of the drier low islands in the east, where the groundwater tended to be too brackish. The breadfruit tree, which produces a large starchy fruit in abundance in the early summer, was also widely distributed. Bananas were an important food crop on the high islands. Tropical yams (*Dioscorea*), which produce large starchy tubers, are found today on a number of the high islands but are of greatest importance as a cultivated crop on Ponape, where they have high prestige and provide an important source of food in the winter. The sweet potato and cassava, introduced by Europeans, now serve as alternate subsistence foods on some of the high islands. On some of the drier atolls in the Marshalls and the Gilberts, the pandanus tree is a major subsistence crop. The edible fruit of some cultivated varieties, in appearance resembling a pineapple, contains starch and sugar that can be made into a flour and stored. Other varieties have large edible nuts. Some varieties of pandanus are cultivated for their leaves, used principally in making plaited sleeping and floor mats and sometimes for thatch.

Many kinds of fishing were practiced traditionally. Often there was a division of labour, with men using techniques requiring canoes in deep water, such as seines and line fishing, and women wading on the waters of the fringing reefs. Deep-sea trolling with sailing canoes was practiced mostly by low islanders. The low islanders also at times made expeditions to certain small, uninhabited reefs and low islands to fish and collect turtle and seabird eggs.

Cutting tools were made from stone and shell. Iron was introduced by Europeans, although some iron tools may have been obtained from Oriental sources in western Micronesia.

Simple pottery has been found only in the western high islands of Micronesia: the Marianas, Palau, and Yap. Suitable clay apparently exists in Truk, Ponape, and Kusaie, but if pottery was ever introduced to these islands, it was not widely used.

Ocean travel

All Micronesians, even the high islanders, relied often on water travel, although the high islanders used canoes principally in the sheltered coastal waters of their home islands. Micronesian canoes had a single hull with one outrigger. Canoes used in protected waters were often simple dugout canoes, but the oceangoing canoes, found

especially in the central Carolinian atolls and the Marshalls, had sides built up of irregular planks that were caulked and sewn together with cord made from coconut-husk fibre.

Some of the atoll dwellers regularly went on trips requiring several nights in the open sea. Extra provisions were usually taken along as gifts and for emergency needs if the canoe were blown off course. In historic times vessels blown off course have ended up in a variety of islands inside and outside of Micronesia. Conversely, vessels from other areas of the Pacific and from the Orient have been blown to Micronesia. It seems clear that, prehistorically, there was communication in chain fashion from the Ellice Islands and western Polynesia through the Gilberts, the Marshalls, and the Carolines to Palau and the southeast atolls and beyond them into the northern Moluccas in Indonesia. Probably there was also deliberate communication across the larger gap between the central Carolinian atolls and the Marianas; in the latter there is a long-established population of cultural Carolinian immigrants retaining their original language.

Property and exchange systems. The most important property among the Micronesians was land. Land-tenure customs varied considerably from island to island, even among those with related cultures.

Land was owned primarily by extended-family groups or lineages. Individuals acquired use rights to particular plots through their kin connections, acknowledging the rights of the group by periodic offerings of first fruits to the kin-group head. Often a community chief and sometimes a superior chief received offerings from each household or larger kin group holding land under his jurisdiction. In some areas, especially in eastern Micronesia, strong chiefs effectively exercised the power of eminent domain and confiscated land from those who fell out of their favour, awarding it to loyal followers.

Since land was a scarce resource in much of Micronesia, various mechanisms developed to govern its distribution. In areas where matrilineal inheritance of land rights was practiced, there were usually provisions that, if necessary, children of the men of the lineage could also inherit use rights to the land worked by their fathers or receive a share outright if the lineage had more than it needed. In general, land was not sold, but it might be given in payment for medicine and nursing services or as compensation for an injury.

In the larger high islands, interior areas not under regular cultivation were considered community property and used for collecting wild food and for temporary gardens. In the atolls practically all land was owned by one or another family group, even small islets with four or five coconut trees.

Feasts as exchange rituals

Large feasts were common throughout Micronesia. The people assembled much food, offered it to the chief, and he in turn redistributed much of it to the people. Sometimes kin groups or communities held alternating semicompetitive feasts in which each tried to outdo the other. Feasts were held to commemorate important transitions in the life cycle, especially marriage and death. A kind of delayed exchange might take place at these feasts, certain relatives being obliged to make presentations of food and goods in return for past or anticipated services.

Substantial payments were sometimes made to practitioners of traditional medicine, especially when the practitioner was not a close relative. Such payments consisted of food and other goods. The precise amount was generally left to the family of the patient, with the understanding that a stingy family might not get the most energetic and effective treatment.

In Palau and Yap, shell and stone valuables were used in transactions at life crises and for certain other specific compensations, such as payment for injuries. These are often called money, but their use was much more limited and specific than that of most money. The best known of them were the large stone discs that the men of Yap manufactured on Palau and carried home in sailing canoes.

A certain amount of trade developed between the low islanders and high islanders, the low islanders providing handicraft products that the high islanders could have made if they had needed to, and the high islanders providing things obtained more easily there. This trade was especially well developed between the low islanders of the central Carolines and the high islanders of Yap and Truk. The most important high-island export was turmeric, used for medicinal and cosmetic purposes, which formed a bright orange body paint when mixed with coconut oil. The low islanders provided shell beads, plaited pandanus mats, and coarse cloth woven from banana or wild hibiscus fibre and used for women's wraparounds and for men's loincloths. Trade was often with particular partners who regarded themselves as distant relatives. An important function of the trade was to provide the low islanders with aid and a temporary dwelling place when their islands were devastated by the periodic typhoons.

RELIGION AND ART

After 1900 Christianity became well established in most major centres in Micronesia. Native religions were no longer practiced in their full original form, although in Yap and some atolls of the central Carolines, traditional religion continued to be practiced until the middle of the 20th century. Missionaries and travellers have left descriptions of certain aspects of the traditional religions, but there is no complete and systematic account.

The basic patterns of religion were probably similar throughout most of Micronesia. The Micronesians were polytheists, believing in several high gods, a large number of spirits attached to specific localities or performing specific functions, and a number of ancestors and deceased neighbours who could sometimes make contact with their living descendants and friends. Practices connected with these three major categories of supernatural beings tended to be distinct and to be handled by different specialists, although a figure might gradually shift from one category into the other.

Micronesians generally believed in at least three vertically arranged levels of the universe: the earth proper, the underworld, and heaven or the sky world. Some of them may have believed in multiple heavens, as did people elsewhere in Polynesia and Indonesia, but the details are now unclear.

Micronesian origin myths generally tell of the origin of particular islands or descent groups or the initial discovery or later conquest of an island by the ruling descent group. The notion of the supernatural creation of the whole human species or of the whole world is either not found or little emphasized in Micronesian mythology.

Ceremonies for the high gods appear to have been principally seasonal offerings of first fruits, performed often in private by a specialist priest with a few helpers. Special appeals to the high gods were probably also made at times of community crisis, such as wars or typhoons. The priests were very likely relatives of the ruling chiefs. The lesser spirits were called on by magicians for specific purposes, most notably for the diagnosis and cure of disease but also for such purposes as success in fishing and agriculture, control of weather, success in love, and prowess in athletic contests, battle, canoe building, house building, and other difficult pursuits.

Communication with spirits

Ancestral spirits were often contacted in dreams and in the trances of spirit mediums, as were the high gods and other nonhuman spirits. They would give people information about the causes of disease, deaths, and other misfortunes and would sometimes prescribe new medicines or new varieties of magic. At times, the spirit mediums would also order their human protégés to perform songs and dances for the entertainment of the spirits, to win their goodwill and insure the prosperity of the community.

Micronesia has little permanent visual art. The best known consists of the painted bas-relief scenes on the timbers and gables of the men's houses in Palau. Stylized wooden masks and human figures have been found in the Mortlock Islands, south of Truk. There was some decoration. Decorative lashings of light and dark sennit twine are found in important buildings. Painting and decoration of canoes is common, following traditional patterns

for each island. Patterns were woven into clothing. Wooden bowls were carved and painted with aesthetic intent.

Much of the most-developed traditional art of Micronesia was ephemeral: body painting and ornamentation with garlands of flowers, singing, dancing, and the recital of myths, tales, and poetry. Oratory was also an important traditional art and still survives. A good orator was expected to make mythological and historical allusions and to use special figures of speech.

THE CHANGING CULTURE

Factors in cultural change. Micronesian culture has been heavily influenced by contacts with outsiders: the Spanish conquest of the Marianas at the end of the 17th century; the entry of European whalers, traders, and missionaries into the rest of the area in the 19th century; the Spanish conquest of the Carolines; German occupation of the Marshalls; the British occupation of the Gilberts at the end of the 19th century and beginning of the 20th; the Japanese occupation of former German and Spanish holdings at the start of World War I, extending temporarily to Guam and the Gilberts in World War II; and the U.S. occupation of the Japanese holdings at the end of World War II under a United Nations trusteeship.

Each of these waves has resulted in substantial racial and cultural admixture in at least parts of the area, especially in the larger and more populous islands but extending out to the small atolls that have traditionally looked to the larger islands as models.

Effects of outside contacts

How one evaluates the effects of these contacts on modern Micronesian culture depends on whether one is interested in the preservation of traditional local cultures or the strengthening of pan-Micronesian culture. Christian missionaries, for instance, have often been less than sympathetic to the local religions and mores. On the other hand, they have encouraged the development of a sense of Micronesian identity by teaching foreign languages with which Micronesians from different islands could speak to each other, by sending out Micronesian missionaries and catechists to other islands and thus increasing inter-island contact, and by encouraging a wider feeling of human brotherhood.

Foreign trade has caused the disappearance of some traditional crafts, such as weaving and pottery, by providing superior imported products and by diverting labour to export products such as copra (dried coconut meat). At the same time, trading vessels have often carried Micronesians as passengers or crewmen to islands in Micronesia and beyond. Internal mobility within Micronesia has led to inter-island migration and to a sharper awareness of the similarities in much of the content of Micronesian cultures. Foreign trade has brought new similarities in ways of life based on the adoption of foreign products and practices. Thus, all the main population centres now use outboard motors for trips in coastal waters, motor scooters and automobiles on land, and many other products of modern technology.

In the United Nations Trust Territory, administered by the U.S., and in Guam, the government payroll has in recent times become a much greater source of cash income for Micronesians than foreign trade and tourism. Nevertheless, these funds are dispensed mainly at the large population centres, while most of the low-island communities continue with much of the traditional subsistence economy, purchasing clothes, tools, cigarettes, and some luxury foods from the sale of copra. Royalties from the mining of phosphate are locally important for the small independent island of Nauru and the island of Angaur in Palau; they have also been important for the Gilbertese inhabitants of Ocean Island, who have moved away to Fiji to accommodate the mining.

The imposition of foreign political authority on Micronesia has tended to lessen the power of the traditional chiefs and political systems, although the foreign rulers have often paid lip service to the ideal of preserving indigenous culture and social organization. In the Trust Territory the Japanese and Americans have tried to establish more or less uniform elected local governments, each usually corresponding to what was originally a small independent society. These elected governments were intended to take care of modern political life, including the execution of policies and laws prescribed by the territorial government, while the traditional political system was left to take care of "social" matters. These arrangements have often been understood differently by the Micronesians involved; the elected local governments have often been regarded by the electorate primarily as a sort of buffer to minimize the interference of the foreign territorial government in local affairs.

In the 1960s the Trust Territory government sharply expanded its budget and personnel. More and more Micronesians were becoming involved in government above the local level. The new Congress of Micronesia was given powers to formulate territorial policy and laws.

U.S. and Japanese immigrants

So far, most of Micronesia has been spared the effects of massive permanent immigration of outsiders. The greatest concentration of non-Micronesians is on the island of Guam, which the United States took over at the end of the Spanish–American War in 1898. Many military personnel and their dependents live on Guam, and other Americans have settled there to do business. Even so, the local government is mainly in the hands of the native Chamorros, who also retain considerable real estate in the southern part of the island.

In the Trust Territory a large immigration of civilians and military personnel occurred during the Japanese period, principally to the larger high islands. They were all repatriated at the end of World War II, when the United States took over the area, and only a few have returned. Non-Micronesians have not been allowed to purchase land during the U.S. period, and until the 1960s most foreign nationals were prevented from entering the area on grounds of military security. In the Gilbert Islands, controlled by the British, there has been little foreign immigration; the islands have a small land area and are densely populated. Some foreign coconut plantations were established at the turn of the century.

Migration

Substantial movements of indigenous population have occurred within Micronesia. In general, people from the low islands have tended to move to the nearest high islands because of population pressure at home and because of the schools, missions, scientific medical treatment, salaried employment, and other advantages of the high islands. The island of Saipan in the Marianas has a substantial population derived from the atolls of the central Carolines over a long period. Ponape has a substantial number of immigrants from nearby atolls and from the Mortlock atolls to the south of Truk. These and other internal movements dissipate the local cultures of the migrants but at the same time work toward a generalized Micronesian culture.

Government schools and mission schools are important factors. Some kind of elementary school is available in every sizable community in Micronesia. Secondary school education is available for selected children in the main population centres. There is now a junior college on Ponape and a small university on Guam. Many students from the Trust Territory have received scholarships to study at the college level in Hawaii or the mainland United States, and a few have gone on to graduate study. Trade schools are relatively undeveloped in the Trust Territory, one exception being the Ponape Agricultural and Trade School established by a Jesuit missionary. Medical practitioners in the Trust Territory and the Gilberts are trained at a British school in Fiji. Peace Corps volunteer teachers provided much assistance in teaching English in the elementary schools of the Trust Territory, although their number was reduced following friction with the territorial government and with some local governments. Attending school takes up time the children formerly spent in learning their indigenous cultures, although while they are in school, the adults and older children are freed from taking care of them. Perhaps the most important single effect of the schools is to teach the pupils enough English to be able to watch motion pictures, listen to English-language radio programs on their transistor sets, talk to visitors, and read English publications—including mail-order catalogs, comic books, main-

tenance and repair manuals, and the Bible. Local radio stations are numerous, and there were television stations on Guam and Saipan in 1971.

Since the U.S. government relaxed its military security checks on entry into Guam and the Trust Territory, an effort has been made to develop tourism as the most promising source of external income for Micronesia. Commercial air service has also been improved. Many Japanese tourists have visited Guam and Saipan, and American and Japanese tourists have gone to the Carolines in increasing numbers. Tourists visit mainly the larger islands. The development of tourism is a controversial issue in Micronesian politics, since some leaders fear that its growth will relegate Micronesians to menial positions while the managerial positions will be held by non-Micronesians.

Decline of traditional political authority

Effects of modernization. All the Micronesian communities acknowledge the de facto authority of the administering powers: Great Britain for the Gilberts and the United States for the Trust Territory and Guam, with Nauru the only independent island. The power of the traditional local political systems has everywhere declined, but more so in some communities than in others. In the Marshalls, for instance, the ownership of land by many of the traditional chiefs has been officially recognized by foreign rulers; the bulk of the people on these islands are tenants of the chiefs. In contrast, on the high island of Kusaie, immediately to the west of the Marshalls, no traditional chiefs remain, even in name, and local authority is entirely in the hands of elected officials, church leaders, and family elders. With the decline of traditional political authority and the increasing availability of imported alcoholic beverages in the main population centres, there has been an increase in violence and petty crime.

Kin ties outside the immediate family appear to have weakened. The distinction between matrilineal and other relatives has also weakened in areas where it was formerly important. The restrictions on marriage between remote matrilineal relatives are being challenged and on some islands (Kusaie, Mokil) completely ignored. Kin groups are being replaced by the police as the agency for settling physical injuries and other personal wrongs.

Micronesians still speak of social relations in the idiom of kinship and attempt to trace or establish fictive kinship with close associates. But kinship is now often invoked to support relationships first established on some other basis, while formerly it was more common for an already existing kin group to decide to cooperate on some enterprise. In the modern situation it is an advantage to be able to trace kin relations equally in all directions: through father, mother, spouse, and spouses of close relatives.

Practically all Micronesians speak a Micronesian language as their first language. Many of them also speak one or more other Micronesian languages as well. English is now widely spoken by schoolchildren and young adults, and it is used in conversations between speakers of different Micronesian languages as well as in talking with resident Americans and outside visitors. Japanese is spoken by many older adults in the Trust Territory who learned the language during the period of the Japanese mandate.

Christianity and traditional religion

In religion most Micronesians are professing Christians, although traditional local beliefs in spirits and magic continue to be held concurrently in many areas. The people of the Marianas are predominantly Catholic; those of the Carolines, Marshalls, and Gilberts are a mixture of Protestant and Catholic. Protestants were the first successful missionaries in the latter area, beginning about the middle of the 19th century, and are still numerically dominant in many communities. Elements of the traditional local religions survive widely in traditional medical practice, which often attributes disease to supernatural causes. The traditional religions are practiced as major alternatives to Christianity in the central and western Carolines. The *modekngei* movement in Palau appears to be a modern revival of traditional Palauan religion, with strong emphasis on health and medicine.

Perhaps the greatest infusion of Euro-U.S. and Japanese culture has taken place in the arts and recreation. In the main population centres of the Trust Territory and in Guam, baseball is the most popular sport, having been introduced in the Trust Territory by the Japanese. Traditional music is heard much less than hymns and popular music of Western origin. Knowledge of traditional sports, dance, and music remains in most places, but these are performed more often at the instigation of curious outsiders than for members of the local communities. The prospective rise of tourism seems unlikely to encourage an authentic revival of traditional arts, crafts, and recreation. In their self-image, as reflected in their expressive culture, the Micronesians already stand with one foot in the modern world.

BIBLIOGRAPHY. Readable accounts of particular Micronesian cultures include, for high-island cultures, HOMER G. BARNETT, *Being a Palauan* (1959); and LAURA M. THOMPSON, *Guam and Its People* (1947); and, for low-island cultures, MARSTON BATES and D.P. ABBOTT, *Coral Island* (1958); and WILLIAM A. LESSA, *Ulithi: A Micronesian Design for Living* (1966). JOHN L. FISCHER, *The Eastern Carolines* (1957), surveys briefly a number of high- and low-island cultures. The role of outside administrations is presented for the Gilbert Islands a British possession, by ARTHUR F. GRIMBLE, *Return to the Islands* (1957); for the Trust Territory of Micronesia in the Japanese period by TADAO YANAIHARA, *Pacific Islands Under Japanese Mandate* (1940); and in the early American period by ROBERT TRUMBULL, *Paradise in Trust: A Report on Americans in Micronesia, 1946–1958* (1959). For additional references, see HUZIO UTINOMI, *Bibliography of Micronesia* (1952); and for some more recent work, the section on Micronesia in CLYDE R.H. TAYLOR, *A Pacific Bibliography*, 2nd ed. (1965).

Microscope

The microscope is an instrument for producing enlarged images of objects that are too small to be seen unaided. Such images may be viewed directly or with a viewing screen or photographic apparatus. Objects for microscopy may be either transparent or opaque. The compound light microscope (see below *Compound microscope*) can be used for viewing objects as small as bacteria, and the electron microscope (see below *The electron microscope*) extends the range to small viruses and large molecules.

HISTORICAL DEVELOPMENT

Simple microscope. The simple one-lens microscope may date from the middle of the 15th century, when low-power magnifiers were used for the examination of insects. From these early beginnings, glass lenses of increased power were developed, culminating in ground lenses of remarkable excellence produced by a Dutch microscopist, Antonie van Leeuwenhoek (1632–1723). In the 18th century, simple microscopes were produced in a cheap, portable form known as the screw-barrel type, which used a screw thread to focus the lens upon the object. Further developments of the simple microscope included perfection of mounts and microscope stands intended for specialized studies in botanical and other fields. After the introduction, in the 1830s, of perfected achromatic lenses, which rendered images free from colour distortions, simple microscopes lost favour except for very low power work, such as in dissection.

Compound microscope. The basic idea of the compound microscope, in which two or more lenses are arranged in such a way as to form an enlarged image of an object, probably occurred independently to several people at about the same time, in the period 1590–1609, in The Netherlands; Hans Jansen, his zon Zacharias, and Hans Lippershey have all been cited at times as its inventor. Shortly after that, microscopes made by opticians in Italy and in England were circulating widely.

Though no real advances were recorded in the development of the optical parts of the microscope during the 18th century, some mechanical variations were introduced. Brass superseded wood, cardboard, and leather as a material for construction of the stand, and better mechanical means were introduced for focussing.

The image produced by the lenses of early compound microscopes suffered considerably from chromatic aberration; *i.e.*, objects in the field of view appeared to be surrounded by fringes of colour. Experiments with telescope lenses had shown that images free from colour could be produced by combining lenses of different dispersions. Dispersion is the variation of refractive index with wavelength, that for blue light being greater than for longer wavelengths in the red region of the spectrum. The telescopes used a combination of a convex (outward-curved) lens made of optical glass of low dispersion (crown glass) together with a concave (inward-curved) lens of flint glass with a high dispersion.

Achromatic microscope lens. As glass technology advanced, application of the principles used for telescopes to microscopes became possible; the first achromatic microscope lenses were constructed in The Netherlands at about the end of the 18th century. Many more achromatic lenses of low power (and often of dubious quality) were produced in the period between 1810 and 1820. High-power achromatic lenses proved much more difficult to construct, because the accumulation of spherical aberrations or distortions caused by curvature in the lens glass often negated the effects of achromatism.

At that time lenses were still being designed empirically, and introduction of the use of test objects, such as the markings on the wing scales of moths and butterflies, enabled some progress to be made with the higher powered lenses. It was with the work of the English microscopist Joseph Jackson Lister (1786–1869), published in 1830, that construction and design of achromatic microscope lenses was placed on a theoretical basis. Lister showed how two separate achromatic lenses could be combined to act as a single lens so that the image rendered would be completely free from chromatic aberration and from distortions caused by curvature of the lens. This discovery opened the way to the construction of high-power microscope lenses in the next 50 years.

Abbe's contributions

For both his contributions to the theory of the instrument and his practical designs, a German physicist, Ernst Abbe (1840-1905), stands out as the foremost figure in the development of the microscope in the latter part of the 19th century. Abbe placed the theory of microscopic image formation on a sound basis by emphasizing the importance of the light diffracted by the object in resolving (making distinct) its fine detail. He introduced the concept of numerical aperture as an expression of the resolving power and light-gathering capacity of a microscope lens, thus permitting its direct comparison with other lenses. Abbe also developed oil-immersion lenses, in which a drop of oil was placed between the object and the front element of the lens. Very soon this type of lens, with its much improved resolving power and high-quality images, was an essential part of the microscopist's equipment. Later, in conjunction with the German firm of Carl Zeiss, Abbe introduced a whole new series of excellent, highly corrected lenses, which rendered the highest quality images yet obtainable. These distortion-free (apochromatic) lenses allowed full practical realization of the theoretical resolving power of the optical microscope by the end of the 19th century.

Developments so far in the present century have included introduction of larger stands with built-in illumination systems and higher standards of accuracy of construction. Especially notable is phase-contrast microscopy (see below *Phase-contrast microscope*), introduced in 1934, which made it possible to examine living cells and tissue specimens without staining them. Other recent trends are the development of flat-field objective lenses for photomicrography and of methods of using computers for the analysis of microscopical images.

Interest has continually centred on the increase of resolving power of the microscope; the work of Abbe showed that this was possible only by increase in the numerical aperture of the optical system (which was not feasible beyond a certain limit) or by the use of a shorter wavelength for the illuminating light. This latter possibility led to the use of ultraviolet radiation as an image-forming agent, but there were technical difficulties with this type of microscope. Little progress in the use of shorter wavelengths was made until the development of the electron microscope (see also OPTICS, PRINCIPLES OF).

THE SIMPLE MICROSCOPE

A simple microscope, a single positive lens or lens combination, is often known as a magnifier, or loupe. Supplied in a mount furnished with a handle, such a lens is commonly called a reading glass. Magnifiers are often furnished in a hinged mounting between two cover plates, so they may be conveniently carried in the pocket. Occasionally, they are mounted on an arm above a simple specimen-support stage so as to serve as a dissecting microscope. Magnifiers supplied in a short tubular mount, designed to be held in place in front of the eye by contractions of the facial muscles around the orbit, are used for fine instrument work and are called watchmaker's eyeglasses. The apparent size of an object viewed directly by the eye depends upon its distance from the eye. As an object is brought nearer to the eye, the angle which it subtends at the eye increases, and so the retinal-image size (and hence the apparent object size) also increases. This process continues until the object has been brought

so close that the eye no longer forms a clear image. This point is generally termed the nearest distance of distinct vision (in a young adult, about 25 centimetres, or 10 inches), and further movement of the object toward the eye will cause the image to be blurred. If, however, a convex lens is placed between the object and the eye, the sharpness of the image may be restored. If the object is at or within the distance between the lens and the point at which parallel rays passing through the lens converge, or focus (focal length), then light rays entering the lens from the object are bent, or refracted, toward the optical axis (to the centre). If these ray directions were prolonged backward, they would meet at a point in space behind the object. It is here that the brain imagines an enlarged image of the object to be located. Termed a virtual image, this image is magnified and erect.

Field of view. Maximum apparent magnification is reached when the virtual image of the object lies at the nearest distance of distinct vision. The area of the object that is seen through a magnifier (the field of view of the magnifier) is related directly to the diameter of the lens and inversely to the distance between the lens and the eye. Thus, to achieve the largest possible field of view with any given lens, the lens should be held as close as possible to the eye. The position of the object should then be adjusted to obtain the sharpest image. In practice, simple magnifiers suffer considerably from aberrations that affect the peripheral parts of the field of view; curvature of the field, distortion, and lateral chromatic aberration (different colours produce different image sizes) are principally involved.

The simplest form of low-power magnifier is a single biconvex (convex on both sides) or plano-convex (convex on one side and flat on the other) lens. Such lenses have a wide field of view; the eyeball rotates in its socket in order to scan the whole field. Spherical aberration, coma (variation in magnification over the area of a lens), and lateral chromatic aberration are not especially troublesome at the low magnifications involved, but there is appreciable curvature of the field and pronounced pincushion distortion (variation in image magnification radially outward from central point of image). In high-power magnifiers (up to 20 magnitudes, or 20 ×), the field of view is limited, and the eyeball does not rotate to scan it. The chromatic and spherical aberrations of this type of magnifier must be very carefully corrected. Distortion is often troublesome, because the distance between the eye and the lens is no longer small in comparison with the focal length of the magnifier (as it is in lower power lenses).

Types of magnifiers. Four principal types of high power magnifiers are recognized.

Stanhope lens. The Stanhope lens (Figure 1A) consists of a solid block of glass with one polished plane (flat) surface lying in the focal plane of the spherical convex upper surface of the lens. To be viewed, the object must be placed in contact with the plane surface; such lenses suffer from a large degree of distortion, and there is considerable lateral chromatic aberration.

Coddington lens. The Coddington lens (Figure 1B) has two convex surfaces but is characterized by a circular groove cut around the periphery of the lens in such a way as to act as a diaphragm. This improves the image quality, and these lenses are superior to the Stanhope type.

Wollaston doublet. The Wollaston doublet (Figure 1C) uses two plano-convex lenses, with their plane faces pointed inward. The lenses are separated by a distance calculated so as to allow a good correction of the lateral chromatic aberration and the spherical aberration and are fitted with a central diaphragm. This type of lens, when used as a magnifier, suffers from an inconveniently short working distance and a restricted field of view.

Steinheil and Hastings magnifiers. Achromatic doublets or triplets are now almost universally used for practical magnifiers; the best known are due to Steinheil and to Hastings. Lenses of this type generally consist of a biconvex (convex on both sides) lens of crown glass cemented between and enclosed by two lenses of flint glass

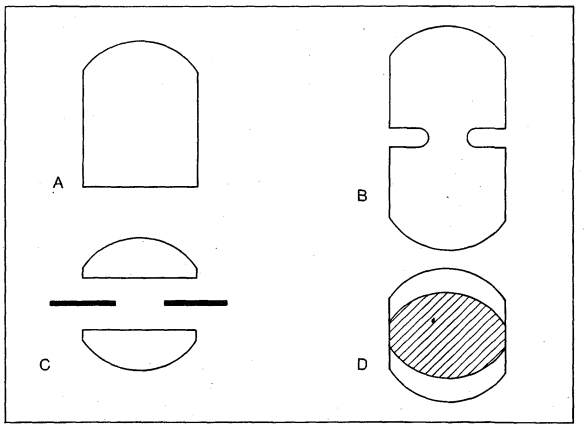

Figure 1: *Various magnifiers.*
(A) Stanhope lens. (B) Coddington lens. (C) Wollaston doublet.
(D) Steinheil achromatic triplet.

(Figure 1D). These cemented triplets are well corrected for spherical aberration and coma (for rays up to 25° from the optical axis), and their distortion is low. At the same time, they produce a very bright image and have a conveniently long working distance.

THE COMPOUND MICROSCOPE

A compound microscope has an objective lens (the lens closest to the object being viewed) and an eyepiece so mounted that they may conveniently be moved relative to the specimen to focus the image. An illumination system, usually added, consists of a condenser-lens system to focus the light onto the object and either a mirror with an external light source or, as is more common today, a built-in light source (commonly a low-voltage tungsten bulb).

In the compound microscope, magnification depends on the objective lens and the eyepiece. The objective lens produces a real image at some finite distance behind its back focal plane, a distance which is known as the optical tube length.

Compound microscopes may be provided with a single body tube for viewing with one eye; such monocular instruments are used for teaching and for work that is not extended or too exacting on the eyes. The more elaborate microscopes used for research purposes or for long periods of study are generally binocular (two eyepieces fitted with some means of distributing the light between them). A typical monocular microscope would normally be provided with three objective lenses with focal lengths of 16, 4, and 2 millimetres, giving initial magnifications of about 10, 40, and 100 magnitudes, respectively. If two eyepieces were provided with a magnifying power of six and 10, for example, the range of total magnification would extend from 60 to 1,000 magnitudes.

Monocular microscopes

Body tube. The body tube, with its associated focussing mechanism, is carried on the arm of the microscope, which is in turn supported by a horseshoe or tripod base. Attached to the arm, at a right angle to the optical axis, is the stage on which the object is placed. Below the stage is the substage fitting, which carries the condenser lens (used to focus light on the object) and either the mirror (if fitted) or the built-in light. The simplest microscopes have no substage. Instead, they have a plain object stage and a body tube fitted with only a coarse focussing movement. A more elaborate instrument has, in addition, a substage with its own centring and focussing movements. The body tube has both coarse and fine focus and a revolving turret at the bottom fitted to carry several objective lenses so that any one may quickly be brought into the optical axis. The largest and most elaborate research stand is of much sturdier construction and has an illuminating system built into the base of the instrument. A mechanical stage carries the slide and allows it to be moved easily and precisely. A binocular tube is provided for viewing with, possibly, a third, monocular tube permanently fitted to carry a camera. In the past, microscopes had their focus controls mount-

ed on the upper part of the arm. The current trend is to place these, together with the stage-movement knobs, at a low level so they may be operated without moving the hand and arm from the table.

For many years the horseshoe form of foot was popular, though the tripod foot was preferred in England. With the introduction of the built-in light source, both of these have given way to construction in which the arm and foot are solidly joined together, the foot being in the form of a box.

The body tube is mounted on a slide or slides to allow it to be moved for focussing. The coarse focus is actuated by a rack-and-pinion mechanism, while the fine focus, working on a slide with a much more restricted range of movement, is worked either by a screw of very fine pitch that has its motion converted and translated to the slide by a lever or by some cam or bell-crank arrangement. The fine focus must have a very free action but one that operates without any appreciable backlash. In some modern stands, in order to achieve maximum rigidity, the coarse- and fine-focus mechanisms act on the stage instead of on the body tube. Such an arrangement is easily adapted to the provision of low-level controls and to the fitting of concentric coarse- and fine-focus control knobs.

Specimen stage. The specimen stage holds the object under examination and must be fixed accurately at right angles to the optical axis of the microscope. In many microscopes, a simple stage with a central hole and spring clips to hold the slide suffice, but research instruments are often provided with either a detachable or a built-in mechanical stage. This device holds the slide and allows it to be moved in two directions by screw threads. Such stages allow the slide to be moved very precisely and systematically over its whole area, and, as they are often fitted with graduated vernier scales, they enable the position of objects to be located and recorded precisely. For work with polarized light and photomicrography, it is an advantage to have a mechanical stage that also allows rotation of the specimen around the optical axis of the microscope.

The objective lenses of the microscope are fitted to a disk of metal known as the nosepiece, which is accurately centred to the microscope axis. Rotation of the nosepiece allows any of the lenses to be brought quickly into use, and the accurate alignment, or centration, ensures that the object will still remain approximately in the centre of the field of view. If more accurate centration is required, it is usual for each objective lens to be mounted on its own individual carrier, which is provided with centring screws.

The substage

The substage carries the condenser and the mirror, if fitted. It slides in a rackwork mechanism to allow adjustment of its position. In some of the cheaper instruments, however, the substage is fixed to the underside of the stage and consists of a helical mount in which the condenser slides. An iris diaphragm, a device which opens and closes to control the size of the illuminating cone of light, is often carried on the substage, rather than on the condenser itself, although this latter arrangement (which is found in the more expensive instruments) is preferable. One essential feature of the substage of any instrument intended for serious work is the provision of screws that allow the condenser to be centred with respect to the optical axis of the microscope.

The built-in light source of large modern microscopes is often mounted in the base of the instrument and comprises a small low-voltage bulb provided with collector lenses and arrangements for focussing and centring the light source. The light is reflected into the condenser either by a front-surface mirror or by a prism. The binocular body employs an arrangement of prisms to present the light from the microscope objective to each eye.

Objective lenses. The value of a microscope lies in its ability not only to magnify objects but also to make their fine details visible. These two features depend for the most part on the quality of the lens that forms the primary image. Such an image must be sharp; the aberrations that reduce the sharpness must therefore be reduced to a minimum. Microscope objective lenses originally were single biconvex lenses that suffered severely from aberrations; nowadays all objective lenses, even those of the lowest power, are corrected as fully as possible. Chief corrections are for chromatic aberration (which produces colour fringes around the edges of the image of an object) and for spherical aberration (which is caused by the curvature of the lens). Spherical aberration causes a hazy, indistinct image, lacking in contrast. Chromatic aberration may be corrected by combining a concave negative element made from glass of a different dispersive power from that of the original convex lens. At the same time, the curvatures of such a combination may be calculated to correct part or all of the spherical aberration as well. Though such corrections are relatively easy with a lens of low magnification, satisfactory correction requires increasingly complicated lens design as power and numerical aperture (discussed below) increase. This usually involves addition of more elements. The design and construction of lens systems of high power and aperture are quite difficult, and these still remain the most costly parts of any microscope.

In addition to the primary aberrations just mentioned, coma, astigmatism, distortion, and curvature of field also have to be corrected by the designer of the lens. Coma causes magnification to differ according to the zone of the lens through which the rays pass, so that portions of the image axis are badly distorted. Astigmatism, if present, results in different appearances in different focal planes. A pinhole would appear to be a radial line at one focus and a tangential line at another. This aberration may cause misinterpretation of the shape of objects if severe at the centre of the field of view; a slight amount of astigmatism is tolerable, however, at the periphery of the field of view. Curvature of field causes the image of a plane object to appear on a curved surface. This means the centre of the field of view may be in sharp focus while peripheral areas are blurred, or vice versa. This defect increases in severity with increase in the power of the objective lens. Though not an intolerable drawback in visual work, curvature of field is undesirable when photographing through a microscope. It may be largely corrected by the use of a special eyepiece, but a more satisfactory solution involves the use of specially designed flat-field objective lenses, which are now commercially available (see also OPTICAL ENGINEERING). Empirical studies in the 19th century led microscopists to realize that the ability of their microscopes to resolve fine details was in some way connected with the angle of the cone of light rays accepted by the objective lens. This was termed the angular aperture. Ernst Abbe, in 1873, showed that this was not entirely accurate, and he was able to demonsrtate that the detail resolved was proportional not to the angular aperture but to the sine of half this angle (α). Abbe gave the name numerical aperture (N.A.) to this mathematical relationship and showed that in the case of a dry lens—*i.e.*, one in which the cone of light rays from the object passes through air—the numerical aperture = sine α. In an immersion system, in which oil or sometimes water or glycerin is placed between the front lens of the objective and the specimen, the numerical aperture is increased and the value of sine α has then to be multiplied by the value of the refractive index of the immersion medium.

Numerical aperture

The numerical aperture of a lens thus is a direct measure not only of its resolving power but also of its light-gathering capacity. Light-gathering capacity, however, is not of great significance in microscope objective lenses, and high numerical apertures are used for the consequent gain in the resolving power that accrues. A further advantage of the use of the concept of numerical aperture is that the fine-detail-resolution performances of two lenses may be directly compared by the use of their respective numerical apertures.

Microscope objective lenses may be classified according to either their focal length or their type and degree of corrections. The most common focal lengths are 75, 50, and 25 millimetres for low-power lenses, 16 and eight millimetres for medium power, and four and two millimetres for high powers. Lenses may also be classed as achromats, semi-apochromats, or apochromats, in as-

cending order of accuracy of corrections; flat-field objective lenses may be produced in any of these grades. Some of the features of the common lens types are summarized in the table.

Characteristics of Various Types of Microscope Objectives

type	focal length (mm)	numerical aperture	initial magnification	working distance (mm)
Achromatic	50	0.11	2.7 ×	50

Semi-apochromatic	16	0.30	10 ×	4.0
dry	8	0.60	25 ×	0.54
	4	0.75	40 ×	0.33
Semi-apochromatic	3	1.25	63 ×	0.65
oil	2	1.30	100 ×	0.12

Achromatic objective lenses. The commonest types of microscope objective lens, achromatic lenses, are corrected so that rays of two widely differing wavelengths (usually in the red and the blue) are brought to a common focus. This correction is usually carried out for an intermediate zone of the lens; if it were done for the marginal zone at the edge of the lens, then the centre would be only poorly corrected, and vice versa. A suitable compromise, therefore, is achieved by correcting for the intermediate zone, which then results in minimal aberration in both the centre and marginal zones. As only two colours are fully corrected, there is at times some remaining colour, known as the residual colour or the secondary spectrum. This appears as a fringe around the edge of objects with sharp contrasts, but it is usually not prominent.

Residual colour

Achromats are also corrected for spherical aberration and coma. This type of objective lens is much used on microscopes intended for teaching and for routine visual observations.

Apochromatic objective lenses. The invention of new types of optical glass in the 1880s, together with the use of the natural mineral fluorite in lens making, enabled Abbe to develop a new type of microscope objective lens in which the colour correction was greatly improved but at the cost of a considerable increase in lens complexity. An apochromatic lens usually possesses a greater numerical aperture than an achromat of equivalent focal length. Care is needed in the use of apochromats because the high power lenses have very short working distances. Expensive, they are ideal for critical work at the limit of resolution of the optical microscope and for photomicrography in colour.

All apochromatic lenses (and semi-apochromatic lenses, which are more common) suffer from a kind of error known as lateral chromatic difference of magnification. This means that the image will be larger in blue light than in red. Thus, dark objects with sharp contrasts at the periphery of the field of view appear fringed with red or orange on their outer margin and with blue on their inner sides. This may be eliminated by the use of special compensating eyepieces that have been computed to introduce a compensatory error of similar magnitude but of opposite direction. This cancels out the lateral chromatic differences of magnification and thus gives the best possible image.

Semi-apochromatic objective lenses. Sometimes called fluorite lenses, these are a compromise between the achromats, on the one hand, and the apochromats, on the other. This compromise allows a reduction in complexity and, hence, in cost. Fluorite and the new optical glasses are used in their construction, but there are fewer elements than in an apochromatic lens. The colour and spherical corrections are better than those of an achromat, the secondary spectrum being much less obvious and, since the number of points of meeting between air and glass (air–glass interfaces) in such a lens is fewer than in an apochromat, the image contrast is often surprisingly high. Again, the numerical aperture of a semi-apochromat is usually 15–30 percent higher than that of an achromat of equal focal length. The lateral chromatic difference of magnification noted above is present in this type of lens, so it is used with a compensating eyepiece to obtain the best possible results. Recently, makers have been deliberately introducing lateral chromatic differences of magnification into their achromatic lenses (which do not normally show this particular fault) in order to eliminate the need for two separate types of eyepiece.

Spherical aberration and the coverslip. With some high-aperture dry objective lenses the protective piece of glass, or coverslip, overlying the mount may introduce a surprising amount of spherical aberration. Though the effect is negligible with low-power objective lenses and may be disregarded, high-aperture apochromatic lenses will give a satisfactory performance only if this factor is taken into consideration. Lenses are normally computed for a definite thickness of coverslip (often 0.17 millimetre), but extra thickness of mounting medium and variation in the thickness of the slip itself may cause wide divergence from this figure. Errors introduced in this way may be compensated for by altering the tube length of the microscope, shortening it if the cover is too thick and vice versa. Alternatively, most high-aperture apochromats are provided with a rotatable collar on the lens mount that varies the separation between the elements of the lens and so adjusts the correction of the lens for spherical aberration. The performance of an oil-immersion lens is, of course, not affected by such variations in coverslip thickness, since there is no air between it and the front element of the lens.

Lenses intended for metallographic work and for studies on opaque objects are normally computed so as to work without a coverslip. In the majority of cases, these lenses are also designed to work with vertical illuminators and must be provided with special antireflection coatings at points of contact between air and glass.

Metallographic lenses

Flat-field objective lenses. All objective lenses of the achromatic, semiapochromatic, and apochromatic types suffer to some extent from curvature of the field, which becomes more marked as the power increases. Such field curvature is troublesome in photomicrography (photography through a microscope), and new lenses have been developed in which this fault has been largely removed. But this has made it necessary to increase the complexity of the lens. In one manufacturer's series of flat-field lenses, the curvature of field produced by the objective lens is cancelled out by a lens in the microscope tube that interposes an equal but opposite curvature of the field. The system is so designed that the same negative lens is common to all the objective lenses of that series, and, hence, it may be fixed in the microscope tube itself. Both apochromats and achromats are available in flat-field versions.

Objective-lens mounts. All microscope objective lenses are fitted into metal mounts that are attached to the nosepiece. To protect the optical elements from damage resulting from the lens inadvertently being brought into contact with the microscope slide, most modern lenses are in resilient spring mounts that compress on light contact with the object slide. Most objective lenses of any one maker are fitted into mounts in such a way that very little adjustment of focus is needed on changing from one power to another. Such lenses are said to be parfocal. Mounts are normally engraved with the magnification of the lens, its numerical aperture, and, usually, the focal length, the tube length at which the lens operates, and the thickness of coverslip for which the lens is computed. A coloured band around the barrel assists in rapid identification.

Eyepieces. The eyepiece forms a further enlarged final image from the real primary image furnished by the objective. The eyepiece may also carry pointers or trans-

Graticules for expediting measurements

parent measuring scales (graticules) and correct for residual aberrations in the image produced by the objective lens. This is important in the compensating eyepieces used with apochromatic and semiapochromatic lenses.

Huygenian eyepiece. Two types of eyepieces are in common use. The Huygenian eyepiece (Figure 2A), sometimes called a negative eyepiece, has a plano-convex field lens nearer the objective lens with a second, smaller plano-convex eye lens above it. The field lens is so called

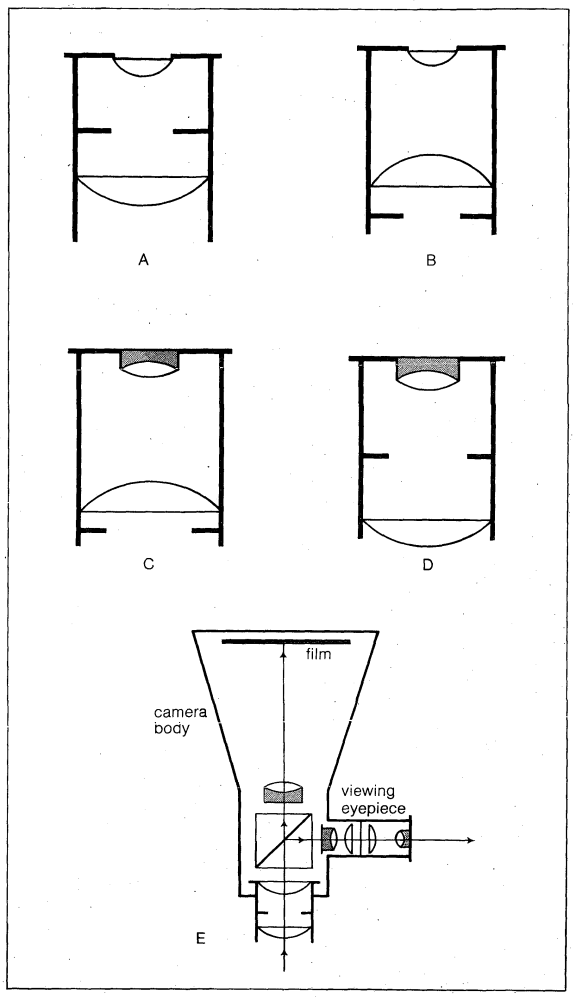

Figure 2: *Various eyepieces.*
(A) Huygenian. (B) Ramsden. (C) Achromatized Ramsden.
(D) Compensating. (E) Photomicrographic.

because it bends the pencils of rays from the objective towards the optical axis of the microscope without altering their individual convergence or divergence, thus increasing the angular field of view. After leaving the eyepiece, all the rays pass through a small circular area above the eye lens; this is known as the Ramsden circle, or eyepoint. Its diameter should approximate the diameter of the pupil of the observer's eye in order to obtain the largest field of view of maximum overall brightness. In the Huygenian eyepiece, the focal length of the field lens is about twice that of the eye lens, and the two lenses are separated by a distance roughly twice the focal length of the eye lens. It is usual to place a diaphragm between the lenses, which limits the field of view.

Ramsden eyepiece. The Ramsden, or positive, eyepiece (Figure 2B) has two plano-convex lenses of approximately equal focal length, arranged with the plane side of the field lens towards the objective lens and the plane side of the eye lens towards the observer. These are separated by a distance of approximately two-thirds their focal length. The focal plane of the eyepiece lies below the field lens, and the diaphragm is placed at this point. The Ramsden eyepiece is especially suited to carry measuring graticules and pointers. Both Huygenian and Ramsden eyepieces have uncorrected lenses, but the spherical and chromatic errors of each lens are arranged to cancel out.

Kellner eyepiece. The Kellner (achromatized Ramsden) eyepiece (Figure 2C) resembles the Ramsden very closely but has an achromatized doublet as an eye lens.

Compensating eyepiece. The compensating eyepiece (Figure 2D) used with apochromatic lenses also has an achromatized doublet for its eye lens; the corrections are matched to a specific objective lens. Formerly, eyepieces were available with adjustable compensation. These could be used with any apochromatic objective lens simply by adjusting the separation between the field and eye lenses of the eyepiece.

Photomicrographic eyepiece. For photomicrography, the eyepiece shown in Figure 2E is now much used, in conjunction with a miniature camera. A device called a beam-splitting cube produces two identical images, thus allowing the user to focus and observe the object up to and at the moment of exposure. Demonstration eyepieces allow a student and teacher to examine the same microscope field simultaneously by means of a similar type of beam-splitting arrangement. The addition of a pointer that is visible to both viewers is common in this type of eyepiece. A comparison eyepiece presents the images from two separate microscopes side by side, so that a detailed comparison of them may be made. Such a devise is of great value in many industrial applications and in forensic microscopy (*i.e.*, the study of material intended for use as evidence in legal proceedings).

Condensers, illumination, and resolution. Although very low power objective lenses may be used on the microscope with the illumination provided from the light cone of a concave mirror, all higher power lenses require a special system of lenses below the stage to provide a cone of light rays of sufficient numerical aperture to match that of the objective lens in use. Such a lens system is called a condenser. It is usually in a mount that can be moved along the optical axis in order to focus the condenser and that has spring-loaded screws to centre the condenser to the optical axis. Other functions of the condenser are to provide sufficient light on the object to allow the use of high magnifications and, in some cases, to provide special types of illumination. Examples of this are the oblique illumination and hollow cone illumination, sometimes used to obtain contrast in unstained or transparent preparations.

For low powers, a simple convex lens (sometimes called a spectacle lens condenser) may be used. This is preferable to the use of a concave mirror, because the condenser is provided with a diaphragm that allows some control over the working aperture of the system. The commonest type of condenser is a two-lens system known as the Abbe condenser. It is cheap, simple, and much used for visual observations with routine and student microscopes, though it suffers very badly from chromatic and spherical aberration, which often make it impossible to utilize the full aperture of illuminating cone provided by the condenser, which in turn makes it impossible to use the full aperture of the objective. An improved three-lens Abbe condenser has slightly better spherical corrections. For certain kinds of careful work, an achromatic condenser is essential. Such condensers are corrected for both spherical and chromatic aberration.

Abbe condenser

Illuminated field. The size of the illuminated field is a function of the focal length of the condenser. Thus, when low-power objective lenses are used, it is advantageous to employ a long-focal-length condenser to obtain a fully illuminated field of view. The same end may sometimes be achieved, however, by removing the top lens of a standard condenser, which then works at a reduced aperture but with an increased focal length. A pancratic (zoom) system, which permits change of focus from a large illuminated field at low power to a small area at high power may be employed. Alternatively, an auxiliary lens may be fitted in the light path to achieve the same end.

If the condenser is arranged to provide a hollow cone of light rays which are of such an obliquity that they cannot

enter the objective lens directly, then only the light diffracted by the object enters the lens and participates in image formation. The effect of this is that the specimen appears bright upon a dark background. Dark-ground microscopy gives images of high contrast but requires an intense light source and an accurately centred optical system.

Objects may be examined with either transmitted or incident light. Most of the work in biology is with transmitted light; the opposite is true for materials such as metals and stone. Either transmitted- or incident-light methods may be adapted to give a reversed contrast effect (the object appearing bright against a dark background).

Light source. In all modern microscopes, the light source is an electric lamp of some form. The condenser of the microscope is used to focus an image of the surface of the lamp into the plane of the object. As the light source is in focus at the same time as the object detail, this method of illumination is called source focus; the term critical illumination has also been used. It is essential that the light source be fairly large and homogeneous to obtain an evenly illuminated field of view. A valuable refinement involves the addition of an iris diaphragm in front of the lamp to provide some control over the area of the objective that is illuminated. To minimize glare, this area should not be much in excess of the visual field. In most research microscopes, the illumination is arranged for the instrument in such a way that an image of the light source is formed in the back focal plane of the microscope condenser by a corrected condenser on the lamp house. The lamp is provided with a variable field stop (similar to the aperture diaphragm on a camera), and the microscope condenser is focussed so that this stop is seen in the plane of the object. When this has been achieved, the evenly illuminated lamp condenser serves as the apparent light source; hence, an evenly illuminated field of view results from the use of a small, intense, but nonhomogeneous light source. This method of illumination is called Köhler illumination, after the name of its inventor. For optimum results, the image of the lamp filament should be large enough to occupy a large portion of the area of the aperture of the back focal plane of the condenser. In practice, this means that the filament should be composed of several parallel coils—the so-called solid-source filament—and that the lens of the lamp-house condenser should be of a suitable focal length. The built-in systems of illumination that are now common comprise a small low-voltage bulb, collector lens train, and field stop.

Source focus

Illumination of an opaque specimen from above the stage is often accomplished by some form of vertical illuminator. In its simplest form, this is a thin glass slip inserted into the objective lens holder at 45° to the optical axis. Light is admitted through a small aperture in the side of the lens mount and is reflected down into the object through the lens, which thus acts as its own condenser. The light reflected from the object then passes back through the objective lens and glass slip to form the image. Many of the incident illuminators now available are designed for dark-ground work. In such cases, the incident light is reflected downward by an annular (ring-shaped) mirror around the objective and is then concentrated onto the object by a ring condenser mounted in the housing. An image of the specimen is formed by the objective lens, which is inserted into the centre of the illuminating housing. The reflected light enters the microscope tube by passing through the central hole in the mirror. Such dark-ground systems often give greatly enhanced contrast, as compared with standard vertical illumination.

Resolving power. Because of diffraction effects, the image of a point source of light can never be perfect, even assuming that all the imperfections in the lens are corrected. The image of a luminous point thus appears as a bright circular disk surrounded by a series of concentric light and dark rings. This pattern is the Airy disk, after Sir George Biddell Airy (1801–92), an English astronomer who first studied it mathematically.

Any image may be considered as being composed of innumerable overlapping diffraction patterns, each corresponding to a given point in the object. Two point sources that are close together will produce Airy disks that appear side by side. If the separation between the objects is reduced, then the diffraction patterns begin to overlap; if the overlap is considerable, then the two points are not seen as separate; *i.e.*, they are not resolved.

The best resolution should be realized when the full aperture of the objective lens is used and the wavelength of the illuminating light is decreased. This has been shown to hold in practice up to a point, beyond which diminution of contrast causes an apparent loss of resolution, in that the visibility of object detail is impaired. This loss of contrast is, however, distinct from the resolution proper. Modern expressions of the theory of microscopic resolution take into account the degree of coherence of the illuminating light.

If an optical instrument is resolving two closely situated points in the object, this fact will not be apparent to the observer unless the magnification of the instrument is such that the final image points subtend an angle of at least one minute of arc at the observer's eye. There is thus a minimum magnification below which the detail will not be perceived. In practice, this is usually taken as a value 500 times the numerical aperture of the lens. Conversely, excessive magnification is useless, since no more information will be presented to the eye, and the diffuse nature of the separate Airy disks making up the image will become apparent, giving an impression of poor image quality. A magnification, therefore, of 1,000 times the numerical aperture is regarded as the upper limit, values in excess of which will constitute so-called empty magnification.

SPECIALIZED TYPES OF MICROSCOPE

Stereoscopic binocular microscopes. In contrast to the binocular image of the ordinary microscope, these produce a truly stereoscopic image; they are invaluable for the examination at relatively low magnifications of many objects, for the assembly of very small electronic circuits and solid-state devices, and for dissecting and detailed surgical operations. An early form of this type of instrument was the Greenough binocular, which consisted of two complete microscope systems with their axes inclined at an angle of about 16°, so that they converged in the plane of the object. More stereoscopic binocular microscopes are provided with prisms to give an erect image for more convenient examination and manipulation of the object. Though the objective lenses may be duplicated, the tendency today is to use a single large objective lens with a device called an aperture-splitting system arranged above it that presents the images to the two eyepieces.

Aperture-splitting system

Ultramicroscope. In 1903, the ultramicroscope was developed as part of a project to study colloidal particles. These tiny particles, suspended in a liquid and too small to be seen in an ordinary microscope, are illuminated from the side with a powerful beam of light at right angles to the microscope's optical axis. Because the particles scatter light, their positions and movements may be seen as flashes against a dark background. Particles as small as five to ten millimicrons (about one-tenth the wavelength of visible light) can be observed.

Metallurgical microscope. This instrument is designed for studying the structure of opaque materials, particularly metals. It may be inverted so that a flat surface of the polished and etched specimen can be placed face down on the stage. It has a vertical illuminator and is usually equipped for photomicrography.

Phase-contrast microscope. Contrast in the image rendered by a microscope is usually due to variations in the light-absorbing ability (optical density) of the specimen. Staining the specimen enhances this effect for certain wavelengths. Living cells and other transparent specimens, however, are very difficult to study, and inducing contrast by staining is frequently impossible. The phase-contrast microscope provides an invaluable tool for the examination of such materials, since contrast is introduced by optical means alone and without any manipulation of the specimen. It does, however, suffer from some

optical defects, the most notable being that accurate measurements of the image are almost impossible to make.

Interference microscope. With the interference microscope, contrast is introduced into transparent objects just as in the phase-contrast instrument but without optical defects inherent in the phase-contrast system; in addition, measurements are relatively easy to make with this type of microscope.

Ultraviolet and fluorescence microscope. Invention of the electron microscope was preceded by continuous effort to increase the resolution of the microscope. One approach was to use shorter and shorter wavelengths, moving into the ultraviolet region of the spectrum. The first ultraviolet microscopes, using ultraviolet light to illuminate the specimen and special quartz lenses, showed a twofold increase in maximum resolving power, as compared with an instrument of the same numerical aperture using green light. Actual operation was tedious, however, largely because of difficulties in focussing the image and the necessity for recording all of the results by means of photography. Recently, the development of television cameras sensitive into the ultraviolet region of the spectrum has much simplified the recording and display of the image produced by the ultraviolet microscope.

With the development of the high-pressure mercury arc burner, a source rich in shortwave radiation became easily available. Similarly, the development of glass filters that transmit light between accurately known limits of wavelength in the ultraviolet portion of the spectrum have combined to make practical use of ultraviolet light for excitation of fluorescence (conversion of ultraviolet light to visible light) under the microscope. The light is focussed onto the specimen, using either a normal or a dark-ground condenser. Certain compounds absorb this energy and re-emit it as fluorescence of a longer wavelength in the visible region of the spectrum. This primary fluorescence is often of characteristic colour and may be of value for the identification of chemical compounds. The objective lens and eyepieces of a fluorescence microscope are similar to those normally used, except that it is desirable to choose lenses in which the cement between components does not itself show appreciable fluorescence. In order that any ultraviolet light that has not been absorbed by the specimen should not reach and damage the eye of the observer, a barrier filter is usually fitted between the objective lens and the eyepiece. The image is formed by the light emitted from the specimen itself, which thus appears luminous against a dark background. Ultraviolet microscopes find increasing use today in biology and medicine.

Fluorescence

Reflecting microscope systems. Interest in ultraviolet microscopy stimulated the redevelopment of reflecting systems, which had been tried at various times since the 18th century. The use of mirrors rather than lenses for ultraviolet is advantageous because of the complete freedom of mirrors from chromatic aberration and because, once focussed in visible light, the same focus applies to ultraviolet and infrared wavelengths. Coupled with these advantages is the fact that the working distance of a mirror system is much longer than that of a conventional lens system of comparable numerical aperture. Drawbacks to the use of mirror systems are that at least one of the reflecting surfaces must be aspherical (*i.e.*, with a nonspherical surface, which makes them difficult to manufacture) and that the front surface mirrors of such a mirror system do not have a very long life because of atmospheric attack and tarnishing. The reflectors used in this instrument consist of a large, aspherical, primary, concave mirror and a smaller, secondary, spherical convex mirror arranged axially with it. Only a few microscopes of this type have actually been constructed.

Reflecting systems have primarily been employed as additions to conventional optics. One ingenious system is added to a lens in order to obtain a long working distance. The mirrors are arranged to project an image into the front focal plane of a lens. Such devices are valuable for examining objects heated in a small vacuum furnace on the stage of the microscope or for carrying out the dissection of living organisms under the microscope.

Infrared microscope. By the addition to the microscope of an image converter (a device which converts an image formed by invisible light, such as infrared or ultraviolet, into a visible image), the longer wavelengths that constitute the infrared region of the electromagnetic spectrum may be made visible. This device attached to a microscope has been used to investigate the infrared transmission or reflectivity of objects and to render visible details in objects which may be invisible in visible light. Though applications are numerous, one particularly valuable field is microscopic investigation of forgeries. Another expanding use is detection of surface defects in silicon crystals used for transistors and other semiconductor devices.

Polarizing microscope. The polarizing microscope is used by geologists and crystallographers as well as by biologists. Ordinary light consists of waves vibrating in all directions. Plane-polarized light waves vibrate in only one plane. A polarizing microscope uses plane-polarized light to illuminate the specimen, which appears bright against a dark ground. In the course of passing through the microscope, the polarized light splits into two beams with different velocities. Their relative difference when they leave the specimen is called the retardation. When measured in millimicrons and divided by the thickness of the object measured in the same units, it gives a quantity termed the birefringence, a numerical value of help in the identification of minerals under the microscope.

Birefringence

Television microscope. The application of a television camera to a microscope is useful for recording and displaying the image to large audiences and for teaching purposes. More recently the scanning inherent in the formation of a television image has been used in measuring portions of the image and in automatic processing of the data obtained. An example of this use is found in the Quantimet image-analyzing computer, in which a microscope image is projected into the photocathode of the tube of a television camera; the output from the line scan passes after amplification not only to a monitor screen for visual inspection but also to a detector that responds to changes in the output voltage as the scanning spot passes over features of varying optical density. Specialized computer circuitry then enables the measurement of the area of specific features and permits the number of items in the field to be counted. Various other parameters may also be measured. Not only does such automation save operator time, but it also increases the degree of accuracy of the measurements.

Laser microprobe. A laser is a device for producing a very intense beam of light that can be sharply focussed. In the laser microprobe, a tiny beam of light from a pulsed laser (which produces laser light in pulses rather than continuously) is focussed onto the specimen from a vertical illuminator system that uses the objective lens of the microscope to focus the beam and allow observation of the area to be analyzed. The intense heat generated by the pulse of laser light vaporizes part of the sample. In one commercial form of this instrument, this vapour short-circuits an auxiliary gap between two electrodes positioned just above the specimen, and it is thus raised by the ensuing electrical spark to a temperature at which its spectral (light) emission may be measured by means of a device for analyzing light (spectrograph). This instrument has been used to analyze traces of metals which occur in living tissues with a minimal amount of damage to the tissue and has applications in the metallurgical, ceramic, and geological fields.

Holographic techniques. The coherence and intensity of laser light can be used to record the microscope image as a hologram, or three-dimensional representation in the form of an interference pattern. The hologram freezes the specimen at one instant in time, and it may then be reconstructed and viewed at leisure.

X-ray microscopy. Theoretically, the use of shortwave X-rays should provide a great increase in the resolving power of the microscope; the practical difficulties, however, are great, and predicted improvements in resolution have not been achieved. X-rays are not refracted by solid glass lenses, so that conventional methods will

not serve for the formation of an X-ray image. A few experimental X-ray mirror microscopes have been built; aberrations are high, however, and, therefore, resolution suffers.

In practice, X-ray microscopy is used not to achieve high resolutions but to analyze the X-ray absorption characteristics of the specimen. For this purpose, contact microradiography may be used. In this process, the object is placed in close contact with a fine-grained photographic emulsion and exposed to a beam of X-rays. After the plate has been developed, the X-ray image may be examined with a normal optical microscope.

Point-projection X-ray microscopy

An alternative technique is point-projection X-ray microscopy, in which an electron gun and condenser system mounted in an evacuated column direct an intense beam of electrons onto a metal cathode, which forms the end window of the tube. A beam of X-rays thus generated emerges and radiates from the foil. If a specimen is placed close to the target foil, its shadow will be cast onto a fluorescent screen or photographic plate placed some distance away. With a focal camera with a length of 10 centimetres and with the object about 0.1 millimetre from the X-ray spot, an initial magnification of 1,000 magnitudes will be achieved. Such an instrument suffers in that exposure times are long because there is difficulty in getting sufficient current into a very small electron spot, and the X-ray output is thus very low.

The X-ray projection microscope has the advantage that its depth of field is very large; stereoscopic photographs may be taken to show the organization of the structures in thick specimens. The image contrast is largely due to differences in the absorption of X-rays, and it is often possible to identify substances present by measuring the X-ray absorption at different wavelengths.

THE ELECTRON MICROSCOPE

Fundamental research by many physicists in the first quarter of this century suggested that cathode rays (*i.e.*, electrons) might be used in some way to increase microscope resolution. Louis de Broglie, a French physicist (1892–), in 1924 opened the way with the suggestion that electron beams might be regarded as a form of wave motion. De Broglie derived the formula for their wavelength (see ELECTRON), which showed, for example, that for electrons accelerated by 60,000 volts, the effective wavelength would be 0.05 angstroms; *i.e.*, one hundred-thousandth that of green light. If such waves could be used in a microscope, then a valuable increase in resolution would result. In 1926 it was demonstrated that magnetic or electrostatic fields could act as lenses for electrons or other charged particles, and this discovery initiated the study of electron optics. In 1931 a two-lens electron microscope was devised. It produced enlarged images of the electron source. Later, in 1933, a true electron microscope was built. A year or so later, the resolution of the optical microscope was surpassed, but the specimen was severely damaged by the heating effects of the electron beam, a problem that was not solved for some years. In 1935 the construction of the first commercially built electron microscope was begun in England, and it was followed soon by production microscopes in Germany and the U.S. Progress in the construction of electron microscopes was rapid, with a great impetus to the achievement of high resolution being the introduction, in 1946, of a device called a stigmator, which compensates for astigmatism of the objective lens.

Electron microscopes are now available that are easy to operate and reliable and that give point-to-point resolutions of less than three angstroms. Such high resolutions, coupled with suitable advances in the methods of specimen preparation, now permit the direct visualization of large molecules. Recently, the transmission electron microscope has been supplemented by the introduction of a scanning electron microscope, in which a beam of electrons is scanned over the surface of an object and used to build up an image of the details of the surface structure. Another development is the electron probe microanalyzer, which allows analysis of the composition of materials to be made by using the incident electron beam to excite the emission of characteristic X-radiation by the various elements composing the specimen. These X-rays are detected and analyzed by X-ray spectrometers built into the instrument. Such probe microanalyzers customarily have facilities to produce an electron scanning image so that structure and chemical composition may be easily correlated.

Differences of types. There are many differences between optical and electron microscopes. The electron microscope requires that the electron beam be in a vacuum, because electrons cannot travel any appreciable distance in air at atmospheric pressure. The column of the electron microscope is evacuated by pumps, and the specimen, photographic plates, and any other necessary apparatus are introduced into the vacuum by means of airlocks or seals. Unlike the optical microscope, in which the lenses are of fixed focus and the distance between specimen and objective lens is varied, the electron microscope has variable-focus lenses, and the distance between specimen and objective lens and separation of the lenses remain constant. The magnification is determined mainly by the value of the current (for magnetic lenses) through the intermediate and projector lens coils. The image is focussed by changing the current through the objective lens coil. A high degree of electrical stability is necessary, because the current in a magnetic lens controls its focal length and magnification. Another difference is that the optical microscope is usually operated (for visual observations, at least) so that the image is a virtual one, and in the electron microscope the final image is invariably real and is visualized on a fluorescent screen or recorded for study on a photographic plate.

In the optical microscope the image is formed by absorption of light in the specimen; in the electron microscope the image results from a scattering of electrons by atoms in the specimen. A heavy atom is more effective in scattering than one of low atomic number, and the presence of heavy atoms will increase the image contrast. The electron microscopist may incorporate more heavy atoms into his specimen for this purpose.

Lenses. Electron lenses may be either electrostatic or electromagnetic. The simplest form of electrostatic lens consists of two coaxial cylinders with voltage potential difference applied between them. Such a lens is not of practical use in the electron microscope. A more convenient arrangement is the unipotential or Einzel lens. In it, three coaxial cylinders or apertures in plates form the lens. The outer two are grounded, while the middle one is at a high negative potential.

Electromagnetic lenses, which are used for the condenser system and for the projector of the electron microscope, differ from the objective lens only in details. The manufacturing and performance tolerances of condenser-system and projector lenses are much tighter than they are for those used as objective and intermediate lenses.

Efforts to improve the resolution of the electron microscope have tended toward production of a single-field condenser-objective lens of low aberrations. In such a lens, the first part acts as a condenser and the second as the objective; the specimen is inserted into the centre of the lens, where the axial magnetic field (the field along the axis of the instrument) is at a maximum.

Electrostatic lens aberrations

Electrostatic lenses show spherical aberration, distortion, coma, astigmatism, and curvature of field. Electromagnetic lenses, because of the rotation of the electron beam during its passage through the lens, also suffer from other less important aberrations. In addition chromatic aberration due to variation in the wavelength of the electrons may be of considerable importance in both types of lens. Such changes of electron velocity may be due either to variations in the high-voltage supply to the electron gun or to energy losses from collisions of electrons with atoms in the specimen. The first of these may be controlled by careful stabilization of the high-voltage supply, but variations in the second cannot be reduced with the electron sources presently in use. For the very thin specimens and the electron energies commonly used, such variation due to energy loss in the specimen may be neglected. The resolving power of the microscope is se-

verely limited by the spherical aberration of the electron lenses. It is not possible to correct this aberration in the same manner as in the optical microscope, because magnetic electron lenses are always convergent lenses. Careful lens design may help, but at present the only practical answer to this problem is reduction of the numerical aperture of the electron lens.

Astigmatism in the electron microscope is largely due to asymmetries in the axial component of the magnetic field of the lens and is the result of imperfect construction of the lens or of the interaction of the electron beam with residual gas molecules in the column. This leads to deposits on the specimen that introduce asymmetries into the magnetic field when they charge up under the influence of the beam. Some astigmatic images may cause great errors in interpretation.

Transmission electron microscope. The transmission electron microscope has three essential systems: (1) an electron gun, which produces the electron beam, and the condenser system, which focusses the beam onto the object; (2) the image-producing system, comprising the objective lens, movable specimen stage, and intermediate and projector lenses, which focus the electrons passing through the specimen to form a real, highly magnified image; and (3) the image-recording system, which converts the electron image into some form perceptible to the human eye. It usually consists of a fluorescent screen for viewing and focussing the image and a camera for permanent records.

Additional requirements are a vacuum system, comprising at least two pumps and their associated valves, and electric-power supplies with essential stabilizers and control equipment.

The electron gun and condenser system. The source of electrons, the cathode, is a heated, V-shaped tungsten filament with its apex, from which the bulk of the emission occurs, towards the condenser lenses. The filament is surrounded by a shield, sometimes called a Wehnelt cylinder, with a central aperture arranged on the axis of the column; the apex of the filament is arranged to lie at or just above or below this aperture. The cathode and shield are at a high negative potential and are insulated from the rest of the instrument. The final electrode of the electron gun is the anode, which takes the form of a disk with an axial hole. Electrons leave the cathode and shield, accelerate toward the anode, and, if the stabilization of the high voltage is adequate, pass through the central aperture at a uniform speed. The control and design of the electron gun are critical in ensuring satisfactory operation.

The intensity and angular aperture of the beam are controlled by the condenser lens system between the gun and the specimen. A single lens may be used to converge the beam onto the object, but, more commonly, a double condenser is used. In this the first lens is strong and produces a reduced image of the source, which is then imaged by the second lens onto the object. Such an arrangement is economical of space between the electron gun and the object stage and is more flexible, because the reduction in size of the image of the source (and hence the final size of illuminated area on the specimen) may be varied widely by controlling the first lens. The use of a small spot size minimizes disturbances in the specimen due to heating and irradiation.

The image-producing system. The specimen, mounted on a copper grid, is carried in a small holder in a movable specimen stage. The operator can control it by a system of micrometer screws and bell cranks working through vacuum seals, so that a large area of the specimen can be examined systematically. The objective lens is usually of short focal length (one to five millimetres) and produces a real intermediate image with a magnification of 20–200 magnitudes. An area of this image is rendered in turn with further magnification by the projector lens or lenses. A single projector lens may provide a range of magnification of 5:1 and by the use of interchangeable pole pieces in the projector a wider range of magnifications may be obtained. Modern instruments employ two projector lenses (one called the intermediate lens) to permit a greater range of magnification and to provide a greater overall magnification without a commensurate increase in the physical length of the column of the microscope. Such a system may be operated so that each stage in turn provides magnification, or the intermediate lens may be used to reduce the image produced by the objective and the projector set to magnify part of it to give the final image.

For practical reasons of image stability and brightness, the microscope is often operated to give a final magnification of 1,000-50,000 magnitudes on the screen. If a higher final magnification is required, it may be obtained by photographic enlargement. The quality of the final image in the electron microscope depends largely upon the accuracy of the various mechanical and electrical adjustments with which the various lenses are aligned to one another and to the illuminating system. The lenses require power supplies of a high degree of stability, and stabilization is provided electronically for a satisfactory standard of resolution.

Image quality

The gun, specimen chamber, and column and camera are evacuated so that the electron beam can pass freely. At the place where the specimen and photographic plates are inserted, air locks provide that only a minimal amount of air is introduced into the column; this reduces pumping time before the microscope is again operational.

Image recording. The electron image must be made visible to the eye by allowing the electrons to fall on a fluorescent screen fitted at the base of the microscope column. Such a screen is satisfactory for quick observations and for focussing and aligning the instrument. A low-power optical microscope fitted outside the column allows the image on the screen to be inspected at a magnification of about ten magnitudes, but the image suffers from poor contrast, lack of brightness, and the inherent grain of the screen. By allowing the electrons to fall upon the emulsion of a photographic plate, the latent image can then be developed and fixed exactly as in ordinary photography, and prints at any degree of further enlargement may be obtained from the negative. Such further enlargement allows all the detail present in the image to be resolved by the eye and also allows some control over the contrast.

Image-intensification systems have been developed using some form of television tube, with the final image presented on a cathode-ray-tube monitor. Image intensifiers permit electronic amplification. Beam currents that would not register any image on a fluorescent screen may be used to permit examination of materials which are susceptible to radiation damage, such as certain types of plastics.

Limitations of the transmission electron microscope. The modern transmission electron microscope has tremendous resolving power, so that large molecules can be visualized. Several limitations may affect interpretation of the image: (1) The object must be placed inside the vacuum of the column; this means that living material cannot be examined, and the biological organization of a specimen may be altered when it is subjected to the preparation necessary for electron microscopy. (2) The penetrating power of 60-kilovolt electrons is severely limited, so that specimens for study in conventional transmission electron microscopes must not be much thicker than 0.1 micron. Elaborate techniques must be devised for slicing bulk specimens or for separating the constituents of a bulk phase. (3) The use of thin sections, in turn, imposes a two-dimensional limit on the micrograph. Stereoscopic techniques that are technically possible by tilting the specimen between two exposures are, therefore, only of limited value. The structure in three dimensions may be difficult to ascertain, and recourse often has to be made to elaborate serial sectioning and reconstruction to obtain this information. (4) The fact that the electron image is formed by the heavy atoms in the specimen scattering the electrons may be a limitation in biological work. The materials of which biological specimens are composed are intrinsically of low scattering ability, and, therefore, heavy metals or their salts must be used in the preparation of such

material in order to introduce the necessary contrast into the image. These reagents may make it difficult to obtain any information about the chemical composition of the specimen.

Current researches are surmounting some of these drawbacks: in particular, study of cell metabolism with the electron microscope is now possible, and chemical information can now be obtained at the ultrastructural level.

Special types of electron microscope. *High-voltage instruments.* Several different types of instrument have been constructed to operate at accelerating voltages in excess of the 100 kilovolts normally used in the conventional transmission instrument. Such high-voltage microscopes are in commercial production for accelerating voltages of up to 1,200,000 volts.

These instruments possess several advantages over the conventional microscope: (1) The theoretical resolving power of the instrument increases as the accelerating voltage increases. (2) Thick specimens are easily penetrated by the beam. (3) Chromatic aberration caused by energy losses and scattering in the specimen is decreased. (4) Specimen heating and irradiation damage are decreased. (5) The resolution of electron diffraction patterns is improved.

Although the gain in resolution is theoretically about two and a half times that of a 100-kilovolt instrument, such increases have not as yet been achieved in practice. It is primarily for the increased penetrating power and consequent reduction in chromatic aberration that the high voltage instruments are used. Technical difficulties still abound in this field, largely because of problems of the adequate stabilization of the very high voltages and of lack of contrast in the material when examined with such high-energy electrons.

X-ray dangers

The operator must have adequate protection from the X-rays that are produced when the electron beam impinges on objects in its path. Progress has been made toward solutions to these problems, and the high-voltage microscope is proving invaluable in the study of metals and alloys. It is possible that biological materials may also be examined if they are enclosed in microchambers inserted into the path of the beam. Bacteria have been examined in this way, but many problems remain with this technique.

The scanning electron microscope. The scanning electron microscope, designed for studying the surfaces of objects directly, utilizes a beam of focussed electrons as an electron probe that is scanned in a regular manner over the specimen. The action of the electron beam stimulates emission of secondary electrons from the surface of the specimen. These are collected and passed to a scintillator crystal (a crystal that produces tiny flashes of light when bombarded with electrons). The light flashes in the crystal operate a photomultiplier tube, which amplifies the electrical signal. The resultant amplified current is used, in turn, to modulate the brightness of a display cathode-ray (television) tube that has its line scan driven in synchronism with the probe beam in the microscope column. There is a point-by-point correspondence between the brightness of each point on the display tube and the number of secondary electrons emitted from any point on the surface of the specimen. In this way, a picture of the surface topography of the specimen is built up. The magnification of the image may be controlled by changing the ratio between the relative sizes of the area covered by the scanning probe and the picture on the display tube.

No elaborate specimen-preparation techniques are required for examination in the scanning electron microscope. Large and bulky specimens may be accommodated. It is desirable that the specimen be rendered electrically conducting, otherwise a sharp picture will not be obtained. Conductivity is usually achieved by evaporating a 10–20-nanometre-thick layer of metal onto the specimen in a vacuum (such a thickness does not materially affect the resolution of the surface details); or, under certain circumstances, an aerosol antistatic spray will achieve the same purpose.

The scanning electron microscope has the valuable feature that the image contrast may be changed by differences in potential across the surface under study. This facility is used widely in the semiconductor field and in studying microcircuit devices while they are operating. Recently, scanning instruments have been used for transmission electron microscopy, with the advantage over the conventional transmission instrument that very low magnification (of about 20 magnitudes) may be used. At the same time, large fields of view are obtained, and very thick sections may be studied; this latter allows easy three-dimensional reconstructions to be made.

The electron-probe microanalyzer. A limitation of the conventional electron microscope is that it provides no chemical information. Electron-probe microanalyzers have been developed since 1947 to carry out nondestructive elemental analysis at resolutions approaching those of the transmission electron microscope. This is done by measuring the intensity of the characteristic X-rays emitted by a specimen when a focussed electron beam impinges on it. Early instruments used a static electron probe, but now scanning is the usual mode of operation, and a scanning X-ray image is built up on a cathode-ray tube. Such an instrument is called an X-ray microprobe analyzer.

X-ray probe microanalyzer

The X-ray microprobe analyzer is so valuable that X-ray spectrometer attachments are now provided for existing transmission electron microscopes. Combined instruments are specially designed with both transmission-electron-microscopy and X-ray microprobe analysis facilities.

The electron-probe microanalyzer has applications in mineralogical and metallurgical fields and is also used in biological work.

Field-emission microscope. In this instrument a fine wire with a rounded tip is mounted in a cathode-ray tube. Electrons are drawn from the tip by a high electrical field and travel toward the screen on which the image is formed. Only heat-resistant metals, such as tungsten, platinum, and molybdenum, can be examined in this way, because the high current density at the metal tip has a great heating effect. The magnification is proportional to the ratio of the radius of curvature of the screen on which the image forms to the radius of the metal tip.

A variant of the field-emission microscope, called the field-ion microscope, is used in metallurgy for direct observation of defects in the crystalline lattice and for assessment of the effects of radiation damage and chemical reactions on the metal surface.

The proton-scattering microscope. This instrument uses a beam of protons from an ion source or gun. The beam is focussed and accelerated onto a crystal of a metal such as copper or tungsten, which serves as the target. The pattern of scattered protons is recorded on a fluorescent screen; the blocking patterns provide information on the orientation of the crystals.

PREPARATION OF SPECIMENS

Optical microscopy. The surface of bulk materials can be studied at relatively low powers with incident light by simply mounting the specimen for ease of handling. Often, more information may be gained if the surface is flattened by grinding and polishing. In the case of metals, it may be necessary to etch the specimen in acids to allow the grain boundaries to be easily differentiated. With smaller amounts of material, such as powders and dusts, the sample is usually mounted on a slide in a resin medium of known refractive index and covered with a coverslip. For examination by incident light, the specimen material may be simply strewn on a slide.

Biological material, both plant and animal, generally requires more preparation. Organisms must be reduced to pieces which are small enough for study under the microscope. If unicellular organisms or small invertebrates are to be studied alive, they are mounted in a suitable fluid medium. Permanent slide preparations may be made of material that is first killed and then treated with chemical reagents that react with the protoplasm and prevent any further change in it. Contrast is obtained by soaking the specimens in dye solutions. Finally, the water in the objects may be removed by treatment with a series of alco-

hols of gradually increasing strength before the preparation is cleared in an organic fluid and mounted in a synthetic resin. This sets hard, fixing the coverslip firmly onto the preparation. When large masses of tissue are studied, the individual cells are separated from one another by the process of maceration (softening by soaking), or, more commonly, the object is embedded in a supporting medium, such as paraffin wax, which is then cut into very thin slices. The resulting sections are attached to glass slides, the embedding material dissolved away, and the section stained in various ways to obtain the required contrast. Dehydration, clearing, and mounting in resin complete the preparation of the slide. In special cases, the tissue is made rigid enough for sectioning by freezing it solid.

Maceration

Rocks and other hard specimens may be cut into thin sections for microscopical examination by using a diamond saw or impregnated wheel. The section is reduced to its final thickness by grinding it down with an abrasive powder.

Electron microscopy. For transmission electron microscopy, the specimen must be in very thin slices, so that the electron beam may penetrate it. Biological material is fixed and dehydrated essentially as for optical microscopy but is embedded in methacrylate or epoxy resin, which sets much harder than the wax and nitrocellulose used in optical microtechnique and allows thinner sections to be cut. The machines used for slicing (ultramicrotomes) usually operate with a knife broken from plate glass and use thermal expansion of the support to move the block forward in the small increments required for each successive section. The thin sections, as they come off the knife, are floated onto the surface of a liquid (usually distilled water) and then picked up on a copper grid; after drying, this grid, bearing the section, may be inserted directly into the microscope.

Contrast in material of biological origin is usually introduced at or just after the fixation stage by the use of osmium tetroxide, which is believed to change chemically after its introduction into the material to a substance (perhaps a lower oxide of osmium or the metal itself) that then provides the required electron density. Further increase in the contrast may be obtained by so-called electron staining of the finished sections when they are on the grids. This is done by floating the grids onto solutions of lead or uranyl salts for short periods of time; after washing and drying, the sections may be examined in the microscope.

Electron staining

For the examination of surfaces in the transmission microscope, it is necessary to take a replica of the surface in plastic, coat the replica with a film of evaporated carbon for strength, and finally evaporate a thin layer of metal onto the surface of the replica at a low angle in order to introduce contrast. Particulate material may be supported on a thin film of plastic carried on a copper grid. Contrast may be added to the biological material by shadowing it in a vacuum with heavy metals at a low angle. This shows up the surface detail just as the setting sun shining along a road shows up the irregularities in the road surface in clear relief. Alternatively, a negative staining technique may be used. In this, the specimens are surrounded by a matrix of the salt of some metal that is opaque to the electron beam. When examined in the microscope, a negative image results with the shape of the particle outlined in sharp relief. This technique is used in studying viruses and in molecular biology.

Metals may be prepared for the electron microscope by obtaining them as foils and then thinning them down further electrolytically to the point at which they will transmit the electron beam. Plastics and rubber may now be sectioned for examination in the electron microscope by freezing and then slicing.

Specimens for study in the scanning electron microscope simply need to be mounted on a specimen-stub holder and rendered electrically conductive either by an antistatic spray or by evaporating onto them a very thin layer of metal.

Middle Ages (c. 395–1500)

The term middle age (*medium aevum*) was first used in the later 15th century by Humanist scholars as a description of that period of western European history between the collapse of Roman civilization in the 5th century AD and the revival of civilized life and learning in which the Humanists believed themselves to be participating. The

purpose of this article, however, is to describe some more positive achievements of those centuries, which saw the emergence of Europe as a cultural unit and the rise and decay of a distinctive civilization within it.

Foundations of medieval civilization

The materials from which this civilization was molded were essentially threefold: the inheritance of classical antiquity, the Christian tradition, and Germanic and Scandinavian social patterns. Classical antiquity, which set the standards of learning, culture, and government by which medieval no less than Renaissance scholars measured their own achievements, passed into Europe by several routes. Over part of Europe, most notably Italy, Spain, and southern France, the Germanic invaders entered a society in which Roman social and political organization, urban life, and even local government continued, much enfeebled but never totally interrupted. In northern Gaul, always more thinly Romanized, this was much less true; in Britain little but the roads and crumbling walls survived as witness to the secular presence of the empire. If, however, Germanic tribes overran the empire, then the Roman and Catholic church rapidly overran the tribes. Most of the invaders were either pagans or followers of the heresiarch Arius, who had denied the true divinity of Christ. This resulted in some persecution of the orthodox in Spain, Italy, and North Africa; but the Catholic baptism of the Frankish king Clovis, soon after 493, was the first of a series of conversions by Germanic rulers that led to the triumph of orthodoxy. Thenceforward, the church was able to play an essential role in preserving literacy and even some classical learning in its liturgy and literature, in maintaining some of the forms of public administration in its diocesan government, in perpetuating the tradition of corporate responsibility for peace and the relief of want, and perhaps most of all in creating a new universal society to replace that once provided by the fallen empire. It was ultimately the Latin Church rather than the Roman imperial tradition that determined the frontiers of modern Europe.

Classical antiquity, however, was also mediated through two other sources. While the empire in the West slowly ebbed away, that of the East, well protected from the north by the Bosporus, survived in Constantinople (or Byzantium). Although sea communications with the West were frequently interrupted and Byzantine culture became progressively more Greek than Latin, the influence of a continuing Roman Empire was great. Byzantine architecture and painting, the forms of imperial government, and the incomparable wealth and size of the greatest of Christian cities continued to exercise a powerful attraction. Ecclesiastical and political differences, culminating in the sack of Constantinople by crusaders (1204) and the growing self-confidence of Western rulers and scholars, much reduced the empire's influence by the 12th century. By then it was not from the Christian Byzantines but from the Muslim Arabs that the West was recovering much of the Greek tradition in mathematics, metaphysics, and the natural sciences, though in interpolated and corrupted translations.

The Germanic influence upon medieval society derived from a long series of migrations, invasions, and settlements, which began in the 3rd century AD and continued into the 12th. Their impact varied greatly, according to the conditions of their entry into the territory of the former empire, but they introduced a quite different pattern of social organization and lordship, one that took on some of the forms of Roman and Christian tradition while wholly altering their emphasis and function.

This article is divided into the following sections:

I. Chronological outline of medieval history
II. Structures and components of society
  The rulers
  The aristocracy
  Other social groups
III. The operation of the medieval world
  Economic patterns
  Forms of lordship
  Church government
  Royal government
IV. The world of the senses and the mind

I. Chronological outline of medieval history

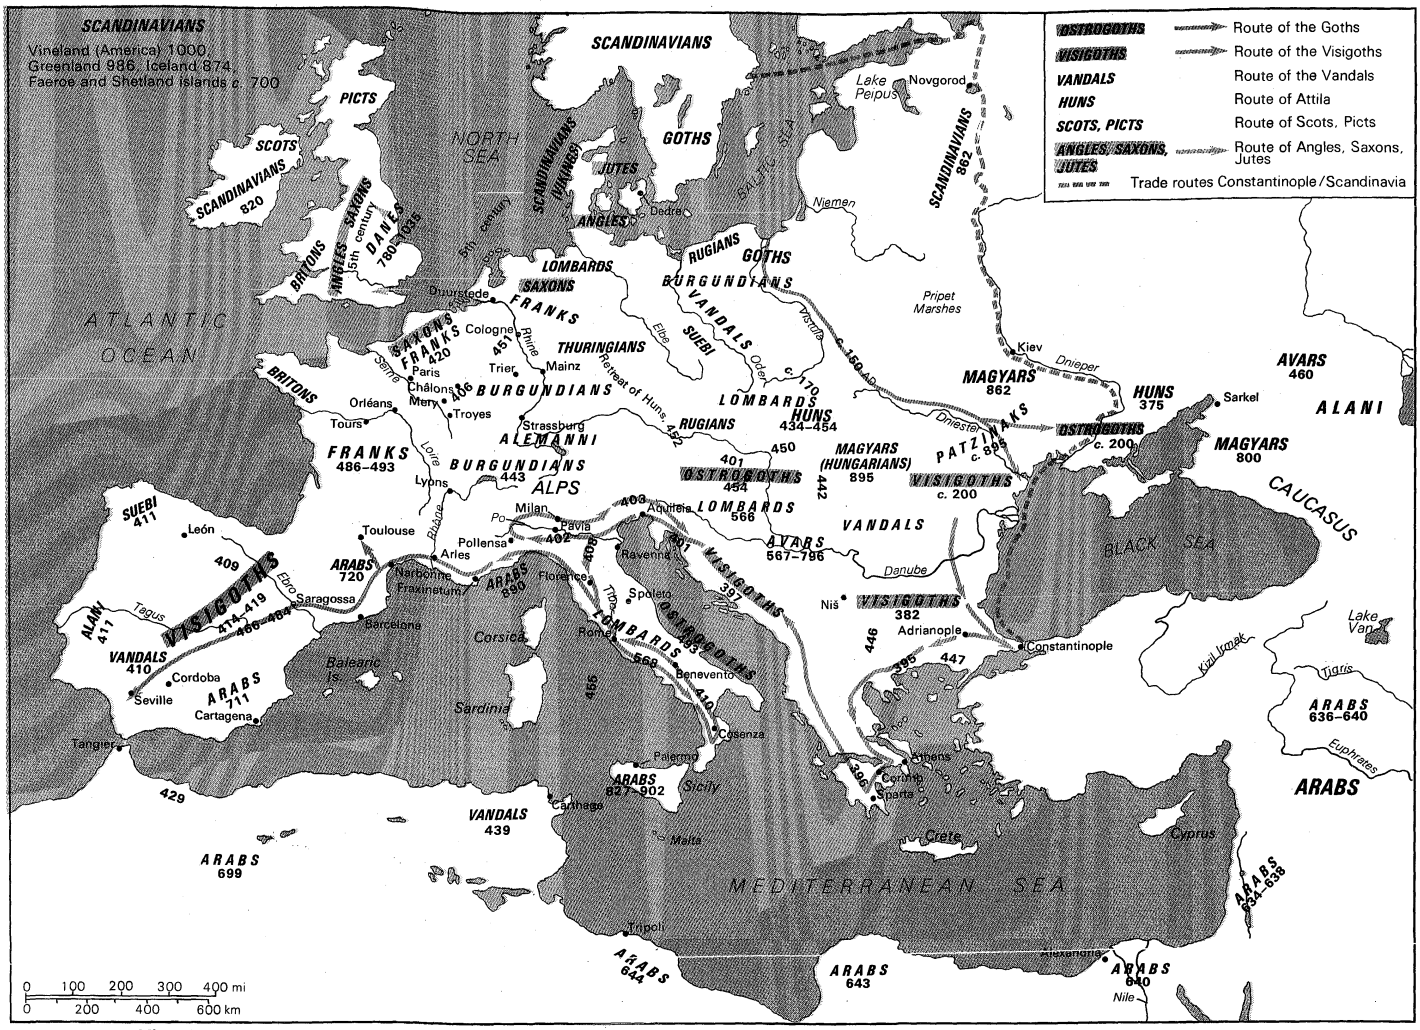
From the time of the emperor Hadrian (died AD 138), the northern frontiers of the empire had rested upon the Danube and the Rhine. In the course of the 3rd century these came under heavy pressure from Germanic tribes —Burgundians, Franks, and many others on the Rhine and Goths and Vandals on the Danube. The Goths, once settled on the plains north of the Black Sea, came, like their fellows on the Rhine, under pressure from the raiding nomadic horsemen of the Steppe—the Alans and Huns. The emperors, often desperately short of men and resources, had long been accustomed to taking some of these neighbours into their pay as allies to defend the frontier against their fellows, quartering them upon the local population and granting their leaders exalted posts in the imperial government. In the 5th century this frontier gave way along its whole length.

Collapse of the Roman frontier

In 410 the Visigoths under Alaric plundered Rome itself, while a Vandal army was ravaging southern Gaul before crossing into North Africa. By 455 the whole province west of Tripolis was in Vandal hands; soon thereafter, the Burgundians occupied the area around Lyons and the Visigoths established their kingdom over southern Gaul and, later, Spain, while Italy fell to an Ostrogothic army under the Romanized though Arian Theodoric after 487. In northern Gaul a Frankish force under Clovis appeared as the dominant power at the end of the century. Under the rule of Clovis' dynasty (the Merovingians), Frankish hegemony was asserted over the Burgundians, the Visigoths of Provence, and later the pagan Germans of Thuringia and Bavaria, where Irish missionaries such as St. Columban (died 615) helped to consolidate the conquest. A sprawling and much divided kingdom thus straddled the earlier frontier of the empire, with its centre in the Rhine Basin. The amalgam of North German peoples who conquered the southern and eastern parts of Britain between 450 and 600 found little and preserved less of the more shallow-rooted Roman society there, though they were later converted by Irish missionaries from the north and by a mission under the monk Augustine (later St. Augustine of Canterbury) sent from Rome in 597.

Only the Frankish and Anglo-Saxon kingdoms lasted long. Under the emperor Justinian (reigned 527–565), Byzantine armies destroyed the Vandal and Ostrogoth kingdoms, but at great cost and to little purpose. From the north the Lombards entered Italy in 568 and created a new kingdom, with its capital at Pavia, that extended southward to Benevento and Spoleto, leaving Byzantium with a precarious hold on the coasts, Rome itself, and the far south. Meanwhile, from Mecca the Muslim Arabs passed rapidly westward, capturing all North Africa and leaving only tiny pockets of Christian resistance in Spain, in Asturias and the Pyrenees. The northernmost point of their expansion was marked by the defeat of a Muslim army outside Tours in 732, though Sicily was to fall to them in the 9th century and there was an Arab stronghold in the Alps until 972. Frankish power was reasserted by Pepin the Short and his son Charles the Great (Charlemagne), under whom the frontier was pushed beyond the Elbe in the east and the Tiber in the south; again the missionaries, including the Anglo-Saxon St. Boniface, followed closely behind the army and consolidated its work. In 800 Charlemagne was made emperor and crowned by the Pope in Rome, founding the medieval empire in Europe out of a fragment of its Mediterranean parent.

The Scandinavians in the late 8th and 9th centuries expanded rapidly. They moved eastward through the Russian river systems to found the great trading centres at Novgorod and Kiev and even to besiege Byzantium. Scandinavian traders and pirates travelled southward to attack Ireland, England, Gaul, and the coast of Italy. Outside Russia they founded permanent settlements in Iceland, Greenland, Ireland and the Scottish islands, eastern England, and Normandy, and some reached North America. In the east the Magyars, a second wave of nomadic Asian horsemen, threatened Germany and Italy before settling eventually in Pannonia—the germ of the modern Hungary. Before these threats the descendants of



Migrations and conquests, 2nd to 10th century.

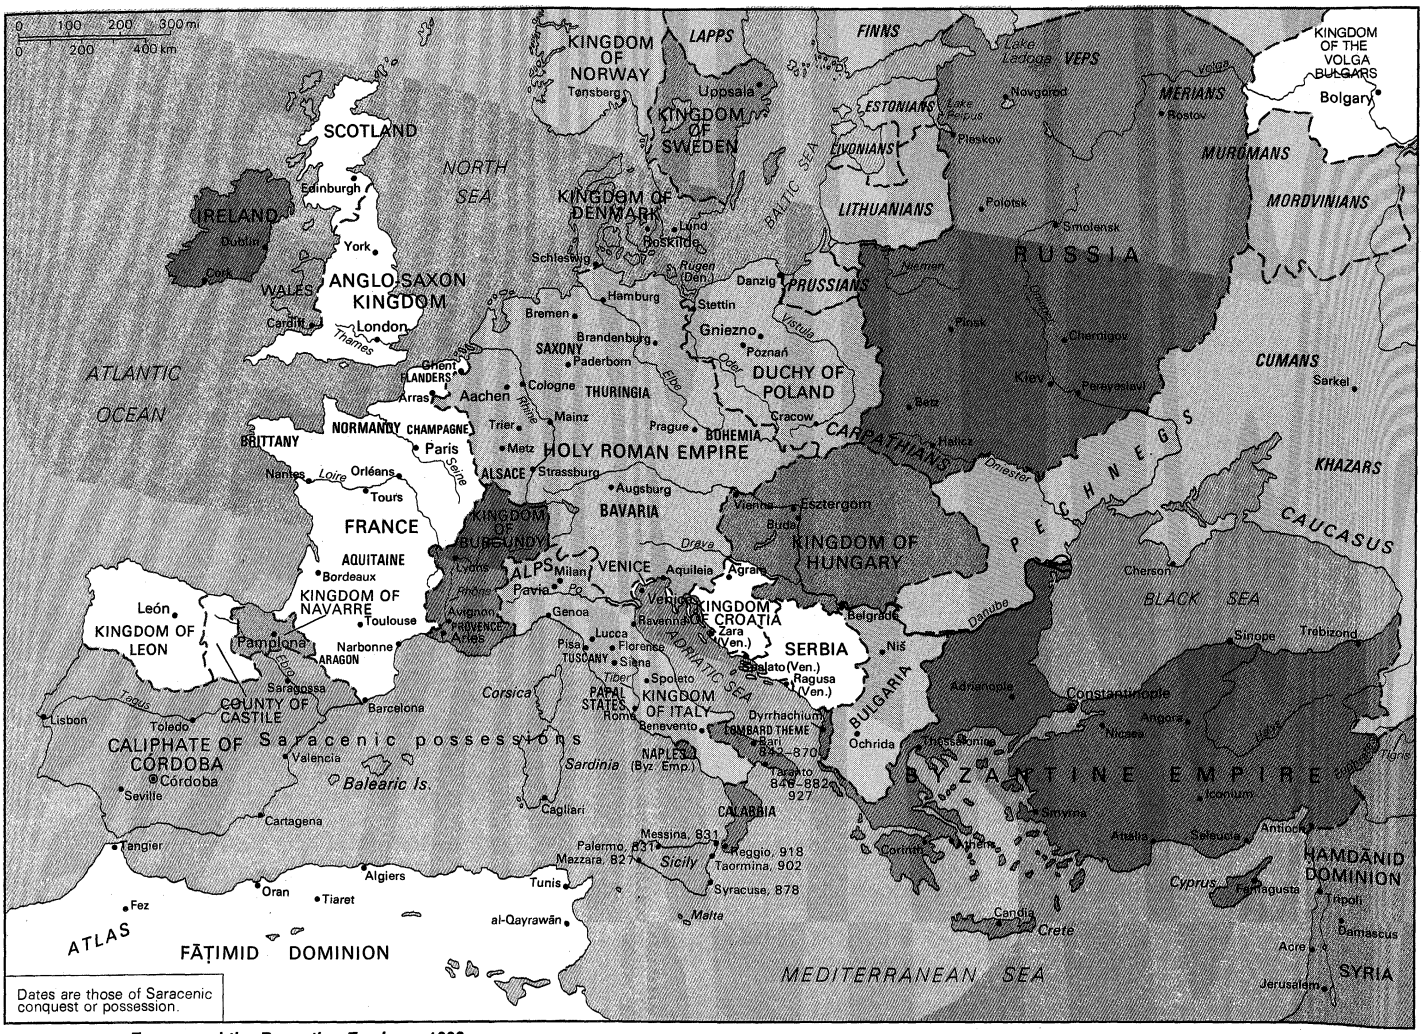
Charlemagne (the Carolingians) survived as kings of the Western Franks until replaced in 987 by their greatest subject, Hugh Capet, but effective political authority had long passed to the local princes. A new Saxon dynasty under Otto I defeated the Magyars and united northern Italy with Germany under the imperial crown in 962. In England, Danish invaders had destroyed all but the solitary kingdom of Wessex of King Alfred, under whose descendants the country was united for the first time.

New territorial and intellectual expansion

As these dangers receded, a new period of territorial and intellectual expansion began. German settlers pressed eastward across the Elbe into former Slavonic territory as settlers and missionaries. In Spain the kings of Leon and Aragon began the long process of reconquest, which was not completed until the fall of Muslim Granada in 1492. In Italy, Norman adventurers expelled the Byzantines from Calabria and the Muslims from Sicily. In Scandinavia, Poland, Bohemia, and Hungary the native princes still ruled, but now as Latin Christians. External missionary advances were matched by an internal revival of ecclesiastical life—first in the monasteries of Burgundy and Lorraine, later in the secular church. Beginning in the later 11th century, under Pope Gregory VII and his successors Rome took the lead in this movement and challenged the emperor and all secular rulers for pre-eminence within Christian society.

Widespread economic revival, reflected in an increasing volume of trade, accelerated internal as well as external colonization, and renewed urban growth, beginning in Italy, was accompanied by a fresh interest in law, both canon (ecclesiastical) and civil. Canon law provided the weapons in the armory of the church in its struggles against such rulers as Frederick I of Germany and Henry II, king of England, lord of Ireland and western France; it also encouraged the growth of local church government and a wide variety of institutions, all under the authority of the papacy and its evolving central bureaucracy. Civil and secular law provided materials for new theories of secular dominion and encouraged the development of more sophisticated forms of government in such states as Norman Sicily, Angevin England, and, later, Capetian France. All these developments supposed and encouraged a desire for more education for clergy and laity, a trend best illustrated by the rise of the first universities (12th century).

The course of the later 12th and the 13th centuries was marked politically by the division of Europe into two political types—that of Germany and Italy, where imperial authority broke up in favour of the Italian city states, the papacy, and the German princes, and that of France, Spain, England, and Scandinavia, where there was a steady advance in the progress of central authority, though on varying principles. Economically, it was a period of rising population, widespread land clearance, and the appearance of a powerful and wealthy merchant class, particularly in Flanders and even more in Italy. In 1231 Frederick II struck the first gold coins of commercial importance to be seen in western Christendom since the failure of the old imperial Roman coinage in the 8th century, and his example was soon followed in Venice and Florence. Intellectually, it was a period of elaborate syntheses of the traditional doctrine of the church with the new learning of Aristotle—first in logic and dialectic, later in natural science and metaphysics. The harmony of rea-



Europe and the Byzantine Empire c. 1000.

Synthesis between church doctrine and Aristotelian learning

son and revelation celebrated in the theological systems of St. Thomas Aquinas (died 1274) and his fellows matched the legal coherence and widespread acceptance of a doctrine of papal supremacy dramatically expressed by Innocent III in the Fourth Lateran Council, in 1215.

The 14th and 15th centuries were beset by difficulties that overthrew most of the assumptions of earlier government and compelled the rise of new ones. Climatic change, famine, and a series of disastrous plagues, beginning with the Black Death of 1347–50, reduced the population in some areas by as much as half and dealt a grave blow to the traditional patterns of agriculture, which were already under strain. Destructive war and recurring pestilence provoked the first extensive peasant revolts—the Jacquerie of France (1358) and the English Peasants' Revolt (1381). In the 15th century similar rural grievances gave rise to revolts as far apart as Catalonia and Swedish Finland and formed an important element in the nationalist risings of Engelbrekt in Sweden and the Hussites of Tábor in Bohemia. Yet for the survivors of the plagues there were distinct advantages: woolgrowing in Spain and cloth working in England, cereal raising in eastern Europe, and many industries rose to new heights of prosperity in these years, which saw the fortunes of such imperial towns as Nürnberg at their zenith.

Politically, the fragmentation of Germany into innumerable petty sovereign states was consummated by the end of the 15th century, though on its eastern border Poland, united with Lithuania under Władysław II Jagiełło, and Hungary, under Matthias I Corvinus, rose to great prosperity. The stability of both France and England was threatened by their long struggle in the Hundred Years' War and the feuds of the greater magnates, among whom the dukes of Burgundy almost succeeded in carving out a new state along the frontiers of France and Germany. Under Charles VII and Louis XI, the Valois monarchy emerged as masters of all France, with a large measure of absolute power similar to that later achieved by the Tudor Henry VII in England. In Spain the fall of Granada and the union of the crowns of Aragon and Castile under Ferdinand and Isabella laid the foundations for Spanish hegemony in the next century.

The papacy, even when in exile in Avignon (1309–77), continued to centralize the government of the church on an ever more elaborate structure of administration, but it faced formidable difficulties because of the rise of nationalist and monarchical feeling, especially in France and England; because of the rise of an educated and often anti-clerical laity; and, above all, because of the Great Schism of 1378–1417, brought about by the election of two rival popes, one for Avignon and one for Rome. Though the 15th-century popes were able to overcome the challenge to their authority presented by a series of councils, they were ill-prepared either by this struggle or by the difficulties of Italian politics to give an effective lead to the demands for ecclesiastical reform increasingly audible by the end of the century.

Intellectually, the 14th century saw the synthesis formed by the 13th-century theologians begin to break up; the dominant school of Nominalist metaphysicians, asserting an unbridgeable gulf between the truths of reason and revelation, pursued epistemological enquiries of great daring but limited application, while at the other extreme the mystical way of Thomas à Kempis and many others

had few academic or institutional consequences. The dominant new current was to be the classical Humanism of the 15th century Italians, with its more restrained parallels north of the Alps. What was new in this movement was not admiration for the classical past but a determined effort to recover the secular and educational values of classical civilization and cast aside the prolonged medieval attempt to adapt pagan learning to a Christian purpose. Armed with the new weapon of the printed book, rapidly diffused in the later 15th century, the Humanists were able to create an autonomous secular education of the kind Europe had lost with the fall of Rome.

Classical Humanism

II. Structures and components of society

For most of the medieval period in most of Europe, the structure of society was determined by the difficulties of providing an adequate and continuous supply of food and raw materials. The proportion of grain reaped to seed sown was generally low; acute difficulties of transport made agricultural specialization hazardous and prices local and unstable. Hence, particularly between the 8th and 11th centuries, the proportion of the population freed of all agricultural tasks was low, and the materials of luxury or warfare were rare and highly prized.

The aristocracy that could be supported by such a society was both in form and origin a blend of Roman and Germanic elements. Late Roman society was marked by the existence of an aristocracy of wealthy landowners whose estates were worked by slaves either maintained in the household or housed on small plots about the great house. Other dependents, of rather higher status, might be freedmen or formerly independent cultivators, such as the *coloni*, whom war or financial distress had brought under the landowner's protection. Well before the formal end of the empire in the West, such landowners had been accustomed to deal out a usurped justice even over their free clients and had maintained armies of *bucellarii* (bodyguards) in their own defense, though rarely placing a high value on military accomplishments. With difficulty they retained their contacts with the towns and with the traditional urban education of their class.

Earlier Roman government had depended upon these towns, which were almost universally in decline by the 5th century. Vandal and, later, Muslim piracy disrupted the vital sea routes to Africa and the East; on land the impotence of local government made communications dangerous; and ever heavier taxation crippled trade. Long-range commerce and the more local urban industries declined, until even wheel-turned pottery became scarce or vanished. The retreat toward economic self-sufficiency and a barter economy was reflected in the near collapse of Western coinage. Over this society, rapidly receding into a pre-Roman localism, there presided, with ever-feebler effect, an emperor or emperors who attained office at the head of an army and according to no settled principle of succession. Once in power the emperor exercised a near-absolute authority over the army, the courts, and the administration, limited only by prudence and the likelihood of mutiny or assassination. Emperors were hailed as themselves divine before the conversion of Constantine early in the 4th century; thereafter, even a Christian emperor who enforced the precepts of the church readily took on a quasi-priestly character.

Decline of the towns

The Germanic invaders who settled in or along the frontiers of this empire lived very differently. Not all seem to have had kings, at least permanently, but the majority, whether as allies or invaders, entered the empire as warrior bands led by chiefs who depended for power on their continued capacity to win battles and to retain followers with gifts of present wealth and hope of more. Kings were ring givers, holders of great feasts, lords of men. Yet their authority rested on other grounds too—their descent from the gods and a belief sometimes current that divine favour was assured the people through the royal lineage. Some of the pagan kings (such as the Ynglings of Sweden) acted as priests, and a king's subjects usually followed him to the font for baptism as they followed him to war. Very special measures, including the earliest recorded Frankish consecration by a bishop, were required to legitimize the succession of a king from outside the ruling dynasty.

The politically active element in the people was represented by the warriors—the freemen—who formed the army; when this was gathered it represented the people for war or peace, and it was the army that acclaimed each new king by raising him upon their shields or enthroning him upon some sacred stone. Among these freemen there was a group of special importance and standing, set apart by their birth and their lord's favour—the *comitatus*, or *gasindi*, already known to the Roman historian Tacitus in the 1st century AD. For them, loyalty to their lord was the supreme virtue, celebrated in epic verse from *Beowulf* on. From their ranks were drawn the barbarian officers of post-Roman and Germanic society, though the highest such posts seem to have been monopolized by a restricted number of noble kin groups, distinguished by their descent and deeds rather than by any set title to property.

THE RULERS

Kings. In the societies in which these disparate patterns blended, beginning in the 8th century, the medieval kings were raised to office by a combination of ritual acts that revealed the elements of their power. Until the principle of male primogeniture became dominant in the late 12th century, the king would first be "chosen" in an assembly from among the kin of the last ruler, whose designation would carry great weight in cases of doubt; this choice was often not complete until the new king had travelled through his kingdom in what has been called a continuous election. After the consecration of Pepin the Short as king of the Franks by St. Boniface in 751, it became increasingly common for the king so acclaimed to be consecrated with a liturgy carefully modelled upon the Old Testament precedents of Saul and Solomon and to be invested with such insignia of kingship as crown, sword, helmet, or sceptre. Before or after this ceremony, the leading men of the kingdom came in to declare their allegiance, often performing symbolic acts of domestic service at the coronation feast. In these ceremonies the king secured both rights and duties. As the anointed of the Lord, he had a special claim on the obedience of the church and a measure of physical security; the murder of Canute IV of Denmark in 1086 horrified Europe, and the violent deaths of kings continued to be regarded as striking at the whole fabric of the divine and human order. This process, whereby the church sharply distinguished the king from the chieftain, in part explains an important transition of the 9th and 10th centuries. Thenceforward, the multiplication of kings, common among the descendants of Clovis or Charlemagne, ceased; only a formal act of the papacy under rare conditions was thought capable of legitimizing such later kingdoms as Hungary (999), Sicily (1139), or Portugal (1143).

Medieval notions of kingship

The church, which played so large a part in creating such a king, was active in prescribing duties; the coronation oaths and prayers insisted upon his obligation to protect the church, the defenseless, and the poor, to make war upon the heathen in the service of Christ, and to ensure that justice was done. It was chiefly in church councils that the king's duty to the whole people was emphasized against his relations with his warriors.

Even where, as with the Capetian dynasty between 987 and 1316, son succeeded father in unbroken descent, it was conventional to refer to the king as chosen by his people, and this became an active principle when there was no obvious claimant, as at the end of the Saxon or Hohenstaufen dynasties in Germany or in such exceptional cases as the founding of the Latin kingdom of Jerusalem in 1099. Among the larger kingdoms of the 13th century, only Germany, beset by frequent changes of dynasty and by the papacy's hostility to a hereditary empire, was still in practice an electoral state. Charles IV's Golden Bull of 1356 formally defined the procedures of election that remained in force in the empire until 1806, although after 1437 the throne was monopolized by the family of Habsburg. In Denmark, Sweden, and Poland the kingship was also formally and often prac-

tically elective, though hereditary right became absolute in France, England, and Spain.

Emperors. Theoretically, after 800 the emperors—the heirs of Charlemagne—stood above the kings. The appearance of a second Christian empire caused endless difficulties with Byzantium, and the nature of its pre-eminence was always diffuse and uncertain. It could be considered a recognition of facts—the attribution of a supreme title to the most powerful of the Latin kings—and many saw Charlemagne or Otto I in this light; but none of their successors enjoyed the same authority as did these founders of empire. The more general view, dominant by the end of the 10th century, was that the empire was specifically Roman, but in several possible senses. Because it was Pope Leo III who had taken the lead in recognizing Charlemagne as the first emperor in the West in 300 years, and, because Leo's successors had the undoubted right to consecrate later emperors at Rome, it could be claimed that the empire was an office within the Christian community, or *ecclesia*. The chief duty of such an emperor would then be the protection of the church and the enforcement of ecclesiastical discipline. When the emperor Henry III summoned the synod of Sutri of 1046, which ratified the withdrawal of three rival popes, he fulfilled one interpretation of this role; when Pope Gregory VII declared Henry IV deprived of his kingship in Italy and Germany for offenses against the church in 1076, he was employing another. Rome was, however, the city of the Caesars as well as of St. Peter, and some claimed that the emperors were the heirs of Augustus and the pagan emperors as well as of Charlemagne, with a universal authority that owed nothing to the church. This view was asserted notably by the apologists of Frederick I Barbarossa (reigned 1152–90), supporting their claims upon the revived study of the Roman civil law; modified by the doctrines of Aristotle, it survived in the writings of Dante and among the courtiers of the emperor Henry VII (reigned 1308–13).

Chief duty of the emperor

Without effective control in Rome, all of these views lacked substance, and such control was made impossible because of political stress in Germany under Henry IV and, later, the rise of the Lombard towns (which inflicted a serious defeat on Frederick I at Legnano in 1176) and the papacy's determination to establish an independent state in central Italy under Innocent III and his successors. After the death of the emperor Frederick II (reigned 1215–50), who had united the crowns of Germany, Italy, and Sicily in his own person, prolonged succession disputes on both sides of the Alps ruined the foundations of central authority in Italy and Germany. After the reign of Otto I (German king, 936–973; emperor from 962), the king of Germany had an exclusive title to the empire, though he could only secure it through coronation at Rome. The universal and ecclesiastical pretensions enshrined in this act had become a fiction long before the last imperial coronation in Rome, that of Frederick III in 1452, the bulk of whose reign was spent trying to maintain a foothold even in his own duchy of Austria.

Popes. If the imperial authority became progressively more confined, that of the popes made great advances, partly at the empire's expense. The foundation of papal authority lay, first, in the claim to inherit all the powers conveyed to St. Peter by Christ and, second, in the special position of the bishop of Rome. Until the 8th century, papal pre-eminence was complicated by the existence of jealous patriarchates of the East, not least the new Rome at Constantinople, whose emperor remained the nominal and sometimes the effective overlord of the city of Rome. By 700, however, most of the other patriarchs were subject to Muslim rulers, and Byzantine military weakness had forced such popes as Gregory I to take on most civil responsibility for the city of Rome. Dogmatic disputes in the Byzantine Empire over the veneration of icons (725–843) hastened a process of estrangement between the Greek Eastern and Latin Western churches that was to deepen eventually into near permanent schism. Rome then was left in solitary eminence in the West. Missionaries from Anglo-Saxon England, which had been converted by Roman agents, came to exercise a dominant influence upon the Frankish kings of the early 8th century; under Pepin the Short, Charlemagne, and the latter's son Louis the Pious, strenuous efforts were made to enforce a single liturgy, canon law, and monastic observance, the authenticity of which was guaranteed by its use at Rome.

Until the 11th century this confirming and legitimizing of action begun elsewhere was the predominant if not exclusive role of a papacy largely under the control of a series of such local Roman noble houses as the Crescentii and counts of Tusculum. The papacy favoured rather than led movements of active reform in the monastic and secular church. With the accession of Gregory VII, however, the papacy assumed the leadership of a movement that saw the inertia of the bishops and archbishops as the chief obstacle to ecclesiastical reform and viewed this situation as a consequence of excessive lay influence on their appointment and conduct. Accordingly, Gregory and his successors pursued a policy aimed at reducing the authority of the secular princes over the church (so provoking the long and bitter Investiture Controversy with the emperors Henry IV and Henry V) and at replacing secular authority with an ecclesiastical government based upon the written canon law and directed from Rome. By the pontificate of Innocent III (reigned 1198–1216) substantial successes had been achieved. The Fourth Lateran Council of 1215, attended by more than 400 bishops and 800 abbots from the whole of the Latin obedience and by representatives of all the greater princes, disposed of secular and ecclesiastical business on the widest scale. The difficulties that beset a full realization of the papal vision of a Christian and priestly monarchy were both internal and external. Internally, the process of centralization of authority made for slow and expensive decisions and was thought to demand a political independence in Italy that, in turn, involved long and costly wars with the Hohenstaufen and their successors north and south of the Papal States. Both centralization and the need to levy taxes on the church at large aroused the distrust and resentment of the local hierarchy, which could be exploited by kings (such as Philip IV of France in his contest with Boniface VIII) who were determined to secure their own right to tax their clergy and to submit them to the royal law.

Papal leadership

The rise of national consciousness that accompanied this resistance as well as the exile of the popes at Avignon made the pope's universal role as arbitrator in secular or ecclesiastical affairs harder to sustain. The double election of 1378 created a schism and weakened the position of the papacy. Because neither contestant would give way, the schism could only be ended by an external agency—a general council of the church held at Constance in the presence of the emperor Sigismund between 1414 and 1418. The energies of the abler reformers of the next 30 years or so were largely diverted to disputing the rival claims to authority of a monarchical papacy and a general council. With the failure of the most ambitious of these at Basel, the papacy emerged from the struggle again in Rome and again enjoying the plenitude of power; but the chief beneficiaries of the struggle were the secular princes, who had secured valuable concessions of control over their clergy as the price of their support.

THE ARISTOCRACY

The greater aristocracy. By 1100 a greater aristocracy had evolved over almost all the Latin West, marked by a combination of three elements. First, its members were normally the lords of a number of men bound to them by an oath of fealty and an act of homage, while they were themselves so bound to a king, a prelate, or the pope; the obligations such bonds involved were various, but the performance of military service was the most widespread and characteristic. Second, this aristocracy commonly exercised a large measure of judicial, financial, and administrative authority over its own men as lords and often over others as royal officers. Third, this was a landowning aristocracy that rewarded its dependents with grants of lands (fiefs), much as its own wealth had been enhanced by grants from kings, and maintained large

Elements of aristocracy

households from the proceeds of the estates retained in the lord's own hand—the domain.

To this combination, or some elements of it, the term feudalism is commonly though inconsistently applied; Marxists sometimes further apply it to a particular form of agricultural exploitation, the manorial system. But none of these elements necessarily supposes the others: in England it could be said that all land was received from the king, yet public authority remained unusually concentrated in his hands; in Germany the greatest princes came to hold rights of jurisdiction from the emperor rather than land, and their reciprocal duties were very slight; in southern France and Italy tenure for homage and service was rare but political authority was exceptionally fragmented.

Within the ranks of the greater artistocracy, certain distinctions came to exist. Originally, there seem to have been a limited number of very great families in Germanic society, defined by birth and sometimes uniquely described as free, but this division slowly gave way to others whose titles derived from functions rather than social rank. The term duke was widely applied to the lords of certain areas, which were incorporated in the Frankish empire without wholly losing their identity—*e.g.*, Bavaria, Burgundy, Brittany, Aquitaine, Saxony—and also to the lesser lords of the loosely constructed kingdom of the Lombards; the Scandinavian jarls or Anglo-Saxon earls after the reign of Canute (died 1035) were similar. In origin the word duke (*dux*) meant military commander, and it was on the basis of military need that the majority of 10th-century duchies emerged; for similar reasons, there appeared the margraves of Italy and Germany, lords of border land with a wider military authority. In Germany duchies multiplied in the 12th century, as in the creation of Austria in 1156, when the title implied membership of the highest rank in the social and tenurial scale; in 13th-century France and 14th-century England the term was only revived for great lordships (appanages) created for the cadets of the royal family.

The most widespread of such titles originally denoting public office and only later social rank or landed wealth was the Latin *comes* (German *Graf*, Anglo-Saxon *ealdorman*), or "count." *Comes* originally meant companion or member of the king's household of specially trained warriors; the appointment of members of the Frankish king's inner circle to the earlier administrative districts of *gau* or *pagus* caused the word to be applied to an officer of Carolingian government, then to a hereditary holder of office and rights, and finally to the head of a noble landed family. The terms duke, marquis, and count were themselves no necessary guide to relative wealth or prestige because some duchies were almost empty titles while the powerful lords of Flanders or Champagne were only counts. The institution of the *Reichsfürstenstand*, the class of imperial princes in late 12th-century Germany, was conceived as defining the highest rank of lay and church princes standing immediately about the throne. While the French institution was to become essentially an empty honour under the monarchical government of later kings, the German class was buttressed with important privileges that gave it enduring importance.

Recognition of rank

The origins of this greater aristocracy and its privileges were diverse. Some Roman senatorial families survived or absorbed their invaders; some descendants of independent chieftains of war bands that did not secure lasting kingdoms entered the Frankish, Anglo-Saxon, or Scandinavian nobility; the descendants of some specially favoured royal companions were able to hold onto the gains of their ancestors. Birth was from the outset probably an essential element of both exalted rank and access to royal favour, but important modifications to this took place between the 9th and the 12th centuries; slowly, the emphasis upon patrilineal descent and primogeniture became ever more absolute, and the extended kin group gave way to the dynasty. The passing of public offices into hereditary possession, the growing importance of military considerations, and a concentration of wealth and influence upon a limited number of indivisible castles all contributed to this effect. Whereas the great Carolingian families of the 9th century derived their names from an ancestor, their successors named themselves after the area of their rule or their principal stronghold.

Entry into this later aristocracy was possible by a variety of routes. Throughout this period the enduring hazard of central authority was that those appointed to maintain its interest would succeed in converting this representation into a right. In Germany even the unfree class of *ministeriales* sometimes succeeded in establishing such claims to the imperial fiefs and castles entrusted to their care and thus forced their way into the aristocracy. In France and England in the later Middle Ages, royal servants were commonly enriched by the opportunity to deprive or buy out those outside the circle of royal favour. There, too, in the 14th century a certain number of great merchants in the service of the crown were able to enter the ranks of the nobility; in Italy, however, the incompatibility of merchant adventure with noble birth had broken down much earlier. In later medieval Europe the emergence of more professional armies (especially in Italy and France during the widespread disorders of the 14th century) provided opportunities for successful soldiers of modest birth to rise into the ranks of an aristocracy coloured by ideals of an elaborate knightly code.

Lesser nobility. It was of the essence of high social rank that the aristocrat should have a large following of men who were themselves of free birth. Every great man, like every king, was made great by his capacity to maintain a retinue and reward his followers. An estate was valuable less for its revenues in money and goods than for the men whose services could be secured from it. The noble retinue was held together by gifts of gold, horses, weapons, or hawks, while those who served their lord well might hope for a gift of land. The numbers of such followers, or knights, were swollen by freemen who were driven by need to surrender their own land to the lord and to receive it back as a conditional grant by him; in return they received a protection modelled upon that extended to the lord's own blood kin. With increasing specialization of warfare, free birth tended to give way to the skills of cavalry warfare as the essential qualification for noble service; these knights (French *chevalier*, German *Ritter*) might live as retainers in the lord's household or hold land from him—a knight's fee, or fief—coming only at an exceptional summons to his feasts, courts, or wars. Many enjoyed a large freedom in the government of their estates and came to form a lesser nobility, bearing arms, using their own seals, and living in more or less fortified manor houses. As the apparatus and conventions of knightly warfare became more elaborate and the influence of the courtly romances more pervasive, membership in the nobility came to depend on knighthood.

Knights

The rise of the knight to this more exalted status was in part a function of the dissolution of the tight bonds of dependence his land tenure would once have imposed. This was a general phenomenon of the later Middle Ages, for the complexity of tenurial obligations made them increasingly inadequate either for defining status or for providing the lord with his honorable retinue. The later medieval principalities therefore owed their legal constitution to the powers of the lord in the exercise of his sovereign rights rather than to his personal claims on the services of his vassals; by a parallel development, the lord's household and following were commonly then paid for their services. Even at the lower levels of society, the same movement can be seen at work. In the 9th century a great estate would normally have a proportion of household slave labour; by the 13th century almost all the household servants would receive some wages, though food, lodging, and security still formed the bulk of their payment.

The church hierarchy. The greater aristocracy throughout Europe included a number of churchmen, for the sees of bishops and many monasteries had received wide grants of land, over which they often exercised more extensive rights than did their lay fellows, both as lords of tenants and as royal officers. Under Charlemagne and later princes, the state intervened to enforce universal acquiescence in the form of spiritual government over the

whole body of the laity, and this could be burdensome or even oppressive. Set aside from their fellows to a different and a higher calling, this aristocracy and its subordinate officers were also, in theory, recruited on quite different principles. In practice, however, high office in the church remained almost wholly the prerogative of the aristocracy and later of the knightly classes. Between the 8th and the 15th centuries it has been calculated that not much more than one-third of the 2,000 bishops appointed to German bishoprics came from non-noble families, and only five are known to have come from the dependent peasantry that formed the great bulk of the population. Certain monasteries and colleges of cathedral canons were explicitly reserved to those of the most carefully authenticated noble birth. Yet access to the highest church offices was in part dictated by other considerations; from the 11th century onward, royal or papal service and mastery of the disciplines of theology and canon law provided the means for men to rise on their ability alone. Suger—abbot of Saint-Denis, a monk of modest origins who became chief adviser to Louis VI of France, and regent for Louis VII—and died one of the most powerful men of Europe, or Thomas Wolsey, a butcher's son who rose to be cardinal and archbishop of York and chief minister to Henry VIII of England, illustrate the advancement that the church could provide, however rarely. Opportunities for this upward mobility were closely related to the existence of an effective royal administration capable of excluding the local magnates from a monopoly of patronage; the hope of modest advances provided many obscure but devoted clerical servants for the infant bureaucracies of 12th-century kings.

Access to church offices

Bishops. The original nucleus of church organization had lain in the bishoprics, groups of which, from the end of the 8th century at least, formed provinces normally presided over by an archbishop or metropolitan. The special interest of the church in political concord, which derived not merely from its dedication to charity but also from the vulnerability and wide extent of its property, made it for long the natural ally of kings and emperors; the anathemas of the bishops were regularly employed to reinforce the sword of the Lord's anointed. Being, if aristocratic, at least not hereditary magnates, the bishops were the allies upon whom the Saxon and Salian emperors of Germany and the early Capetian kings of France largely depended as a counterpoise to their greater secular subjects. Episcopal estates were treated as royal estates whenever the king journeyed about his kingdom, and the burdens of military service on German ecclesiastical estates were often unusually heavy; the royal administration was staffed and directed by the clergy, and the church's endowments were used to reward them. In return the bishops secured great privileges; the archbishops on either side of the Rhine—at Reims, Sens, Mainz, Trier, or Cologne—were at once powerful landowners and retainers of a wide measure of delegated royal authority, and these were only among the more visible examples of a movement in progress throughout Europe. Theoretically, the success of the Gregorian reform movement in the 11th and 12th centuries had stemmed from the distinction it drew between the bishop's absolute obedience to canon law and his subordinate obligation to the prince. But in practice, the bishops continued to depend on royal authority for defense against grasping lay neighbours, for the enforcement of ecclesiastical discipline (particularly in matters of heresy), and, in the later Middle Ages, for protection against the growing anti-clericalism of some of the educated laity and even the financial demands of the papacy.

Secular clergy. From the 5th century onward, the original constitution of the diocese, which rested upon the bishop and a small group of clergy living with him at a central point, altered substantially. Subordinate centres grew up within the diocese, some large and early ones served by groups of resident clergy but the great majority caring for only a small parish and served by a single priest. Recruitment to these was wide; some houses of canons and wealthy parishes provided revenues for men of high birth or influence, while others were served by men drawn from the peasant population, who were little more than domestic servants of the landowner who had built the church. The widespread grant of parish churches to monasteries and religious communities (as many as one-third of the parishes of a diocese could be so granted) and the prevalence of absentee clergy, such as pluralists holding several benefices or scholars engaged in study at the universities, meant that many churches were served by substitutes—vicars, who enjoyed only a proportion of the revenues of their office, often a quite inadequate one. Besides these, most parishes also provided some employment for a floating population of clerks in minor orders. With a rapid decline in the creation of new parishes in western Europe after the 12th century, it was the endowment of chantries, the setting aside of money and buildings exclusively for the saying of mass for the soul of the founder, that provided the greater number of new, if modest, benefices, though these were often attached to other parochial or charitable obligations.

The determined efforts made first by the early Carolingians and then by the reformers of the 12th and 13th centuries to provide an efficient system of supervision and control over the local pastoral work of the diocese ultimately produced an administrative hierarchy parallel to, though partly distinct from, the pastoral one. The rise of the bishop's formal jurisdiction saw the appearance of a host of legal and financial agents, ranging from the powerful archdeacon to the humble summoner, whose task was to enforce attendance at the church courts. The increasing centralization of church government at Rome in the 13th and 14th centuries required the appearance of other officers, proctors of bishops and abbots at Rome, collectors of papal taxes, and, later, such disreputable figures as the itinerant peddlers in papal indulgences and dubious relics—the pardoners.

Administrative hierarchy

Regular clergy. By the mid-13th century there existed beside this hierarchy another one, the regular clergy, living under a formal and corporate rule more demanding than the minimum canonical requirements of the seculars. Between the 5th and the 11th centuries this sector had been overwhelmingly monastic, composed of autonomous houses ruled over by an abbot with near absolute powers and devoted to the maintenance of the regular liturgical cycle; there was one pre-eminent rule, that of St. Benedict, which envisaged a life of corporate self-sufficiency as the norm. In the 11th and 12th centuries a number of variations on this rule appeared, designed to heighten the emphasis upon manual labour, corporate poverty, or solitary contemplation; in a more striking departure, some houses of canons under the flexible rule of St. Augustine were, it was hoped, to combine monastic rigour of life with active parochial work, while military orders founded in the course of the Crusades in the Holy Land and Spain and on Germany's eastern frontier combined the yet more disparate profession of war with monastic ideals. All these were property-owning corporations, as were the houses of nuns and canonesses that lived under similar conditions; their presidents, especially the abbots of the more well-to-do Benedictine abbeys, were often wealthier than many bishops and were drawn from a similar social background. Only among the Cistercian lay brothers was entry into the monastic life readily open to men of humble origin. The original followers of St. Francis (died 1226) were often drawn from a much wider variety of classes, but by the end of the 13th century both they and the followers of St. Dominic, originally intended to be educated preachers trained to combat heresy, had become orders of friars with a strong academic tradition, excluding all but the most talented of the very poor. These men renounced all property (even corporate), were especially engaged in the work of preaching (notably in the towns), and travelled constantly. By 1300 the multiplication of religious orders had come to a virtual standstill.

Clerks. Beyond the regular and beneficed secular clergy was a large body of clerks, in minor orders or in none, who had the crowns of their heads shaved in the tonsure without proceeding further, thus securing some of the legal immunities of the clergy with few of their

duties. The clerks of the royal or imperial chapels who formed embryo civil services represented an exceptional group of such men, but many more were to be found at the universities of the 12th and 13th centuries, and a still larger number yet were loosely attached to a parish church or joined a vagrant body of "hedge-priests" that canon law struggled for centuries to regulate or abolish.

Educated laymen. An important test for determining membership in the clergy was literacy. But in the 13th century (and occasionally earlier) there appeared in Europe a body of educated laymen of a kind that had not been seen there since the collapse of Roman secular education; lawyers and administrators in the royal service might now have an entirely secular career, and most merchants were necessarily literate. The 13th century produced two celebrated author kings, the emperor Frederick II and James I of Aragon (though even in the 14th century Edward III of England could barely write a few painful letters).

The growth of literacy

Between 1300 and 1500 the proportion of educated laity rose steadily; in part, the change was manifested in the growing importance of lay patronage in architecture, poetry, and the production of devotional manuscripts, the latter only the most striking example of a much more general and more active participation of the laity in the devotional life. On the other hand, the secular agents of government were jealous of ecclesiastical claims to privilege and immunity. Anti-clericalism in western Europe was as old as the Christian state, but the lawyers who staffed the sovereign governments of the 14th century had an alternative theory of the state to set against that of the church, and clerks such as Marsilius of Padua, William of Ockham, and Wycliffe were providing a theoretical justification for lay intervention in the affairs of the church as far-reaching as the claims of Pope Innocent IV for papal authority in the secular world had been a century earlier. At the opening of the 14th century the French chancery was directed by two lawyers, Pierre Flote and Guillaume de Nogaret, who launched a virulent and largely successful attack upon the universal claims made for the papacy by Pope Boniface VIII (1294–1303). Though even the revolutionary Hussite movement in Bohemia (1419–36) failed to subvert the authority of the church, the autonomy of ecclesiastical government was under pressure throughout Europe, largely because there now existed an educated laity able to perform the tasks hitherto reserved to a uniquely literate clergy.

OTHER SOCIAL GROUPS

Townspeople. The urban society of the Roman Empire in the West was breaking down long before the deposition of the last emperor in the late 5th century, and it continued to fade with few interruptions until the 10th century. The estimated population of Rome fell from more than 1,000,000 in the 1st century AD to 40,000 in the 7th; nevertheless, it long remained the largest city of the Christian West, although tiny compared to the greater Muslim cities or Constantinople. Many Roman towns continued to be occupied, often because they remained, or became, the seats of bishoprics or abbeys and so centres at least of consumption, or because their walls offered some shelter from a long series of invaders. Commercial activity continued in those ports of Italy still in touch with Byzantium and perhaps on a modest scale in some of the Lombard towns. It even increased in such northern ports as Duurstede in the Rhine Delta, the Viking entrepôt at Hedeby (in Schleswig), and the Russian cities trading through the Black Sea. By the end of the 11th century the recovery of urban life was more general. Merchants trading over long distances began to appear as an urban aristocracy, wealthy men anxious to secure a larger measure of control in the government of their towns. In Venice this development was already clearly visible, and the fleets and trade of this port stimulated a revival of town life throughout northern Italy. The origins of these early capitalists are much disputed: some may well have been fortunate peddlers, but more can be shown to have been members of the lesser aristocracy, or tenants or officers of great churches, with capital to invest in goods and transport. In Italy the participation of the landed aristocracy in the life and trade of the towns was shown by the presence of clusters of their tall stone towers within the city walls rather than on outlying hill tops.

Recovery of urban life

Increasing political stability on land and contact with the Levant by sea saw the rapid increase of such trading communities in size and influence. The Italian cities of Genoa, Pisa, Lucca, and Siena rose to challenge the earlier dominance of Venice and Milan. In Germany the Rhineland towns were already a political force to be reckoned with in the civil wars at the beginning of the 12th century, but they came to be overshadowed by the great prosperity and activity of the Baltic towns of the Hanseatic League, such as Lübeck, Hamburg, and later Danzig (Gdańsk), and later by the prosperity of such South German towns as Augsburg and Nürnberg. In Flanders textile manufacture, based in part on imported wool, produced in the 12th century a precocious industrial community with a large unstable proletariat concentrated in such towns as Ypres, Ghent, Bruges, and Arras; alone of the northern cities these could compete in influence with the greater Italian centres such as the manufacturing town of Florence (with a population of perhaps as high as 200,000 in the 13th century, largely supported by its textile industry) or the equally large Milan, celebrated for its metalwork and, most notably, its armories. Paris by the end of the 12th century was already acquiring most of the qualities of a capital city for the fast-growing area of Capetian power, with a population estimated at 80,000.

By the 13th century the Italian towns commonly contained a group of aristocrats by birth or by wealth long possessed whose political dominance was challenged by the more substantial of the merchants. Below these were the retailers and masters of the smaller crafts and then the wage labourers, apprentices, and beggars, who were normally without a political voice but whose grievances sometimes broke out in violence and even bloodshed. The urban nobility of Italy was without true parallels north of the Alps and it was the greater merchants, or merchant adventurers of the later phrase, who formed the directing elite in most towns. Although even at the end of the medieval period the towns' share in the wealth and population of Europe was still very limited (over most of the Continent perhaps not above one-tenth of the total), their influence was much greater. Since the 14th century, access to the towns had been an important agent in social change, and the continuing or growing prosperity of some 15th-century towns was in marked contrast to the widespread decline of agricultural production and profit. Politically, the merchant interests of the towns were of the first importance, for it was only they who could provide the large sums of ready cash with which the kings of the later 15th century established royal authority over the magnates. To the degree that the king could continue to enjoy the taxes of the burgesses of his towns, he could maintain or extend his authority; without them he was reduced to competing with his own magnates on little better than equal terms.

Agricultural society. The countryside during the Roman period was chiefly cultivated either by the slaves of the great *villa* estates or by more or less free cultivators, sometimes bound by the government to remain on their land in order to maintain a tax-paying population but otherwise not labouring under grave personal disabilities before the law. In the Germanic societies of the invasion period, a threefold division of the agricultural population was common—the people *par excellence* (the *karl*, *ceorl*, or *bôndhi*), free peasants cultivating their own land, bearing arms, and so participating in the public assemblies of *gau* or hundred; a more obscure group often described as freedmen (*aldiones* for the Lombards and Bavarians, *Leti* among the Germans, Franks, Frisians, and also perhaps in Kent), possibly freed slaves, possibly the survivors of an earlier conquered population who enjoyed limited rights but did not usually play an active part in the courts; and the thralls, slaves either captured in war, condemned to their state by the law, or reduced to it by penury. Such bondsmen might sometimes have their own huts, plots of land, and

houses and therefore enjoy a minimal independence.

These forms tended to merge so that over much of western Europe by AD 1000 the characteristic villager (villein) held a substantial plot in the village fields but equally was expected to perform such onerous services on a lord's domain as ploughing, reaping, and carting and was subject to his lord's will in much the same fashion as the earlier landless slave. In addition, the village community would usually contain other men with smaller plots of land (cottagers), whose rents in labour and goods were correspondingly lighter, and also a small number of slaves, in the old sense of the word. All these unfree cultivators could be described as serfs, however diverse their economic conditions. In parts of Europe, notably in northern Germany and eastern England, the earlier free peasantry still formed an important element in the population, and by the 14th century their ranks were swollen by numbers of villeins whom changing economic conditions had allowed to commute their servile obligations for fixed rents in money. The settlers who had been persuaded to take up holdings in the planned land clearances of the 12th and 13th centuries by offers of considerable freedom of tenure had reached the same goal by different means. At the other end of the social scale, the landless wage labourer was now much more common.

The timing of this process, whereby many of the earlier free peasants were first assimilated to the legal if not the economic conditions of Roman slaves and then increasingly recovered their personal liberty to become rent-paying tenants, was extremely uneven. The cycle was complete for much of Italy by 1200 and for most of France and England by 1400, but the free peasantry of Scandinavia, parts of eastern Europe, and Castile was only beginning to feel the presence of a serf-owning class of landlords in the 14th and 15th centuries, at a time when it was fast becoming obsolete elsewhere.

Beggars and outlaws. A society that was at best only just above subsistence level maintained a large body of vagrants. Economic disasters such as plague or famine forced a desperate population to attack the crops of more fortunate neighbours; in the late 12th century, freelance mercenaries roamed Europe in search of employers and booty, while the 14th and 15th centuries saw more organized (and so more formidable) free companies of professional troops whose favoured fields of operation were France and Italy, where their captains traded their services like sovereign princes. All large towns either generated or attracted their share of beggars and petty thieves; in François Villon, 15th-century Paris produced a universal poet to express the pleasures and much more frequent miseries of this vagrant life. Town and country alike lacked any effective police force, and therefore, although the majority of known or suspected criminals could be dispossessed of land and property, even murderers were rarely apprehended. At times in 13th-century England only one in 100 murderers was ever brought to trial and convicted. The rest fled, many apparently into the forest to live like beasts or find an organized band of outlaws, idealized tales of which became widely current in the later Middle Ages in the legends of Robin Hood. The local community protected itself as best it could against such bands, but the assistance of a

The vagrant life

local knight at the head of his retainers could rarely be distinguished from the nuisance it was supposed to abate. The fate of these outlaws was bound up with that of the forests, and both were in decline by 1500. But with the first signs of a recovery of population, vagrancy and unemployment were probably increasing.

Women. A society directed by warriors and celibate clergy was not one in which women would exercise extended rights very often. After *c.* 1100 patrilineal descent was almost exclusively the test of nobility, while matrilineal descent was often the test of serfdom. The property rights of women, though protected by canon and secular law, were confined; it was a cherished freedom for widows to be allowed to refuse a second match proposed by lord or kin. Practice, however, did not altogether conform to this appearance. In barbarian society in the period after the invasions, and sometimes long after, matrilineal descent was often important—the house of Charlemagne traced its origins back to a daughter of Arnulf, bishop of Metz. Although few queens ruled in their own right, many exercised great political authority, as in the minority of their sons; the regency of Blanche of Castile for St. Louis in France was a notable and successful example. The remarkable Queen Margaret succeeded in uniting the three kingdoms of Sweden, Denmark, and Norway under her regency in the Union of Kalmar of 1397, an act that influenced the future of all Scandinavia. Similarly, although debarred from the priesthood by their sex, a number of women played a leading role in ecclesiastical affairs. St. Catherine of Siena and St. Bridget of Sweden played a major role in achieving the return of the papacy from Avignon to Rome in 1377; both were celebrated adepts of the spiritual life, the female contribution to which is also attested by the works of Margery Kempe in England. The influence of women was also felt in their role as patrons, sometimes of Christianity itself, as when a number of the invading chieftains of the 5th and 6th centuries were first married to Christian princesses and then converted. Queen Margaret of Scotland (died 1093) was responsible for the thoroughgoing reform of the church in her kingdom, which brought it rapidly into the mainstream of the Latin Church; another notable lady, Matilda of Tuscany (died 1115), had been the last refuge of the reforming papacy for almost a generation.

As patrons of the arts, and above all of poetry, Eleanor, duchess of Aquitaine and wife first of Louis VII of France and then of Henry II of England, and her daughter Marie, countess of Champagne, were the leading figures of their century. At Marie's request, Chrétien de Troyes translated Ovid's *Art of Love* and also wrote one of the first courtly romances to be based on Geoffrey of Monmouth's Arthurian history. In Marie de France the courtly romance found a skillful female writer—appropriately, because these tales, which evolved from the masculine world of the chanson de geste, reveal the growth of a new social convention in which women had a larger part and a higher function. Foreshadowed in the diffusion of the cult of the Virgin Mary in the 11th century, this new convention was developed in the Italy of Petrarch and Dante.

III. The operation of the medieval world

Diversity and complexity of medieval society

The most striking feature of medieval society was its peculiar diversity and complexity. Although scholars often conceived the world as a hierarchy in which all power was mediated from God according to a single ordered descent, in practice four distinct types of structure coexisted, overlapping and modifying one another profoundly but each with its own laws and objects. The first was the economic structure, essentially a diverse and inefficient agricultural society with islands of commercial activity. The second was the seignorial, the structures by which this economic activity was adapted to provide a surplus for a small class of lords and occasionally for great merchants. The third was ecclesiastical, in theory an autonomous economy of salvation in which all the forms of secular life had their spiritual counterpart. The fourth and for long the most tenuous was the centralized monarchical structure of the sovereign state. The triumph of this last over the earlier claims of church and magnate government marks the end of medieval society.

ECONOMIC PATTERNS

Latin Europe by 1500 covered a great diversity of lands and climates. A first division was that between the heavy soils of Germany, northern France, and Britain and the predominantly lighter soils of the Mediterranean lands of Spain, Languedoc, and Italy, in which vines and olives formed an important adjunct to grain.

Medieval communities. Both main types of agriculture were conducted by cultivators who lived, where possible, in large settlements, with their churches, mills, and barns, the whole settlement often walled, as in the *bastides* of southern France, or at least hedged against animal and human marauders. Both economies contrast with those that existed on their perimeters and in the less fertile or more broken country of the interior. In the Celtic lands of Ireland, Scotland, and Wales, in Spain and the foothills of the Alps, as well as in Hungary and the Latin Balkans, a largely pastoral economy flourished, depending on flocks of cattle, sheep, or goats and producing a quite different pattern of living. As oxen provided the essential power for the cereal farmer's plough, and milk, cheese, salt, and meat were as important to his diet as a minimum of crops were to the most pastoral of societies, so most medieval communities represented a precarious balance of forces between the needs of crops and beasts. Beyond these types of communities there existed various types of highly specialized settlements, such as the fishing communities of the North Sea coast, the salt evaporators of southwestern France, the fenmen and the miners, sometimes solitary and sometimes organized in tightly knit communities, as were the tin miners of Cornwall and Bohemia. With few technological resources and poor communications, all medieval communities were largely conditioned by their environment.

Some of the Mediterranean communities of Italian cultivators had been organized as great estates (*latifundia*) in the late and post-imperial period; each tenant held only as much land as could support him and his family while he worked on the lord's estate. Very early, however, the comparatively widespread use of coinage allowed landowners to abandon such direct exploitation, which was clumsy and time consuming, in favour of a variety of leases for terms of years or lives. By such means the community became one of independent cultivators, each with his own field. Similar tenancies prevailed over much of southern France, where a Roman Law much modified by custom and the decay of the judicature continued to regulate contracts and the functions of the market.

The triangle formed by the Rivers Loire and Rhine contained the chief area of nucleated cereal-growing settlements, though there were notable extensions of this into Britain to the west and into Franconia, Swabia, Bavaria, and the German east. In the Loire–Rhine region, with its heavy soils and wet climate, the earlier small enclosed fields of the Iron Age gave way widely to the characteristic open fields of the medieval vill, where the arable land of the community lay in large blocks cultivated by heavy, ox-drawn ploughs. The mechanical difficulties of turning such an implement and the need for effective drainage produced a characteristic effect of long narrow parallel strips running down contours of the hills. Such cultivation required a regular alternation of crops because there were few means available for restoring the fertility of the soil except allowing either half or one-third of the land to lie fallow each year. Similarly, the other resources of the land in pasture, woodland, water, and common grazing needed careful annual regulation because there was constant tension between the needs of men, crops, and beasts. This required an organism whose common life maintained some continuity regardless of the divisions that accidents of lordship might impose; later, the village was often a legislative body, enacting its own bylaws.

Open fields of the medieval vill

Until the 13th century this open-field cultivation continued to support the classical manorial organization. The lord drew his profit partly from his possession of a share of the vill's arable land, which was exploited for him by

his tenants for some of the week, and partly from the exercise of his right to compel his tenants to use his ovens and mills, at a price, and to control and exploit the use of the surrounding waste land. In practice such communities had always maintained a population of landless men—slaves earlier and labourers later—and there usually were tenants who owed rent or personal services of a less strictly economic variety. (Such free tenancy became widespread with the clearing of outlying lands in the 12th and 13th centuries, especially in the planned colonies along the frontiers.) Again, principally under the impact of increasing internal trade and a greater circulation of money, cumbrous forms of exploitation tended to break down in the later Middle Ages as the domain was leased out and the lord allowed his tenants to commute their labour dues into cash rents. When, in the late 14th and 15th centuries, the relation between land and labour shifted drastically in favour of the tenant over most of western Europe, the economic centralization of the local community focussed on the lord's estate almost vanished, though the need for common action in the agricultural cycle did not. In contrast to these tightly knit, often productive and vulnerable agricultural communities stood the much looser society of the higher lands, where settlement was necessarily dispersed and where social bonds rested much more exclusively upon the ties of the kin or clan than they did in the nucleated villages. Even the arable farmers in a scattered community had more independence than did their lowland fellows. The Icelandic sagas written down in the 13th century, in manuscripts typically preserved in farmhouses rather than in monastic libraries, provide a vivid picture of such communities.

Increasing volume of economic exchange

The increasing economic specialization of the period between 1100 and 1500, which saw vine growing and sheep rearing rise to the status of basic rather than supplementary occupations for whole communities, was made possible by a great increase in the volume of exchanges, itself a function of greater political stability. These exchanges took place pre-eminently in three settings: the markets, chiefly for local produce, held at short and regular intervals; the trading communities of the towns; and the occasional great fairs, annual events to which merchants travelled from the ends of Europe and the proceeds of which enriched such fortunate princes as the count of Champagne, lord of the fair towns of Provins, Troyes, Lagny, and Bar-sur-Aube.

Urban growth. Early concentrations of population in settlements occurred for political, ecclesiastical, or defensive reasons as often as for commercial ones; but the period from the 11th century onward saw the widespread rise of classes of men engaged in the commerce of exchange or manufacture and settled for that purpose in urban groups. Many of these were originally only merchants in a subsidiary sense; and many towns were barely distinct from large villages, being surrounded by the town fields cultivated by the citizens and containing within their boundaries numerous livestock and small patches of cultivated ground. Yet, a common interest among merchants or craftsmen produced associations of considerable importance. Merchants guilds developed—groups of men whose interests extended far beyond the political horizons of the lords of most towns, anxious for the reduction of tolls and in need of their own courts of justice appropriate to the urgent demands of itinerant commerce. It was these who led the struggle for urban autonomy in Europe north of the Alps—a movement which almost always involved conflict with the local lords, especially bishops and abbots, but was often favoured by princes such as the counts of Flanders or Henry the Lion, duke of Saxony, in the German east—and thus the juridical phenomenon of the town as a corporate person emerged, created within a pattern of territorial lordships. Similarly, such towns acted corporately, much like their contemporary landed magnates, seeking to subordinate neighbouring communities to the authority of the city magistrates, to compel the man of the countryside to acknowledge the legal and economic primacy of the urban centre, and to divert profitable trade routes to their own advantage. The 12th-century crusading movement reflected such local hostilities—the Byzantine monopoly enjoyed by Venice was challenged by the direct access to the trade of the East offered by the crusader states, often maintained by the rival fleets of Pisa, Genoa, or Lucca. Long intercommunal wars, such as those between Pisa and Genoa or between Venice and Ravenna and Pola (now in Yugoslavia), saw the rise of a small number of city republics governed by elected consuls combining birth and commercial substance in a unique blend. Within such towns there existed other interests also driven by their common economic interests into corporate action.

In some towns, such as London or Bologna, a civil organization based on a geographical division into wards or quarters existed in potential conflict with the alternative divisions by occupation or wealth. Associations of craftsmen and retailers formed themselves in guilds that had many objects beyond the commercial. Among the earliest known forms of such guilds were those of prayer; and many guilds had their own chaplains, churches, and such distinctive religious pageants as the cycles of plays performed by the various mysteries (or crafts) at Wakefield in England. Many also maintained a form of insurance for their members, for the old, and for the widows. But all came to be devoted largely to the regulation of their crafts—especially entry to them—and to the struggle for their interests against the competing ones of their suppliers or of related trades. The interests of the masters of these crafts were often opposed to those of the greater merchants, thus producing a struggle for control of the machinery of town government. Equally, however, other divisions cut across this classification by trades. Within the guilds there was a struggle between masters and men, between those anxious to reduce competition and those bent on a larger independence. Occasionally, and most strikingly in the industrial towns of Flanders in the 13th and 14th centuries, this produced proletarian risings of wide impact; at Courtrai in 1302 an army largely drawn from the Blue-nails, the hired dye workers, inflicted a defeat upon the forces of the King of France and the Count of Flanders; frequently, the larger Flemish towns acted to free themselves from the power of the count or to maintain their communications with the English wool trade against the pressures of France.

Struggles for the control of town government

Though an urban proletariat of this kind was rare in medieval Europe, conflict between an urban oligarchy of landowners or great merchants (the *popolo grasso* of Italy) and the lesser craftsmen and labourers (the *popolo minuto*) was extremely common; it was at its fiercest where the cities enjoyed great autonomy, especially in Italy, where there was no effective or extensive central authority to maintain order. Hence, there were frequent civil wars in the Lombard towns, complicated by their external relations with each other, with the papacy, and with the empire; and there was a wide variety of forms of communal government, ranging from such attempts at radical democracy as the rising of the Ciompi of Florence in 1378 to an increasingly dominant model of dictatorship, such as that exercised by the Malatesta of Rimini, the Visconti of Milan, or even the Medici of Florence.

The independence of the Italian city-states, which was complete by the end of the 14th century, had rested in part upon the successes of the Lombard League against the empire in the late 12th century. North of the Alps, particularly in Germany and the German-settled lands of the east, towns established similar but rather more restricted liberties against the greater princes and formed into leagues of economic communal interest, of which the most notable was the Hanseatic League of Baltic towns, which secured a near monopoly of the profitable northern trade in timber, furs, wax, and amber. First clearly organized in the late 13th century, by the 14th the league was the dominant commercial force in northern Europe. In alliance with the Teutonic Knights and by an aggressive policy of embargo and blockade, it secured privileges superior even to those of the native merchants in Russia, Sweden, Norway, England, and Flanders. Only in the later 15th century did the league begin to decline, with the failure of the Knights, the increasing commercial ac-

tivity of the western kingdoms, and the decline of the Baltic herring fisheries.

Urban independence on the Lombard or Hanseatic model was exceptional, however; in France, Spain, parts of Germany, and England the towns remained firmly within the framework of royal or princely government, not least because only the king could be relied upon to maintain political and fiscal stability at home and to negotiate commercial privileges abroad. Contingents from the towns formed a numerically formidable element in the royal army at Bouvines (1214), when Philip Augustus defeated a combination of Norman, Flemish, and imperial forces aiming to restore the earlier independence of some of the greater vassals. The protection of merchants had been a duty to which 11th-century popes had recalled kings; it was the financial support of the towns that was of importance in the triumph of the "new monarchies" of 15th-century France, Spain, and Tudor England.

Protection of merchants

FORMS OF LORDSHIP

Upon these economic structures there rested a variety of structures of lordship. The earliest that can be discerned in the centuries after the migrations were extremely complex, being functions of a power that was at once one of property, of kinship, of public function, and even sometimes of priesthood; only in the course of the later medieval period did these elements of authority come to be distinguished and sometimes divided.

Serfs. The economic bases of lordship in its least complex form lay in the ownership of men: the large household of slaves was the lord's property, and they worked his land. They enjoyed no rights against their lord, and he was responsible for maintaining peace and regulating their duties; such households of slaves became rare quite early over most of Europe. Domestic slavery was still an active force in the Iberian peninsula and Southern Italy at the end of the Middle Ages, though only in Sicily and the Balearic Islands were slaves widely engaged in large-scale agriculture. The responsibility of the lord for his own domestic servants remained near absolute, the successors of many household slaves were the serfs who settled on small plots of land; the descendants of other freer men were reduced to a similar status by poverty, war, the burdens of public taxation or even by the justice of the church. Like the Roman slave, the medieval serf had no public rights against his lord; he was *adscriptus glebae*

—so bound to his land that he could not leave it, and a part of its stock to be sold with it. The lord, by virtue of holding the land, was responsible for all police jurisdiction over his unfree men in his own court. His serfs were unable to marry without the lord's consent; in theory, their goods were his to tax at will during their lifetime and to confiscate at their death; their children were born into serfdom; and in all disputes there was no appeal from the lord to any higher tribunal.

Practice diverged at least in part from this grim theory. The agricultural cycle in which these serfs lived was conservative and complex, and custom operated powerfully to maintain it. Correspondingly, the disputes of tenants with each other and with the lord were regulated essentially by local custom, which was proclaimed by the body of the tenants in the lord's court. The rights of the lord to the labour of his serfs through the year and at the chief seasons of ploughing and harvest were also fixed by custom and were rarely (and slowly) altered except at times of sudden crisis. The rights of the lord to the property of the serf were equally confined, so that the serfs' duties were expressed as the obligation to render produce for the great feasts of the year or to take their grain to the lord's mill, their flour to his ovens, or their grapes to his wine press or to make fixed payments at the marriage of a daughter, a father's death, or entry into a peasant holding, whether by inheritance, marriage, or purchase. Any or all of the other services could be commuted for money payments also, and in western Europe, at least, the function of the lord's court in regulating serf labour on his demesne was becoming obsolete by 1500, though its other functions still had a long future.

The bond between serf and lord

In some parts of Europe the duties of the serfs included services that are less comprehensible; and the very intimate bond between serf and lord might contain elements more accessible to an anthropologist than to an economist or historian. In many cases the autocratic power of the lord was mitigated not merely by force of custom but also by close and frequent personal contact. The plans of early manor houses and castles show no extensive private rooms for the lord's use: he dined with his servants in his great hall, where he meted out justice. There was, until the later Middle Ages, little provision for private gardens for the lord's use; all but very great men could be found working at their own harvest. And feasts in the hall brought together the whole village community.

The lord had need of other services beyond those of his house and arable land; the greater Carolingian estates had even carried their complement of carpenters, smiths, potters, and weavers, free or unfree, as well as the usual haywards, shepherds, and beekeepers. Men personally as unfree as the serf might also undertake more responsible tasks; the *ministeriales*, pre-eminently of Germany, acted not only as bailiffs but even bore arms as knights, though in such cases the dignity of the occupation came ultimately to cancel the defect of birth.

Feudal bonds. Men of free birth were found over all Europe, though in varying numbers, who recognized the authority of a lord for some purposes—holding his land in return for rent or services less servile than those of the villein. Most areas of Scandinavian settlement, much of Saxony, and the Low Countries were marked by numbers of such men, who often pronounced judgments in their lord's court or escorted him through his estates, providing a contingent of men-at-arms in war and rent-paying tenants in peace. Lordship of this kind stemmed directly from the ownership both of land and of some of its tenants; the profits of lordship were, however, drawn from much wider sources than the labour of serfs or the rents of free tenants. Either by grant or by usurpation, a great variety of forms of indirect taxation were open to the lord. The levy of tolls on rivers, bridges, or roads was perhaps the easiest source of revenue open to any man; a license to hold a market in a vill would not be sufficient in itself but also involved payments for the holding of stalls and even a tax on individual transactions. Very great men might even mint their own coinage; consequently, the currencies of France, Germany, and Italy were extremely fragmented and often unstable.

The most distinctive form of medieval lordship, however, was that which is often called feudal, from the Latin *feudum*, meaning "fief," which was its central feature. In essence this was a fusion of the earlier *precaria*, a grant of land made for a fixed term in exchange for services or rents, with the very general commendation by which a man placed himself under a lord's protection by becoming his man or vassal. Some of those who had served their lord well would receive from him a benefice of land or revenue as a reward; others in dire need of protection would surrender their own land to the lord to receive it back as a benefice from him. When the tenant's right to his land became hereditary and his tenancy, or fief, ceased to be a reward for past services and became the reason for services to be performed in the future, feudal tenure was fully developed. These processes can already be traced before the end of the 9th century in the Carolingian Empire.

Lord and vassal. By the 12th century such tenure was to be found throughout Latin Europe. It was characterized by a number of symbolic acts. The first was homage, the process by which the man knelt and placed his hands between those of his lord, so putting himself at the lord's disposal and under his protection. The next was the oath of fidelity, sworn by the man to his lord, sometimes sealed with a kiss. Then came investiture, by which the lord handed over some token of the fief to his new man. This sequence was first fully described in the year 1127, but its various elements can be traced or inferred very much earlier, though they were not all necessarily found together. The bond so created was much more than a form of land tenure; it was first a human relationship, in which the lord assumed many of the rights and duties of a father and from which the man could escape only if the lord directly attacked his life or family. If the lord died leaving a child as heir, it was the duty of the tenants to maintain the heir's rights until he came of age; similarly, if a tenant died leaving children under age, their wardship was the lord's. Not the least of the man's obligations might be that of attending the lord at the great feasts of the year, which were at once parties, parliaments, and law courts.

Creation of feudal bond

Duties and rights. The duties of the lord to the tenant were usually only generally stated; he was bound to protect his man in war and peace, in the field, and in the law court. Carolingian legislation sought to ensure that every man had a lord to answer for him; a lordless man was a man in danger himself and a danger to others. The duties of the man to his lord varied enormously. Sometimes, even very early, the terms of his tenure were minutely defined. More often the general phrases of aid and counsel were called on to cover every possibility. As in the case of the servile tenant of the vill however, a general subordination to the lord first became fixed by custom and then often commuted into a money rent. The aid the man owed was primarily military aid, essentially service with the full equipment of a knight—lance, sword, helmet, mail hauberk, and powerful horse. A great man's household usually contained a permanent body of these knights, who were often landless young men of good birth but no fortune; but the obligations of the enfeoffed knights living in the estates they held of their lords were early restrained, by custom at least, to a period of service in the field of 40–60 days and sometimes a limited period of garrison duty or castle guard at the lord's fortress. Not all personal aid, however, was military: there were also the sergeanties—fiefs held on condition of performing other services. These ranged from fulfilling the highest offices in the lord's household, such as steward, constable, or marshal (or even jester), to picturesque or purely honorific obligations, such as providing the lord with an annual goshawk, a leash of hounds, or a pair of gloves. All such services might come to be commuted for money payments; by 1200 it was common for the bulk of the knights liable for royal and even magnate service to settle their obligations by the payment of sums of scutage (literally shield money). Because, by then, service was seen as a burden on land and because this land might be in the hands of a church, a minor, or a woman or might be

Payment of scutage

divided up among many heirs, such payments were a convenience to the tenant. The campaigning season and the high costs of a changing pattern of warfare often made money payment just as attractive to the lord.

Sometimes the lord might need financial aid for less strictly military reasons; again, custom came to distinguish the aids that he could levy from his tenants by right from those extraordinary ones for which the tenant's consent had to be sought. Practice varied, but the four most frequent were the knighting of his eldest son, the marriage of his eldest daughter, his setting out on crusade, or the ransom of his body.

Although in all these cases custom tended to establish the tenants' right in their land, there were three important traces of the lord's continued interest in what his ancestors had once granted: the relief, payable by an heir on entering into his inheritance; escheat, by which the lord recovered control of a tenure for which no direct heir could be found; and forfeit in the case of a tenant's treason or failure to perform his duties. The financial exploitation of these incidents of tenure and of the rights of wardship and marriage was among the most widespread of grievances against kings and great magnates in the 13th and 14th centuries.

The counsel that a tenant owed his lord also acquired a formal sense. By virtue of having tenants, a lord had an honour court, where disputes between tenants or between lord and tenant were heard. The tenant's duty to attend (to perform his suit of court) was of the greatest importance to the lord: it was the number and dignity of the suitors to his court that gave its judgments authority and stability. Around this central institution of the lord's court grew up in the greater honours much of the apparatus of a sovereign state. The greater officers of the lord's household, most notably the steward, or seneschal, played an active part in overseeing the lord's estates, and in the later Middle Ages they often formed a council with regular sessions to audit the accounts of their lord's estates and developed their own code of legal precedents. In the 13th century, treatises upon the customs of such tenurial courts appeared in considerable numbers side by side with studies in Roman or royal government (the *Sachsenspiegel* in Germany or the work of Beaumanoir in France may serve as examples). Only their homage to the king or emperor, with a variable liability to be summoned to his court, distinguished the greater magnates of France or Germany from sovereign princes.

Hierarchy of lordships

Theoretically, society could be conceived as a hierarchy of such lordships, with the sovereign at its head; but the practice was usually very different. In Germany the obligations of vassalage long retained traces of their servile origins, so that great men assumed them only with reluctance. It was correspondingly rare for a man to be the vassal of more than one lord; hence, a hierarchy of homages could appear in the late-12th-century *Heerschild* (a formal definition of social standing according to the number of intermediate lords between a man and the emperor) with the emperor at its head, the greater churches beneath him, then the imperial princes, who had done homage only to the emperor or the church, then counts, then noblemen, and so on. Even here, however, the consent of the other princes (the *Reichsfürstenstand*) was necessary for admission to the highest ranks, and the obligations such homage entailed were relatively very slight. Elsewhere—in France particularly—homage to more than one lord was frequent (the county of Champagne was held of 10 different lords), so that no such organizing principle could operate. What determined the permanence and vitality of tenurial networks was in part political and military circumstance, in part the extent to which some higher authority was able to intervene between lord and vassal, and in part the extent to which this lordship over men or tenants was able to absorb earlier administrative or public authority.

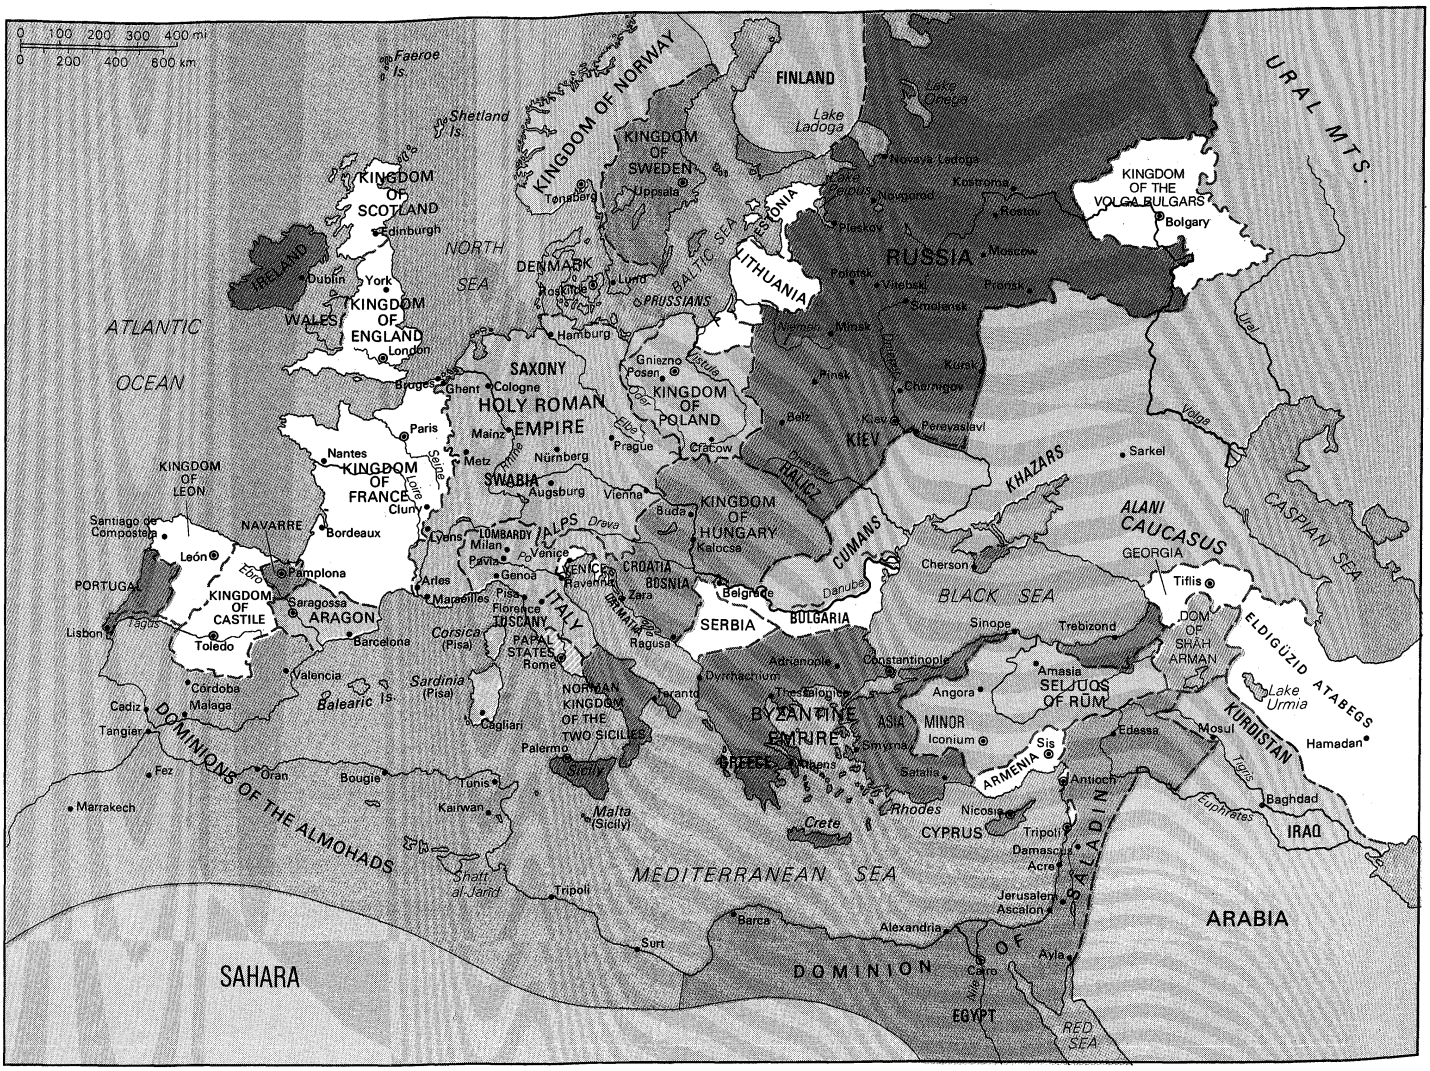
Acquisition of public authority. Some scholars have held that this passing of public authority into the domain of private right was the most essential and characteristic element of a feudal society; it was certainly extremely widespread. In the 9th century there existed two types of local government that might be described as public: first, the residual Roman institutions of Gaul and Italy, with such modifications as the Carolingians had introduced, and, second, the public assemblies in which Germanic and Scandinavian societies had long been accustomed to do justice. In practice, these institutions had largely fused in the period since the barbarian invasions, so that the bulk of Latin Europe could be divided up into *pagi* (German *Gauen*) roughly comparable to an English shire in size and function, each presided over by a count (*comes*, *compte*, or *Graf*) who was the king's representative, most notably at the local court (the *mallus* or *thing*). To this court all free men brought their disputes, the later distinction between civil and criminal justice being as yet unknown. The law of the court might derive from tribal custom, as it had been preserved in either such laws as the Salic, Ripuarian, Burgundian, and Bavarian codes or the collective memory, or, further south, it might be in the Vulgar Roman Law. In any case, it was the suitors of the court who determined the procedure and prescribed the appropriate forms of proof, such as the swearing of solemn oaths in special form, the undergoing of an ordeal (carrying a red-hot iron a prescribed distance, being plunged into cold water, holding a hand in boiling water), trial by battle, or, exceptionally, the scrutiny of sworn or even written evidence. All but the last of these were means of securing God's direct judgment rather than a merely human decision, but every preliminary step was determined by the court and particularly by a group of men learned in the law—*scabini*, *échevins*, *lagamen*, or *Rachinburgen*. Only in the 13th century, when the ordeal was condemned by the church and largely abandoned by the laity in favour of sworn and written evidence, did these lawmen give way to lawyers with special training.

The *pagus*, like the shire, was a military and financial unit as well as a legal one: it was presided over by a count whose responsibility it was to assess revenues, summon warriors for the royal army, and maintain the peace. To assist him in this task, lands were attached to his office, but he was also encouraged to secure the allegiance of the leading men of his *pagus*. In this way, to his authority as a royal representative he added his personal claims over the *castellani*, lords of the principal fortresses of the district whose military importance often allowed them to assume the direction of such subdivisions of the *pagus* as the *centena*, hundred, or wapentake. These, similar in procedure and competence to the courts of the *pagus* or shire, were early and generally in private hands; some may have been from their inception.

Fragmentation of authority

In the widespread fragmentation of authority of the 10th and 11th centuries, the offices of count and castellan became hereditary over most of Europe, so that it was often no longer possible to distinguish the authority of the count from that of the lord or the suitor of the *mallus* from the vassal of the count. Under such conditions, the jurisdiction and procedure of the public court merged with that of the court of vassals. Meanwhile, jurisdiction in the county, having become attached to property, could also be divided; and thus it often passed into the hands of lesser men who held it of the count as absolutely as he held his from the crown. Within the county there now existed liberties, or franchises, islands within which more or less of the count's justice was in the hands of a local lord and from which the count's agents were excluded. The greatest holders of franchises were the churches; the abbot or bishop's advocate exercised a near absolute secular authority that made such offices one of the greatest prizes of magnate competition. While some of these franchises were larger than counties or even extended over several, at the opposite end of the scale, all public authority over an area no larger than a vineyard might pass into the hands of a local knight subject to no restraints except those involved in his homage to a lord.

While the fiscal, legal, and military unity of the county either disintegrated or was reconstituted along the frontiers of a count's personal honour rather than earlier administrative or tribal divisions, there also appeared between the count and the king a number of intermediaries —dukes, marquises, or counts—holding several counties.



Europe and the Mediterranean about 1190.

From W. Shepherd, *Historical Atlas*, Harper & Row, Publishers (Barnes & Noble Books), New York; revision copyright © 1964 by Barnes & Noble, Inc.

In origin, the duchies and margravates of the 10th and 11th centuries had been military commands, conferring on their holders only those rights over the counties of their area that were required by the pressing needs of defense; between the 10th and 13th centuries, these intermediaries fought a desperate battle against their sovereigns, on the one hand, and their neighbouring counts, on the other, to make this military authority (often over a former tribal district) into a more or less universal and exclusive jurisdiction. The results were extremely uneven: some of the German duchies that emerged from the civil wars of the 12th and 13th centuries were coherent units, though they were smaller than their predecessors; the duchy of Normandy was a tightly organized unit until it passed to the French crown under Philip II Augustus in 1202–04; but the dukes of Aquitaine and Burgundy had only a tenuous and formal hold on their outlying vassals.

New forms of warfare. The growth of such lordships had originally owed much to military considerations. The decline of the popular courts and public jurisdiction had been accompanied by the appearance of innumerable private fortresses, often little more than a wooden stockade upon an earth mound (the motte) with a larger enclosure at its foot for stock and dependents (the bailey). These proliferated in the Loire-Rhine triangle in the 10th and 11th centuries, though they did not spread widely in England or Germany before 1100. These fortresses were as important to defensive warfare as the mail-clad rider was coming to be in offense, for the possession of such strong points was a protection against all but the most formal and deliberate assault, which few commanders could keep a force in being long enough to conduct. In the 12th century the increasing number of stone-built castles, a more widespread use of paid troops, and the evolution of improved methods of siege warfare (some perhaps learned from the Muslims and Byzantines during the Crusades) altered the terms of warfare. Successful offense and defense required greater expertise and more extensive resources; correspondingly, the units of military independence tended to be much larger. The early motte and bailey castles could probably be thrown up in a matter of days, certainly weeks, and could be cast down yet more rapidly; but Château-Gaillard, built by Richard I of England to protect Normandy from attack along the Seine valley, took years to build and cost more than three times the whole annual revenue of the duchy: it was still capable of resisting prolonged formal siege with artillery four centuries later. In the 12th and 13th centuries, series of these defenses were being put up by such princes as Frederick II in Sicily or Sancho I in Portugal, but by the 15th century, gunpowder and engineering expertise were making such combinations of fortress and dwelling obsolete.

Private fortresses

A parallel development began to affect mounted warfare around 1200. Although chain mail was expensive, it was far less so than the combinations of plate and mail (or finally plate alone) that appeared in the later Middle Ages; similarly, the horses needed to carry this heavier equipment were scarce and exceedingly costly. The fully armed knight of 1300 was a more formidable figure than his predecessor of 1100, but he was a rarer, a more expensive, and a more limited commodity. The word knight had once meant farm worker; in the 11th century it meant

a mounted and well-equipped soldier, though by no means necessarily one of high social standing. By the 14th century, it was a term for an aristocratic elite, with its own elaborate ethic of love and war. The orders of knighthood founded in the 14th century by kings for their greater nobles and most eminent captains—such as the Order of the Garter established by Edward III or the later Order of the Golden Fleece founded by Philip the Good of Burgundy—reveal the extent to which the forms of chivalry were embraced by the whole range of the aristocracy.

Decreasing military importance of knights

At the same time, however, the military importance of the knight was reduced by the appearance of the more lightly armed men-at-arms or sergeants, and a trained infantry of pikemen and archers—crossbowmen, among whom the Genoese mercenaries excelled, and the longbowmen of English armies in Wales, Scotland, and France. The knights, with their prohibitive cost, increasing vulnerability, and declining flexibility, were becoming obsolete just at the time the ceremonial of knighthood was being most fully developed. The new armies of the 15th century were largely professional; they contained a high proportion of trained and well-armed infantry, which could be kept in the field for a whole campaigning season. The maintenance of such forces, with their extensive infrastructure of transport, victualling, and engineering, strained even the resources of a kingdom, and over most of Europe the near independent lordships of the great princes failed to survive. There were many great, rich, and privileged magnates in 16th-century Europe, but only in parts of Germany and Italy did they retain a complete local autonomy. It was rather by their influence on central government than their independence of it that they maintained political importance. By the 16th century, for the first time since the Roman Empire, centralized public authority covered much of Europe, though now within the frontiers of the national state.

CHURCH GOVERNMENT

Parallel with this structure of secular lordship stood that of the church, in which the opposing tendencies of central authority stemming from a single source and the collective authority of the community existed in a similar tension as in the court of a lord's vassals or in later royal councils.

The papacy. At the head of this church stood the papacy in Rome; after a long struggle with the German emperors of the 11th and 12th centuries, the political and formal independence of the papacy was ensured. After 1059 the popes were elected by the chapter, later called the College of Cardinals according to a carefully defined procedure. The intervention of all lay authority in papal elections was expressly excluded in the revised electoral decree of 1060, and that of 1179 provided for a strict majority principle in all papal elections; two thirds of votes made and still make a pope. Once elected, the pope possessed a widespread and unique authority: he was the final source of appeal; the only source of authoritative pronouncements upon dogma and doubtful points of canon law; the necessary source of the authority to make substantial change in the structure of the local churches, such as the founding of new bishoprics, or the transfer of bishops from one see to another. From the time of the exile at Avignon (1309–77) onward, it was normally the pope who provided, by his own authority, for every bishopric in Latin Christendom, and by a variety of channels he also disposed of a very substantial patronage in lesser dignities.

Growth of papal bureaucracy

Around the pope, conducting an ever-increasing volume of business, there grew up all the institutions of a centralized monarchy. The cardinals, chosen by the pope alone formed the papal council, or the consistory. The 12th, 13th, and 14th centuries saw the rise of specialized departments to deal with legal matters, matters of penance, and finance (the Apostolic Camera); and, most important of all, it saw the rise of an elaborate chancery to direct the issue of the various forms of papal documents (known as bulls from the use of the *bulla,* a leaden seal used to authenticate many of them). A papal chancery had existed from very early times, but the enormous volume of papal business, most of which was necessarily done in writing, gave the forms of the chancery in the later Middle Ages an exceptional importance—even in the shaping of papal policy.

Papal bulls not only contained decisions in legal disputes, valuable privileges for some churches, and the pope's diplomatic and pastoral correspondence; they were also a source of law, to be collected, studied, and compared by the canon lawyers with the writings of the early Fathers and the decisions of early church councils. The earliest centre for the systematic study of canon law was Bologna, but its influence was spread throughout Christendom. The early materials of canon law were the foundation of the reforming work of the papacy between 1050 and 1150; from then on, the rise of canonical science required a steady expansion of the active participation of the papacy in the everyday work of the church. By the 14th century the papal court was attended by an army of proctors who represented the prince and many of the greater churches, so constant was traffic with Rome.

The means of papal action beyond the immediate neighbourhood of Rome were provided by legates, either resident or specially commissioned, who enjoyed most of the sovereign authority of their master to hold councils, legislate, and punish. The penalties of disobedience were excommunication (cutting off specific individuals from all human contact with the Christian community), interdict (the suspension of all the sacramental functions of the church—usually directed against an entire community or state), or, against princes, the launching of military expeditions with a papal blessing. The religious orders directly under papal protection, particularly the friars, provided a means of action and an intelligence service to set beside that provided by the reports of the collectors of papal taxes, often Italian merchants, and by the Inquisition. Founded in the early 13th century for the detection and extirpation of heresy, this institution was presided over by inquisitors drawn from the Dominican and Franciscan orders, but they answered directly to the pope and possessed an extensive staff of men outside the orders.

The bishops. The local organization of the church depended essentially upon the bishops, grouped under an archbishop or metropolitan. The archbishop received a special vestment, a pallium, from Rome as a token of his authority; he was specially charged with the consecration of the bishops of his diocese; he might hold provincial councils or even visit bishoprics to examine their administration; on occasions he could hear appeals from a bishop or take disciplinary action against one. In general, however, his authority suffered from being squeezed between that of the bishop and Rome; the same was even more true of those archbishops who claimed to be primates (*i.e.*, to enjoy the obedience of other archbishops).

The bishops' administration

The bishop, originally elected in theory by the clergy and people of his diocese, was, in practice, appointed by some kind of compromise between the claims of the secular lord of the area, of the clergy of the cathedral church, and of Rome. By the 13th century most bishops possessed a central administration consisting of several offices: a specialized court for dealing with church affairs; a chancellor who kept the bishop's seal by which his formal acts were authenticated and under whose supervision the registers containing copies of these were maintained; a treasury for collecting the revenues—both from his estates and from more specifically ecclesiastical dues, such as a proportion of the tithes of the faithful or charges arising out of the ordinary exercise of his office. All these offices were staffed from the clerks of his household, increasingly to be distinguished from the chapter of beneficed canons, headed by a dean, who served the cathedral church. Although these canons were originally the bishop's household, by the 13th century they formed a compact corporation, sharing the revenues of the diocese with their bishop but often not appointed by him or subject to his strict control.

Within the diocese the bishop had wide responsibilities: he alone could ordain clergy, consecrate churches, receive children into full membership of the church at confirmation, or impose penances for the graver sins. No one

could teach or preach in the diocese without his permission, and he alone could admit novices to religious vows or bless the heads of religious houses. All judicial authority in the diocese was exercised by him either in person or through deputies, and without his sacraments the liturgical life would cease. In a more positive sense, he would teach and regulate the whole diocese as well as act as guardian of all church property, which could neither be received nor given away without his consent.

Some of these duties he could perform in person or, in case of absence, through a regent or vicar general. He could proceed through his diocese, visiting it parish by parish to scrutinize the conduct of clergy and people. He could summon the clergy (and some of the laity) to a synod once or twice annually; there judicial and disciplinary business was also done quite often between the 9th and 12th centuries, though later it was more an occasion for the publication of injunctions either of the bishop's own choice or drawn from recent provincial or papal pronouncements. Some bishops were diligent preachers, particularly to their clergy, and most performed works of charity in the feeding of the poor and the maintenance of hospitals and almshouses.

Much work necessarily remained in the hands of agents. Of these, the chief were the archdeacons, sometimes called the "bishop's eyes" since their duties were essentially disciplinary. Like the bishops, they made visitations throughout their archdeaconries and held courts to which they summoned both delinquent clergy and lay offenders against the comprehensive regulations of the church in marriage, usury, wills, heresy, blasphemy, and the observance of feast days. Their arbitrary procedures and frequent assessment of fines made them widely feared and resented. Most archdeaconries were subdivided into districts presided over by archpriests or rural deans, usually chosen from among the parochial clergy.

Archdeacons

Parish organization. The chief centres of the devotional life of the medieval church were parish churches served by a priest and a variable number of assistants. The priest was normally appointed by the bishop on the presentation of an influential lay patron. The archdeacon was supposed to examine each candidate's suitability, but the surviving records of visitations do not suggest that the task was often performed conscientiously. The parish was maintained out of the land attached to the church (the glebe) and the revenues from the faithful. From the 9th century the payment of tithes, a tenth of the annual proceeds of agriculture and trade, had been obligatory on Christians; although many tithes passed to religious corporations or vanished into the hands of unscrupulous collectors, they remained the largest single element of many parochial revenues.

The parish clergy were principally charged with the salvation of their parishioners; this was to be achieved by the regular administration of the sacraments, baptism, mass, and, above all, the last rites. The priest was also expected to offer an example of good living, expound the basic precepts of the Apostles' Creed and Lord's Prayer, promote concord among his parishioners, admonish sinners, and denounce grave offenders to his archdeacon or bishop. Since the priest was often the only man able to read or write in his community, he would often have to act as an elementary teacher and village notary. At a time when the houses of the peasantry and even most manor houses were modest wooden structures, with slight and crude decoration, the parish church was a striking contrast, an elaborate stone building with walls bearing paintings of the gospel narrative and the Last Judgment and with vestments and church ornaments of considerable splendour. As the building dominated the settlement, so the feasts of the church provided a rhythm of ritual and recreation that in part supplemented, in part reinforced that imposed by the seasons of the agricultural year. Yet there is abundant later medieval evidence to show how widely the older pagan cults survived under a thin veneer of orthodoxy.

The regular clergy. Beside this hierarchy of the secular church stood the regular clergy. The earliest widespread communities of monks had been in theory strictly subordinate to their bishop. In practice, however, widespread recognition of the monastic life as the pattern of religious excellence, the active missionary work of such monks as St. Columban and St. Boniface, and the favour of great families gave the monasteries a position of substantial privilege. In lands under Irish influence, the authority (as opposed to the sacramental power) elsewhere exercised by the bishop was often held by an abbot; but much more widely the greater monasteries enjoyed a large immunity from episcopal influence. In the 11th century and later, such houses—led by Cluny—placed themselves directly under the protection of Rome as a means of excluding the bishop's authority; and for the rest of the Middle Ages, quarrels over the bishop's right to secure an oath of obedience from the abbot, to visit the monastery to scrutinize its observance, and to exercise his office over the numerous churches and clergy attached to such abbeys were almost commonplace. Parallel to the growth of such conflicts was the rise of congregations of regulars, in which houses of a common observance, such as those of Citeaux, Hirsau, or Prémontré, were organized in a hierarchy that allowed the order itself to discipline and correct its members, to legislate for the whole congregation, and to ensure a common rule of life among its far-flung membership. After 1215 all the Benedictine houses not involved in such arrangements were required to organize themselves into local general chapters, though the tradition of autonomy made such provisions unevenly effective. The way of life of the friars, with their dispersed and itinerent congregations, involved a more complex organization modelled upon that provided by St. Dominic in 1216. Under Dominic's organization, the order was divided and subdivided into provinces, ruled by masters, and chapters; elaborate regulations provided for the election of masters and legislation for the order was promulgated in assemblies of elected representatives. Most of these features were taken over by the Franciscans before the end of the 13th century. Relations with the hierarchy of the secular church were sometimes strained because the friars were under the direct protection of Rome and enjoyed a correspondingly extensive, though much contested, immunity from episcopal jurisdiction. In this way, many of the religious orders were involved in a hierarchical system of centralized dependence parallel to that of the secular church; and in some respects they were more responsive to the needs of Rome than were the bishops. Certainly, the religious orders were widely regarded as less identified with ecclesiastical nationalism as pursued in the 13th and 14th centuries.

Direct protection of Rome

Church councils. Although ecclesiastical authority, even in the orders, was exercised on a largely monarchical pattern, the church also contained important elements of corporate authority; it was by definition a society in which there was a distinction of offices but not of persons. The earliest genuine law of the church was substantially contained in the decrees of the ecumenical councils of the 4th and 5th centuries; and such gatherings continued to be held in the East, though their authority was not accepted in the West. After the formal ending of the investiture contest, Pope Calixtus II summoned the First Lateran Council of 1123, claimed as the ninth ecumenical or universal council of the church and the first to be held in the West. The legislation of this and its successors (the last being that of Vienne in 1311–12) was given very wide currency, although according to the general opinion of canonists it was of no greater binding force than the decrees of the pope alone. In the 14th century, opponents of papal authority, such as Marsilius of Padua, viewed the pope as an officer of the whole church subject to its control when assembled corporately in a general council. The double election of 1378 and the prolonged schism that followed allowed such theories a wider currency. It was the Council of Constance (1414–18) that ended the schism, but that of Basel (1431–49) introduced another —in part as a consequence of the belief that the pope was subject to the constant surveillance of the council, standing in the same relation to it as an Italian magistrate stood to the city that appointed him. Such corporate doctrine failed because the council became itself less and

The Lateran councils

less representative; the limitations upon central authority that emerged were those imposed by the enlarged rights of secular rulers over the national churches.

The value of councils of bishops to promulgate decrees and pursue reform for a kingdom or province was generally recognized, but their ecclesiastical authority was, in theory, extremely limited. In practice, the legislation of provincial councils and even synods sometimes allowed local customs or variations from the universal law of the church, but this was by way of dispensation. There was no innate legislative authority resident in the members of the church to set aside or counter that of the Universal Church; and the major function of such councils was rather to select, emphasize, or interpret such aspects of the general law as the decisions of the general councils. The purpose of the participation of many bishops was to give these pronouncements immediate weight, to ensure them a wide circulation, and perhaps to encourage a common understanding of their meaning and importance. Councils, however, were sometimes summoned by the king to assert his divine authority over his turbulent subjects, to enforce his policies with the double sanction of the secular and spiritual sword, or to confront the pope with the consensus of local ecclesiastical opinion as a means of putting pressure on him to abandon a policy. Such gatherings, however, rarely claimed to constitute autonomous local churches; and the nationalist claims made on behalf of the French church under Philip IV the Fair or for the English church under Henry VIII rested on the authority of the sovereign in his kingdom, not the corporate sovereignty of a council of the national church.

The universal claims of the papacy, even if practically confined to the Latin obedience, were constantly threatened by the strong secular particularism of Europe's medieval history. Between the 5th and the 12th centuries the gravest danger was one generally subsumed under the term simony—that is, the constant likelihood that ecclesiastical rights would be subordinated to temporal interests and then fragmented, like them, to become merely aspects of private property. The hereditary lay abbots of the 9th century; the parish churches built as financial investments by their founders and bought and sold amid general acquiescence between the 7th and 12th centuries; and a widespread trafficking in offices, never wholly eradicated, all illustrate the gravity of this danger. These abuses were formally abolished and actually much reduced by the reformers of the 11th and 12th centuries, largely by means of a centralized law. Between the 13th century and the Reformation, the danger was that the political and linguistic boundaries within which the new national states were growing up would also divide the church. Against this danger, the traditional weapons of papal authority proved much less effective, and new ones were not forged before the end of the period.

ROYAL GOVERNMENT

The growth of the centralized institutions of predominantly royal government is a phenomenon that was involved with the rise of certain technical skills in the collecting and organizing of information. Until the 13th century there were no maps of great practical value; the statistics occasionally collected by medieval governments were often inconsistent and made according to erratic principles. Until near the end of the period, the usual methods of accounting and bookkeeping precluded most calculations performed by a modern government. It is a notorious defect of medieval chroniclers that the numbers they attribute to populations or even comparatively small armies are almost invariably the purest fantasy. The technology of transport was equally primitive; the best roads in the 15th century were still the Roman imperial streets, for all their thousand years of neglect, and winter flooding still affected most river systems in spite of some large-scale drainage works that had been undertaken in the Netherlands, Italy, and elsewhere. Under such conditions a central government wholly free of "constitutional" restraints would still be obliged to leave its local agents a large measure of independence, and the custom of the neighbourhood was necessarily the chief regulator of political as well as social and economic relations.

The royal household. The seed from which all medieval institutions of central administration were to grow was the immediate personal household of the king; its members were the only permanent staff he had, and only their intimate personal association with their lord was a guarantee to others that they did indeed represent his views and bear his authority. The essential elements of the early royal household therefore provided the framework of the first departments of state.

The chief elements of the royal household were four—the hall, the chamber, the chapel, and the courtyard, with its horses and stables. The whole household, but in particular the hall, which was at once palace, law court, and dining room, was directly governed by the steward (*dapifer, seneschal,* or *drost*), under whose direction the guests were seated and the feasting conducted, while the wine was under the charge of a butler (*pincerna, Oberschenk*). Under the later Merovingians in Gaul, the mayor of the palace (literally chief of the house) became a figure so powerful as first to overshadow and then replace his king; elsewhere, though less powerful, the steward was the usual chief deputy of the king. Under the Capetians of France he was charged with the annual scrutiny of the accounts tendered by the king's local bailiffs, the provosts; in Normandy, Jerusalem, and elsewhere he was the natural choice as regent in his lord's absence; the butler shared some of the prestige of the steward but had yet few defined functions.

Officers of the hall

The chamber, the room in which the king slept or took private counsel, was also the natural place to store his treasure; hence, the chamberlains were often specially charged with the collection of revenue and handing it out as the king had need. The papal treasury was known as the Apostolic Chamber, and the papal chamberlains were widely entrusted with financial missions.

The chamber

The chapel, containing the royal altar and relics (the term chapel derives from the *capella,* the short cloak of Saint Martin preserved among the chief relics of the Carolingian royal treasury), was served by chaplains, to say the daily mass, assisted by a body of clerical assistants. As the chief and sometimes only literate members of the household, these men were responsible for drawing up such documents as the earlier kings required; among their number and often at the head stood the chancellor, whose special task was the authentication of royal acts, usually with the seal, which he kept.

This royal household was constantly on the move, carried on carts or packhorses, and hence the great importance of the last two major household offices, those of the constable and marshal. The duty of the count of the stable (constable) was closely associated with the organization of the army, and hence the term came to be used of commanders of garrisons as well as the central household officer. The office of the marshal was originally more humble but shared the military fortunes of that of constable. In the 14th and 15th centuries constable and marshal came to a new importance as military commanders and correspondingly acquired judicial competence as presidents of the courts of chivalry, which dealt especially with military discipline, the division of ransoms, and the right to bear a coat of arms.

The growth of a permanent bureaucracy. These early household offices, with characteristically unspecialized duties, changed greatly under the impact of two forces. First, these central offices had a tendency to become hereditary, much as the local offices of count or duke had done; since the domestic service of the king, at least on public occasions, was itself a very great dignity, the most powerful families claimed the right to perform it, so that the office came to be the prerogative of great magnates who were too preoccupied elsewhere to perform their duties in person. Even the chancellorship sometimes became attached to certain archbishoprics—Reims or Mainz, for instance; since the king's domestic needs continued, a distinction evolved between the hereditary dignitaries such as high steward or archchancellor and the men of much humbler rank who actually performed the

routine duties of the household. Second, the increasing volume of business done in the king's name—judicial, administrative, or financial—demanded ever more elaborate records and a more extensive staff; therefore, the offices of government were less mobile, and a physical distinction became common between the constantly itinerant household about the king's person and the more cumbrous (though rarely wholly static) departments of permanent officials. Furthermore, the processes of government, especially in the chancery or (particularly well documented) the English exchequer, became arts or mysteries that demanded a staff of financial or legal experts with a specialized training. Thus were born the chief departments of state; well beyond the end of the medieval period, however, their principal officers were still considered the king's servants in a literal sense. This household character of public office made the distinction between loyalty to the king's person and loyalty to the office extremely hard to draw and frustrated many early efforts at "constitutionalism."

The chancery

Of these departments of state, the chancery was perhaps the most essential, for without a means of transmitting a number of recognizably authentic commands or recording the business already done, no large measure of centralized activity was possible. The first sign of the emergence of a chancery proper is the appearance of stereotyped formulas for the drafting of documents, classified according to their purpose. The papal chancery was the earliest office to develop this skill on a large scale; the rhythm of the text and the forms of authentication for papal bulls were already formalized before the mid-12th century. Similar tendencies are found in England in the reign of Henry II, and in France only a little later. (The urban notaries of Italy and parts of southern France were already using formalized business documents, though for a much more restricted area.) The second sign is the appearance of a substantial collection of records; apart from the financial records, dealt with below though often compiled by chancery clerks, the essential element was the keeping of copies of documents issuing from the chancery, distinguished according to their character. Papal registers had probably been kept from a very early date, and a later copy of the Register of Gregory I still survives; an imposing and ever more complex consecutive series of original registers survives from the early 13th century. These were in the form of books. In England, where the great period of initial expansion lay in the period between 1190 and 1216, and in France, where the early royal archives have suffered much graver losses at the hands of time, the characteristic record was a series of parchment membranes stitched together to form long rolls. These archives evolved rapidly through the 13th, 14th, and 15th centuries, with the preservation of many more classes of document, including informal memoranda. Such records served the purposes of both governor and governed, for they provided precedents and the material for the reform and improvement of administration for the king's servants. They also provided authentic copies of title deeds or privileges for a subject at odds with his fellow or even the king himself. The conventions of the chancery had a marked tendency toward autonomy; efforts at magnate control in England or extensive reform of papal administration in Rome were partly frustrated by the elaboration and conservatism of chancery procedures that might at other times offer a useful defense against arbitrary government.

Among the most immobile elements of medieval government were those connected with the collecting and checking of the royal revenue. Until the 13th century, the only coinage current was the silver penny (or denier), so that large sums could only be transported packed in barrels of great weight. It was therefore natural for royal treasuries to appear as places of permanent deposit, from which the itinerant court or army could be supplied at need. Often the treasury would also be the first site of any permanent archives. The rendering of accounts by the sheriffs, provosts, bailiffs, or seneschals who were local collectors of royal revenue was a matter that could not be performed at a wholly itinerant court. Not only was it necessary for auditors and agents to have a known place and time at which to meet, but all except the least sophisticated forms of accounting required the keeping of records of former debts and present liabilities. Under Charlemagne, a *Capitulare de villis* envisaged a wide enquiry into the estates of the emperor, though only fragments of the returns survive; similar surveys were being made in 11th-century France and Germany on a small scale, but no early text can rival the record of Domesday Book (compiled in 1086/87), a survey of almost all of England, shire by shire and fief by fief, drawn up by the clerks of William the Conqueror. It is still preserved among the English public records.

The growth of permanent records

The rise of the exchequer as a semipermanent office and court for the hearing of accounts and the adjudication of financial claims was an early and striking feature of Anglo-Norman government on either side of the Channel. The exchequer took its name from the checkered cloth used by the royal officials as an accounting device. The cloth was used as a kind of abacus and may have owed something to Arabic skill in mathematics transmitted by the Norman settlements of Sicily. Certainly in existence soon after 1100, its first surviving Pipe Roll of 1130 is the earliest record of receipts of its kind for all of medieval Europe. In France the Capetian Kings for more than a century used the Knights Templar as their bankers, so that it was not until after the withdrawal of his treasure from their hands by Philip the Fair in 1295 that a fully independent Chambre des Comptes emerged, with a comprehensive staff of financial experts.

The cumbersome machinery of such financial bodies was a grave impediment in times of political, financial, or military crisis, although as in the case of the chanceries, due process offered some protection against arbitrary government. The frequent wars of the English kings and their long absences in France, as well as their desire to escape the oversight of great officers approved by their magnates, encouraged the appearance of various financial systems within the household to compete with that of the Exchequer; the wardrobe under Edward I, for example, expanded from its original function as the king's domestic treasury to become the organ responsible for the payment of his whole army or, under his descendants, of the chamber itself.

The king's council

As these departments of state became more fixed, professional, and independent, royal councillors who gave a political direction to the government acquired a distinct existence. From the beginning, the king's household had been of shifting composition, and a number of men enjoying his special confidence were often to be found there even if they were not holding household office. In the early 13th century the king's more or less permanent advisers began to take on a more formal character as the king's council. This council, often given definition by the taking of a common oath, was as omnicompetent as the king it served, and correspondingly, in times of political crisis, magnates or great assemblies sought to impose their nominees—as in England in the crisis of 1258–65 or France in 1356–57 or Aragon under Alfonso III. The direct and personal nature of the council's functions made such efforts almost always abortive. Only in Scandinavia, where the union of the three crowns involved prolonged regencies and uncertainties of succession, did the Råd enjoy a large independence from its king, though many German princes of the 14th and 15th centuries were compelled by their estates to accept a nominated council. In the 15th century the powers of last resort possessed by the king and exercised in consultation with his council allowed the formation of offshoots of this council as prerogative courts of justice, administration, and finance.

Birth of parliamentary bodies. Over the same period, the larger assemblies in which some royal action had long taken place were also taking on a clearer form and defined functions, issuing in the assemblies of estates to be found over most of Europe in the 15th century. Three distinct influences lay at the origin of this development—ancient custom, feudal law, and administrative convenience. The Germanic tribes described by the Roman his-

torian Tacitus in the 1st century AD gathered regularly in arms to determine matters of general importance. In some respects it was the size of such gatherings that decided the size of the kingdoms to which they elected chieftains; such gatherings of the warriors continued well into the period of Frankish rule, even in those areas where the powers of the king were very great. In Scandinavia meetings of the *thing* never wholly passed into the power of magnates or royal officials, though elsewhere they changed radically.

As the old *mallus* or *thing*, with its lawgivers and its president, had become the court of an hereditary count and his vassals, so the assembly of freemen was widely altered in the same way. To the king's great courts his chief tenants were summoned by virtue of their obligation to give their lord counsel; the number of those who came was the critical test of the king's authority. The decline of French royal power in the 10th and 11th centuries or of German kingship in the 11th and 12th centuries can be plotted on maps by examining the composition of their great courts, especially at the chief feasts of the Christian year (or at principal landmarks in the life of the royal family, such as marriages and the knighting of the eldest son).

Since these large sessions of the tenants were also the most solemn courts a king could hold, great issues would be brought to it; since they were usually held at known times and places, those who desired the king's help in securing justice would seek them out. There were, however, further reasons why the king should try to enlarge the attendance at his courts or councils; the bonds of land tenure in most of Europe before 1300 had long ceased to articulate all the elements of society. To regulate the affairs of merchants, for instance, the feudal bond was worthless to secure counsel or consent. More important still, the obligations of feudal tenure no longer provided the forms of taxation needed for the defense of the state, and whatever methods of raising money supplemented them required the consent of the community in a new sense. The princes of the late 13th century claimed to be lords of states, not merely of associations of men; in their conflicts with the papacy, in their assertion of legislative authority, in their claims to the financial support of the whole community, kings required a very general assent. Unless qualified representatives could be gathered, the king's will could not be known or the justification of changes publicized; the rise of the representative assembly is parallel to the rise of royal propaganda.

Representative institutions

In the 13th and 14th centuries these considerations produced a variety of experiments. In France after 1300, two meetings of the estates of magnates, churchmen, and burgesses were held often: one for the provinces of northern France (Languedoil), another for culturally different provinces of the south (Languedoc). Provincial gatherings of this kind were naturally prevalent in the states of Germany, where the dynastic disputes and poverty of many of the princes made them peculiarly subject to the pressures of their estates of knights, burgesses, and clergy; the imperial Reichstag, attended theoretically by the tenants in chief (chief vassals) of the emperor and representatives of the imperial towns, was intended to cover the whole of Germany but was as powerless as its central authority. In the kingdoms of Spain, signs of development appeared very early, representatives of the towns being summoned in 1188 in Leon; by the mid-13th century, the presence of townsmen in representative assemblies was customary throughout the country. In Aragon magnates and knights were separate elements, but elsewhere the more usual pattern of the three estates of nobles, churchmen, and burgesses prevailed. The English gatherings to which the term parliament came increasingly to be applied differed in important respects. From early in the 13th century, the king had summoned his tenants in chief to meet at the same time the central courts of justice and finance were in session; thus, royal officers, innumerable representatives of the shires and boroughs, and the magnates were gathering at one time. By the end of the 13th century, it was becoming common for special representatives to be summoned from the shires and the boroughs to attend these parliaments; by the mid-14th century, their attendance had become the rule, but the clergy had largely withdrawn, except for the great ecclesiastical magnates who sat with the temporal lords, while the knights of the shire and the burgesses of the towns met together as a single body. Hence, there emerged a quite exceptional body with two chambers and a permanent representation of the non-noble landowners to contrast with the much more widespread model of the three estates.

English Parliament

The business undertaken by these gatherings was extremely various. For reasons essentially of convenience, it was customary to publish legislation at such assemblies, as church councils had done for centuries. In Aragon and Catalonia, Scandinavia and much of Germany, the consent of the assembly was required to legitimize such enactments; custom produced much the same effect in England, and the Aragonese kings of Sicily (who replaced the Angevins there during the War of the Sicilian Vespers, 1282–1302) proclaimed the same principle. Yet more frequently they were assembled to assent to taxation, sometimes, though never wholly, saving the prince the difficulty of negotiating with each town or community for a contribution to the common need; they continued to constitute also the most weighty public court for the hearing of great causes. Though summoned essentially to consent to decisions made by the king and his inner council, such assemblies necessarily possessed a potential power to refuse or demand a precedent redress of grievances; and as the powers of central government became greater, efforts to impose restraints on the prince in the name of the community became more widespread. Such restraints had long been recognized in theory, but the rise of these larger assemblies provided a focus for such claims that was more effective than the earlier courts of feudal tenants. Precocious efforts to subordinate royal government to the scrutiny of the magnates in Parliament, and even to require general assent to the appointment of officers of state, occurred in England between 1258 and 1265 and continued with some formal success in the 14th and 15th centuries. It was a successful struggle in the 14th century to require parliamentary consent to all extraordinary taxation that ensured the regular summons of such gatherings and made possible their use as an occasional forum of political discontent or even revolution, as in the reign of Richard II.

The States General in France made similar efforts at political control of the kingship in the crises associated with the capture of King John, between 1356 and 1358 and again in 1413. The Cortes of Spain secured an even larger measure of success; in 1287 the magnates extracted from Alfonso III of Aragon the Privilegio de la Unión, which conferred upon the Cortes even the power to depose an unjust king; here, too, assent to taxation was a prerogative of the assembly, though grants were made only by the burgesses. The weakness of these estates were very like those of the 15th-century councils of the church in their conflicts with the pope. Essentially they were occasions, rather than permanent bodies, which were either summoned by the king or—if gathered by any other means—were unrepresentative. Their control over the monarchy lasted only so long as they were in session, and exhaustion or particularism frustrated their long continuance. The kings could normally exploit either the localism or the diverging class interests of their estates to prevent any continuous supervision. In Catalonia in the 15th century, the Cortes possessed a Diputaçio del General, a standing committee to watch over the government, which not only granted but collected and spent any extraordinary taxation; but the forms of taxation divided the burgesses from the knights and nobles. In England there was less division of class interest but no effective or continuous supervision. In all cases, the resistance of the magnates was a precondition of large claims on behalf of the estates; yet a prolonged and successful magnate resistance destroyed that fusion of local and class interests upon which the estates depended for their vitality.

Law and legislation. The Germanic invaders who occupied the highest offices of post-Roman Europe were for the most part incapable of conceiving of legislation in the

Customary law

classical or modern sense. The law by which all human affairs were regulated was that of the ancestors preserved in custom, an eternal system of right relations. Good law was ancient law, and new law was bad. The function of the legislator, therefore, was to proclaim or interpret the law, not to change it or make it; the laws of King Alfred, which open with the Ten Commandments and continue with a compilation of earlier law, are wholly characteristic. The codes of customary law enacted in the mid-14th century for Poland by Casimir III or for Sweden by Magnus Eriksson about 1350 show the long continuance of such traditions, though these later codes—and, indeed, all written customs for a kingdom—in some sense represented an attack on more local custom. The administration of the law, however, was recognized as mutable at all times; the Merovingians occasionally and the Carolingians quite frequently issued ordinances for the Frankish empire, as did Anglo-Saxon and Danish kings in England. The disintegration of political authority between the 10th and 12th centuries made legislation of wide scope very rare indeed; it was the rise of centralized institutions to enforce one law, written or customary, and of large assemblies in which to publish it that later allowed the multiplication of statutes and edicts of general application.

Outside the towns, where the enforcement of the law was unambiguously the function of the community and its officers, the authority behind such legislation was inevitably that of the king. The earliest general edicts of the post-Carolingian period were therefore royal proclamations; the first extensive example was the *Liber Augustalis*, promulgated by Frederick II for the Kingdom of Sicily in 1231 as the Constitutions of Melfi. Only slowly, and with uneven success, did the view gain ground that such proclamations must be made in large assemblies of fixed or even representative constitution. Where the general edict was a recognition of the limitations of royal authority, as in the celebrated Great Charter (Magna Carta) of King John of England in 1215 or the Golden Bull of Charles IV in 1356, it was in form a royal grant. As a consequence, general legislation, though increasingly necessary in later medieval kingdoms, had formal weaknesses as a limitation upon royal authority that were usually fatal. It was the legal autonomy of the princes, nobility, and towns that set a limit to royal authority, not "constitutional" edicts in the name of the community. Of these the king alone could be the author.

The growth of royal justice

The need for general legislation arose largely from the great expansion of judicial business done by the king and his courts. The right and duty to do justice was so fundamental an element in early conceptions of government that almost every aspect of political authority was exercised in judicial form. The local organs of taxation and military recruitment were the courts of count, prince, or petty baron, to which freemen came to settle their differences; the English exchequer was, both in form and in practice, rather a court than a counting house; the meetings of the estates as Parliament, Reichstag, or Cortes were courts before they were representative assemblies. Similarly, a centralized judicial system involved a centralized government and also a wealthy one.

Early royal government seems to have had little specific legal competence; the king's duty to see justice done was fulfilled by the appointment of honest judges rather than by hearing frequent appeals. Where custom was both decisive and localized, central courts had little attraction; where the modes of proof—by oath, ordeal, or combat—were intended to invoke divine rather than human judgment, there was little room for a theory of appeal; where travel was slow and literacy rare, centralized justice was extremely difficult to enforce. Therefore, the first technique available to the king who sought to enforce his law lay in the dispatch of trusted agents from his court to preside at local assemblies and to reduce the autonomy of counts or royal bailiffs. Under the Carolingians, special *missi*, often churchmen of high rank, performed this duty; in England the itinerant justices formed the model for the earliest French *baillis* in the 12th century. Under the French king Louis IX, in the 13th century, friars were often employed as *enquêteurs* to scrutinize local government and amend the faults of local officers; under Louis's successors the scrutiny was rather of their devotion to the king's interest.

As early as the 12th century such devices were already giving a new importance to the king's central court, for matters of difficulty were often referred by the travelling judges to the king's own hearing; the existence of a body of such judges provided a volume of general legal experience at the centre and a certain degree of consistency of procedure in the provinces that pointed the way toward a single royal law and enhanced the value of a central judgment. At the same time, the king's court as the unique tribunal for disputes between his great tenants and as the last resort of injured litigants was attracting a greater volume of business. Although the ordeals and judicial combat never vanished entirely as methods of proof, they lost ground rapidly in western Europe in the 13th century to the procedures of written evidence and judicial enquiry; this made the theory of appeal easier to accept, and the practice was accelerated by two fundamental characteristics of medieval litigation. The first was that it was an absolute duty to pursue possible rights to their limit; this was pre-eminently true of religious communities that never died and never forgot, for whom failure before the law meant despoiling the saint to whom their church and estates were dedicated, but a secular family was scarcely more forgetful. The second was that judgments, to be effective, had to be accepted by both parties; the object of the court was to secure agreement and the voluntary submission of the unsuccessful litigant. In a society largely devoid of specific offices of enforcement, where those who appeared before the courts were often neighbours, this insistence upon the acceptability of judgments was essential. It made all the more valuable the judgment of a tribunal whose authority could not be refused. Hence, there emerged in all the larger states a variety of central courts.

The French *parlement*

In France the regular gatherings at the king's court produced the distinctive institution of the *parlement*, essentially an omnicompetent supreme court that began in the 13th century as a committee of the king's councillors with some expert legal assessors but that by the mid-14th century had become a fully organized and almost wholly professional body with three principal organs—the Grand Chambre, in which the decisions were pronounced; a Chambre des Requêtes, which scrutinized appeals and distributed them to the appropriate tribunals; and a Chambre des Enquêtes, which carried out the judicial enquiries upon which the final judgment rested. From its position as supreme court, the *parlement* came to exercise a wide supervisory power even over the Chambre des Comptes; in this it continued to resemble the English Parliament as it had in its origins. Unlike the English institution, however, its nonprofessional element tended to diminish, and it achieved a substantial measure of independence in the appointment of its officers. But, having no control over financial supply and no representative or political basis, it was rarely capable of serious resistance to royal autocracy. With the collapse of English and Burgundian power in France in the late 15th century, a number of local *parlements* were created to serve the reunited territories, the earliest being that of Toulouse; in these, however, the crown's right of nomination prevented any serious threat to the legal unity of the realm.

In England the two courts of Common Pleas and King's Bench came to operate as supreme courts, especially for civil cases, while the royal monopoly over serious offenses was chiefly exercised by the itinerant justices of assize; over all these stood the high court of Parliament, which the litigant could petition for redress. The judicial authority of the king and the king's council offered the litigant a further source of appeal.

In Germany political fragmentation prevented the evolution of a law unified by administrative practice, so that the need for a common code was reflected in the formal Reception of Roman Civil Law in 1495, a measure without immediate or widespread practical consequences.

Throughout the medieval period, central courts tended to attract an ever larger proportion of litigation from the

local courts. As a court of appeal, the French *parlement* slowly eroded the importance of the local Grands Jours (the solemn sessions of the courts of the earlier great lordships), except in those cases in which these were themselves transformed into *parlements* at the end of the period. In England police jurisdiction passed into the hands of justices of the peace, unpaid crown officials appointed by the crown from among the local landowners; all important civil litigation was conducted in London, leaving the old shire courts, once omnicompetent, only a shadowy existence. The letters of the Paston family show a group of minor Norfolk gentry engaged in a long series of lawsuits that kept the head of the family almost constantly in London as well as employing a considerable number of the professional lawyers who were so characteristic a product of the 14th and 15th centuries, both in France and England. These lawyers were among the earliest literate laity, the first trained secular administrators, and the chief agents of the unification of postmedieval states (see further EUROPEAN LAW, MEDIEVAL).

Revenue and taxation. The whole fabric of the centralized state depended on the mobilization of great resources for the crown. Even the earliest rulers of the Heroic Age had needed a hoard from which to reward their followers and to draw the gifts upon which relations with neighbouring chieftains depended. Such hoards were accumulated by successful plundering and the tribute of subject peoples; they were themselves the great prize of war, as when Charlemagne's forces sacked the Avars' Ring (chief fortress) in 795/796, and the treasure was carried across Europe by the cartload. The rich furniture buried with the ship of a petty king in East Anglia at Sutton Hoo in the 7th century shows how magnificent and how diverse these hoards must have been. With the stabilization of settlement between the 9th and 12th centuries, the pursuit of plunder and tribute became a more marginal enterprise, still actively pursued by the Vikings and the Magyars (and later, in the 9th and 10th centuries, by the German settlers along the Eastern frontier) but rarely available to most princes of post-Carolingian Europe. By this time, the fragmentary system of Roman taxation had also broken down, so that the central or royal revenues that existed were mostly those open to any great landowner. For many rulers these resources were still largely in food rents, which the owners travelled about their estates to consume where they were produced. Throughout the medieval period these revenues from the king's own estates were an essential element of his power; the extent and distribution of the royal domain were touchstones of his authority.

The rise of a money economy

Beyond the revenue in kind produced on the king's estates or collected by his bailiffs, supplemented by a proportion of the trappings of his dead followers and any quasi-judicial fines that could be seized to his use, the king's revenue lay in services, such as his right to summon the army or to secure labour for his fortresses, cartage for his crops, or suitors for his courts. All these services and many of his food rents needed constant vigilance to enforce or secure; no prolonged expansion of central authority could rest on this anarchic foundation.

Such primitive sources of supply were the consequence of the almost complete collapse of a system of money exchanges across Europe, which was itself a consequence both of economic regression and perhaps a shortage of bullion; until the opening up of the central European silver mines on a large scale in the later Middle Ages, Europe had few supplies of ore for coinage. The monetary chaos of the 7th and 8th centuries was in part relieved by Charlemagne's introduction of the first medieval European silver coinage of commercial use, his pound of 240 pennies (deniers), coins of excellent quality and weight. Yet the multiplication of local mints and unstable values made even the abundant silver coinage of the 14th century awkward to use and offered innumerable opportunities for malpractice—from coining on a small scale by petty forgers to large but undisclosed devaluations by princes.

For all its inconveniences, however, the use of money to replace food rents or services rapidly became widespread as soon as the circulation of coinage and the evolution of a market made it possible. In the 10th century the great domains of Italy were already being leased out; and by the end of the 14th century rent rather than labour was the characteristic peasant due everywhere in Latin Europe except in parts of Germany and Central Europe. Similarly, it became increasingly common to commute the obligations of free tenants and feudal vassals to money payments; the very term aid (*auxilium*), originally meaning simply the help a man owed his lord, had by 1200 come to mean a tax. The king could in theory impose what dues he liked, as could any other lord; these arbitrary tallages were of considerable importance in areas where, as in Capetian France, there were large towns on the domain to contribute to it. The exploitation of the forests also contributed in fines and licenses; market tolls and even a primitive form of sales tax all went to swell the domain revenue. Though these profits could all be commuted and so more readily applied to the common needs of the kingdom, they still formed an extraordinarily complex and miscellaneous collection of rights of fluctuating value, which was far beyond the capacity of any central accounting system to assess or collect in detail. Hence, the importance of the local revenue collectors, stewards of the royal domain, sheriffs, provosts, vicars, and so forth; in general, the practice was to allow these officers to collect the normal profits of lordship for themselves in return for a fixed payment, accounting in detail only for such extraordinary revenue as heavy judicial fines or tallages. Fixed incomes of this kind suffered through a fairly marked inflation over much of 13th-century Europe.

Taxation

Rising costs of government in the 12th and 13th centuries required new and more comprehensive taxes little connected either with the ownership of land or the exploitation of vassals. The church, with its tithes, had long collected a form of income tax; under Innocent III the so-called charitable subsidy was imposed on the whole church by the papacy. Lay princes first employed a similar principle to finance the Crusades of the later 12th century by imposing a tax on the movable goods of their subjects. By the end of the 13th century such taxes were frequent. In many respects they were the first manifestation of an act of sovereign government in Europe for centuries, being applicable to all subjects upon a uniform principle—although in practice the collectors often struck bargains with whole communities rather than pursue the complexities of universal assessment. The fifteenth and thirtieth granted by the English Parliament at regular intervals from the reign of Edward I, were also employed occasionally in France, where a combination of a hearth tax and a variety of forms of sales tax (such as the notorious gabelle, a salt tax) became the most characteristic and permanent forms of national taxation. Customs dues, particularly on comparatively valuable and portable goods such as wool, wine, and cloth, also became widespread in the 13th century; it was at this time that elements of a genuine commercial policy first appeared in the conduct of princes, so that merchants began to secure legal and political rights as a class (as opposed to local privileges).

Loans from merchants and Jews

These merchants owed their political influence very largely to the possession of large sums of cash or increasingly trustworthy systems of credit. Kings, and lesser rulers too, constantly found that their need for money was urgent but that their means of realizing it were slow. It took several years for a grant of a subsidy by subjects to be assessed and collected, but no army or even household could go without wages so long. Until the late 12th century the sources of available credit were chiefly the Jews, exempt from the prohibitions of the church against usury, and goldsmiths. The Jews, generally prevented by law from holding land, were very widely found in the towns, living sometimes under the protection of the church and often under that of the king, who exacted heavy sums in return for his protection and sometimes assumed the rights of a Jewish creditor himself. The life of the Jewish community was extremely precarious, for the Jews were constantly subject to the civil disabilities

imposed by the church and were the most frequent victims of a wanton crusading zeal and sporadic violence; they found in kings harsh and inconsistent protectors who not infrequently expelled them from their lands as a measure of extortion or political appeasement.

In the 12th century the order of Knights Templar, whose widespread estates were intended to provide revenue for the Crusades to the Holy Land, acted as the first large-scale Christian bankers. By the 13th century, particularly, secular bankers began to appear in such Italian communes as Piacenza, Siena, and Lucca; ironically, many of them gained their experience by collecting papal revenues. The bankers often lent money to the Italian princes, who secured their loans by granting the bankers the right to collect customs revenue. The whole revenue system of the Angevin kingdom of Naples was controlled by the Florentine bankers who had financed the original conquest. Politically, this type of loan was widely suspect; and there were widespread failures of such enterprises in the years after 1350, as was also the case with the much humbler money changers north of the Alps, the hated Lombards or Cahorsins. In the 15th century a certain number of great banking houses north of the Alps appeared to rival the Medici of Florence; especially notable were the royal merchant Jacques Coeur in France and the later Fuggers of Augsburg. With the decline of the Italian bankers, princes were compelled to fall back upon their own merchants, and these became subject to frequent forced and interest-free loans, disguised under such a term as "benevolence." Only the grant of monopolies or freedom from other taxes could make such exactions tolerable, but with the aid of these the prince could maintain himself against the greater feudatories, whose particularism threatened the interests of the towns and king.

Military service. Changing patterns of taxation were closely related to changes in forms of warfare and of royal right to military service. The earliest war-band leaders were the leaders of an army that comprised, it seems, all free men of military age; their annual gathering could be regarded either as a military review or a public assembly. The special importance of a more heavily equipped and mounted warrior, already manifest in the 8th century and developing steadily thereafter, reduced the numbers of such warriors who could be found and altered their relations to the crown; it was as vassals, rather than as subjects, that they answered the king's call. The older and wider obligation on all men not of servile condition died out rapidly in the 11th and 12th centuries, except as a duty to provide labour, the most lightly equipped garrisons for the large stone castles now so widely present, or as a vague and largely unenforceable obligation to form a local militia in time of invasion. Only in the Italian towns was a public obligation to serve in the armies of the republic widespread and effective. Correspondingly, service with the army became attached to property, with the usual consequences. The vicissitudes of property made the gathering of an army difficult, and custom came to limit the length of service ever more narrowly until 40 days became the usual extent of obligation. Moreover, outside England the quotas of knights provided by the greater vassals for their king were usually far below his needs or their capacities. Under these conditions, wages early appeared as an extra inducement to service: the king would often contract with a magnate to secure a fixed number of knights, sergeants, and horses for a lump sum, which the noble or experienced contractor would then redistribute. By the 14th century this system was widespread; its effects in peacetime were often grave, but it did provide an alternative for the failures of the tenurial system.

Increasing use of mercenary soldiers

At the same time, the king's duty to provide for the safety of the realm allowed the use of a more universal obligation. In England all men were required to bear the arms appropriate to their rank and to practice their use; special commissioners of array then chose men to be paid in the king's service as archers or sergeants. In France the Valois kings required the community to provide contingents of troops but in practice normally used this as a means of raising money instead. A serious failing of such systems of raising forces was that at a war's end a large body of unemployed troops was unleashed on the countryside. France, Alsace, and Italy had as much to fear from the casual ravages of unemployed mercenaries as they had from the deliberate assault of an enemy. At the very end of the period the French kings, with their *gens d'armes*, created by an ordinance of 1445, laid the foundation of a permanent standing army that the emperor Maximilian sought to emulate. The European medieval aristocracy in its most characteristic form had been a military one, secure within its crowded fortresses and rendered formidable by its near monopoly of the essential arms of warfare, the mounted and fully equipped knights who were the great men's vassals. By 1500, however, the connection between noble birth, military prowess, and the basic composition of an army was fast breaking down, even before gunpowder hastened the last of the fully armoured knights from the battlefield.

IV. The world of the senses and the mind

The communities of the early Middle Ages lived on intimate terms with a largely hostile environment. Storms on sea and land, floods, pestilences, and famine were constant hazards. Even in the more densely settled parts of Europe, impenetrable forest and trackless fen covered large areas. These areas were often believed to be the haunts of demons and, in fact, provided refuge for brigands and outlaws as well as wolves and wild beasts. The uncultivated moorlands and mountain passes were safely crossed only in haste and with company.

Pagan religious survivals

The religious beliefs of the pagan tribes were appropriate to this environment of apparently random disaster. The gods of the Germanic tribes were wanton and crafty, and fertility cults were probably widespread though intensely local. Formal belief in Odin, Thor, or Freyja gave way rapidly before the missionary fervour of Arian and Roman missionaries, but many pagan elements passed into the superficial Christianity of the first converts. Devotion to local saints was often (even deliberately) based upon earlier pagan cults, while churches were built on the sites of temples or sacred groves. Early miracle stories often attribute markedly pagan qualities of willful jealousy or capricious good will to the saints. The mere possession of such wonder-working relics as the Holy Lance of the empire was supposed to confer a title to the crown and a formidable military authority to its holder. There was a brisk traffic in such objects among princes, while the sacred groves and wells of the earlier religion rapidly took on the name of some local saint for the peasant population. Augury, the sacrifice of cattle, and a host of other pagan rites continued throughout the period, though the ecclesiastical police system was more and more successful in sharpening the distinction between acceptable devotion and witchcraft.

Christian life at the parish level necessarily reflected such conditions. In a literate society it was the ceremonial performance of the sacraments that was of paramount importance; indeed, preaching was a late and occasional addition to the duties of the parish clergy. The blessing of harvests and houses, the averting of plague, fire, and invasion by regular formal intercession were the essential functions of the parish clergy. Correspondingly, communal disaster and outbreaks of anti-clericalism were closely connected. For the salvation of the individual the church required annual confession and very occasional taking of the sacrament. Private confession and private penance became the rule by 1100, but penance might be done by extensive travelling. By the 12th century, pilgrimages were made to the great international shrines of Jerusalem, Rome, Santiago de Compostela, or even St. Thomas of Canterbury, as well as to a host of lesser local shrines, insuring against the future or expiating past crimes. The Crusades, in part intended to restore the pilgrim road to Jerusalem, were themselves a means of securing full remission of sins for the participants. Their frequent failure or diversion to trivial or political ends made them a dying force after 1300, but the need for such concrete means of salvation continued (see CRUSADES). Papal jubilees and the organization of a system of indulgences

secured by generous alms met this need, though offering many opportunities for abuse.

Until the 12th century, when Manichaeism spread through Italy and southern France, the orthodox church in the West was notably free of the doctrinal divisions that rent the Eastern Church. Eradicated by prolonged and bloody war, this heretical view had little later influence, but the source of its success—the wealth and pastoral inertia of the secular church—was to produce a multitude of dissident movements that laid stress either upon the defects of the propertied clergy or upon the direct illumination of the individual, notably by the reading of the Scriptures; already in the 12th century the Waldenses had adopted such views. In the late 14th century, John Wycliffe in England preached individual salvation and criticized the whole fabric of the church, sacramental and hierarchic. Wycliffe's doctrines met with little response in England but provided the starting point for the Hussite movement in Bohemia, where economic, political, and doctrinal revolution united to threaten the whole social and ecclesiastical order of eastern Europe.

In part this multiplication of dissent drew on the anticlericalism of the more educated laity and on wider knowledge of the Scriptures in vernacular versions, but it also coincided with the end of the period of monastic reform and development; while the fervour of St. Francis produced a new order to perform a vital function within the church, the devotional tendencies of the 14th and 15th centuries associated with the names of Meister Eckehart or Thomas à Kempis were largely devoid of institutional consequences. At the opposite extreme of this interior devotion was the proliferation of extravagant sects such as the recurring appearance of the flagellants in the years after the Black Death and its successors ravaged Europe. The prophetic form of much of the Scriptures, the frequency of disasters that appeared, at least locally, to portend the collapse of human society, and the general belief that the centuries after Christ's coming represented the last age of mankind produced a steady trickle of sects believing in the imminence of judgment or the new Jerusalem, encouraged by an easy distortion of the view of such academic prophets as Joachim of Fiore.

Communal organization

Against the hostility of their world, seen or unseen, medieval societies also fell back upon a wide variety of communities vowed to mutual support. The minimal privacy of the characteristic medieval household gave all houses a communal quality. It was common for several generations to live, eat, and sleep under one roof, which often enough covered the livestock too. The earliest forms of Germanic settlement and organization rested upon the kin group, the early codes all supposing that the kin had absolute responsibility for its members. In the unstable society of the early Middle Ages, the bonds of commendation by which men bound themselves to a protector provided a substitute for the security and social cohesiveness of the earlier kin group. The medieval impulse toward the formation of communities bound together by oaths may be seen also in the trading guilds of the communes, in the councils of kings and princes, and even in the societies of rebels or robber bands.

The tightly knit character of most medieval communities was a result of the relative immobility of the population. While the church and warfare were international occupations, in which a man might serve from one end of Europe to the other, and though merchants travelled with their wares across a multitude of frontiers, the bulk of the agricultural population rarely journeyed more than a few miles from their village, and many townsmen were equally confined. News travelled slowly and inaccurately, borne by pilgrims, peddlers, bailiffs, and beggars; marriage outside the village was unusual; and local dialects sharply contrasted. On the edge of this society, however, some adventurous travellers were covering huge distances. The Vikings sailed south to the Mediterranean, east and south to the Black Sea, and west to Iceland, Greenland, and the coast of North America. In the 13th century, the Venetian traveller Marco Polo crossed the breadth of Asia to China, where several Franciscan missionaries were to follow. In the 15th century, Portuguese seamen groped their way south along the African coast in pursuit of gold and a sea route to the Indies, rounding the Cape of Good Hope in 1488. In 1492 a Genoese seaman, in the service of Ferdinand and Isabella of Spain, crossed the Atlantic and returned; remarkable though Columbus' voyage was, the rapidity with which its significance was assessed and exploited provided proof of how much the European view of the world was changing.

Technological advances

Primitive though the vessels and instruments of these navigators were, they showed a marked advance over the equipment of their predecessors, an advance that was widespread and accelerating in the 14th and 15th centuries. From the 9th century on, water power was extensively harnessed to mill flour, replacing the infinitely laborious querns of past millennia; it was also at work driving the hammers of the ironworkers and the first fulling mills, which revolutionized the social patterns of cloth working. In the late 12th century, windmills also began to be used widely, while at about the same time changes in the forms of harness allowed horses to take over some of the ploughing and carting formerly performed by oxen. In the 13th century, mining techniques for the first time allowed the driving of deep but drained shafts beneath the surface to the richer iron, copper, tin, and lead of Bohemia, Sweden, or Cornwall. By 1500 the demand for charcoal for smelting and timber for shipbuilding was already pressing hard upon the once inexhaustible forest of an older Europe.

As a consequence of these changes, the use of iron became common, even in the implements and houses of the poor. Metal cooking pots, glass bottles, and glazed wheel-turned pottery came into widespread use. Houses of stone or even brick often now had the chimneys and glass windows formerly found only in palaces. Domestic furniture of these centuries survives to show that it was no longer confined to crude benches, tables, and chests but was more carefully fitted and elaborately decorated. In the 15th century the former cloth-working town of Arras expanded its manufacture of the tapestry hangings for which it would be long famous, while silk, linen, and cotton came into wider use. Sumptuary laws showed how much wider a range of society was able to dress in the materials and fashions that had once been the hallmark of the highest rank.

Architecture

The earliest surviving medieval architecture is ecclesiastical; outside the area of continuing Byzantine occupation, these are small churches sometimes built out of the fragments of former Roman buildings and always derivative in style. Some of the greater Carolingian churches, however, were more ambitious in scale and conception, and the surviving 11th- and 12th-century Romanesque churches show the emergence of a wholly distinctive architectural convention in enormous and complex buildings. Gothic emerged in early-12th-century France and became the dominant style of the Latin West. In Italy the success of this style came late and was short-lived, for it was overtaken by the revived classical models before it had long taken root; but over much of northern Europe the Gothic survived into the 20th century.

The earliest surviving medieval domestic architecture is found in a few stone houses of the towns and in the modifications of fortresses to serve more domestic purposes. By the 13th century the stone palaces of princes were constructed with the skills first practiced in churches. Such planned towns as Aigues-Mortes foreshadowed the elaborate fortifications of many towns of the 15th century, within which numerous multistoried houses of wealthier merchants survive to the present. The single chamber of the lord's hall or the peasant's hut was increasingly giving way to the house divided into rooms, though in much of rural Europe there was little to distinguish the cabins of the poor of 1500 from those of a millennium earlier.

Recreation

The recreations of most ranks of society are poorly attested before the later Middle Ages. Among great men and warriors, the life of the hall and forest was pre-eminent. In the hall the long eating and heavy drinking of the lord's followers were favourite motifs of the heroic poetry once sung by household or itinerant poets, and feasts were an essential focus of social life. Coronations, wed-

dings, and funerals were all celebrated with banquets. Pagan customs of punctuating the year with such events were either contested or taken over by the church; the gathering of the harvest and the celebration of Christmas were regular occasions of the kind, and from time to time the enthronement of a bishop produced a banquet of extraordinary splendour. The earliest texts stress the quantity (rather than the quality) of food and drink, but the more detailed later medieval records show that scarce or exotic foods and an extreme elaboration in their preparation were becoming the marks of ceremonial extravagance, the highest achievement of the pastrycook being such "subtleties" as the Holy Trinity surrounded by choirs of angels. Eating, drinking, and singing were supplemented by various forms of gambling, to which the Germanic peoples were so addicted that men were known to stake their own liberty on the fall of the dice and so condemn their descendants to slavery. Backgammon, chess, and (late in the period) card games were played by those with leisure and means.

The principal recreations of the nobility in the countryside were hunting and fighting, both of which were originally conducted in an extremely dangerous way. The main beasts chased were the deer, boar, wolf, and bear, with rabbits, hares, and foxes serving as a lesser challenge; all were usually pursued on horses with packs of hounds, the variety and qualities of which were discussed in numerous later medieval treatises. The support of the chase was an important economic and legal institution. The rearing of the lord's dogs and other services for his hunting were conditions of some tenures, and the preservation of hunting rights was a source of revenue and a cause of oppression. Another honourable sport was falconry. There was an appropriate bird for each rank of society, and in this sport women might participate more often than in the hunt.

The holding of sham battles for enjoyment and exercise became general in the 12th century, when the ransom of prisoners was an accepted means of support for skilled but landless knights. By the end of the century, the practice was so widespread as to attract the condemnation of the church and to represent, it was supposed, a threat to the stability of the state, since gatherings of armed men could readily become rebellions. In later centuries, this generalized melee gave way increasingly to highly formalized jousting between individual knights wearing armour especially adapted for a variety of possible rules of combat. In the 14th century this was still a possible means of capture, ransom, or death; by the end of the 15th it was almost entirely a sport.

For the less wealthy, the available entertainments were rarer and less elaborate but not perhaps much safer. Football, wrestling, or fighting with staves, regulated by few conventions, produced a heavy casualty rate, as did brawling in innumerable unregulated alehouses. Brewing was a cottage industry frequently engaged in by women, who sold their product subject to a seignorial right to examine the quality of the drink. In a society in which sugar was expensive even for kings and in which honey was prized but scarce, the thick beer and mead of the north was not only a focus of recreation but also an essential element of diet, as was the wine of the south.

Medieval music

Among the earliest of recorded arts was that of song, and a substantial body of medieval music has survived. The best known is the ecclesiastical plainsong, whose origins are attributed to the liturgical reforms of Pope Gregory I, which was elaborated into the complex polyphony of the 14th and 15th centuries, when for the first time the names of individual composers are recorded. The songs of troubadours and minnesingers of the 11th and 12th century show the rise of a sophisticated secular music that was increasingly accompanied by a variety of musical instruments. Well before 1500 the playing of music as an autonomous and often purely secular art was already established.

The decorative arts of painting and sculpture had undergone a similar progress, but here the revived interest in the secular products of classical antiquity and extensive lay patronage may have hastened the emergence of such arts from a wholly ecclesiastical setting to produce the flourishing schools of Italian and Flemish painting and the extensive sculpture of 15th-century Italy. In both cases the remarkable triumphs of the earlier period, the mosaics of Ravenna or Norman Sicily, for instance, or the sequences of sculpture across the west face of Autun or Laon were subordinate to a larger ecclesiastical unity —the liturgical drama of the church; the sculpture of Donatello and the painting of Botticelli were not, whatever the piety of their creators.

The rise of the professional painter of pictures to be considered as a creator in his own right is largely matched by the decline of the illumination of manuscripts, which reached a peak of elaboration in the mid-15th century just as the earliest printed books were heralding the end of the role of the handcopied manuscript.

The rise of printing

Printing on wooden blocks spread rapidly in the second half of the 15th century, and by 1500 presses were at work in every major country in Europe. Though the earliest printed books were extremely expensive and their purpose frequently liturgical, their potential importance was great because they could cater to the new market of the educated laity. These now included far more than the circle of great men who commissioned the splendid psalters and books of hours of the 14th and 15th centuries, which had overthrown a monastic monopoly of lavish manuscripts that had prevailed since the time of Cassiodorus and his copyists at Vivarium in the 6th century.

Education

The institutions and the subject matter of education had already proceeded according to a similar rhythm. The only schools of Europe in the 8th century, except perhaps in parts of northern Italy, were those attached often to monasteries and more rarely to bishoprics. Independent thought, even in theology, was extremely rare; theology remained under the long shadow of St. Augustine of Hippo, and the Greek learning and originality of John Scotus Erigena in the 9th century was little pursued. The rise of the new skills in dialectic in the 11th and 12th centuries produced two phenomena: first, a confidence in rational thought as a means of solving problems, especially those raised by the conflict of authorities; and, second, a number of teachers whose exceptional talents attracted scholars from the farthest ends of Europe. The self-confidence and European reputation of Abelard reveal this movement at its most distinctive. Around such teachers grew up either religious communities such as that of Saint-Victor of Paris or the earliest universities. In the 12th century the lawyers of Bologna, the doctors of Salerno, and, above all, the theologians of Paris were becoming organized bodies governed by a chancellor; by the 13th century the universities possessed their own statues regulating the arduous courses of study toward recognized degrees. The crown of studies was the pursuit of the highest knowledge, theology. The forms of 13th-century university study gave rise to the characteristic theological achievements of the period, the *summae* of the Dominican St. Thomas Aquinas and the Franciscan St. Bonaventure. The founding of universities received a new impetus at the end of the 14th and 15th centuries, when they spread into Scandinavia, Scotland, and eastern Europe. It was in these years that most secured a large independence from external ecclesiastical government, and in the councils of Constance and Basel the universities claimed a position of the highest authority.

Much of the earlier confidence in the capacity of intellectual endeavour according to the established forms of enquiry drained away in the 15th century. Logicians in the tradition of Duns Scotus and William of Ockham asserted the essential disparity of faith and reason; the canon law proved incapable of resolving the most pressing problems of ecclesiastical authority or of securing effective reforms; and the only literary forms that offered novelty and room for growth were the vernacular literature of the court and the classical poetry of the Humanists. Whatever changes occurred in education were generated not in the universities but in the schools of such Italians as Vittorino da Feltre near Mantua or of the Brethren of the Common Life in the Netherlands. These first insisted upon the effects of education, on the whole

personality, where the numerous grammar, guild, and charitable schools had provided only a grounding in the mechanics of literacy. The retreat of the monopoly of the church in education stands beside the work of the explorers and the rise of the absolute monarchies as an important mark of the ending of medieval society.

BIBLIOGRAPHY. The fullest account of medieval Europe in English is that of the *Cambridge Medieval History*, 8 vol. (1924–36; 2nd ed., 1966–), of which only the Byzantine volumes have been re-edited, as has the first volume of the companion *Cambridge Economic History of Europe* (1966). GEORGES DUBY, *L'Économie rurale et la vie des campagnes dans l'occident médiéval*, 2 vol. (1962; Eng. trans., *Rural Economy and Country Life in the Medieval West*, 1968), summarizes much recent work and shows well the directions of current research; FRANCOIS L. GANSHOF, *Qu'est-ce que la féodalité?*, 2nd ed. (1947; Eng. trans., *Feudalism*, 1952), is the classic analysis of the structures of feudal tenure. FRITZ KERN, *Gottesgnadentum und Widerstandsrecht im früheren mittelalter* (1914; Eng. trans., *Kingship and Law in the Middle Ages*, 1939, reprinted 1968), is the most convenient introduction to its subject. *The Handbook of Church History*, ed. by HUBERT JEDIN and JOHN DOLAN (1965–), gives a full and recent account of the period from the 8th to the 12th centuries; for the later period, A.C. FLICK, *The Decline of the Medieval Church* (1930), is still useful; R.W. SOUTHERN, *Western Society and the Church in the Middle Ages* (1970), gives a more general introduction. On the towns HENRI PIRENNE, *Medieval Cities* (1925, reprinted 1956), has lost little of its value; DANIEL P. WALEY, *The Italian City-Republics* (1969), covers the period between the 11th and the 14th centuries in greater detail. GEOFFREY BARRACLOUGH (trans.), *Medieval Germany, 911–1250: Essays by German Historians* (1961); JOHANNES HALLER, *Die Epochen der deutschen Geschichte* (1928; Eng. trans., *The Epochs of German History*, 1930); ROBERT FAWTIER, *Les Capétiens et la France* (1942; Eng. trans., *The Capetian Kings of France*, 1960); and EDOUARD PERROY, *La Guerre de cent ans* (1945; Eng. trans., *The Hundred Years War*, 1951), give useful examples of national history. On England the first 5 volumes of the *Oxford History of England* (1937–59), are authoritative. JOHAN HUIZINGA, *Herfsttij der Middeleeuwen* (1950; Eng. trans., *The Waning of the Middle Ages*, 1954), is a controversial classic. The largest and most representative collection of medieval texts in translation is that in the Columbia "Records of Civilization" series, supplemented by that of the *Oxford* (formerly *Nelson*) *Medieval Texts*. The standard English bibliography of medieval history is L.J. PAETOW, *A Guide to the Study of Medieval History*, rev. ed. (1931, reprinted 1964).

(Ma.Br.)

Middle American Peoples and Cultures

The physical spine of Middle America is the broad mountain chain extending from the southern end of the Rockies to the northern tip of the Andes, with Middle America in the area from northern Mexico to Nicaragua. The mountain chain marks off the area into four major regions. The heartland of Middle America is the central valley of Mexico. A second region is the highlands along the southern Pacific slope of Mexico. Beyond the Isthmus of Tehuantepec are the southeastern highlands in the Mexican state of Chiapas and in Guatemala. The arid region in the northwest of Mexico is a fourth region.

Within these four major geophysical regions there is tremendous variety in ecology, climate, soil, and the possibilities of human life. The mountains crumple the face of the land into a multitude of valleys and micro-environments; the result is a mosaic of crops, peoples, and settlements about which it is difficult to generalize. The high valleys of central Mexico, Oaxaca, Jalisco, and Guatemala have been the most densely settled parts of Middle America. But the lower slopes of mountains near the seacoasts have also carried substantial populations. The steamy tropics of the Isthmus of Tehuantepec and the hot limestone thumb of Yucatán have also been heavily populated.

The Indians of Middle America live almost everywhere in the region. The basic requirement for human settlement is water. The major river systems and the high valley lakes have been the primary settlement sites since prehistoric times.

CULTURAL PATTERNS

Cultural areas. While the social heritage of Middle America is highly complex, within the broad historical flow five separate cultural areas can be distinguished. They are regional configurations of the basic Middle American cultural patterns. One cultural area is that of the Maya. The southern, highland Maya were and are concentrated in western Guatemala and the state of Chiapas in Mexico. The northern Maya inhabited the Yucatán Peninsula of Mexico and the jungle of Petén in Guatemala. The Maya of these two regions form a continuous territorial and historical entity. (There are also contemporary Maya people in Veracruz and San Luis Potosí in Mexico, known as the Huastec.) The monumental ruins left by the pre-Columbian Maya are one of the puzzles of anthropology; theirs is the only civilization known to have flourished in a tropical rain forest.

The Mayan cultural area

The southern Mexican highlands and the adjacent coastal regions form a second cultural area within the basic Middle American pattern. This region covers most of the present Mexican states of Guerrero and Oaxaca, the southeastern part of Veracruz, and parts of Puebla and Morelos. Its highland people developed the traditions of the Mixtec and Zapotec, whose ruins survive at Mitla and Monte Albán, whereas the coastal people seem to have been somewhat isolated from them.

A third cultural area is the central Mexican highlands, including the valleys of Puebla, Toluca, and Morelos, along with the eastern slopes of the Mesa Central and parts of the Balsas River Basin. This area was the centre of the Aztec Empire. Mexico City is built on the ruins of the Aztec capital of Tenochtitlán, and descendants of the Aztecs still live in the area.

The mountain chain around the high lake of Pátzcuaro, in present-day Michoacán, forms another cultural area. The relative isolation created by the mountains permitted the Tarascans to work out their own cultural variant. They reached a level of social and political organization comparable to that of the Aztec and the Maya.

A fifth cultural area is northwest Mexico. This region is not historically or culturally a single unit; it exhibits three major types of ecology and three major types of human adaptation. The high mountains provided possibilities for simple agriculture without irrigation, whereas the desert required settlements around valley bottoms dependent on floodwaters in the rainy season. In the west the abundant shellfish were the basis for a coastal culture. The historical forces at work in the northwest area were different from those in the four other cultural areas. The population was taken over by the Jesuits, who built mission communities. The relative isolation of the region following the collapse of Spanish power, together with the weakness of the succeeding Mexican governments, permitted the survival of a blend of Spanish-Indian culture.

Language groups. Hundreds of languages were spoken in Middle America. Some linguists have grouped them in a number of phyla, or superfamilies, each phylum being at the same classificatory level as, say, Indo-European. The Hokaltecan superfamily includes the Yuman family (four surviving languages, two extinct); the Serian family (one surviving language, four extinct); the Coahuiltecan family (four extinct languages); the Tequistlatecan family, with one living language; the Supanecan family (one surviving language, two extinct); and the Jicaquean family, with one living language. A second phylum, Uto-Aztecan, comprises the Piman family (four surviving languages, eight extinct); the Taracahitian family (two surviving languages, 39 extinct); and the Aztecoidan family (three surviving languages, 18 extinct).

Attempts have been made in the past to associate the large family of Mayan languages (about 27 living languages) with several other Meso-American Indian languages (the Mixe-Zoque and Totonacan families, primarily) as the Macro-Mayan or Macro-Penutian languages; the latter term supposes an association also between the Mayan languages and the Penutian phylum of North American Indian languages. These groupings are not generally accepted by modern linguists.

The Oto-Manguean phylum includes the Oto-Pamean

family (six surviving languages, one extinct); the Chinantecan family (one living language); the Zapotecan family (two surviving languages, one of which, Zapotec, is so diversified that its many dialects constitute mutually unintelligible languages); the Mixtecan family (three living languages); the Popolocan family (four surviving languages, one extinct); the Chorotegan family (eight extinct languages); and the Amuzgo family (one living language).

In addition to the four phyla there are the Tarascan family of one living language; the Huavean family of one living language; and the Xinca-Lenca languages spoken in small enclaves in the southern part of the region. Finally, there are also 39 extinct languages that linguists have not been able to relate to each other or to any other (see MESO-AMERICAN INDIAN LANGUAGES).

Characteristics of Indian cultures. This linguistic variety shows how diverse were the cultures of the aboriginal population. Even though it is possible to generalize broadly about cultural resemblances or patterns, the actual cultural unit was local or regional. This is true despite the existence of larger political units, such as the Quiché of classical Guatemala, or the Aztec Empire. The broad characteristics of the Indians of Middle America may nevertheless be sketched in profile, if the caveat that the profile is everywhere varied by local circumstance is heeded. When the Spaniards conquered the Indians, they removed the indigenous ruling class and placed themselves at the apex of society. They also brought Catholicism, horses, cattle, wheels, iron, and new forms of political and economic organization. The Indian culture of today is a blend of indigenous elements, the culture of the Spanish, and the historical precipitate of the 500 years since the conquest.

Middle American cultures exist in located, named communities, each of which has a physical centre housing the patron saint of the community. The basis of subsistence is maize (corn), cultivated in small plots; but there is a myriad of crafts and artisans, and communities tend to be economically specialized. The family is the basic social unit, each living in a separate structure. Males and females wear distinctive costumes; where they have adopted modern dress, it is chiefly among the men rather than the women. Men do the heavy agricultural tasks and women the domestic chores. Men are in charge of the indigenous cults; women are more prominent in the Catholic aspects of religion. There is little restriction on any economic activity, and no taboos hedge occupational choice; but modern economic organization is little developed. The marketplace is the focus of economic life.

Families are internally hierarchical, with males and elders dominating. Both the father's and the mother's kin are recognized in tracing relatives, but there is a patrilineal emphasis in the transmitting of names and of some real property. Marriages are arranged for sons and daughters by their elders, who negotiate among themselves through a series of fixed visits and gift exchanges. Often the groom must perform service for his in-laws; during this period he may reside with them, later to set up his own abode. Marriages are easily dissolved in the absence of children, and a man may have a succession of wives; when children arrive, however, they stabilize a marriage.

Community political organization

The community's political organization is housed in a central building, usually opening upon a plaza. The personnel of the political organization form a hierarchy, with its top members recognized as spokesmen or representatives of the Indian community by the national government. The political offices are closely interwoven with a similar hierarchy, whose personnel serve the local church and the religious brotherhoods (*cofradías*), and plan the annual festal cycle. The personnel of the two hierarchies tend to alternate their periods of service between the civil and the religious wings. All adult men serve in this civil-religious hierarchy; in small communities they eventually reach the top posts and retire to become respected elders (*principales*). The annual change of personnel is accompanied by ritual.

There are no social classes in the Indian communities, but there are considerable differences in prestige, wealth, and individual achievement. There is an age hierarchy, especially among males, largely based on previous public service in the civil-religious hierarchy.

In the life cycle of these Indians, the important events are Baptism and marriage. There are no puberty rites; and death is accepted matter of factly, followed by a Catholic wake. The concepts of sickness and disease are various. Illness is often thought to be caused by invasions of wind (*aires*) into the body or by disturbed emotional states, or it is thought to be most likely to strike during certain periods. Foods and natural substances are thought to be hot and cold, strong and weak; these conceptions are used both in diagnosis and in curing. Those who cure are specialists or semispecialists, frequently believed to perform witchcraft or other noxious magic.

In the realm of the sacred there are a large number of supernatural beings and places. The deities are arranged in a vague hierarchy, sometimes with the Christian God at the apex. Christian saints are the chief focus of worship, but with them are associated various pagan attributes and forces, including the natural forces of wind, rain, and lightning. Some saints have strong cults, their effigies being housed in a cult house or special temple and cared for on a daily basis. Liquor is consumed during sacred ceremonies and in that context is itself sacred.

The annual cycle is regulated by the European calendar. There is a series of religiously derived festivals, the chief of which are All Saints' Day, All Souls' Day, Easter week, and the Day of the Cross (in September). At least 82 different Indian communities still use the old pre-Conquest calendars in some agricultural rituals and for purposes of divination.

The prevalence of animism

The world view is animistic in the sense that the Indians see the world as peopled by spirits, souls, ghosts, and witches capable of inflicting harm if the proper ritual precautions are not taken. Omens, dreams, and talismen are of great importance. People are also believed to transform themselves into animals and mystically eat the life from a victim. Some communities execute witches. In religious practice, ritual conformity is more important than inner piety; if a person does not hold a ritual office, he engages in very little daily religious activity.

Slander, gossip, and envy are strongly condemned, although they are an important means of influencing social behaviour. In general, however, the rule of law, as expressed in the formal organization of the civil-religious hierarchy, is much more important than personal leadership. Great ambition is discouraged, but industry and diligence are much lauded.

This generalized profile of Middle American cultures fits most closely the areas of the former high cultures—the Aztec, Maya, Zapotec, Tarascan, and Mixtec areas. It needs modification for the northwest culture area, where the communities have less economic specialization and interdependence. It also does not fit some coastal Indians who have become part of the export economy, such as the vanilla-growing Totonac of Veracruz, or the Indians who work on the sisal plantations of Yucatán, where many approach the status of a rural proletariat.

DEMOGRAPHY AND HISTORY

The Indians of Middle America are all descended from Asiatic forebears who crossed the Bering Strait and moved southward. They tend, except in the Isthmus of Tehuantepec, to be small in stature (155–160 centimetres or a little over five feet on the average), with brown to coppery skin, straight black hair, and dark-brown eyes often set above high cheek bones, sometimes with epicanthic folds. The Maya facial features are particularly distinctive, being flatter than those of the other groups; the Maya also have more prominent noses, and a tendency to rounder heads. Mexico is basically a mixed (*mestizo*) nation; there has long been extensive interbreeding between Indians and non-Indians. In Guatemala there has been much less interbreeding. But the term "Indian" is not a biological designation so much as a social, cultural, economic, and linguistic summary of the differences between some rural ways of life and the dominant national

culture. Race in and of itself is not socially as important as it is in other parts of the world. The usual census definition of "Indian" is based on linguistic criteria, and the population figures for Indians must therefore be read as figures for speakers of Indian languages.

In Mexico there are more than 2,500,000 speakers of Indian languages, chiefly in the states of Oaxaca, Chiapas, and Michoacán, and in the Yucatán Peninsula, although some Indian language speakers are found in all of the states except Aguascalientes, Nuevo León, and Tamaulipas. More than half the population of Guatemala, or nearly 2,000,000 persons, are speakers of Indian languages. More than 1,000,000 of them are concentrated in the western highlands; other Indian areas in Guatemala are the Verapaz and the eastern highlands.

The earliest inhabitants

Prehistoric periods. More than 10,000 years ago, the Middle American Indians were hunters who roamed the country in bands of four to ten persons. Their quarry were mammoths, llamas, bison, and wild horses, as can be seen from the remains found at Tequixquiac, north of the central valley of Mexico. Some also hunted small game and gathered the seeds of wild plants. The seed gatherers and the big-game hunters coexisted for thousands of years, until a climatic shift around 7500 BC favoured the seed gatherers.

About 4500 BC, cultivated squash and gourds became part of the subsistence of the Indians, and they adopted a seasonal nomadic pattern. Around 3500 BC the basic crops were domesticated: maize, beans, and squash have been found in remains of Tehuacán. The Neolithic era was beginning. By 2500 BC farming supplied about 10 percent of the food intake of the people, and by 2000 BC the first permanent settlements based on farming had been established, apparently villages of fewer than 100 persons. After 2000 BC farming became of major importance, and in the main areas the people were fully sedentary. They now produced forms of pottery.

From 1500 BC to the beginning of the Christian Era (often called the Formative period), the basic techniques of intensive agriculture were worked out, the full range of cultivated plants was developed, the pottery and art styles were formed, and the transition from small villages to ceremonial towns of 5,000 inhabitants was completed. The archaeological evidence of this may be seen in the central valley of Mexico at El Arbolillo, Zacatenco, Tlatilco, and, finally, Ticoman. The same developmental sequence occurred in the Formative period of highland Guatemala, as shown in the excavations at Kaminaljuyú near Guatemala City.

From the beginning of the Christian Era to about 1000 AD, the cultures of Middle America passed through their Classic or Florescent period. In the Pyramids at Teotihuacán and at Cholula, in the Oaxaca valley at Monte Albán, in the ruins at Tikal and Uaxactún in Petén, and at Copán and Piedras Negras, there is monumental testimony to the rise of theocratic civilizations. The differentiation between the earthbound peasants and the class of priests is marked by the spread of the hieratic art called by archaeologists the Olmec style, the greatest example being at La Venta in Tabasco, Mexico. Olmec art made much use of carved jade and the symbol of the jaguar. In the symbolic vocabulary of Middle America, the jaguar is associated with Tlaloc, the god of rain and fertility and therefore represents the forces of nature that make the crops grow. Tlaloc also dwells in caves from which lightning is thought to come; caves mean towns and settlements, so the jaguar probably represents the control of society as well as of nature. Jaguars are carved on axes, pots, and human likenesses; men wear jaguar skins; and human faces are depicted with jaguar-like mouths.

Mayan theocratic societies

This symbolism fitted well the new theocratic societies of the Maya—the Nahuatl, the Zapotec, and the Mixtec. Large raised pyramids were built for the public enactment of religious rites by the ruling priestly class. These structures were ceremonial centres where priests and specialists lived, and where the populace assembled for periodic rituals. The priests were important in the agricultural cycle, for which the ancient calendars were first devised. These calendars evolved into precise instruments for the measurement of time and came to express the philosophical ideas of the priestly intellectuals. The full poetry of Middle American calendrics is expressed in the Maya calendar "long counts," for which stone pillars were erected.

The ceremonial centres of the Classic period produced many luxury items made from imported goods such as seashells, feathers, obsidian, fine flint, jade, cotton, and cocoa beans. The centres paid for these imports by exporting finished ceremonial objects to the peripheries. The economy of the city-states of this period depended on the intensive cultivation of maize and on huge drafts of peasant labour for the building of the temple complexes. The building was done with a rather simple technology for beasts of burden, a functional wheel, and metal tools were lacking. The major achievements of the Classic period were its calendrics and its religious thought, which represented the efforts of the priestly class to systematize the universe and make it predictable.

Around the end of the Classic period a warrior group came into power. With the coming of the warriors a period of militarism began. War gods replaced the rain gods, and the jaguar symbolism gave way to the eagle complex in iconography. Human sacrifice, an occasional thing in the Classic period, became a mass phenomenon under the warlords of the Toltec and Aztec empires. The Toltecs, and later the Aztecs, were expansionist. When the Spaniards arrived, the Aztec Empire extended over most of Middle America, from the central valley to Yucatán, with garrisons, frontier fortifications, and foreign colonies. With the fall of the Aztec capital in 1519, the Guatemala conquest of 1524, and the long-drawn-out battles with the Indians of the northwest region, the Spaniards ended the isolation of Middle America.

The Conquest and its effects. The Spaniards overthrew the urbanized, class-structured high civilization of the Aztecs and established a system of alliances with the tributary states. The conquerors decapitated native society, substituting the Spanish for the Indian nobility. They introduced a host of new agricultural techniques and crops, along with steel, horses and cattle, mines, European crafts, and new forms of social organization. They also created dichotomies between ethnic and racial groups, giving them different rights and obligations.

From the colonial period to independence

In the early colonial period following the conquest, a small minority of Spaniards administered and controlled vast Indian populations. The religion of the conquerors spread rapidly, as did many of their domesticated plants and animals. In this period the Indians were grouped into villages modelled on the grid plan, with a central plaza on which stood the church and town hall. The basic economic institutions were the encomienda and the religious reservation: the encomienda was an allotment of land and labour to a Spanish overlord, used in the densely peopled areas of the former high civilizations; the religious reservation was established by the Jesuits in the northwest. The encomiendas integrated the Indians into the whole economy of New Spain, while the religious reservations tended, on the whole, to isolate them.

The later colonial period saw the abolition of the encomienda and the secularization of the religious reservation. Where previously the upper strata of the Indian population had intermarried with the Spanish, the later colonial period brought a more rigid separation of the Spanish and the Indians. Although the encomienda was legally dead, its economic consequences persisted: the colonial-plantation economy developed, along with the cattle ranch and the mining complex. Indian lands were taken over at an increasing rate, and the Indians gave up whatever illusion they may have had as to the benefits to be gained from the white man's culture.

Mexico and Guatemala became independent of Spain in 1821. The early republican period involved the Indians only marginally. As the native Spanish and mestizos threw off European domination with the slogans and banners of the French Revolution, they neither considered the Indians nor involved them in their struggles. For the Indians it was a time of cultural and social consolidation, spent in the building of defenses against land encroach-

ment and in the erection of communication barriers to protect their cultural heritage.

The later republican period was for Mexico and Guatemala a time of nation building, of moderate industrialization, and of commercial agriculture. The Indian was seen as anachronistic, an obstacle to the march of triumphant nationalism. For the Indian, the consequences were drastic. The national and international economy led him to develop a social structure and cultural pattern that would keep the Indian community intact, even at a low economic level. The strong corporate Indian community reached its most definitive form under the pressures of land-grabbing and anti-Indian social policies.

In the Mexican revolution that began in 1910, the Indians won a place in the political structure. The official policy became pro-Indian. This policy exalts the Indian heritage and makes it the root of the national heritage. In its economic and political aspects it aims at "incorporation" of the Indian into national society on terms set by the Indians themselves. It also provides special services to Indians, as demonstrated in the many programs of the Instituto Nacional Indigenista de Mexico in health, road building, agriculture, and literacy. It employs themes from Indian culture, as in the murals of the Mexican neo-Realists and the music of modern Mexican composers. In Guatemala a similar policy had a brief vogue, but it was reversed following the counterrevolution of 1954.

But the forces shaping contemporary Indian life lie largely outside these official policies. Population increase, the expansion of physical and cultural communication, industrialization, urbanization, and political participation are the basic forces that will determine the future of the Indians of Middle America.

The Indian population in Mexico in the 1970s was stable or declining, while that in Guatemala was increasing. The differences lay not so much in vital rates as in social and cultural dynamics. In Mexico there has been considerably more urbanization—with a greater flow of Indians to the cities—than in Guatemala; and when Indians are urbanized they become mestizos and ladinos. In the rural parts of Mexico there has also been a movement of Indians into Mexican society at a faster rate than in Guatemala. Thus, in the 1970s, only about 12 percent of the Mexican people were still counted as Indians, while the category comprised more than 50 percent of the Guatemalans.

BIBLIOGRAPHY. The most authoritative work on Middle America is the monumental *Handbook of Middle American Indians*, ed. by ROBERT WAUCHOPE, 11 vol. (1964–71). These volumes cover all aspects of the area from physical geography, linguistics, archaeology, physical anthropology, ethnology, to social anthropology. ERIC WOLF, *Sons of the Shaking Earth* (1959), is the best single book on Middle America. SOL TAX (ed.), *Heritage of Conquest* (1952), is a professional anthropological estimate of the content of Middle American Indian culture. *The Maya and Their Neighbors* (1940), is an introduction to the archaeological and historical problems of the region and contains the basic essay on Indian history by OLIVER LA FARGE. S.G. MORLEY, *The Ancient Maya*, 3rd rev. ed. (1956); J. ERIC THOMPSON, *The Rise and Fall of Maya Civilization*, 2nd ed. (1970); and MICHAEL D. COE, *The Maya* (1966), give the different views on that civilization. G.C. VAILLANT, *The Aztecs of Mexico*, rev. ed. (1956), is a basic book; and H.J. SPINDEN, *Ancient Civilizations of Mexico and Central America*, 3rd rev. ed. (1968), is important for its calendrical correlations. For an understanding of the colonial period, the works of BERNARDINO DE SAHAGUN, trans. by A.J.O. ANDERSON and C.E. DIBBLE, *The Florentine Codex*, pt. 9–10 (1959); and A.M. TOZZER'S annotated translation of Landa's *Relación de las cosas de Yucatán* (1941), is essential. For historical accounts, R.N. ADAMS, *Crucifixion by Power: Essays on Guatemalan National Social Structures, 1944–1966* (1970), is an up-to-date survey. GEORGE M. MCBRIDE, *The Land Systems of Mexico* (1923, reprinted 1971); FRANCOIS CHEVALIER, *La Formation des grands domaines au Mexique* (1952; Eng. trans., *Land and Society in Colonial Mexico: The Great Hacienda*, 1963); and NATHAN L. WHETTEN, *Rural Mexico* (1948), give an adequate picture. The modern studies in Middle American communities are listed in HOWARD CLINE, "Mexican Community Studies," *Hispanic American Historical Review*, 32:212–242 (1952); and in R.H. EWALD, *Bibliografía comentada sobre antropología social guatemalteca, 1900–1955* (1956). Modern developments are described in J.L. ARRIOLA (ed.), *Integración social en Guatemala* (1956); W.E. MOORE, *Industrialization and Labor* (1951); and by R.N. ADAMS in *Political Changes in Guatemalan Indian Communities* (1957).

(Ma.N.)

Middle Eastern and North African Peoples and Cultures

The name Middle East has become a conventional term designating the whole area extending from the Atlantic coast of Morocco and Mauritania eastward across North Africa to Afghanistan. So defined, it includes the Sahara and the Mediterranean coast of Africa (the countries of Morocco, Algeria, Tunisia, Libya, Egypt, and The Sudan), the Arabian Peninsula, Iraq, Turkey, and Iran. This area is now regarded as a broad cultural unit, primarily in terms of its overarching Islāmic civilization.

A number of distinctive cultural features give the area unity and justify the use of the term Middle East. These take the form of similar constellations of subcultures across the area consisting of urban networks with their agrarian and pastoral hinterlands. Parts of the area are often treated separately: the Maghrib, a term that designates the peoples of present-day Morocco, Algeria, Tunisia, and Libya; Mashriq, the eastern area including the present countries of The Sudan, Egypt, Syria, Lebanon, Israel, Jordan, Iraq, Saudi Arabia, Yemen (Aden), Yemen (Ṣan'ā'), Oman, Kuwait, and other Gulf emirates; Anatolia (Turkey); and Iran.

CHARACTERISTICS OF MIDDLE EASTERN CULTURE

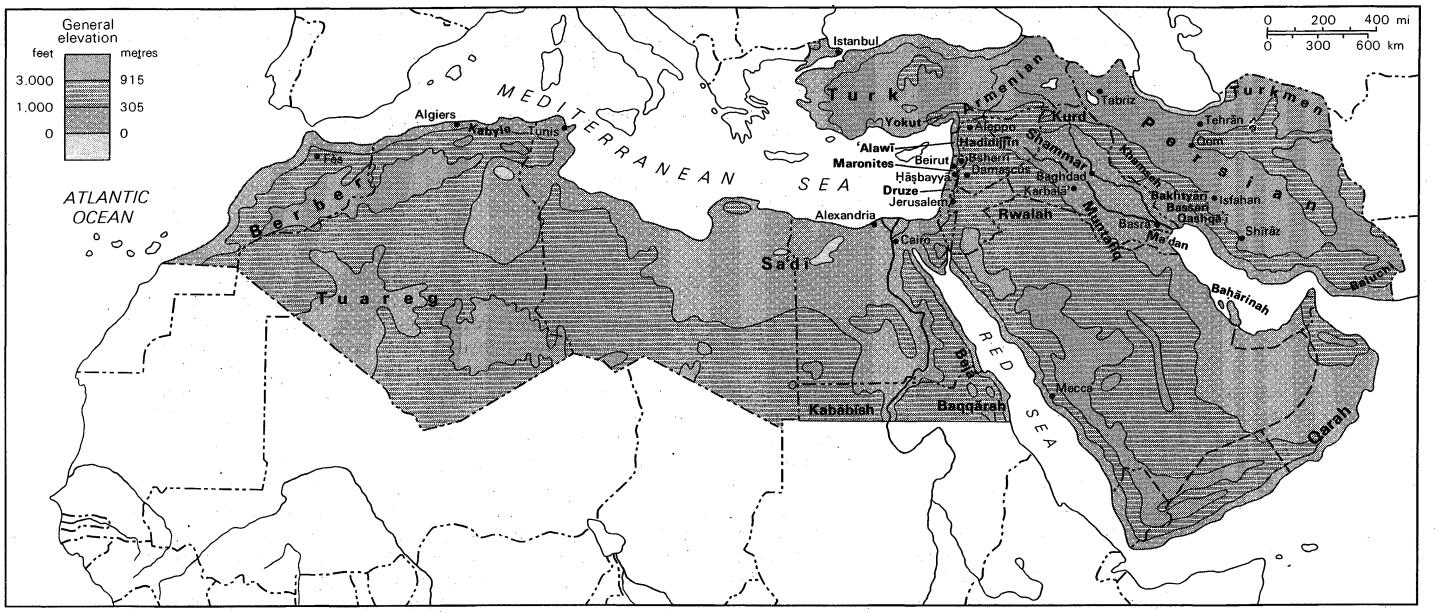
Historical overview. Scattered Paleolithic evidences of man have been found throughout the Middle East. With the Neolithic Period, however—that period commencing about 10,000 years ago, during which plants and animals began to be domesticated—a geographical concentration appears, and an evolution of Middle Eastern cultures took place in the sickle-shaped zone extending from the Nile Valley to the valleys of the Tigris and Euphrates rivers and down the eastern slopes of the Zagros Mountains in Iran. Exploration of eastern Turkey and northern Iran has indicated that the earliest domestication of plants and animals occurred in that central area. About 2,000 years later, civilizations based on irrigation began to develop, first in the lower reaches of the Tigris–Euphrates Valley and then in the Nile Valley. This irrigation technology led to the development of states and empires. Scholars traditionally have looked upon the areas along the Nile and Tigris–Euphrates rivers and between as the region of the earliest development of the ancient high civilizations of the Old World. In recent times, however, evidence from southern Arabia, especially the Yemen, has led to an extension of this area.

By Greco-Hellenic times, trade connections had been established with the Far East. As civilization developed in Europe, the Middle East from Morocco to Iran became an area of passage. There was increasing movement into and across the area, not only in the form of massive invasions but in commercial, diplomatic, and religious contexts. This began most intensively at the time of the rise of the Arab kingdom and of Islām (AD 640), and it accounts for the concept of the Middle East as that central area of Islāmic control that reached from Morocco to Iran, incorporating or incapsulating a multitude of peoples, languages, and cultural adaptations.

Unity and diversity. In very broad terms, the culture of the Middle East consists of great urban centres separated by dispersed rural peasantries in the mountains and plains, along with a variety of patterns of nomadic pastoralism in the steppes and deserts. But this tripartite division tends to oversimplify the ecological diversity and ignore the cultural continuity of the whole Middle Eastern area, which should be thought of as laced together by a number of connecting institutions. Indeed, the Middle East has always been linked by its merchants, scholars, religious brotherhoods, and other communicating agents.

The cities

A complex urban life is one of the most distinctive characteristics of the Middle East, and this has been true throughout its recorded history. More than a dozen of the world's greatest cities are found there: Alexandria, Al-



Distribution of Middle Eastern and North African peoples and cultures.

giers, Aleppo, Baghdad, Basra, Beirut, Cairo, Damascus, Fès (Fez), Isfahan, Istanbul, Jerusalem, Mecca, Shīrāz, Tehrān, Tabriz, and Tunis. Jerusalem is a world centre for three major religions: Judaism, Christianity, and Islām. Mecca is another major centre for Islām, and many secondary and tertiary urban centres are also religious centres, such as the Druze community's holy towns of Ḥāṣbayyā, Rāshayyā, and B'qlīn, in the Lebanese mountains. There are also the sacred Muslim towns of Tarīm in southern Arabia, Karbalā' in Iraq, and Qom in Iran. The Maronite Christians of northern Lebanon have their sacred town in Bsharrī. The city as sacred ceremonial centre has from antiquity been a major cultural characteristic of the Middle East.

The extensive urban civilization of the area is closely associated with nonurban patterns of nomadic pastoralism and various types of peasant agriculture, as well as with the connecting institutions mentioned above. It is important to bear in mind the antiquity and continuity of these stable, complex centres of civilization situated in optimum locations, with less complex cultural systems effectively tied to them by the integrator networks. As a whole, this culture has survived 10,000 years with few breakdowns until the most recent times.

Peoples and languages

Another characteristic of the Middle East is its cultural diversity. It includes the Bedouin tribes of northern Arabia, the Oriental Jewish and Assyrian Christian communities, the Muslim Ibāḍīs of Algeria and Oman, the Turkmen of northeastern Iran, the Kabyle Berbers of Algeria, and the Kurds, Armenians, and others. But most of these communities are widely dispersed. The Middle East is at once a vast patchwork of dispersed peoples and languages and a fragmented area of enclaved ethnic groups locally dominant over others scattered among them. Probably there is no complete enumeration of such groups, much less an agreement upon their status or their demographic features. Even as some are clearly disappearing, new ones are forming. Most conspicuous among the new ethnic groups are the Algerian and Palestinian nationals and the Afro-Lebanese caste appearing in Lebanon.

The linguistic structure of the Middle East is also very complex. Four major language stocks are represented: Semitic, Hamitic, Indo-European, and Ural-Altaic. In all but the most remote communities, people are multilingual, commonly with some knowledge of at least one European language. But there are marked dialectal distinctions carrying caste, class, and political significance, especially in urban centres. These include such distinctive hybrids as the argots of Persian Gulf sailors or of the servant classes in Mediterranean cities. Finally, every urban quarter, rural village, religio-ethnic group, or pastoral tribe has its own linguistic forms, its own vocabulary, its secret names for people and places.

CITIES AND LINKAGES

Urban life. Whether it is a port of trade or a ceremonial centre or a political centre, the Middle Eastern city possesses certain marked characteristics. It is roughly circular in shape and divided into a number of distinct sections or "quarters." Some cities still have walled quarters, with gates shutting them off from each other guarded by watchmen. The government or political centre of the city forms one quarter, with its garrison, hospitals, and palace or fortress; it also contains the major mosques associated with the particular Islāmic sect of the ruling elite, together with Muslim schools and universities.

Structure of the Middle Eastern city

A second important quarter of every city is the permanent covered marketplace, the bazaar or suq, situated near the government quarter. The bazaar is a labyrinth of alleyways, divided into sectors according to crafts and types of merchandise and with small mosques and chapels scattered through it. The alleyways are covered; often they are arched with stone, as in the old bazaar at Aleppo or in those of the great cities of Iran; sometimes, in the smaller towns, they are simply shaded by mats. The caravansaries of inter-city and inter-regional trade are located in the bazaars.

The residential quarters were traditionally reserved to Muslims. Depending upon the size of the city, these might be divided according to sect, ethnic group, or city of origin. Non-Muslims generally live outside the city walls in their own quarters: Christians of many sects, Jews, and villagers from the hinterland. Each of the residential quarters of these other ethnic groups or non-Muslim religious groups contained its own small bazaar and its religious centres and schools.

Outside the city lies an agricultural zone from which the city draws food and other necessities. In this area are located the slaughterhouse, tanneries, and the spinners and dyers that supply the textile workshops in the city bazaar.

Integrating networks. Middle Eastern cities have historically been connected with each other by caravans and coastwise or riverine sailing craft. The organization of commercial ventures between cities was undertaken by the merchants and carried out as joint endeavours. Merchant families maintained houses or branches in a number of cities—kinship networks that continue today at all levels of society. The caravan routes have existed since antiquity, adapted to the major carrying vehicle, the camel. Today trucking routes follow virtually the same tracks. Along the routes are stopping places, often forti-

Merchant organizations and religious brotherhoods

fied *khāns* (caravansaries) associated with villages or towns where food and drink and other amenities were available to the caravan people. The locations of many cities and towns all across the Middle East, from Morocco to Iran and well into Anatolia and Armenia, were determined by the caravan routes.

Another institution linking the Middle Eastern cities is that of the religious brotherhoods, both Muslim and Christian, whose networks of mission stations or religious centres have often been parallel to and part of the commercial network. Sometimes a particular brotherhood was itself also a commercial network covering vast areas in which people were sparsely dispersed in oases or nomadic groups but across which it was important to transport goods. One recent example was the Sanūsīyah Brotherhood, whose founder, Sīdī Muḥammad as-Sanūsī, moved from Iraq in the 19th century to the oases of present-day Libya. Ultimately the expansion of Sanūsīyah followers gave rise to a network linking the Mediterranean ports with the Saharan and trans-Saharan trade routes. The order promulgated learning, stimulated and promoted commerce, and maintained a communications network, emerging as the military leadership of Libya in the wars of the 20th century. The leader of the brotherhood, a descendant of the founder, became the ruler of the Kingdom of Libya for its short life.

Many other institutions link the cities and settlements of the Middle East with the rural agrarian hinterlands and the pastoral tribes. Some are extensions of the power centres of the kingdoms, provinces, or empires that have appeared and disappeared before and since the rise of Islām, such as the armies of the ruling elites and the courier services of rulers and governors. At lower levels there are the mass migrations of ethnic groups, the annual seasonal movements of nomads, the networks of peasant markets, and the itinerant gypsy groups providing tinkering, tattooing, and stud animals for breeding. Among the wandering groups and individuals are Ṣūfī mendicants, essentially beggars but often reputed to be agents of the state; the jongleur, or itinerant singer, who sings his way across the country and may also be an agent of a particular ruler; itinerant medical practitioners, barbers, circumcisers, tooth pullers, and census takers; country peddlers; and animal traders. Thus no district or community of the Middle East has ever been isolated from news of the world or from the centres of power. In the most remote areas one is always surprised at how much the peoples of the villages know about the external world. No tribesman or goat herder is under the illusion that his people are the only living people on Earth. A continuity and ramification of contact across languages and religions are quite clearly built into the ideologies, the social relationships, and the economy and technology of the traditional Middle East.

Migrant groups

The cities and the integrating mechanisms described above are the dominant Middle Eastern social structures, the major centres of political power, knowledge, formal culture, and sacred ceremony for very large numbers of people. It is incorrect to think of the Middle East as an agglomeration of ethnically distinct people and cultures. With the exception of dense concentrations of cultivators along the two great river systems, the Nile and the Tigris–Euphrates, the cultural and population centres lie in the network of ancient and contemporary cities. The cities themselves are multi-ethnic in character. Even though a religious centre such as Mecca may exclude all except Muslims, it is still a great gathering place of peoples, illustrating the ethnic diversity of the followers of Islām. The very structure of the Middle Eastern city is exemplary of the area in general, of the coexistence of many different ethnic, religious, and linguistic groups. The governing apparatus of the state is everywhere the mediator between these ethnic groups and has in fact served to maintain an equilibrium among them for thousands of years. Only since the 19th century has this ancient network, upon which the Ottoman Empire was built, begun to dissolve and break down. This fragmentation has taken place under the impact of the expansion of Western and Eastern nations and of industrialization.

PEASANT CULTIVATORS

Perhaps 70 percent of the peoples of the Middle East are peasant cultivators. With a few notable exceptions, such as those in the Berber highlands of Morocco and Algeria, peasants live in nucleated village settlements on marginal lands near their fields. Berber highland settlements tend to be dispersed hamlets within areas belonging collectively to kinsmen.

Property and tenure

Within the sphere of state or provincial control, the peasant communities are often dominated by landlords and pay taxes to the state. Elsewhere the cultivating population is often found in ethnically distinct enclaves that challenge the power of the state to collect revenues. The "land of government" generally includes areas in the vicinity of urban centres, open plains easy of access, and settlements on established trade routes. Examples are the Nile Valley; the lower reaches of the Tigris and Euphrates, from Baghdad to the marsh areas of the Shatt al-Arab; the plains of Esdraelon and the lower foothills of old Palestine; the vicinities of Tunis and Fès in the Maghrib; the plains of western Syria from Damascus north to Aleppo; and the coastal plains of Turkey and Iran along the Black and Caspian seas.

Forms of land tenure vary exceedingly. Individual tenure is rare in comparison to the great estates of urban landlords and rural aristocratic families. The latter might in the past encompass as many as 90 villages, as in the Syrian plains or in Egypt, or be interspersed with freehold peasant plots, as were the estates in the Lebanese mountains controlled by the great feudal families. Communal management of the lands associated with a village was a customary means of distributing the land among the villagers, according to the supply of men and oxen. Such communal tenures were known in the Levant as *mushāʿ* but appear in many parts of the Middle East in various forms depending on local resources. Everywhere, however, a major category of property has been *waqf* (Arabic) or *habous* (Berber) land—*i.e.*, land or other property controlled as a religious or charitable endowment by ecclesiastics or trustees. Control of such property was the basis of the power of the Muslim religious brotherhoods, the Christian monastic orders, and the saintly lineages. Even at the lowest levels of society, the classes of priests and *imāms* or mullahs of the village churches and mosques based their power upon the control of property.

Village communities

Modern Eastern villages show common organizational traits. Everywhere the patrilineal family dominates, with alliances between families made by marriage and economic cooperation. A village council composed of the heads of larger families maintains local customs, decides on the filling of such local offices as village herdsman and field guards, and acts in times of threat to the village as a whole from predatory landlords, armies of the state, or pastoral tribesmen. Internal economic specialization is not very great, especially in the villages of the state-controlled areas. Most families are relatively self-sufficient, and productive and maintenance tasks are divided according to sex. The status of women has long been misrepresented as "low"; it is, rather, protected and varies with the status of the whole family.

Communities of the relatively autonomous areas (highland Berbers, Druzes, Maronites, ʿAlawīs, Kurds) are often more complex. Here are found patrilineal alliances of families in the form of clans and a ranking of clans and families as political and religious leaders. Such communities may ally with each other territorially, forming "tribal" entities.

A universal feature of the Middle Eastern social landscape is its lack of homogeneity at all levels, even familial. Most villages in which one ethnic or religious category predominates will also have at least a few families of a different group who provide a local specialization, such as making pottery or herding the village flocks. This is also true for many rural areas. For example, the Kurdish mountain area at the juncture of the countries of Iraq, Turkey, and Iran is also inhabited by communities of Jews, Arabs, Assyrians, Turks, and Armenians. The most ethnically homogeneous areas are probably the Berber

highlands of Morocco and Algeria, but even there the "tribes" are usually heterogeneous in origin.

Crops and crafts

Methods of cultivating the land are various. Cash cropping in cotton, cereals, and sesame is widespread in the plains areas; truck gardening in vegetables is also important, especially near urban centres. Wheat and barley and such legumes as chick-peas and lentils are ancient and ubiquitous throughout the Middle East. Arboriculture is equally important. A variety of nut and fruit trees is cultivated in the Zagros and Taurus mountains. The olive and the fig are apparently almost as ancient as cereal cultivation around the Mediterranean. Southern Iraq is the major date-producing area of the world. A rich variety of subtropical fruits, including apricots, oranges, and tangerines, is also long known in the area, deriving from the east. Tea, rice, and coffee are found in Iran and the Yemen.

Rural crafts are also widespread. To a great extent they belong to the relatively self-sufficient peasant householding economy, but there is some production for the market, especially in the vicinity of major cities. Manufactured pottery, textiles, mats, trays, and baskets form staple rural crafts. The "industrial village" of Bayt Shabāb, in central Lebanon, has for many centuries produced cotton textiles, church bells, and large pottery jars. While various ethnic groups tend to specialize in particular crafts, this specialization is often determined by the locality. Thus, the Jewish communities of the Yemen specialized in metalcrafts, vineyard cultivation, and wine making, but in the Levant and North Africa they found other occupational niches related to literacy and money handling. Armenians in their traditional homeland area engaged in all occupations; elsewhere, they held special status as merchants to the *shāh* in Iran or as craftsmen in southern Turkey and in the cities of the Levant.

NOMADIC PASTORALISTS

Kinds of nomadic tribes. The various nomadic pastoralist societies of the Middle East have been much written about but constitute only 10 to 20 percent of the population. Control of the long-distance caravan routes and of particular resources that can only be reached by caravan, such as salt in the Sahara, lie with the nomadic tribes and have given rise to concentrations of power, such as the confederations of the Tuareg of the Sahara, of the Shammar of northeast Arabia, and the Khamseh of the central Zagros Mountains of Iran. Many nomadic pastoralist societies, however, are primarily specialized animal breeders occupying marginal lands and usually combining small-scale cereal cultivation with their pastoralism. The Kabābīsh of the northern Sudan, the shepherd peoples of the Levant and of parts of Libya, and others depend not only upon their flocks and herds but also upon agricultural or other resources. Sheep and goat breeders such as the Sa'dī of Libya and Egypt, the Mawālī and Ḥadidiyyīn of the Levant, the Muntapīq of southern Iraq, and the Bāṣerī (Basseri), the Bakhtyārī, and the Qashqā'ī of Iran are marginally associated with agriculturalist. The Bedouin of the Arabian Peninsula and North Africa, who specialize in camel breeding, occupy steppe and desert areas. Cattle herders, much less common, are represented by the Baqqārah (Baggara) of The Sudan and the Qarah of southern Arabia. Unique in the area, if not in the world, are the marsh-dwelling Ma'dan of southern Iraq, whose water buffalo are their major economic resource. The camel, by virtue of its speed and mobility, its weight-bearing capacity, and its ability to live upon desert vegetation, enables specialized camel pastoralists to dominate other societies.

Control of caravan routes

Patterns of movement. The nomadic pastoralists follow two patterns of movement: horizontal nomadizing and vertical transhumance. Both are seasonal adaptations to grazing conditions. In horizontal nomadizing the flocks move from permanent sources of water during hot, dry summers into steppe and desert pasturages during the cooler, moister winters, returning to the permanent wells in late spring. The Rwalah Bedouin of northern Arabia have traditionally summered in the vicinity of the Azraq oasis, patronizing the markets of 'Ammān and Damascus, and moved deep into the north Arabian steppes during the winter. Vertical transhumance is characteristic of sheep and goat herders in mountainous areas. They winter their flocks on warm lowland pasturages and trek to highland summer pasturages through areas often rather densely occupied by peasant cultivators. Numerous Berber tribes of Morocco and Algeria have subsisted in this way, as have the Yokut peoples of southern Turkey. Best known, however, are the great shepherd tribes of Iran's Zagros Range, the Bakhtyārī and the Bāṣerī.

Nomadic social organization

The nomadic pastoral peoples of the Middle East all have a clan or lineage organization, and all appear to be patrilineal in descent and inheritance, except for the matrilineal Berber Tuareg of the Sahara. Most large and wealthy tribes also have socially ranked clans, with aristocratic lineages holding leadership. The camping units of nomadic pastoralists generally comprise a core of kinsmen; the camps of tribal leaders contain more distant kin, along with such members of specialist castes as blacksmiths, camel traders, or hunters and water scouts.

The ethnic diversity general in the Middle East is found also among the nomadic pastoral peoples, who include Berbers, Arabs of North Africa, Beja (Bujah) and Baqqārah peoples of the Red Sea littoral and northeastern Sudan, Turks, Turkmen, Kurds, and various Persian and Baluch peoples. All are nominally Muslim.

CULTURAL CHANGES IN THE MIDDLE EAST

Colonialism and revolution

Marked economic and political changes in the Middle East began in the early 19th century with the European colonial penetration of North Africa, southern Arabia, and the Persian Gulf. At the end of World War I, the Ottoman Empire was dismembered, and Iran was united under a new dynasty. During the period between the wars, national boundaries and parliamentary institutions were arbitrarily established throughout the Middle East, except in the Arabian Peninsula and Palestine. Nationalist movements appeared, and the years 1925–30 saw rebellions and disturbances throughout the area. There were large population movements, such as the exchange of Greeks and Turks. The repressive pacification and suppression of the Berber peoples of Morocco and Algeria was carried out. The colonization of Palestine by European Jewish communities brought clashes with the British and with the indigenous peoples, mostly Arab peasants. Within a decade after World War II, national independence had been achieved by Syria, Lebanon, Iraq, and Jordan. Israel had been established, the long Algerian revolution was underway, and Morocco, Tunisia, Libya, and Egypt had been declared sovereign states. Everywhere the traditional economic patterns and institutional networks had been severely affected. Foreign economic enterprises controlled the exploitation of Middle Eastern resources, using the area as a market for manufactured goods and as sources of petroleum, fruits, and a few minerals. Industrialization of the Middle Eastern economies was minimal, except in the state of Israel, dominated by a sophisticated and highly trained elite largely of European origin.

By the mid-1960s, however, a number of countries in the Middle East were moving toward secularized nationalist regimes and acquiring greater control over their own resources and populations. The ancient cities had become centres of industrialization; the old urban–rural networks fed a steady flow of peasants to the cities, and, as in the rest of the industrializing world, shantytowns sprang up around the major cities. Both Algeria and the Levant supported internment camps of hundreds of thousands of refugees, and it is these concentrations of displaced peoples, chiefly peasants, that gave rise to revolutionary movements and the beginnings of organizational change in the Middle Eastern societies.

By the 1970s the Middle Eastern societies had not yet made the transition to modern organization. Throughout much of the area there was a greater division than ever between tiny, rich elites and masses of displaced peasants and impoverished pastoralists. Land reform and redistribution had only partially succeeded in Iran, Algeria, Egypt, and Syria. Secularized legal and judicial systems,

expanded national education systems, and basic industrialization were developing slowly and sporadically. In farming, modern technology and marketing practices were gradually being adapted to Middle Eastern climatic and soil conditions.

Mies van der Rohe, Ludwig

Ludwig Mies van der Rohe was one of the leading architects of the 20th century. Regarding architecture as "logical structure," he evolved a classically balanced, utterly simple architectural style. His buildings were marked by an uncluttered, almost skeletal exterior framework, little division of interior space, and masterful craftsmanship and simplicity of detail. World architecture continues to oscillate between his precepts and those of his contemporary, Le Corbusier. But while Le Corbusier, inspired by the white plasticity of Mediterranean architecture felt that "passion can create drama out of inert stone," Mies, brought up in the chill, rationalist climate of northern Europe, was a classicist. He was the supreme craftsman, who kept applying and refining the same basic structural and aesthetic principles he had discovered early in his career to every new architectural problem he was asked to solve. "I would rather be good than original," he has said. But Mies's mastery of proportion and detail, which has been compared to that of great Renaissance artists, such as Lorenzo Ghiberti, is not easy to match. In an age of built-in obsolescence, his was most of all an architecture of quality.

Artemis Verlag und Verlag fur Architektur, Zurich

Mies van der Rohe.

Early training. Ludwig Mies (he added his mother's surname, van der Rohe, when he had established himself as an architect) was born on March 27, 1886, in Aachen, or Aix-la-Chapelle, Germany, one of the great historic cities of Europe and once the centre of Carolingian culture. His father was a master mason who owned a small stonecutter's shop. Helping his father and working on various construction sites as a boy gave Mies a feeling for the nature of materials and craftsmanship that is rarely acquired in architecture schools. Mies never received any formal architectural training, a lack of which he seemed almost proud. At the age of 15 he was apprenticed to several Aachen architects for whom he sketched charcoal outlines of "Renaissance" ornaments on large sheets of brown paper pinned to the wall, which the plasterers would then form into stucco building decorations. Although Mies thought it a grueling task, it developed his skill for linear drawings that was to produce some of the finest architectural renderings of his time.

Influences on Mies's architectural development. In 1905, at the age of 19, Mies went to work for an architect in Berlin, who, it turned out, specialized in the design of wooden buildings. Mies felt that he knew too little about this material and soon left his job to become an apprentice with Bruno Paul, a leading furniture designer who worked in the Art Nouveau style of the period. Two years later he received his first commission, a traditional suburban

house. Its perfect execution so impressed Peter Behrens, then Germany's most progressive architect, that he offered the 21-year-old Mies a job in his office, where, at about the same time, Walter Gropius and Le Corbusier were also just starting out.

Association with the Werkbund

Behrens was a leading member of the Deutscher Werkbund, and through him Mies established ties with this association of artists and craftsmen, which advocated "a marriage between art and technology." The Werkbund was inspired by the English arts and crafts movement of William Morris and John Ruskin. But while Morris set out to revive medieval craftsmanship in romantic protest against the industrial revolution, the Werkbund, with equally romantic zeal, welcomed technology almost to the point of idolatry. What was needed, its spokesmen declared, was to give form and meaning to machine-made things, including machine-made buildings. This new and "functional" design for the industrial age would then give birth to a *Gesamtkultur*, that is a new universal culture in a totally reformed man-made environment. Endlessly and often poetically discussed, these ideas were not so much a program as a vision, an article of faith. It was a faith that, throughout the first half of the 20th century, motivated the "modern" movement in architecture and was designated the "International Style," by the architectural historian Henry-Russell Hitchcock and the architect Philip C. Johnson, in their book of the same name published in 1932.

It was soon obvious to Behrens that Art Nouveau, with its sensuous undulations, was hardly what the Werkbund envisioned. Instead, he began to emulate the pure, bold and simple Neoclassic forms of the German early 19th-century architect Karl Friedrich Schinkel. Although Mies was impressed by many of Behrens's works, such as the Berlin Turbine Factory of 1909—an original Neoclassic statement in steel and glass—and the German Embassy at St. Petersburg of 1911, it was Schinkel, not Behrens, who became the decisive influence on Mies's search for an architecture of *Gesamtkultur*. Throughout his life, the elegant clarity of Schinkel's buildings seemed to Mies to embody most perfectly the form of the new environment.

Influence of Karl Schinkel and Hendrik Berlage

Another decisive influence was Hendrik Petrus Berlage, a pioneer of modern Dutch architecture, and the first European actually to view Frank Lloyd Wright's American houses that so excited the European avant-garde. Mies encountered Berlage in The Hague, where Behrens had sent him to supervise the construction of a full-scale wood and canvas mock-up of a large house for Mme H.E.L.J. Kröller, a prominent art collector. Mies stayed a year because Behrens's design did not satisfy Mme Kröller, who then asked Mies to submit his own. Although Mies's more elegant version was never built either, his year in Holland gave him time to acquaint himself with Berlage's work and philosophy. Berlage's work inspired his own love for brick and the Dutch master's philosophy inspired Mies's credo of "architectural integrity" and "structural honesty." Later, teaching in Chicago, Mies defined "architectural integrity" to his students: "I hope you will understand that architecture has nothing to do with the invention of forms." As to structural honesty, Mies went further than anyone else to make the actual rather than apparent or dramatized supports of his buildings their dominant architectural features.

Work after World War I. In Imperial Germany only university graduates could become officers, and thus throughout World War I Mies served as an enlisted man, building bridges and roads in the Balkans. When he returned to Berlin in 1918, the Kaiser's Germany, with its arrogant hostility to the modern movement, had gone down in defeat, and despite the hunger and violence there seemed to be in the turmoil of the revolution a new hope that gripped every artist and intellectual and inspired a prodigious burst of new creativity. Architecture, painting, and sculpture, according to the manifesto of the Bauhaus —the avant-garde school of the arts just established in Weimar—were not only moving toward new forms of expression, but were becoming many-facetted and international. Never before had painting and sculpture—among them Dadaism from Zürich, a nihilistic, iconoclastic, antirational movement in the visual arts and literature; de Stijl from Holland, an abstract geometric movement characterized by the use of rectangles and primary colours; and the Russian abstract movements of nonobjectivism in painting and sculpture known as Constructivism and Suprematism—so decisively determined architectural thought. Mies was in the thick of it. Though hardly gregarious, he became a leader of the *Novembergruppe*, a group named after the German revolution of November 1918, which had also advocated an artistic one. He joined the *Zehnergruppe*, a group dedicated to popularizing the concepts of modern architecture, helped found and finance the magazine *G* (for *Gestaltung*, or "form giving") in which many of his theoretical projects were published, and organized many exhibitions. But there was virtually nothing for him to build, and his foremost building of this period—an Expressionist memorial to the murdered Communist leaders Karl Liebknecht and Rosa Luxemburg, dedicated in 1926—was demolished by the Nazis.

Mies's most important work of these years remained on paper. In fact, these theoretical projects, rendered in a series of drawings and sketches that are now in the New York Museum of Modern Art, foreshadowed the entire range of his later work. The Friedrichstrasse Office Building (1919) is one of the first proposals for an all-glass building and establishes the Miesian principle of "skin and bones construction." The "Glass Skyscraper" (1921) applies this idea to curved forms so that the facade reflects itself. Both of these building designs were uncompromising in their utter simplicity. Other theoretical studies explore the potentials of concrete and brick construction, and of de Stijl form and Frank Lloyd Wright concepts. Few unbuilt buildings surpassed them in the variety of ideas and in their influence on the development of architecture.

Werkbund exposition of 1927

This influence was apparent at the first postwar Werkbund exposition at Weissenhof near Stuttgart in 1927. The exhibition consisted of a housing demonstration project planned by Mies, who had by then become the Werkbund's vice president. Europe's 16 leading modernists, including Le Corbusier and Mies himself, designed various houses and apartment buildings, 33 units in all. Weissenhof demonstrated, above all, that the various architectural factions of the early postwar years had now merged into a single movement—the "International Style" was born. Though not a popular success, it was a critical one, and Europe's elite suddenly began to commission modern villas, such as Mies's Tugendhat house (1930) at Brno, Czechoslovakia. Intellectuals who could not afford villas took to the new steel furniture and interior designs Mies, architect and designer Marcel Breuer, and designer Mart Stam had displayed. But the exhibit did little, if anything, to advance the Werkbund's social purpose. None of the buildings designed for low-cost prefabrication and industrial production was actually prefabricated or mass-produced. The problem, it seemed, was not design alone, but lack of popular demand for the new style. Yet Mies held fast to his belief that the path of industry "must lead from quantity towards quality—from the extensive to the intensive" so that "industry and technology will join the forces of thought and culture."

Technology and culture did merge in the German Pavilion (also known as the Barcelona Pavilion), which is indeed best described as an architectural statement of quality, thought, and culture. The pavilion was commissioned by the German government for the 1929 International Exposition at Barcelona. It exhibited nothing but itself—a sequence of marvelous spaces on a 175 by 56 foot (53.6 by 27 metre) travertine platform, partly under a thin roof, and partly outdoors, supported by chromed steel columns. The spaces were defined by walls of honey-coloured onyx, green Tinian marble, and frosted glass and contained nothing but a pool, in which stood the sculpture of a nude by Georg Kolbe, and a few of the famous chairs Mies had designed for the pavilion. It was art for art's sake and luxurious art at that.

Appointed director of the Bauhaus

In 1930, Mies was appointed director of the Bauhaus, which Gropius had brought from Weimar to Dessau in 1925. Between Nazi attacks from outside and left-wing student revolts from within, the school was in a

state of perpetual turmoil. Though not cut out to be an administrator, Mies soon won respect as a stern but superb teacher. "If Mies doesn't make good architects of us, he'll at least teach us to judge what good architecture is," one of his American students wrote home at the time. When the Nazis closed the state-supported school, Mies tried for a few months to continue it on a private basis in an empty telephone factory in Berlin. But modern design was as hopeless a cause in Hitler's totalitarian state as was political freedom. Mies announced the end of the Bauhaus before the Nazis could close it.

Mies in America. Four years later, in 1937—again after working mainly on projects that were never built—Mies moved to the United States. Philip Johnson, who had met him at the Bauhaus and was an ardent admirer, had arranged for a commission, a country house in Wyoming. It was never built either. Soon after he emigrated Mies met the architect John Holabird who was looking for a man to head the School of Architecture at Chicago's Armour Institute (later the Illinois Institute of Technology). Mies demanded "a completely free hand and $10,000 a year." He got a free hand but a lower salary. By the time the age limitation forced him to retire in 1958 the school was world-renowned for its disciplined teaching methods as well as for its campus, which had been designed by Mies. A cubic simplicity marked the buildings that could easily adapt to the diversified demands of the school. Exposed structural steel, large areas of glass reflecting the grounds of the campus, and a yellow-brown brick were the basic materials used.

Design of Illinois Institute of Technology

Also in Mies's retirement year the Seagram Building on New York's Park Avenue, a skyscraper office building with a glass, bronze, and marble exterior, which Mies designed with Philip Johnson, was dedicated. The International Style, with Mies its acknowledged leading master, seemed at its zenith. The United States in the '50s had a faith in material and technical progress that seemed similar to the earlier German notion of *Gesamtkultur*. It was forgotten that only eight years earlier the magazine *House Beautiful*, voicing widespread unease, had attacked Mies's first buildings in America, specifically the house for Dr. Edith Farnsworth in Plano, Illinois, as a sinister threat to the American way of life, and Frank Lloyd Wright had even hinted that the men of the "International Style" might not be altogether "wholesome people." But now Henry Luce, the publisher of *Time*, *Life*, and *Fortune*, proclaimed that "the twentieth century revolution in architecture has been accomplished and it has been accomplished mainly in America." Miesian glass boxes, largely realizations of those paper projects of the post-World War I days, appeared all over the land, indeed all over the world.

Soon, however, the pendulum of taste and conviction swung back. Steel bones and glass skins seemed no longer a new beginning but the end of architectural creativity. "We must explore and expand the horizons of our architecture," said Eero Saarinen, perhaps the most promising of the younger generation of modernists. And he added: "In this sense, I align myself humbly with Le Corbusier and against Mies van der Rohe." Even Philip Johnson, the faithful disciple, turned away from the master's single-minded devotion to simplicity to a more romantic historicism.

Late work. Mies himself remained unperturbed. Busier than ever in his life, he remained faithful to the tenets he had developed in the 1920s and created beautiful buildings with them—among them the Chicago apartment houses (1949 and 1951); Lafayette Park, a housing development in Detroit (1956–63); the One Charles Center office building in Baltimore (1963); a museum in Houston (1958); the Federal Center in Chicago (1964); the Public Library in Washington, D.C. (1967); and, most Miesian of all, the Gallery of the Twentieth Century in Berlin, dedicated in 1968.

A heavy man, badly plagued by arthritis, he had come to look, as Peter Blake, one of his biographers, put it, like a granite monument of himself. Divorced in 1930, he lived alone in a spacious apartment in an old building near Lake Michigan in Chicago until his death on August 17, 1969. His office was in a nearby old loft building. He loved his splendid collection of paintings by Paul Klee, smoked expensive cigars, wore exquisite clothes, and read German philosophers. Though he seemed hard to approach, those who did found him friendly, utterly unpretentious, and cheerfully apt to reminisce.

Last years

To the charge that his buildings are cold, he replied that though milk can be cold or warm, there could hardly be a cold or warm architecture. He saw no necessity, he said, "to invent a new architecture every Monday morning." He disdained any style that was nothing more than a personal statement of the architect, a monument to his own ability. Mies's architecture was meant to be anonymous. Architecture, he said, "is the will of an epoch translated into space—living, changing, new." Mies never considered himself more than an instrument of that will.

MAJOR WORKS

Perls house, Berlin (1911); Kröller house project, The Hague (1912, not executed); Urbig house, Neubabelsberg (1914); Liebknecht-Luxemburg Monument, Berlin (1926); Wolf house, Guben (1926); cantilevered tubular-steel chair (1926); Weissenhof flats, Stuttgart (1927); German Pavilion, Barcelona Exposition (1929); Barcelona chair (1929); Tugendhat house and chair, Brno, Czechoslovakia (1930); Illinois Institute of Technology, Chicago (1939–41); Farnsworth house, Plano, Illinois (1946–50); Promontory Apartments, Chicago (1949); Apartment houses, Lake Shore Drive, Chicago (1949–51); Seagram Building, New York (1956–58); Bacardi Building, Mexico City (1961); Federal Center, Chicago (1964); Gallery of the Twentieth Century, Berlin (1968); New National Gallery, Berlin (1968); I.B.M. Building, Chicago (1971).

BIBLIOGRAPHY. The most important collection of drawings is in the Ludwig Mies van der Rohe Archive of the Museum of Modern Art in New York City. A selection of these has been published as *Mies van der Rohe: Drawings in the Collection of the Museum of Modern Art,* introduction and notes by LUDWIG GLAESER (1969). Bibliographies are contained in PHILIP C. JOHNSON, *Mies van der Rohe,* 2nd ed. (1953), a brief, scholarly, and most readable book that first introduced Mies to America; ARTHUR DREXLER, *Ludwig Mies van der Rohe* (1960), a comprehensive and critical analysis of the architect's work; PETER BLAKE, *The Master Builders: Le Corbusier, Mies van der Rohe, Frank Lloyd Wright* (1960, each of these essays published separately in 1964), the most detailed, personal, and authoritative biography to date; and WERNER BLASER, *Mies van der Rohe: The Art of Structure* (1965), a fairly complete collection of photographs and drawings of Mies's work with his own brief introduction. Information may also be found in publications on 20th-century architecture, notably S. GIEDION, *Space, Time and Architecture: The Growth of a New Tradition,* 5th ed. (1967); and on the Bauhaus, notably *Bauhaus and Bauhaus People* (1970), a collection of personal reminiscences by former Bauhaus members in which Mies is recalled by HOWARD DEARSTYNE.

(W.V.E.)

Mi Fei

One of the dominating figures of Chinese art, Mi Fei's (in Pin-yin romanization also Mi Fei) erudite yet natural calligraphy and his landscape style were complemented by an eccentric personality and caustic tongue. His far-reaching influence owes as much to his scathing critical writings and lively connoisseurship as to his artistic activities. For later generations he came to represent the ideal type of scholar-gentleman who combined artistic excellence with a leisured independence of the material world.

Mi Fei's original name was Mi Fu. The second character of his name, Fu, was later changed to another, originally homophonous character, the reading of which was subsequently confused with a third character read as Fei. This is the name by which he is known today. In accordance with Chinese practice, Mi Fei also used many other names and nicknames to sign paintings, pieces of calligraphy, or articles; among the best known are Yüan-chang, Hai-yüeh Wai-shih, and Hsiang-yang Man-shih.

Mi Fei was born in 1051 of a family that had held high office in the early years of the Sung dynasty (960–1279). Because his mother had been the wet nurse of the emperor Ying Tsung (reigned 1064-67), he was brought up within the Imperial precincts, mixing freely with the Im-

"Tower of the Rising Clouds," attributed to Mi Fei, colour on silk. In the Freer Gallery of Art, Washington, D.C.

perial family. As a young boy, Mi Fei showed precocious talent, particularly in calligraphy. Although he expressed a distaste for the formal lessons prescribed for a future official, he displayed a lively intelligence by his quickness in understanding learned argument, an aptitude for excitingly original poetry, and an ability in painting and calligraphy.

His professional career

In later life Mi Fei followed a checkered official career with frequent changes of post. He began as a reviser of books in the Imperial library and subsequently served in three posts outside the capital of K'ai-feng, in the Honan Province. In 1103 he was appointed a doctor of philosophy and was briefly military governor of Wu-wei in the province of Anhwei. He returned to the capital in 1104 to serve as a professor of painting and calligraphy, taking this opportunity to present to the Emperor a painting by his son, Mi Yu-jen. He then undertook the position of a secretary to the Board of Rites before setting out on his final appointment as military governor of Huai-yang, in Kiangsu Province, in which post he died in 1107, at the age of 57. He was buried in Tan-t'u, in Kiangsu Province, under an epitaph written for him by Mi Yu-jen.

Mi Fei was married and had five sons, of whom only the two eldest survived infancy, and eight daughters.

Mi Fei's writings were extensive. A collection of his poetry, the *Shan-lin chi*, has been lost, but still existing are the *Pao-chang tai-fang lu* ("Critical Description of Calligraphics in Mi Fei's Collection"), and *Hua shih* ("Account of Painting"), containing records of his own and others' collections of paintings, essays on aesthetic history, and criticism of paintings. There also exist three posthumous collections of his writings, *Pao-chin ying-kuang chi* ("Literary Works of Mi Fei), *Hai-yüeh ming-yen* ("Remarks on Calligraphy"), and *Hai-yüeh t'i-pa* ("Inscriptions and Colophons by Mi Fei").

Throughout Mi Fei's life, the workings of a highly individualistic temperament were evident. This was manifested in his fastidious attention to cleanliness, his preference for the clothes of ancient Chinese dynasties, and his love for strange rocks and ink stones, which he collected. To this eccentricity of personality must also be attributed his comparative failure in his official career. Despite his undoubted ability, his friendship with the leaders of both principal political factions, the poet-statesman Wang An-shih and Su Tung-p'o, and his family connections, he never rose to any office higher than that of a second-class secretary to the Board of Rites. The reason, his epitaph states, was that "he could not endure to bow and scrape before the world." An example of this upstanding independence is his attitude toward art collectors; he divided them into two classes, busybodies and connoisseurs—utterly deriding the former as illiterate and intent simply on ("Inscriptions and Colophons by Mi Fei").

His calligraphic style

As an artist, Mi Fei is best known for his calligraphy and landscape painting. His calligraphic style rejected what was inaccessibly unusual or flamboyant and was formed by patient and catholic study of the great Chinese calligraphers of the past. His theoretical writings in the *Shu shih* and *Hai-yüeh ming-yen*, which contain some of the most penetrating remarks written on the subject of calligraphy, indicate that Mi Fei believed in a respect for historic styles suffused with the calligrapher's own creative talent. Most of all he valued spontaneity and self-expression, eschewing the contrived and saccharine.

Mi Fei's paintings, such as "Tower of the Rising Clouds" (Freer Gallery of Art, Washington, D.C.) represented a break with the past. Before the Sung dynasty, landscape painting in China had depended essentially on line for its description of the world. Mi Fei, however, concerned with depicting the misty rivers and hills of the lake district of Honan Province, introduced a technique of extremely moist washes and horizontal texture strokes. Later known as "Mi dots" (*Mi tien*), this technique rendered a vivid impression of that rainy and cloud-clad Chinese region. This technique of "splashed ink" (*p'o-mo*) was Mi Fei's own invention; it attracted enthusiastic contemporary attention and remained a compelling influence throughout the history of Chinese painting.

MAJOR WORKS

The few well-documented works by Mi Fei are now all lost. Imitations and copies of works exist in the following collections: Yale University Art Gallery, Moore Collection, New Haven, Connecticut; Ōsaka Municipal Museum of Fine Arts, Ōsaka, Japan; Ogawa Collection, Kyōto, Japan. Extant paintings reflecting Mi Fei's style: Hanging scroll (Nakamura Collection, Tokyo); "Auspicious Pine Trees in the Spring Mountains" (National Palace Museum, Taipei, Taiwan); "Tower of the Rising Clouds" (Freer Gallery of Art, Washington, D.C.).

VAN GULIK, *Chinese Pictorial Art As Viewed by the Connoisseur* (1958), translations of important Mi Fei texts dealing with connoisseurship and seals; and *Mi Fu on Ink Stones* (1938); NICOLE VANDIER-NICOLAS, *Le Houa-ché de Mi Fou (1051–1107) ou Le Carnet d'un connaisseur à l'époque des Song du Nord* (1964), annotated translation of Mi Fei's *Hua shih* ("Account of Painting"); and *Art et sagesse en Chine: Mi-Fou (1051–1107) peintre et connaisseur d'art dans la perspective de l'esthétique des lettrés* (1963), a biographical study of Mi Fei; WAI-KAM HO, "Mei Fei," *Encyclopedia of World Art*, vol. 10, col. 84–90 (1965), an important biographical article, with an excellent bibliography.

(C.S.-y.)

Migrant Labour

Workers who move about systematically, seeking and engaging in seasonal temporary employment without becoming residents of the areas in which they work, are called "migrant labourers." Throughout the world, the wages, working conditions, and standard of life of migrant workers are low in comparison with other groups of workers, almost always the lowest. The union- and government-established labour standards available to industrial and regular agricultural workers generally do not exist for migrant labour; and where there are statutes their implementation is limited and irregular. Migrant labourers are the rural equivalents of the urban poor.

Migrant labour is primarily but not exclusively agricultural; it generally involves harvesting activities and is mostly manual, repetitive, easily learned, and demanding of almost no skill. Migrant workers pick cotton, cocoa beans, grapes, tea or tobacco leaves. They cut sugar cane and pineapples and gather artichokes, beans, carrots, sugar beets, or other cash crops. They also harvest corn, small grains, or wheat. Because all of these activities require physical strength and call for much bending and reaching, migrant labour is also called "stoop labour."

CHARACTERISTICS OF MIGRANT LABOUR

Criteria of migrant labour

Migrant labour must be distinguished from other forms of employment with similar characteristics and similar problems. Labour migration in Europe—often involving the crossing of national boundaries in search of employment or better employment—is different, since it usually involves a permanent or quasi-permanent resettlement of the worker and his family. Casual labour, in which a worker shifts, often daily, from employer to employer, is also different, because the casual labourer does not change his residence. Seasonal or part-time labour, offering the worker employment only on a seasonal or occasional basis, is again different, in that it does not involve either a change of residence or frequent changes of employers.

Association with industrialization. Migrant labour is associated with the developed or "middle" stages of industrialization and its technology and organization. While the demand for migrant labour stems, in part, from the seasonal nature of worker requirements in agriculture and related industries, it is not a phenomenon characteristic of agricultural societies. It was probably unknown in antiquity and is not significant today in the underdeveloped economies of Asia and Africa; high levels of demand for migrant workers are related to rapid increases in farm output, decreases in permanent farm employment, long periods of rural migration, increasing urban wages, and fairly rapid mechanization and commercialization of agriculture. The demand for migrant labour is particularly high in the case of market farming, where production is increasing or where numerous small farmers specialize in one or two cash crops and are joined in production or marketing associations.

The propensity to work as a migrant labourer stems from the unfavourable economic and social conditions in which the worker finds himself at what is called his "home base." Technological displacement, radical changes in sharecropping systems, long business recessions, drought and crop failures, and various forms of discrimination are factors inducing workers to enter the migrant stream. Lack of education, industrial accidents, and ill health also force many to become migrant. The supply of migrant labour thus develops in response to the push of need, not from a romantic desire to wander. In a minority of cases, particularly those in which a poor region, state, or nation is adjacent to a much richer one, workers respond also to the pull of better opportunities; in spite of its misery and degradation, migrant labour appears to them as a way to a higher standard of life in the future.

As national economies mature and move through the secondary (mostly industrial) stage to more developed stages, both the demand for and the supply of migrant labour decrease. The demand for it decreases because of mechanization; in the U.S., for example, the harvesting of wheat and cotton that required the employment of many migrants before World War II is now largely mechanized and done by regularly employed farmhands. The supply decreases as higher real standards of living and greater employment possibilities make migrant work less attractive. For a small number of employed workers in affluent areas, migrant labour provides secondary (or additional) employment opportunities.

In mature economies migrant labour contributes little to total agricultural output and a negligible amount to nonagricultural output. Nevertheless, the availability at the right time and place of migrant workers can be crucial, since without them large crop losses may occur. This may spur private employers, planning authorities, and governments to take remedial actions to improve the conditions of migrant labourers in order to assure their continued availability. If native migrant workers are in short supply, the gap may be filled by the temporary—legalized or tolerated—migration of foreign workers from poorer countries. In the Communist countries, where the use of migrant foreign labour is politically unacceptable, the flow of migrant workers is supplemented with organized brigades of urban youth encouraged to contribute their labour voluntarily to the common good.

The migrant flow. Most migrant workers move in well-established patterns or "streams." The migrants usually flow from the south to the north (in the Southern Hemisphere, however, they move in the opposite direction), as geography makes for later harvests in northern latitudes; also, the poorer areas with the labour surpluses tend to be in the south. Migrants make detours and side trips as they hear of better or new opportunities. The various "crews," families, or individuals that make up the migrant stream do not all follow the same pattern: some move from place to place, others make a big journey to a set of places with known jobs, while others make only one move and then go back to "home base."

ECONOMIC AND SOCIAL CONDITIONS OF MIGRANT WORKERS

In all employment relationships the matching of unemployed workers and job vacancies is a haphazard and complicated process, but the labour market for migrant workers is notably disorderly. One basic reason is that the employment relationship is ephemeral. To the worker, the identity of the employer is hazy, even unknown. To the employer, the typical workers have no individuality as he thinks of them often as alien drifters, "wetbacks," "Okies," etc. With minor exceptions, employers do not systematically recruit migrant workers and have no regular personnel specialists or procedures. Even though most labourers migrate year after year, they do not enjoy reemployment rights, are not organized in unions, and have little access to systematic means of job seeking; they tend also not to exploit the available services of public placement or other governmental agencies, limited as these are.

The role of the contractor

Middlemen, job brokers, labour contractors, crew leaders—*patrones* in Latin America, *sirdār* in the Asian subcontinent—arise out of the fundamental disorganization of the migrant labour market. Labour contractors, in addition to bringing the workers together, transporting them, supervising them, and dispensing their pay, search out the employers and negotiate wages and working conditions. In some areas the contractors have made themselves so essential that without them workers cannot find employment and employers cannot get workers.

Living conditions and wages. The conditions under which migrant labourers live are abysmal. Their misery has been formally documented by investigative bodies down the years: the U.S. Industrial Commission of 1901, the Royal Commission of Labour in India of 1933, the U.S. President's Commission on Migratory Labor of 1951, and others. Novelists, moved by the migrant workers' plight, have aroused sympathy with such masterpieces as John Steinbeck's *The Grapes of Wrath* or Mulk Raj Anand's *Two Leaves and a Bud*. Social scientists, particularly economists, however, have tended to ignore the issues posed by migrant labour. Governmental statistics on migratory labour are scarce, often contradictory, and approximate at best.

Migrant workers are often cheated even of the low

wages they earn. They work long hours and under exacting requirements. Total employment is always limited; in a year most migrants work less than one quarter of the working days. Child labour is widespread, and the children that do not work are not adequately provided for; they often do not go to school, as in most places schools are open only to residents. Housing amounts to hardly more than a roof over the head, often tar or tent. Tuberculosis, infant and maternal mortality, dysentery, enteritis, smallpox, and typhoid are all more prevalent among migrant labourers than among the general population. Literacy levels, social cohesion, and political participation rates are always exceptionally low among migrant workers, while crime and all other indexes of unacceptable social behaviour are high. Contributing to this picture of misery is the fact that the migrants, whether national or foreign born, are fundamentally alien to the community in which they work. The local population, if eager to see them come, is even more eager to see them go. They have difficulty in gaining access to local health and social services, are often deprived of their rights, do not enjoy easy recourse to the courts, and are abused by exploiters and sometimes the local police.

Difficulties of regulation. The fact that the migrant is "here today and gone tomorrow" makes the regulation of his working and living conditions difficult. Local, state, and national authorities generally acknowledge the existence of serious problems associated with migrant labour, yet in the face of these, generally claim they are unable to deal with them effectively. The International Labour Organization has consistently prodded governments to expand their legislation in this area. Efforts are being made to develop regulatory standards protecting workers during their journeys, to discourage migratory movements of undesirables, and to stabilize workers and their families near their place of employment.

The task of providing migrant workers with governmental protection and assistance is full of complex difficulties. Regulatory legislation ideally should be applied at the "home base" of the migrants as well as along the stream of migration and at the place of employment. But advances in one area often create difficulties in another due to uneven social and economic conditions. On the one hand, mechanization and permanent migration is reducing the number of migrant labourers, while, on the other, relocating them is difficult because their low educational attainments and lack of skills force them into urban poverty. Where legislation has been passed and improvements have been achieved, the major effect has been to force employers to provide more housing and sanitary facilities and to regularize the activities of the labour contractors.

PATTERNS OF MOVEMENT

The United States. In the United States in the 1960s about 400,000 people yearly were occupied in migrant work. In the previous decade the number was about 600,000 yearly; in 1940 there were 1,000,000; and it is possible that in the middle 1920s as many as 2,000,000 workers were in the migration streams. There are not many reliable statistics. Interpretation of scattered data suggests that the following trends and relationships have occurred since World War I: (1) the migrant labour population has been declining, albeit at a decreasing rate; (2) migrant agricultural workers have tended to become a larger proportion of all agricultural (nonfamily) workers; (3) foreign workers—while their participation varies with the rulings of the federal immigration administration and with requirements of foreign policy—constitute an increasing proportion of all migrant workers; and (4) the size of the national migratory labour force varies inversely, and the foreign labour force directly, with improvements in the total level of employment.

In the 1960s more than half of the migrant workers were 25 years or younger; fewer than one in ten was 55 years or older. Three out of four migrant workers were males, with males outnumbering females in all age groups. Almost half of the female migratory workers were between the ages of 25 and 54. In terms of areas of permanent residence a little less than two out of four migrant workers originate in the South. Over 55 percent of all migratory workers had eight years of education or less.

Three major patterns characterize the movement of migrant workers in the U.S. (1) On the East Coast, migration begins in winter when workers from Southern states move south to Florida to work on the citrus crop. From there, joined by others coming from Texas and Puerto Rico, they move north along the coast ending up in August and September gathering tomatoes and other vegetables on Long Island and potatoes as far north as Maine. Negroes constitute a large proportion of those on the East Coast. (2) The largest stream of migrants flows north and west from Texas in the spring to the north central, mountain, and Pacific Coast states. The crops they harvest are fruits and vegetables, sugar beets, and some cotton. The workers are natives of Mexican descent with whom some "wetbacks" (immigrants from Mexico) join; they travel mostly with their families and end work early in December. (3) A large number of Spanish-Americans work on harvesting vegetables, moving from Southern California northward through the Pacific Coast states. Thus some migratory farm work is done in almost every state, with most labourers coming from Texas and the Southeast. About half of the man-days of such employment occur in California, Michigan, Texas, and Florida.

These migrant workers suffer from unemployment, inadequate housing, little education, exclusion from normal community life, and the denial of services that others take for granted. In the middle 1960s they grossed an annual average income of about $1,700, working an average of 150 days if they worked in nonfarm activities as well. Those who worked only as migrant farm workers averaged $800 for about 82 days of work.

One of every five poor people in the United States is a migrant worker and entitled to the various governmental antipoverty manpower and social programs. Yet, an analysis of federal antipoverty expenditures from 1965 through 1968 shows that only one out of every 50 dollars was spent to help migrant workers, a pattern suggesting that there is considerable truth in the oft-quoted statement that more money is spent on migratory birds than on migratory labour.

In spite of this, it is probably true that the 1960s saw more improvements in the living and working conditions of migrant workers in America than any previous decade. A number of states and localities established special migrant committees to implement and expand legislation. "Crew registration laws" were increasingly adopted by the states, and their implementation is having beneficial effects. Most important, after years of inactivity attempts were being made by labour unions to organize migrants, with some success in California and Wisconsin.

Western Europe. Migrancy as described above does not involve very large numbers in Europe because of the longer history of urbanization. Migrant agricultural workers are still active in the rice harvest of northern Italy and in some of the vegetable harvest of Portugal and France.

The European migrant worker frequently moves across national boundaries in response to seasonal fluctuations in the labour demand of specific industries. This type of migration rarely involves the workers' families and generally calls for only one move. Thus Italian workers go to work in Swiss hotels, Polish workers go to mine English coal, etc. The problems of European migrants are less acute than those described above; they generally involve difficulties in acculturation and in qualifying for national health and social service programs.

Africa. Migrant labour is one of the most important problems of the developing nations of Africa, where migrancy is clearly an intermediate stage of the movement from rural agricultural to urban industrial life. The phenomenon does not conform to the general characteristics described earlier. Workers migrate to urban rather than to agricultural employment; they work with one rather than many employers; and they often stay in one job as long as three years.

Migrancy in Africa is very clearly a response to the pull

of expanding industrial opportunity and the lure of city life rather than to a push away from the poverty of rural life; it is thus a step in the process of building an industrial labour force. The worker who moves does so alone and with considerable reluctance. He often goes because he needs cash for a particular purpose (*e.g.*, the "bride price"). He is not prepared to give up his contacts with the village, where there is security in old age, sickness, or periods of unemployment. African migrancy is nonetheless quite similar to the migration that occurs in the middle stages of industrialization. In the regions where the migrant workers come from one finds the decline of traditional subsistence agriculture, changes in ownership patterns, and drought; one rarely finds workers displaced by mechanization of production.

Migrant labour is also to be found in many other nations. India has probably more migrant workers than any other Asian country; these are involved mainly in the harvesting of tea, cotton, and rice. In Australia and the southern nations of Latin America migrants work on ranches more often than on farms and are engaged in wool shearing and meat processing.

BIBLIOGRAPHY. There are no classic or standard works on this subject. Most of what is known is derived from the reports of investigative and governmental commissions. For the U.S. the most recent and the most complete is *Migratory Labor in American Agriculture*, Rept. of the President's Commission on Migratory Labor (1951). More recent data may be found in *Domestic Migratory Farmworkers, Personal and Economic Characteristics*, Agricultural Economic Rept. No. 121 (1967), and other serial publications of the Department of Agriculture. For information on other countries, the reports of the International Labour Organization are important. In particular see *Migrant Workers*, Rept. 5 of the 37th Session (1954) and the 38th Session (1955) of the International Labour Conference; and *African Labour Survey* (1958), for good information on African migrancy.

For greater details one should turn to the series of reports of the Subcommittee on Migratory Labor of the U.S. Senate Committee on Labor and Public Welfare. They are available for almost every year since 1955. The journal literature is thin and generally narrowly focussed. The following are examples of the type of work available: E.P. EDWARDS, "Children of Migratory Agricultural Workers in the Public Elementary Schools of the U.S.," *Harvard Educational Review*, 30:12–52 (Winter 1960); and J.C. GLASS, "Organization in Salinas," *Monthly Labor Review*, 91:24–27 (June 1968).

(O.A.O.)

Migration, Animal

The term migration may be applied to the cyclic or periodic travels of an animal if it returns eventually to the original place of departure. Such movements can be contrasted with emigrations, which involve a change in location not necessarily followed by a return journey; invasions or interruptions, both of which involve the appearance and subsequent disappearance of great numbers of animals at irregular times and locations; and range expansion, which tends to enlarge the distribution of a species, particularly its breeding area.

The migration cycle is often annual and thus closely linked with the cyclic pattern of the seasons. The migration of most birds and mammals and many of the fishes are on a yearly cycle. In many cases (*e.g.*, salmon and eels) animals with a relatively long life-span return to the place of birth in order to reproduce and eventually die. In other cases, as in certain invertebrates, where the animal has a relatively brief life-span and reproduces rapidly, migrations may not occur in every generation. The daily movements of certain fishes and invertebrates have also been called migrations because of their regular occurrence. This type of movement, however, is not to be confused with migration in the strict sense.

Most migrations involve horizontal travel. The distance traversed may be a few miles or several thousands of miles.

Some migrations take a vertical direction and involve no appreciable horizontal movement. Certain aquatic animals, for example, move from deep water to the surface according to the season. Certain birds, mammals, and insects migrate altitudinally in mountainous areas, going from the upper zones, where they breed, to the foothills or plains during seasons when the weather is severe and unfavourable. Such vertical travels involve essentially the same type of environmental change as horizontal, or latitudinal, migrations over long distances.

SURVEY OF MIGRATIONS IN ANIMALS

Lower invertebrates. Many marine invertebrates travel considerable distances during certain seasons. A large proportion of them, however—particularly planktonic organisms, plant and animal aquatic drifters—do not travel deliberately but are carried by ocean currents. Planktonic organisms also travel vertically in a daily rhythm. Very small or microscopic animals remain at great depths during the day and rise at dusk, concentrating in the upper layers of water during the night. Their predators, particularly fishes, follow them in their cycle. The daily activity of pelagic birds (*i.e.*, those living on the open sea rather than along the shore), such as petrels and shearwaters, which feed on planktonic crustaceans and squids, follows this same rhythm. Planktonic migration

A seasonal change of habitat, analogous to migration, is made by some Polychaeta (sandworms). Along the coast of Europe, clam worms (*Nereis*) live during the colder months in rock crevices and among algae. During the summer, however, they become planktonic and swim out some distance from the coast, where reproduction occurs. In the South Pacific, near Samoa and Fiji, the palolo worm (*Eunice viridis*) lives among coral reefs, where it develops posterior segments filled with genital (reproductive) cells. These are cast off, and the worm rises to the surface. The phenomenon occurs regularly on the first day of the last quarter of the October–November moon.

Some of the best known migrations among the invertebrates occur in crustaceans during the reproductive period, when some of them travel as far as 150 miles (240 kilometres). Generally in the crabs, females move into shallow coastal waters to mate and to lay their eggs. After the eggs have been laid, the females return to deep water.

Some freshwater crabs, such as the Chinese crab (*Eriocheir sinensis*), after remaining for three to five years in freshwater, migrate to brackish water, where mating occurs. Females with eggs externally attached then travel to the sea and remain a few miles offshore for several months during winter. The following spring they enter shallower water near the shore. Here the eggs hatch. Young crabs spend a year in brackish water and migrate upstream the following spring, settling in freshwater and growing to maturity.

Some crabs, such as robber crabs (*Birgus*) and land crabs of tropical regions (*Geocarcinus*), have adapted to life on land. They migrate to the sea to reproduce and then return inland and are followed at a later time by the young.

Insects. Migration among the insects is best known in locusts and butterflies; a great number of other insects, however, including some of the smallest, are migrants. Broadly speaking, insect migration is of three types—some insects emigrate on one-way journeys to breed; others migrate from a breeding area to a feeding area; still others migrate from breeding areas to hibernation sites. Types of insect migration

In the first type, adults with a life-span limited to a single season emigrate from their breeding site, deposit their eggs, and die. Such migratory flights can be very short or very long but, because they are always one-way journeys, cannot be regarded as migration in its strictest sense. The best known examples of such flights are those of locusts, particularly the desert locust (*Schistocerca gregaria*), a species found in tropical and subtropical countries of the Old World. The migratory, gregarious form arises from the solitary form as a result of various conditions—*e.g.*, lack of food, crowding.

The desert locusts breed only when and where seasonal rains permit; as a consequence of climatic conditions, therefore, the insects migrate from one breeding area to another. If the available food decreases and the numbers of insects increase too drastically in a particular area, migratory locusts develop. They differ from nonmigrato-

ry forms in colour, structure, behaviour, and physiology. Swarms numbering up to 10,000,000,000 individuals periodically invade territories in Africa, southwestern Asia, and southern Europe, covering areas as large as 400 square miles.

Other migrant insects travel beyond the limits of their breeding range and either die or return to the breeding range. The painted lady butterfly (*Vanessa cardui*) "migrates" in the spring, when its population becomes too large for local conditions, from the peninsula of Lower California in Mexico to the Mojave Desert in Southern California. Eggs are laid in the desert region, but the species does not become permanently established there and makes no return flight. Such movements are known in about 250 species of butterflies.

In the second type of migration—migration in the strict sense—insects migrate from a breeding area to a feeding area. In the feeding area the females develop mature ovaries and then return to lay their eggs in the place from which they came or a similar region.

Cockchafers (*Melolontha melolontha*), a species of beetle, leave the site where they emerge as adults and move to a feeding area, generally in a forested region, where maturation of the eggs takes place. They then return to the area where they developed from eggs and lay their own eggs. This process may be repeated several times during the life of the insect. Although the distances covered by the cockchafer may not be great, the regularity of the phenomenon is characteristic of true migration.

In the third type of migration, insects travel from their breeding areas to places where they hibernate or aestivate —*i.e.*, pass the summer in a dormant state. The place of hibernation or aestivation may be outside the zone where climate permits breeding. The following season, they return to the breeding place and lay their eggs. This type of migration, which can involve great distances, is made by insects with unusually long life-spans. The lives of these insects include a diapause, or period of dormancy during which development is suspended.

In warm countries the coccinellids, a family of beetles, and certain moths leave the hot lowlands and migrate to the mountains, where they aestivate and later hibernate. In spring they return to the breeding areas.

Migration of the convergent ladybug

One coccinellid, the convergent ladybug (*Hippodamia convergens*), lives in valley regions of California, where the eggs hatch in March or April and develop into adults one month later. In early summer they migrate to the mountains, particularly to the Sierra Nevada, where they may lay eggs if food is abundant and the weather warm. Generally, however, the adults gather in clusters and remain inactive until October, when rains initiate a period of activity, after which they travel to lower altitudes and hide in forest litter, passing the winter in a state of dormancy. As many as 30,000,000 ladybugs may congregate on a quarter acre. In spring they mate, fly back to the valleys, lay their eggs, and die.

The flight before diapause of some insect groups may cover thousands of miles. In North America, the monarch butterfly (*Danaus plexippus*) is a well-known example of a wide-range migrant with an extensive breeding range. The number of generations varies with the latitude; as many as five generations may occur each year in the south and only one in the north. In summer the insects travel northward to Hudson Bay. Individuals of the last generation of the year migrate southward in autumn to Florida, Texas, and California, where they hibernate after travelling nearly 2,000 miles (3,200 kilometres). They gather in sheltered sites, particularly on trees where they cluster on trunks and big branches. In spring part of the populations migrate back to the northern breeding areas. Some of the returning butterflies are members of the first generation that develops from the overwintered insects; others represent successive generations that develop as the insects progress toward more northern latitudes. The recapture of marked butterflies has revealed that they travel as much as 80 miles (130 kilometres) in one day. The longest distance recorded thus far for the complete flight of a migrant monarch butterfly is 1,870 miles (3,010 kilometres).

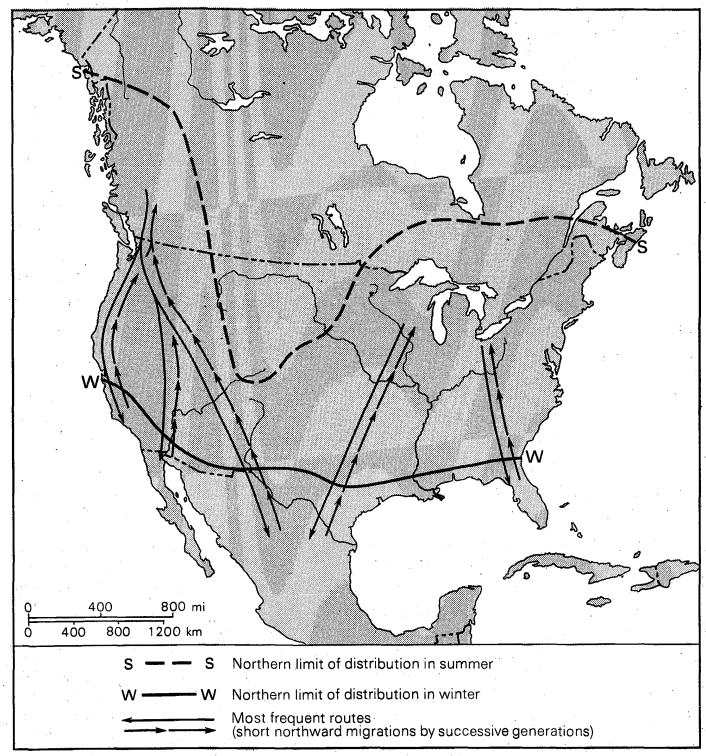

Figure 1: Migrations of the North American monarch butterfly (*Danaus plexippus*).
From M. Ricard, *The Mystery of Animal Migration*

Fish. Many species of fish wander annually through a particular area of the ocean. Some are true migrants, travelling regularly over great distances. Young fish usually leave the spawning grounds for areas where they develop into juveniles, before joining the adult stock at the feeding grounds. Adults move to the spawning grounds, then return to the feeding grounds. Migratory patterns of fish are related to oceanographic factors and to currents. Eggs, larvae, and young drift passively with the current, although migration of adult fish toward breeding grounds is usually against the current. Adult movements thus are directional rather than passive, and the fish respond to environmental conditions—*e.g.*, climate.

Three categories of migratory fishes can be distinguished: oceanodromous, anadromous, and catadromous.

Oceanodromous fish. Oceanodromous fish, which occur widely throughout the world's oceans, live and migrate wholly in the sea. They differ mainly from one another by the method and extent of their migration.

Herring migratory patterns

Herring (*Clupea harengus*), extensively studied because of their economic importance, are the best known of the oceanodromous type and can be classified into several populations, or local races, which do not mix freely. In addition, each has a particular migratory behaviour. In the North Sea, distinct groups spawn in different seasons and on different grounds: Buchan herring spawn in August and September off the coast of Scotland and migrate to the coast of southwestern Norway; Dogger Bank herring spawn in September and October in the central part of the North Sea and along the English coast and then migrate to the Skagerrak, an arm of the North Sea between Denmark and Norway; Downs herring spawn from November to January off the French coast, mainly between Dunkirk and Fécamp, then feed in summer in the middle and northern parts of the North Sea, sharing the feeding grounds with other populations. The diversity of migration and of reproductive seasons is closely connected with the annual cycle of oceanographic conditions in the North Sea.

Cod (*Gadus morhua*) have migration patterns similar to those of herring. The migrations of other fish cover even greater distances; in the Atlantic, for example, white tuna (*Germo alalunga*) are found in winter around the

Azores and the Canary Islands, where they spawn in spring. They then migrate northward to the Gulf of Gascogne and afterward to the waters around Iceland, arriving there in July. Populations of red tuna (*Thunnus thynnus*) occur throughout the Mediterranean Sea and the eastern Atlantic. In May and June they spawn in the western Mediterranean. During summer they spread northward to feed, finally reaching the Arctic Ocean. Similar migrations occur along the North American coast in the Atlantic and throughout the Pacific.

Anadromous fish. Anadromous fish live in the sea and migrate to freshwater to breed. Their adaptations to conditions of different habitats are precise, particularly with regard to salinity of the water.

Salmon (*Salmo, Oncorhynchus*) spawn in the cold, clear waters of lakes or upper streams. Eggs are laid in gravel beds. The young of the Atlantic salmon remain in freshwater for two to three years, sometimes as long as six; Pacific salmon sometimes migrate to the sea in their first year. Adult fish usually remain in the sea for two or three winters, but sometimes only one. Then, as grilse (adolescents) or as adults, they return to freshwater and spawn, after changes occur in colour and other external features. Some Atlantic salmon die in freshwater after a single spawning; others return to the sea.

The tagging of salmon has shown that European types may cross from Norway to Scotland, as well as the reverse. Pacific salmon are probably distributed over the Pacific Ocean and Bering Sea, between latitudes 45° N and 65° N with surface waters of 2° to 11° C (36° to 52° F).

Experiments in Canada and the United States, in which young salmon migrating to the Pacific have been tagged, have shown that a high proportion of the fish return to the river where they hatched. Tagging also has revealed that the same Atlantic salmon return year after year to a particular river. Adults reared from experimentally transplanted eggs return to the stream where they were hatched or grew, not to the stream where the eggs were laid. Aside from other means of orientation, such as reference to celestial features, topographical features are believed to play an important part in recognition of the original habitat. The sense of smell, or olfaction, however, has the most important role. Experiments have shown that migrating salmon are attracted to the waters of the stream in which they are going to spawn. Experiential imprinting at an early stage of development enables a grown fish to respond to waters that contain substances with a particular odour or that have a characteristic temperature.

Catadromous fish. Catadromous fish spend most of their lives in fresh water, then migrate to the sea to breed. This type is exemplified by eels of the genus *Anguilla*, numbering 16 species, the best known of which are the North American eel (*A. rostrata*) and the European eel (*A. anguilla*).

Eel migration

European eels and North American eels spawn in warm saline waters of the Atlantic, at depths of 400 to 700 metres (about 1,300 to 2,300 feet), in an area centred near latitude 26° N longitude 55° W called the Sargasso Sea. The pelagic eggs develop into leptocephali—transparent, leaflike forms with relatively small heads—that are carried by the Gulf Stream to the shallow waters of the continental shelves. When they are about two and one-half years old and about eight centimetres long (a little more than three inches), a metamorphosis occurs. The leptocephali are transformed into so-called elvers, which are bottom-dwelling, pigmented, and cylindrical in form. They arrive in coastal waters as glass eels and begin to swim upstream in freshwater streams in spring. Their migration upstream is spectacular, as the young fish gather by millions, forming a dense mass several miles long. In freshwater the eels grow to full size, becoming yellow eels. They live as such for ten to 15 years before changing into silver eels, with enlarged eyes; they swim downstream to the sea, return to the spawning grounds (Sargasso Sea), and die.

The migration of these eels is not entirely understood, particularly their return to the Sargasso Sea. It may be

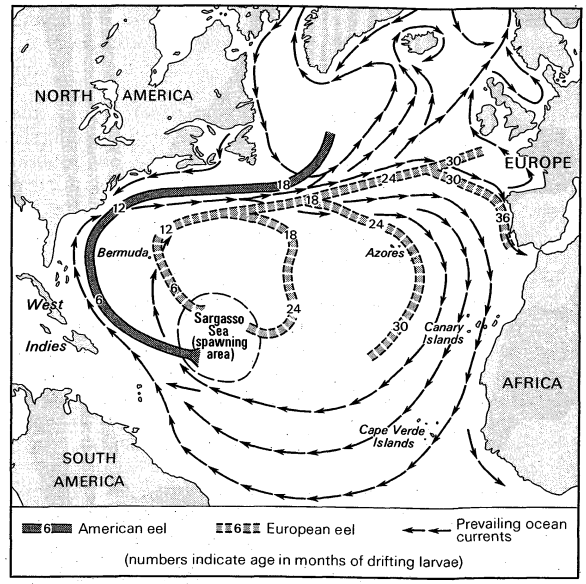

Figure 2: Migration of eels in the Atlantic Ocean.

that European eels and North American eels belong to the same species.

Reptiles and amphibians. The range of seasonal movements of most reptiles and amphibians is probably very limited. Generally incapable of travelling any great distance, they respond to unfavourable conditions by lapsing into a state of lethargy. This type of response makes it possible for them to stay in one place for an entire year.

The only migration-like movements of reptiles and amphibians are made during the reproductive period. Frogs and toads then concentrate in particular areas such as ponds and lakes; thousands travel toward these sites from year to year. After reproduction, the animals disperse and again settle over their usual range.

Turtle migration

The South American river turtle, or arrau (*Podocnemis expansa*), migrates along rivers in large masses that may impede the passage of boats. The turtles gather on sandbars of large rivers to lay their eggs. In the Galápagos Islands, giant land tortoises (*Testudo elephantopus*) stay chiefly in the upper humid zone, where food is abundant, but go down to the dry zone to lay their eggs. Despite their great body weight and slow pace, they travel some 30 miles (50 kilometres) across rough country.

Sea turtles, on the other hand, migrate over long distances, lay their eggs on special beaches, and then disperse over a wide area. Green turtles (*Chelonia mydas*), who deposit their eggs on the coast of Costa Rica in Central America, disperse through the Gulf of Mexico and the West Indies. Green turtles that have been tagged on Ascension Island, halfway between Africa and South America, have been recovered on the coast of Brazil, 1,400 miles (2,300 kilometres) away.

Birds. Migration is most evident among birds. Most species, because of their high metabolic rate, require a rich, abundant supply of food at frequent intervals. Such a situation does not always prevail throughout the year in any given region. Birds have thus evolved a highly efficient means for travelling swiftly over long distances with great economy of energy.

The characteristics of migratory birds do not differ greatly from those of nonmigratory forms; many intermediate types exist between the two groups. All transitional forms, in fact, may be manifested in a single species or in a single local population, which is then said to undergo partial migration.

In addition to regular migration, nomadic flights may also occur. This phenomenon takes place, for example, among birds of the arid zones of Australia, where ducks, parrakeets, and seedeaters appear in a locality following infrequent and unpredictable rains, breed, and then move to other areas. Nomadism is a response to irregular ecological conditions.

In Europe. The populations of many northern and eastern European species of birds have pronounced migratory tendencies; the populations of western Europe, on the other hand, are more sedentary.

Some birds are nomadic in winter, others spend the colder months in the southwestern part of the continent or in the Mediterranean region. Many migrant populations migrate to Africa south of the Sahara. Geographical conditions determine several main routes. The Alps are an important barrier to migratory birds. About 150 species travel westward and southwestward; others travel southeastward.

Tits (*Parus*), goldfinches (*Carduelis carduelis*), and blackbirds (*Turdus merula*) are usually sedentary in western Europe; they are usually migratory, however, in northern Europe, where their flights resemble a short migration. Starlings (*Sturnus vulgaris*) are sedentary in western Europe, where large numbers gather from eastern Europe. Large flocks also pass the winter in North Africa.

Insectivorous (insect-eating) species, such as warblers, flycatchers, and wagtails, are highly migratory and spend the winter in the tropics, chiefly in Africa. They migrate to Sierra Leone on the west coast, Tanzania on the east coast, and all the way southward to the tip of the continent. Most of these migrants use different routes to cross the Mediterranean, chiefly in the western portion, although some migrate only southeastward. Golden orioles (*Oriolus oriolus*) and red-backed shrikes (*Lanius collurio*) go to East Africa by way of Greece and Egypt. Swallows—particularly barn swallows (*Hirundo rustica*) and house martins (*Delichon urbica*)—and swifts (*Apus apus*) pass the winter in Africa south of 20° N latitude, particularly in South Africa, in the Congo River region, and in some coastal areas of West Africa.

From J. Dorst, *The Migrations of Birds;* published by Houghton Mifflin Company

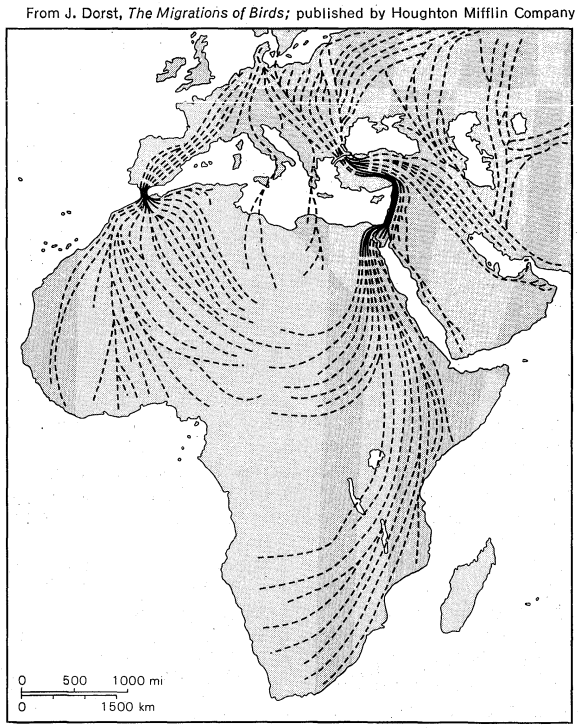

Figure 3: Principal routes taken by the European white stork (*Ciconia ciconia*) between nesting grounds in Europe and wintering grounds in Africa.

Migration routes of storks, ducks, geese, and swans

Among nonpasserines—*i.e.*, nonperching birds—one of the best known migrants is the stork (*Ciconia ciconia*), which migrates to tropical Africa along two well-defined flyways. The stork population nesting west of a line that follows the Weser River in West Germany flies southwestward through France and Spain, past the Strait of Gibraltar and reaches Africa by way of West Africa; the eastern population, by far more numerous, takes a route over the straits of the Bosporus, through Turkey and Israel, to east Africa. These well-separated routes are probably a result of the stork's aversion to long flights over water.

Ducks, geese, and swans also are migrants. These birds winter partly in western Europe and partly in tropical Africa. In Africa they are likely to spend the winter in lake and river regions from Senegal in western Africa to the Sudan in eastern Africa, where thousands of garganeys (*Anas querguedula*) and pintails (*A. acuta*) congregate annually. Some ducks leave their breeding grounds to molt (a process by which old feathers are replaced) in areas where they are most secure from predators during the time they are unable to fly; this is known as a molt migration. After molting, the ducks fly to their final winter quarters. Wading birds (Limicolae) also are typical migrants, most of them nesting in tundra of the Arctic region and wintering along the seacoasts from western Europe to South Africa.

In North America. North American birds must endure the same hazards of winter as European species. The geographical arrangement of the continent determines the main routes of migration, which run from north to south and include the Atlantic oceanic route, the Atlantic Coast route, the Mississippi flyway, the central flyway, the Pacific flyway, and the Pacific oceanic route. A great many birds pass the winter in the Gulf States, where the climate is favourable and food is abundant, but the principal wintering area extends through Mexico and Central America to Panama, which has the greatest density of winter bird residents in the world.

The ruby-throated hummingbird (*Archilochus colubris*) nests in southern Canada and winters in Central America as far south as Panama. Some of these birds fly nonstop across the Gulf of Mexico. Because of their food requirements, many American flycatchers (Tyrannidae), which are mainly insectivorous, have the same migratory behaviour as the hummingbirds. Others, like the phoebe (*Sayornis phoebe*), spend the winter in the Gulf States. Birds such as the American robin (*Turdus migratorius*) and several species of grackles assemble in the Gulf States in enormous flocks. The seasonal flights of the American wood warblers (Parulidae) are among the most spectacular on the North American continent. Some spend the winter in the Gulf States and in the West Indies; others, such as the blackpoll warbler (*Dendroica striata*), travel to Guiana, Brazil, and Peru by way of the West Indies. The spring migration routes of the Canada goose span the Continent of North America in an east–west direction from Hudson Bay as far south as Chesapeake Bay.

South America is winter quarters for several tanagers, such as the scarlet tanager (*Piranga olivacea*) and the bobolink (*Dolichonyx oryzivorus*); these birds migrate through the eastern United States and past Cuba to the swampy regions of Bolivia, southern Brazil, and northern Argentina. This area of South America is also winter quarters for the American golden plover (*Pluvialis dominica dominica*), which travels in an enormous loop over much of the New World. After nesting in the tundras of Alaska and Canada, the plover assemble in Labrador in easternmost Canada, then fly to Brazil over an oceanic route (the shortest possible route) about 2,400 miles (3,900 kilometres) long. Their return flight traverses South America, Central America, and the Gulf of Mexico, then follows the Mississippi Valley.

The role of wet and dry seasons

In intertropical regions. Birds of tropical regions migrate according to the rhythmic succession of wet and dry seasons—a profoundly influential factor on the annual cycle of animals and plants alike.

The migratory behaviour of birds has a unique regularity in Africa, where life zones are arranged symmetrically by latitudes away from the equator. Some migrants never cross the equator. The standard-wing nightjar (*Macrodipteryx longipennis*), which nests in a belt extending from Senegal in the west to Kenya in the east along the equatorial forest, migrates northward to avoid the wet season. The plain nightjar (*Caprimulgus inornatus*), on the other hand, nests in a dry belt from Mali in the west to the Red Sea and Kenya in the east during the rains and then migrates southward to Cameroon and the northern Congo region during the dry season.

Other birds migrate across the Equator to their alternate seasonal grounds. Abdim's stork (*Sphenorhynchus abdimii*) nests in a belt extending from Senegal to the Red Sea; after the wet season, it winters from Tanzania through most of southern Africa. The pennant-wing nightjar (*Cosmetornis vexillarius*), in contrast, nests in the Southern Hemisphere south of the Congo forests during the austral, or Southern Hemisphere, summer, then starts north with the onset of the rainy season. It spends its winters in savannas from Nigeria to Uganda.

In coastal and pelagic regions. Among the migrating seabirds, a distinction must be made between the coastal and the pelagic, or open-sea, species. Birds such as guillemots, auks, cormorants, gannets, and gulls—all common to the seashore—stay in the zone of the continental shelf. Except during the breeding season, they are dispersed over a vast area, often preferring specific directions of travel. Gannets (*Sula bassana*) nesting around the British Isles spread in winter along the Atlantic coast of Europe and Africa to Senegal, the young travelling farther than the adults. Pelagic birds, most of which belong to the order Procellariiformes (petrels and albatrosses), cover much greater distances and, from a few small nesting areas, roam over a large part of the oceans.

Wilson's petrels (*Oceanites oceanicus*), which nest in the western sector of the Antarctic (South Georgia Island, Shetland Islands, and South Orkney Islands), spread rapidly northward in April along the coasts of North and South America and stay in the North Atlantic during the summer. In September they leave the western Atlantic, travelling east, then southeast, along the coasts of Europe and Africa toward South America and their Antarctic breeding grounds, arriving there in November. These petrels thus travel in a great loop through the whole Atlantic Ocean, in a flight pattern correlated with the direction of prevailing winds. The same pattern is used by other seabirds normally carried by the winds. Albatrosses, such as the wandering albatross (*Diomedea exulans*) that nests on small Antarctic islands, circle the globe during their migrations. One such bird, banded as a chick at Kerguelen Island in the southern Indian Ocean and recovered at Patache, Chile, travelled in less than ten months at least 8,100 miles (13,000 kilometres)—perhaps as much as 11,200 miles (18,000 kilometres)—by drifting with the prevailing winds.

The significance of prevailing winds

In the Pacific, short-tailed shearwaters (*Puffinus tenuirostris*) nest in enormous colonies along the coasts of southern Australia and in Tasmania, then migrate across the western Pacific to Japan, remaining in the North Pacific and the Arctic Ocean from June to August. On the return migration they go east and southeast along the Pacific coast of North America, then fly diagonally across the Pacific to Australia.

Arctic terns (*Sterna paradisaea*), whose breeding range includes the northernmost coast of Europe, Asia, and North America, spend the winter in the extreme southern Pacific and Atlantic, chiefly along Antarctic pack ice 11,000 miles from their breeding range. American populations of the Arctic tern first cross the Atlantic from west to east, then follow the coast of western Europe. Arctic terns thus travel further than any other bird species.

Modes of migration. The migration flights of birds follow specific routes, sometimes quite well defined over long distances. The majority of bird migrants, however, travel along broad airways. A single population of migrants may be scattered over a vast territory so as to form a broad front hundreds of miles in width. Such routes are determined not only by geographical factors—*e.g.*, river systems, valleys, coasts—and ecological conditions but are also dependent upon meteorological conditions; *i.e.*, birds change their direction of flight in accordance with the direction and force of the wind. Some routes cross oceans. Small passerine (perching) birds migrate across 600 or more miles of sea in areas such as the Gulf of Mexico, the Mediterranean Sea, and the North Sea. American golden plover, wintering in the Pacific, fly directly from the Aleutian Islands (southwest of Alaska) to Hawaii, the 2,050-mile (3,300-kilometre) flight requiring 35 hours and more than 250,000 wing beats.

The speed of migratory flights depends largely on the species and the type of terrain covered. Birds in migration go faster than otherwise. Rooks (*Corvus frugilegus*) have been observed migrating at speeds of 32 to 45 miles per hour; starlings (*Sturnus vulgaris*) at 43 to 49 miles per hour; skylarks (*Alauda arvensis*) at 22 to 28 miles per hour; and pintails (*Anas acuta*) at 31 to 51 miles per hour. Although the speeds would permit steadily flying migrants to reach their wintering grounds in a relatively short time, the journeys are interrupted by long stops, during which the birds rest and hunt for food. The red-backed shrike (*Lanius collurio*) covers an average of 620 miles (1,000 kilometres) in five days as follows: two nights for migration, three nights for rest, five days for feeding.

Most migrations occur at relatively low altitudes. Small passerine birds often fly at less than 200 feet. Some birds, however, fly much higher. Migrating passerines, for example, have been observed at altitudes as great as 14,000 feet (4,000 metres). The highest altitude recorded thus far for migrating birds is 29,500 feet (9,000 metres) for geese near Dehra Dūn in northwest India.

Pelicans, storks, birds of prey, swifts, swallows, and finches are diurnal (daytime) migrants. Waterbirds, cuckoos, flycatchers, thrushes, warblers, orioles, and buntings are mostly nocturnal (nighttime) migrants. Studies of nocturnal migrants using radar on telescopes focussed on the moon show that most migratory flights occur between 10 PM and 1 AM, diminishing rapidly to a minimum at 4 AM.

Most birds are gregarious during migration, even those that display a fierce individualism at all other times, such as many birds of prey and insectivorous passerines. Birds with similar habits sometimes travel together, a phenomenon observed among various species of shorebirds. Flocks sometimes show a remarkable cohesion; the most characteristic migratory formation of geese, ducks, pelicans, and cranes is a "V" with the point turned in the direction of flight.

Gregariousness during migration

Mammals. Seasonal movements are not widespread among terrestrial species of mammals, because walking speed is relatively slow and energy consumption great. Marine and flying mammals have a much greater tendency to migrate, a tendency that is directly related to their locomotive powers.

Terrestrial mammals. True migration among mammals occurs mostly among large artiodactyls (split-hoofed animals) living in habitats with wide fluctuations of climatic and biotic conditions.

In North American Arctic regions, herds of caribou (*Rangifer tarandus*) settle during the summer in the barrens—rather flat wasteland with little vegetation. In July, the animals begin to move irregularly southward and spend the winter in the taiga, or northern forests, through which they wander freely with no general directional trend. Each herd seems to move in accordance with local conditions and without a well-defined pattern. The caribou again move northward as early as late February and return to the barrens. These migrations follow the same routes from year to year.

In former times, American bison (*Bison bison*) migrated regularly through the Great Plains. Herds of as many as 4,000,000 animals moved from north to south in fall and returned when spring rains brought fresh grass to the northern part of their range. Bison travelled over more or less circular routes and spent the winter in areas 200 to 400 miles from the summer range. Other North American mammals, such as elk (*Cervus canadensis*), mule deer (*Odocoileus hemionus*), and dall sheep (*Ovis dalli*) still migrate regularly in areas undisturbed by man.

Large African mammals migrate in accordance with the succession of wet and dry seasons, which can greatly modify the habitat. Some antelope remain in small areas throughout the year, but many species undertake seasonal movements over a large range. In the Serengeti region of Tanzania, plains animals, particularly wildebeests (*Connochaetes taurinus*) and zebras, travel more than 1,000 miles in their seasonal migrations. Herds spread outward during the rains and concentrate during the dry season

around water holes. Elephants (*Loxodonta africana*) wander great distances in search of the best food and water supply.

In southern Africa, hundreds of thousands of springbok (*Antidorcas marsupialis*) once migrated according to the rhythm of rainfall over their vast range. They moved in herds so dense that any animal encountered was either trampled or forced along with the herd. These huge migrations often resulted in enormous losses from starvation, drowning, or disease—natural methods for controlling overpopulation. Such movements, involving lesser numbers, still occur in parts of South West Africa and in Botswana.

Flying mammals (bats). A few bats native to Europe and Asia make short flights to winter quarters. In the Soviet Union, the common pipistrelle (*Pipistrellus pipistrellus*) and the frosted bat (*Vespertilio murinus*) withdraw to hibernating places at some distance from their summer range. In Germany, the large mouse-eared bat (*Myotis myotis*) leaves its winter quarters in Brandenburg in March or April and travels as much as 160 miles (260 kilometres) to its summer habitat in northwestern and northeastern Germany. It regularly returns to the same winter locality. Schreiber's long-fingered bat (*Miniopterus schreibersii*) changes its habitat in winter and moves over 100 miles or more according to a complex pattern. These local movements represent an adjustment to winter conditions and the search for more habitable caves.

Migratory bats in the United States

Other bats travel even greater distances. In the United States, the red bat (*Lasiurus borealis*), the large hoary bat (*L. cinereus*), and the silver-haired bat (*Lasionycteris noctivagans*)—three species that roost primarily in trees and shrubs—are true migrants with strong powers of flight. They summer in the northern U.S. and in Canada and winter in Georgia, South Carolina, Florida, and probably also in the southwestern states. The southward movement is made from mid-August to November. Migration flights occur at night, and during the day under favourable conditions. Large numbers follow the coast some distance from land, and all three species are found at sea far from the coast and in Bermuda. Fruit bats and flying foxes (*Pteropus*) native to the tropical regions of the Old World make regular mass migrations, following the seasons for fruit ripening.

Marine mammals. Antarctic whale migrate regularly to the tropics, a fact long known to whalers. By systematically marking whale by shooting into them steel tubes engraved with a serial number, man has obtained evidence of actual movements. A young fin whale (*Balaenoptera physalus*) marked in February in the Antarctic, at latitude 65° S, was captured two years later, in July, off the coast of South Africa, 1,900 miles north. During the austral (Southern Hemisphere) winter, whale migrate to areas rich in food, particularly the northwestern coast of Africa, the Gulf of Aden, and the Bay of Bengal. Antarctic whale—particularly humpbacks (*Megaptera novaeangliae*), a highly migratory species—can be divided into five distinct populations around Antarctica; each population migrates separately, and individuals usually return to their respective zones, though interchange may occur. The Antarctic population does not, however, migrate entirely into warm waters during the winter, and a segment of the population seems to stay behind at about latitude 50° S.

Northern whale have the same migratory habits as Antarctic whale. Northern blue whale (*Balaenoptera musculus*) migrate northward along the east coast of the United States, then through Davis Strait to Baffin Bay (north of Canada) or Spitsbergen to the waters off northern Scotland or the coast of Norway. They are believed to migrate southward along the same routes. Part of the North Pacific stocks of the northern blue whale winters in the Indian Ocean and in the seas bordering Indonesia.

Smaller cetaceans (porpoises and dolphins) migrate in the same way, as indicated by population fluctuations within a particular area; but little is known about their distribution and migration.

Noteworthy migratory habits occur among the pinnipeds (seals and walrus), some of which disperse over wide areas at times other than the breeding season. The harp seal (*Pagophilus groenlandicus*) lives in summer in northernmost Arctic waters, but reproduces in the White Sea (an arm of the Arctic Ocean extending southward into the landmass of the Soviet Union), in the eastern North Atlantic, and around Newfoundland, where young are born between January and April. The seal then returns to more northern latitudes. Northern fur seals (*Callorhinus ursinus*) reproduce only on the Pribilof Islands, off southwestern Alaska, from May to November, and the colonies then disperse into the open seas. The males stay in the Gulf of Alaska and off the Aleutian Islands; the females go farther south, to southern California, some 3,000 miles away.

NAVIGATION AND ORIENTATION

Migrants often return to breed in the exact locality where they were hatched or born. This journey homeward, particularly that of birds, may cover thousands of miles.

Homing experiments

Homing experiments have demonstrated the ability of animals to orient themselves geographically. Such experiments involve removing animals from a specific point (usually the nest), transporting them for various distances, and analyzing their speed and degree of success in returning. Starlings have returned to their nests after being transported 500 miles (800 kilometres); swallows have returned a distance of over 1,100 miles (1,800 kilometres). A Manx shearwater (*Puffinus puffinus*) returned from Massachusetts to Britain, 3,050 miles (4,900 kilometres) across the Atlantic, in 12½ days. Laysan albatrosses (*Diomedea immutabilis*) returned to Midway Island in the Pacific after being released at Widby Island, Washington; the journey covered 3,200 miles and took 10.1 days. Experiments with certain fishes and mammals have demonstrated similar homing ability.

It is apparent that homing animals use familiar landmarks; both random and oriented searches have been observed in birds and fish. Homing experiments with gannets observed from aircraft have demonstrated that, after release, the birds explore the region and hesitate as they apparently look for landmarks. Landmarks vary from topographical (*e.g.*, mountain systems, river systems, coastlines) to ecological (*e.g.*, vegetation zones) to climatic (*e.g.*, air masses differing in temperature and humidity, prevailing winds). Fish may orient themselves by using similar clues in the same way. Passive drifting is an important factor in the movements of larvae and young fishes, such as those of the eel, cod, herring, and plaice, and even in adults that are passive after spawning, such as herring and cod. As a result of drifting with the current, the movements of such fishes are similar from year to year.

Familiar landmarks and exploration do not, however, explain how migrants find their way along routes covering many hundreds or thousands of miles nor do the results of most homing experiments.

Birds. A compass sense has been demonstrated in birds; that is, they are able to fly in a particular constant direction, regardless of the position of the release point with respect to the bird's home area. It has also been shown that birds are capable of relating the release point to their home area and of determining which direction to take, then maintaining that direction in flight. The navigational ability of birds has long been understood in terms of a presumed sensitivity to both the intensity and the direction of the earth's magnetic field. It has also been suggested that birds are sensitive to forces produced by the rotation of the earth (Coriolis force); however, no sense organ or physiological process sensitive to such forces has yet been demonstrated to support this hypothesis.

Experiments have shown that the orientation of birds is based on celestial bearings. The sun is the point of orientation during the day, and birds are able to compensate for the movement of the sun throughout the day. A so-called internal clock mechanism in birds involves the ability to gauge the angle of the sun above the horizon. Similar mechanisms are known in many animals and are

closely related to the rhythm of daylight, or photoperiodism. When the internal rhythm of birds is disturbed by subjecting them first to several days of irregular light–dark sequences, then to an artificial rhythm that is delayed or advanced in relation to the normal rhythm, corresponding anomalies occur in the homing behaviour.

From M. Ricard, *The Mystery of Animal Migration*

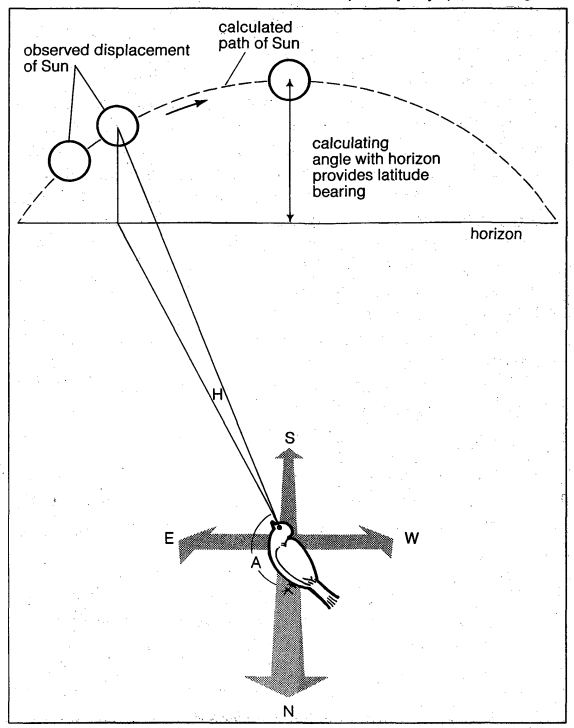

Figure 4: Matthews' hypothesis of solar navigation by birds. Birds can visualize the complete trajectory of the sun and determine its zenith and altitude at midday (angle H) in order to derive the latitude. Angle A is measured from the north to the point at which a vertical from the sun cuts the horizon. From this longitude can be derived.

Two theories have been formulated to explain how birds use the sun for orientation. Neither theory, however, has thus far been substantiated with proof. One theory holds that birds find the right direction by determining the horizontal angle measured on the horizon from the sun's projection. They correct for the sun's movement by compensating for the changing angle and thus are able to maintain the same direction. According to this theory, therefore, the sun is a compass that enables the birds to find and maintain their direction. This theory does not explain, however, the manner in which a bird, transported and released in an experimental situation, determines the relationship between the point at which it is released and its goal.

The second theory, proposed by British ornithologist G.V.T. Matthews, is based on other aspects of the sun's position, the most important of which is the arc of the sun —*i.e.*, the angle made by the plane through which the sun is moving in relation to the horizontal. Each day in the Northern Hemisphere, the highest point reached by the sun lies in the south, thus indicating direction; the highest point is reached at noon, thus indicating time. In its native area a bird is familiar with the characteristics of the sun's movement. Placed in different surroundings, the bird can project the curve of the sun's movement after watching only a small segment of its course. By measuring maximum altitude (the sun's angle in relation to the horizontal) and comparing it with circumstances in the usual habitat, the bird obtains a sense of latitude. Details of longitude are provided by the sun's position in relation to both the highest point and position it will reach—as revealed by a precise internal clock.

Use of celestial navigation by birds

Migrant birds that travel at night are also capable of directional orientation. Studies have shown that these birds use the stars to determine their bearings. In clear weather, captive migrants head immediately in the right direction using only the stars. They are even able to orient themselves correctly to the arrangement of night skies projected on the dome of a planetarium; true celestial navigation is involved because the birds determine their latitude and longitude by the position of the stars. In a planetarium in Germany, blackcaps (*Sylvia atricapilla*) and garden warblers (*S. borin*), under an artificial autumn sky, headed "southwest," their normal direction; lesser whitethroats (*S. curruca*) headed "southeast," their normal direction of migration in that season.

It is known, then, that birds are able to navigate by two types of orientation. One, simple and directional, is compass orientation; the second, complex and directed to a point, is true navigation, or goal orientation. Both types apparently are based on celestial bearings, either the position of the sun or the patterns of the stars, which provide a navigational "grid."

Other animals. The methods of directional orientation used by birds are similar to those used by other animals. Orientation to the sun has been demonstrated in various crustaceans, particularly in the sand flea (*Talitrus saltator*). Various insects, particularly bees and certain beetles (families Scarabeidae, Tenebrionidae, and Carabidae) use the sun to plot their course with remarkable accuracy.

Fishes also are able to use celestial bearings; salmon presumably use the sun. Experiments with the parrot fish (*Scarus*) have demonstrated a sun compass reaction that may also occur in other fishes. Localization of the sun is, however, much more difficult in water than in the air, because of the characteristics of light rays passing through water. Experiments suggest that topographical clues are also used by fishes to recognize their range, particularly their spawning grounds. Visual bearings in this respect have great importance. It is possible that chemical substances also provide clues; the role of olfaction in the salmon has been described (see above, *Anadromous fishes*).

Visible landmarks are used by mammals, at least for orientation within short distances. Scented trails are probably helpful within a limited area, proportionate to the size of the animal; olfaction plays an important role in the life of mammals. Some mammals, however, migrate over enormous distances and are able to return after being taken far away from their home territory; bats, for example, have returned 165 miles (265 kilometres) to their caves. Random exploration plays a part in such movements, but it is possible that some type of true navigation is involved in certain of these movements.

PHYSIOLOGICAL STIMULUS OF MIGRATION

Migration, like reproduction and other phases (as molting in birds), is part of the life cycle and depends on a complex internal rhythm that affects the whole organism, particularly the endocrine glands (glands of internal secretion) and the gonads. Migration must thus be viewed in relation to the entire annual cycle.

Each year birds return to particular areas to breed, and remain there until the members of the brood can care for themselves. There is no relation between the reproductive and migratory stimuli, yet the two phenomena, although independent, are nevertheless stimulated by the same factor.

A physiological study of certain migrants has revealed that metabolic patterns usually change prior to migration, and fats accumulate in the body tissues. The whitethroat (*Sylvia communis*) weighs an average of 12 to 13 grams (about 0.4 ounce) during the breeding season, 16 to 19 grams (about 0.6 ounce) in the autumn, and 20 to 24 grams (about 0.8 ounce) in the winter. Food consumption increases with the autumn molt, reaching a peak at the beginning of the migration season. These fundamental physiological changes, chiefly under the control of the thyroid gland, are correlated with migratory activity. Such fluctuations are not observed in nonmigratory species.

Variations in metabolism and related phenomena are controlled by an endocrine gland, namely the pituitary gland, which is located in the lower part of the brain and acts as a command post, sending out instructions in the

The role of the pituitary gland in migration

form of secretions called hormones. That the pituitary has a cycle independent of environmental factors is demonstrated by the regularity with which phases such as reproduction occur from year to year in the lives of some birds, and by the diverse response of various species and populations to the same environmental factors. That the pituitary is, however, influenced by environmental factors, such as variations in day length and the intensity of the sun, has been demonstrated experimentally.

Gonadal development and the deposition of fat, for example, are influenced by the pituitary, which responds to increasing day length in springtime by accelerating the rate of gonadal development. The pituitary thus governs the development of gonads and, in addition, affects all metabolic processes, including development of the thyroid gland, so as to prepare the animal physiologically for migration. If only the pituitary and variations in day length were involved, migration would be triggered at definite times, because the pituitary cycle is fixed, and photoperiodism is a highly predictable phenomenon; such a lack of flexibility, however, would inevitably cause migrant populations to suffer catastrophes because ecological conditions are irregular—meteorological events, such as the arrival of spring, and biological phenomena, such as flowering, foliation, hatching of insects, and availability of food, are highly variable from year to year. The pituitary thus serves only to prepare the bird for flight; the proper ecological conditions, on the other hand, are necessary to initiate it. The availability of food is an important factor. Temperature and weather conditions also have an influence—a sudden period of cold weather during autumn may induce the immediate departure of many migrants.

Sensitivity to changes in the weather and other environmental conditions varies markedly among species. Some, such as the woodcock, snipe, lapwing, starling, and lark, rely on surrounding conditions to initiate their spring and autumn migrations, and the patterns of their flight depend on temperature and barometric pressure. Others, such as the swift, cliff swallow, Baltimore oriole, and short-tailed petrel, are less weather dependent, and, since the dates of their arrival and departure are not regulated by the weather, they occur with remarkable regularity each year.

The factors that stimulate migration in animals other than birds are not yet well understood. Ecological conditions play a great part in the migratory activity of mammals, who react to general food shortage by moving to another region. Whale, for example, leave the Antarctic region as winter modifies the oceanographic conditions. Seals disperse when the food supply in the area of their breeding colonies is depleted. Environmental factors are of primary importance in the migration of fishes and marine invertebrates. Annual movements of water masses change physical conditions such as temperature and salinity; biotic conditions are influenced accordingly.

ORIGIN AND EVOLUTION OF MIGRATION

The origins of migration remain in the realm of pure conjecture; neither observation nor experiment has resolved the matter. The explanation, however, must be related to geographical and climatological factors that have prevailed since the Tertiary Period, which ended some 2,500,000 years ago. The great Quaternary ice ages, which came later, were very important in altering the distribution of animals over a large part of the world, but migrations occurred long before.

Migration, as it is now known among modern birds and mammals, probably appeared gradually by stages. Some animals changed their habitat only slightly, never leaving the same general region. The movements of other animals were more erratic, their dispersal being oriented toward the most favourable places. Such movements are the first stages of true migration—a phenomenon characterized by elaborate mechanisms—which gradually acquired stability through natural selection. At first, many populations must have perished rather than attempt to flee from unfavourable conditions. Only a fraction of such populations probably sought more favourable conditions elsewhere, but natural selection favoured the "migrants," and migratory tendencies were retained.

Causes of change of habitat

In some cases, original habitats were in present-day wintering areas, and animals developed a tendency to leave in spring in order to breed in other territories. Seasonal changes of weather and food supply in these newly settled regions forced the animals to migrate in fall, and they thus retreated to their former range. Among birds nesting in the Northern Hemisphere, hummingbirds, tyrant flycatchers, tanagers, orioles, bee-eaters, and swifts have distinct tropical affinities; in recent geological times these birds gradually spread northward as glacial ice receded and the continent became warmer. Other birds, such as plover, ducks, and geese, originally lived in what is now their breeding area. Gradual climatic changes forced them to spend their winters in regions far to the south. Migrations thus appear to be the consequence of invasions or emigrations, during which animals settle in new areas during a segment of the annual cycle.

Migratory birds use the routes by which their ancestors first invaded new regions after the glacial recession. The yellow wagtail (*Motacilla flava*) and the wheatear (*Oenanthe oenanthe*) settled in Alaska; they migrate annually into other parts of the Western Hemisphere but spend their winters in the warm regions of southeastern Asia and even Africa, probably following the migratory route of their ancestors. A typically North American species, the grey-cheeked thrush (*Hylochichla minima*), which has extended its breeding area to northeastern Siberia, returns to spend the winter in the central regions of South America.

ECOLOGICAL SIGNIFICANCE OF MIGRATION

There are many ecological implications of migration. The food resources of some regions would not be adequately exploited without moving populations. The sequence of migratory movement is closely integrated in the annual cycle of ecosystems characterized by productivity fluctuations. Migratory behaviour concerns only species located at specific trophic levels (zones of food availability) where maximal fluctuations occur both in breeding areas and in wintering regions. Migrant birds avoid equatorial forests where productivity is constant throughout the year, and food surpluses do not occur. They do congregate, on the other hand, in savannas where productivity varies with the seasons.

Such a coordinated sequence is particularly apparent in the case of birds migrating from the northern Arctic regions to tropical winter regions; both life zones are characterized by broad fluctuations in productivity. In the Arctic, vegetal and animal production is very high during the summer; ducks and waders nest in great numbers, exploiting these resources. As winter comes, food becomes scarce, and water birds migrate to the tropics, where the rainy season has caused food production to increase to optimal levels. Ducks and wading birds concentrate in the most favourable areas, remaining until spring, when productivity is lowest. By then the condition of breeding areas is again favourable for the birds. The life cycles of these birds are closely attuned with the cycles of their various habitats, and the sizes of bird populations are controlled by the capacity of both areas to sustain them.

Migration, then, has considerable ecological significance. It enables fast-moving animals to exploit fluctuating resources and to settle in areas where life would not be tenable for animals incapable of rapid travel. On the other hand, peaks of food production would be unexploited without the periodic presence of migratory populations.

BIBLIOGRAPHY. G.M. ALLEN, *Bats* (1939), a classic book on bat biology with a chapter on migration; F. BOURLIERE, *Vie et moeurs des mammifères* (1951; Eng. trans., *The Natural History of Mammals*, 3rd ed. rev., 1964), a modern review of mammal biology with a chapter on migration; J. DORST, *Les Migrations des oiseaux* (1956; Eng. trans., *The Migrations of Birds*, 1962), a modern review of all aspects of bird migration; D.R. GRIFFIN, *Bird Migration* (1964), a useful summary with a good chapter on orientation; F.R. HARDEN JONES, *Fish Migration* (1968), a standard book, with

many classic references; G.V.T. MATTHEWS, *Bird Navigation* (1955), an original attempt to explain bird orientation; R.T. ORR, *Animals in Migration* (1970), a modern review of migration patterns among animals; E.J. SLIJPER, *Walvissen* (1958; Eng. trans., *Whales*, 1962), a modern review of whale biology, including a chapter on migration; A.L. THOMSON, *Bird Migration*, rev. ed. (1942); and C.B. WILLIAMS, *The Migration of Butterflies* (1930), two classic books, still useful; A. WOLFSON, "Ecologic and Physiologic Factors in the Regulation of Spring Migration and Reproductive Cycles in Birds," in A. GORBMAN, *Comparative Endocrinology* (1959), an accurate review of the physiology of bird migration, somewhat out of date but still useful.

(J.P.D.)

Migration, Human

Migration is commonly defined as the permanent change of residence by an individual or a group. Since the definition does pose the problem of deciding what is "permanent," statisticians collecting migration data must usually rely on more or less arbitrary criteria. In statistics of international migration, for instance, a person is usually classified as an immigrant if he has stated his intention of settling in the country of entry for at least one year.

Various authors would like to include further limiting clauses in the definition. In particular, some would prefer to exclude all forced moves from the concept of migration, even though it is not always easy to say whether a move of residence is or is not forced. Similarly, some sociologists would like to limit the migration concept to moves from one social system to another, but the central problem here is that modern man participates simultaneously in various social groups. Some of these groups have their members concentrated in a small area, whereas others (*e.g.*, the Roman Catholic Church) have their members spread over the whole world. As a consequence, anyone who moves his residence leaves behind some of the social groups to which he belongs, while other groups to which he is affiliated are to be found also in his new place of residence. This means that if migration is to be defined as moving from one social system to another, the difficult decision must be reached as to how far group affiliations must change before one can say that there has been a move between different social systems.

Distinctions between migration and other moves by man

The criterion that migration be a "permanent" move differentiates migration from various other types of human moves. One of these is nomadism, the way of life of those having no fixed abode. The nomadic way of life may be brought about by economic necessity, as in the case of certain hunters and gatherers or of cattle-breeders who follow their livestock about. For other peoples, such as gypsies, nomadism is a tradition. A modern phenomenon akin to nomadism is migrant labour (*q.v.*). "Seasonal moves" differ from nomadism in that moves are made only twice a year, between winter homes and summer abodes. The Lapps offer an example of a people who have retained this mode of life up to the present.

Another type of human move is commuting—referring to the daily, or sometimes weekly, journeying to work of people who live a considerable distance from their jobs. Commuting has increased enormously in the developed countries over the past half century or so. Temporary moves are also made in tourism, which nowadays involves vast numbers of people. Quite often when moves to temporary homes are involved, tourism resembles migration, but its temporary character places it in a different category.

THE DYNAMICS OF MIGRATION

Motives for migration. The argument that man migrates because he is inherently restless—nomadic by nature—is countered by the argument that man is inherently sedentary, remaining fixed until some force impels him to move. The former proposition provokes the question as to why many people do *not* migrate; whereas the latter provokes the reply that many migrants were obviously by no means forced to move. Some further explanation for the migration phenomenon is needed, and this has been sought in the concepts of "push" and "pull." Migrants may be pushed by circumstances in their region of origin—for instance, exhaustion of natural resources. Conversely, they may be pulled by attractions in their region of destination—for example, better employment opportunities.

The "push-pull" factors in migratory patterns

Some investigators have tried to explain all migrations by push factors only, whereas others have stressed pull factors exclusively. It is undoubtedly true that push factors sometimes suffice to bring about migration (such as in the case of famine). In other instances, pull factors may be entirely responsible for a migratory movement (such as in gold rush). In most cases, however, both push and pull factors play a role. A prospective migrant weighs the circumstances in his region of origin and the attractions as well as the disadvantages of every potential region of destination. Such interregional differences thus usually form a prerequisite for migration (see below).

In highly developed countries, exceptions to the rule that interregional differences form a prerequisite for migration are rare. Only where economic development has not progressed very far do push factors alone sometimes suffice to bring about migration. Thus a dearth of basic means of livelihood may mean that moving elsewhere—anywhere—is seemingly the only solution. Then, migration may also be affected disproportionally by defective communication. Occasionally, rumours grossly exaggerate the opportunities in potential regions of destination with the result that a migration "craze" sets in.

There are indications that in many of the present developing countries, notably in Asia and the Middle East and more recently in Africa, this kind of push migration obtained after World War II. In these countries, according to some authors at least, agricultural crises produced rural–urban migration streams far in excess of what would be warranted by economic opportunities in the cities. The authors who adhere to this view speak of overurbanization.

Distance and direction of migration. Communication, as already implied, is important for migration, because obviously if interregional differences are to bring about any sizable migration, conditions in the region of destination must be known in the region of origin. The communication factor is principally responsible for the inverse relation between volume of migration and distance. This inverse relation was discovered by the British statistician Edward G. Ravenstein, whose first "law" in his classic "The Laws of Migration," published in 1885, stated that the great body of migrants proceed only a short distance. This has been proved true in numerous migration studies in several countries.

Not only geographical but also technical distance (by which is meant distance as influenced by the available means of transportation and communication) and social distance are important for migration. Aspects of social distance such as religions and language differences may seriously impede migratory movement.

Contrasts between international and internal migration

The difference in physical as well as social distance is the main distinction between international migration and internal migration (that is, migration within a country). International migrants not only often cover great physical distances but also face an unaccustomed cultural environment and a strange language. It is thus not to be wondered that the volume of internal migration usually far exceeds that of external migration. Within the context of internal migration, local moves can be distinguished from migrations over longer distances. The latter in the majority of cases are economically induced, whereas local moves are usually motivated by housing factors.

Ravenstein's second "law of migration" was concerned with the routes followed by internal migrants. In his momentous work, *The Growth of Cities in the Nineteenth Century*, published in 1899, the American statistician Adna F. Weber, paraphrased this "law" as follows:

> Since, then, the current of migration is toward the cities and yet the bulk of migration is for short distances only, we can see the manner of the movement; it is a migration by stages having for its object the satisfaction of the demands for more labor in the cities.

Migration by stages, then, is a process whereby a general migration over long geographical distances may take place

even though each individual migrant may cover only a short distance at each move. Since migrants tend to cover not only short geographical distances but also short social distances, there is also what may be called migration by steps—that is, migration from rural areas to the big cities via small- and medium-sized towns. The processes of migration by stages and migration by steps were first recognized around 1900, and recent studies show that they still play an important role in internal migration. A new "step" has, however, been added to the migration by steps—the migration from the cities to the suburbs.

Demographic factors. In former times, an entire tribe or nation sometimes migrated as a unit. Today, migration is usually an individual or family affair. This raises the question whether the migrants in a population differ, on the average, from the nonmigrants, and, if so, in what way.

The demographer Dorothy S. Thomas, reviewing studies concerning migration differentials published up to 1938, concluded that the only generalization about this subject that can be considered definitely established concerns age. There is a great preponderance of adolescents and young adults among migrants, particularly migrants from rural areas to towns, as compared with the age ratios in the nonmigrating population. No doubt the likelihood of improving living conditions through migration is greater for young people than for their elders, who are already established in their jobs and residential neighbourhoods.

Influence of age and sex factors

Migration is not selective by sex. Whether males or females migrate more to a certain region depends on the relative opportunities for either sex in that region. There is a tendency, however, for single women to cover shorter distances than men when migrating, possibly because in most countries the pursuance of a career, which may necessitate long-distance migration, is still considered less important for women than for men.

Influence of socio-economic factors

With regard to family status and family composition, a general finding is that married couples without children or with only very young children migrate much more than do couples with older children. Especially in the case of migration to the suburbs, there is a preponderance of families with small children.

Many studies in Germany, the United States, and Sweden have indicated that migrants from rural to urban areas tend on the average to have higher intelligence, education, and socio-economic status. This finding has puzzled and sometimes alarmed social scientists since before the turn of the century. In the 1950s, however, it was recognized that this positive selection is a consequence of the fact that only in the towns is work available for the highly skilled.

A recent phenomenon is the selective migration of highly trained persons—engineers, physicians, scientists—from less developed countries to more developed countries (and sometimes from the less affluent developed nations, such as Great Britain, to the more affluent, such as the United States). This is called "brain drain." Opinions differ as to the extent of the brain drain, and as to its consequences for developing nations.

Migratory selection according to ethnic origin or race is evident in many societies. This results from cultural or social factors. The cultural values of one ethnic group may be more conducive to migration than that of another. More often, however, migration differentials by ethnic group or race are a direct or indirect consequence of discrimination. The wanderings of the Jews form a clear example. In the United States, differences in educational opportunities as well as residential segregation explain differential migration as between whites and nonwhites.

TYPES OF HISTORICAL MIGRATIONS

Over the ages there have been many migratory movements, which various authors have tried to classify under a few broad headings.

Primitive migrations. Probably the oldest type of human migration is that resulting from such push factors as a people's inability to cope with natural forces or their flight from a stronger foe. Though termed "primitive" migration, this type of migration is not confined, however, to "primitive" peoples.

If one takes it that *Homo sapiens* made his appearance on earth in one particular place, primitive migration is the process by which he eventually populated the whole globe. This process of "dispersion" took place almost entirely in prehistoric times, so that not much is known about the routes followed. It is likely that the American Indians reached their country from Asia by way of the Bering Strait, while Oceania also appears to have been peopled from the West. The Americas and Oceania seem to have been the last parts of the world to be settled.

Tribal migrations

In the primitive migrations of former times, usually peoples as a whole and not merely families or small groups migrated. In German this is called *Völkerwanderung*, which may be translated as folk, or tribal, migration.

For over 2,000 years, tribal migrations played an important role in European history—from the incursion of the Dorians in Greece in the 11th century BC to the Norman raids and conquests between 800 and AD 1200. The Germanic migrations of the 4th, 5th, and 6th centuries AD in particular gave rise to much change. The Germanic peoples had originally lived on the shores of the Baltic Sea, but for many centuries they had been moving southward in search of new agricultural land. In the second half of the 4th century, the easternmost of their tribes, attacked by Huns coming up from the Eurasian steppes, invaded the Roman Empire to find a new place to settle. Other Germanic tribes followed suit. Some of them moved hundreds of miles in the course of the next two centuries. Probably none of these tribes was larger than a few score thousand. Numerically these migrations were thus not very important, but their consequences for history were enormous.

Tribal migrations over long distances have also taken place in other continents. One further example is the dispersion of the numerous Bantu tribes in Africa, who between 700 and AD 1200 moved from the neighbourhood of Lake Victoria westward into the Congo area and between 1200 and 1800 moved southward, reaching as far as present day Natal and South West Africa.

Primitive-type migrations, however, also include certain more recent movements of individuals and families. The flight from hunger of large numbers of Irish and German farmers in 1846 and the years following is a case in point. In Ireland and in the lower Rhine area of Germany, millions of people had become dependent on the potato for their livelihood. When in 1845 and 1846 the potato crop failed twice in succession, emigration was for many the only solution.

The 20th century has unfortunately seen a sharp increase in the volume of a category of migrants part of whom also fall within this section—namely, refugees (*q.v.*) Those refugee movements—which are neither forced nor planned but are due to people either judging the political situation in their country of residence unbearable or fearing that it will become so in the near future—may be classified as primitive migrations. Examples are the flight of more than 700,000 Arabs from Israel in 1947–48 and population movements between India and Pakistan in the same years, which involved 14 million people. Certain other refugee movements, in particular the transfers of people dictated by governments, belong to the type of migration dealt with in the next section.

Deportations and exiles

Forced or induced migrations. "Forced" migrations refer to people moved either by the state or by some other social institution that wields power over them. The most stringent forms of forced migration are deportation and slave trade. Deportation has been employed by most governments, at one time or another, to get rid of criminals, political opponents, or other persons deemed undesirable. One widely known example is the movement of some 150,000 British convicts to Australia between 1788 and 1867. Another instance is the exile of 1,000,000 Russians to Siberia during the 19th century. In the course of World War II, the Nazis deported 7,000,000–8,000,000 people, including at least 5,000,000 Jews who were subsequently murdered. After the war, the Allies decided that all Germans living outside the new German borders should be transferred to within them; this involved 9,000,000–10,000,000 people. Meanwhile, the Soviet government de-

ported to Central Asia 400,000 Volga Germans and 600,000 members of other minorities accused of collaboration with the Nazis.

Slave trade was widely practised for thousands of years in Africa, the Middle East, and Europe, where slavery was for a long time a well established institution. From 1510 until late in the 19th century, African slaves were hauled to the Americas. Estimates as to the number of slaves who left the African coast run as high as 20,000,000; a sizable number, however, did not survive the Atlantic passage. In 1942 Hitler revived a form of slavery in Europe by forcing men from the occupied countries to work in Germany. Their number reached eight million in 1944 (see SLAVERY, SERFDOM, AND FORCED LABOUR).

Apart from deportations and slavery, there are instances in which social institutions induce people to move by less severe methods. The term forced migration is really too strong for these cases; it would be better to speak of induced migrations. A widespread modern form of induced migration is transfer of staff. In the military services as well as in certain other governmental agencies and in large, dispersed private companies, personnel may be moved from one place to another by order.

Migrations of adventurers and minority groups

Free migrations. When there are neither push factors nor political forces inducing people to emigrate, nor as yet a migration tradition based on intensive communication between regions of origin and destination, there may be migratory movements of adventurous or deviant individuals or groups. The 19th-century Atlantic migration, for instance, started with these "free migrations." At first, around 1830, students and other young intellectuals predominated among the migrants from continental Europe to North America. They were motivated by their alienation from European society during a period of political reaction. In the course of a few decades, this was followed by the emigration of small groups, mainly religious minorities such as Pietist communities.

The significance of free migration is not in its volume, which is seldom large, but in the example it sets. It is a pioneer movement.

Chain migration. Through the mechanism of chain migration, the pioneer movement noted above can easily lead to migration on a large scale. Chain migration is based on the effect of letters from early migrants to relatives and friends at home. Visits home also exert a strong influence. These personal contacts form a most potent means of communication. Once the first migrants have induced some relations to follow them, these too in turn write to relations and friends. Thus a migration chain is started that may operate for scores of years and result in the movement of thousands of people.

In the purest examples of chain migration, the later migrants settle in the vicinity of the first migrants. In such countries as the United States and Australia, this has produced numerous colonies of people living close together who all hail back to a small region, sometimes one town or village, in Europe. Several examples of such colonies having developed around a single original settler are known. Chain migration does not always result in such colonies, however; the later migrants may disperse after having reached the country of immigration.

Some colonies that had "proprietors" (capitalists to whom kings had granted lands overseas) were also heavily advertised to the very first of the prospective settlers. William Penn's success in colonizing his Pennsylvania in the 17th century, for example, was largely due to his own skill as a promoter, for he wrote enticing tracts and on preaching journeys in Europe described the opportunities offered by his colony. His successful promotions were imitated by others.

Mass migration. Chain migration played a key role in bringing about a new phenomenon during the 19th century—namely, long-distance mass migration. In many countries of Europe especially, emigration became a style, an established social pattern, an example for collective behaviour.

The Great Atlantic Migration

The largest of the intercontinental mass movements was that from Europe to North America: the Great Atlantic Migration, as it has been called. Between 1820 and 1970 about 41,000,000 people left Europe for North America. Five million went to Canada, 36,000,000 to the United States. The flow to the United States reached its peak in the last decades of the 19th century and the first two decades of the 20th century, when it was further stimulated by agricultural crises in Europe. Between 1880 and 1910, 17,000,000 Europeans entered the United States. After World War I, the stream diminished due to American immigration restrictions and changing conditions in Europe.

Two other migrations accounted for between 15,000,000 and 20,000,000 people each since 1820. One was the movement from Europe to South America. This stream was made up mainly of southern Europeans. The other was the migration from European to Asiatic Russia. The figure quoted includes 1,000,000 exiles during the 19th century and 1,000,000 deportees during World War II, but for the remainder this migration was a voluntary movement. In the three decades before World War I alone, more than 5,000,000 Russians settled in Siberia.

Other important intercontinental migrations include European migrations to Africa, Australia, and New Zealand, and Japanese, Chinese, and Indian migrations to the Western Hemisphere. It should be pointed out that most of these migratory movements are still going on. Some, in particular migration from Europe to Australia, have reached a high level only since World War II.

An important mass movement that is *intra*continental is the Chinese emigration to Southeast Asia, which started many centuries ago but rose to large proportions in the 19th century. The present number of Chinese, both original migrants and descendents, in Southeast Asia is usually given as 12,000,000. Malaysia, Thailand, Indonesia, Singapore, and Vietnam have the largest numbers of Chinese immigrants.

In the 20th century, a new type of international mass migration has sprung up, in which the moves are mostly within one continent. This is the migration of unskilled labourers from less developed to more developed countries. Examples are the streams from southern Europe and North Africa to northwest Europe; from Malawi, Zambia, Botswana, and Lesotho to Rhodesia and the Republic of South Africa; from Upper Volta to Ghana and the Ivory Coast; and from Mexico to the United States. Because most of these migrants return after a few years, this is a mixed form of permanent migration and temporary labour transfer.

Modern migrations. The development of extensive mass-communication systems in modern societies has made migration less dependent on the personal messages and individual promotions that had played such a large role in earlier chain migration. Modern migrants tend to get their information concerning the region of destination from newspapers, television, official agencies such as labour exchanges or immigration offices, and so forth.

Rural–urban migration

The principal current of modern migration all over the world is toward urban areas. Of course, cityward migration is not a new phenomenon. Various indications show that the earliest historical cities, those of Mesopotamia in the 4th millennium BC, experienced regular in-migration. Rome attracted migrants by the thousand as early as the 3rd century BC. In the later European Middle Ages, the development of trade and crafts, which tended to be concentrated in the towns, added impetus to cityward migration.

Only with the Industrial Revolution, however, did cityward movements begin to predominate in the pattern of migration. Particularly in Europe, North America, and Australia, and New Zealand did large-scale migrations toward the towns take place in the second half of the 19th century. London, for instance, gained 200,000 people by migration in the 1850 decade, Paris as much as 280,000 in the five years 1876–80. Similarly heavy rural–urban migration began in Latin America and the Soviet Union after World War I, and in most of the remainder of the world after World War II. A single figure may serve to illustrate the magnitude of this movement: in India net migration to the towns amounted to 5,500,000 people in 1951–60.

In the rich countries, however, urbanization nowadays

takes a scattered form: suburbanization has set in. Even before 1900, large towns started losing migrants to the suburbs. Net out-migration is now the rule for these cities. This results in a large increase in commuting.

FACTORS DETERMINING THE VOLUME AND DIRECTION OF HUMAN MIGRATION

Incentives to migration. The volume and direction of every migration stream are determined by numerous factors that may be classified as, on the one hand, incentives to migration, and on the other hand, obstacles and alternatives to migration. As has already been stated, the incentives usually take the form of interregional differences, though in some cases the push of circumstances in the region of origin or the pull of attractions in the region of destination may be sufficient.

A dwindling food supply, exhaustion of natural resources, or overpopulation are push factors that may result in migration. A pull factor leading to migration may be the discovery in one particular region of a coveted asset: for instance, gold or diamonds. A migratory movement based exclusively on push or pull factors can grow to large proportions very quickly, but it tends to endure only temporarily. As communication improves, either some alternative to migration is found or the migration reverts to the normal type based on true interregional differences. The 19th-century Atlantic migration, for example, showed a more or less push character up to about the time of the American Civil War, being largely the result of disorganization in European countries. Later, knowledge of the differences between the Old World and the New became the principal migration factor.

The interregional differences that nowadays determine volume and direction of migration streams may be divided into various categories.

Differential economic opportunities. Differences in the demand for certain types of labour or for labour in general have for a long time been the main migration incentive. Differential economic opportunities may come about as a result of discovery or exhaustion of natural resources, technical innovations, development of new trade routes or establishment of new frontiers, changes in the division of labour, or changes in taste.

Differential standards of living. Although one would expect differences in real income between various countries or regions to be relevant to the volume of migration, in statistical studies their effect is in fact usually found to be nominal.

Differences relating to housing and the residential environment. This factor has recently become more important in determining the volume and direction of migration. It forms the basis not only for the entire large-scale suburbanization movement but also for much of the migration of elderly people. Aspects of the residential factor are quality of dwellings and of residential neighbourhoods, climate, and scenery. Where an absolute shortage of dwellings prevails, such as was the case in many European countries after World War II, differences in the availability of dwellings also play a role.

Differences relating to social amenities. Such urban amenities as recreational facilities (theatres, cinemas, concert halls), institutes of higher education, and specialized hospitals certainly influence the migration decisions of some individuals. Statistically, however, they have been found to contribute only marginally to the explanation of the volume and direction of migration streams. Modern urbanization is clearly based on employment factors and not on "the lure of the city lights."

Cultural and political differences. Often a minority in a country prefers the cultural and political values that obtain elsewhere. This may be a reaction to more or less revolutionary cultural and political changes in their country—as was, for instance, the case with regard to the many Germans who left Germany during or shortly after 1933. It may also be, however, that the values and views of the minority itself have changed, while the dominant culture remains more conservative. Many Europeans left for North America from the 17th to the 19th centuries because of the religious freedom in the New World.

Obstacles to migration. Obviously for migration to take place conditions in the potential region of destination must be evaluated by the migrants as the more favourable. Interregional differences that are negatively evaluated act as obstacles to migration.

Vested interests. Irrespective of interregional differences there is a factor that is likely to exert a negative influence on migration. To a person who has established himself in a certain region, with personal property, contacts with relatives and acquaintances, and familiarity with local customs, the prospect of migration may be less attractive. These personal ties between the individual and his own region may be termed "vested interests." It is impossible to measure the inverse relation of vested interests to the volume of migration streams, but studies of nonmigrants and their motives for not migrating suggest that vested interests may exert considerable influence.

Personal and cultural obstacles to migration

Defective communication. Another major obstacle to migration is lack of information concerning opportunities in potential regions of destination. This is a consequence of defective communication resulting from great physical, technical, or social distances or other barriers to communication. The latter include national or linguistic boundaries or historical partitions that have not yet lost their traditional influence. The volume of international migration is thus generally much smaller than that of internal migration, except when the social distance between two countries has been greatly lessened by prior migration and there is no language difference, as in the case of Ireland and England. If, on the other hand, a linguistic boundary exists *within* a country, its effect on migration is clearly discernable. In Belgium, for instance, the effect of the boundary between the Dutch-speaking and the French-speaking part of the country was found to equal that of a distance of 50 miles.

Transportation difficulties. Migration may be further curbed by difficulties of transport—to which, of course, distance may contribute. These difficulties may be technical or financial. In the case of intercontinental migration, the expense of the journey not infrequently limits the number of migrants, especially from the poorer countries. In recognition of this problem, some governments give financial aid to emigrants. Certain countries anxious to attract immigrants, in particular Australia and South Africa, also offer to defray part of the travelling expenses.

Emigration and immigration restrictions. Finally, among the obstacles to migration should be counted social norms that are opposed to emigration or, in the country of destination, to immigration. Such norms may be of an informal nature, but often they are formalized into official emigration or immigration restrictions. In the United Kingdom, for instance, laws against emigration were passed in 1719, 1750, and 1782. In Japan emigration was strictly prohibited from 1636 to 1868. Military considerations prompted many German states to restrict emigration severely in the 19th century.

Political restrictions on migration

Immigration restrictions are, broadly speaking, of two types: either foreigners need a permit to enter the country or they may freely enter but need a permit to take a job. The latter system is usually applied in Europe. As of Nov. 8, 1968, however, all migration restrictions have been abolished within the European Economic Community, so that nationals of any of the six Common Market countries may now freely settle and work in the other five. Within the European Free Trade Association, too, immigration restrictions have been slackened.

The English-speaking immigration countries outside Europe usually rely on an entrance visa. For a long time they were inclined to select immigrants on the basis of national preference, favouring Europeans with an emphasis on citizens of the United Kingdom. The United States institutionalized this preference in 1921 with the introduction of the quota system. The maximum of the nationals of any country to be admitted in any one year was fixed, under this system as revised in 1924, relative to the percentage of persons originating from that country resident in the United States in 1890. The quota principle was retained, with various alterations, until 1968, though in fact during the 1950s more immigrants were admitted outside the

quotas, under special laws, than were admitted within the quotas. As of 1968 the quota system was abolished and preference was given, within an annual grand total of 170,000, to relations of U.S. residents, refugees, and highly trained workers.

The Commonwealth immigration countries, Canada, Australia, and New Zealand, never had an official quota system, but their preference for Britons and other northern Europeans was unmistakable. In the 1960s these countries changed their policy to give preference to highly trained and skilled workers, regardless of national origin. Meanwhile, the United Kingdom in 1962 introduced severe restrictions on the entrance of citizens from the Commonwealth and colonies, who had formerly been freely admitted.

Migration models. Over the past four decades, demographers and statisticians have developed a number of analytical techniques and mathematical models to measure the influence of the various factors mentioned above on the volume and direction of migration. The more sophisticated of these models are highly successful in explaining variations in the volume of migratory streams. It is generally found that interregional differences relating to housing and the residential environment are mainly responsible for local moves and short-distance migration, whereas migration over longer distances is predominantly determined by differential employment opportunities. Other incentives to migration play a subsidiary role, except in those international movements that are principally politically motivated. In nearly all instances, the volume of migration streams shows a strong inverse relation to distance, indicating that communication is also a highly relevant factor.

The influence of distance on migratory patterns

That the same interregional differences may be evaluated quite differently by various persons is evinced by the fact that migration is nearly always a two-way movement. The streams in both directions between two regions often do not even differ much in size, at least in internal migration. To some extent return migration of migrants who have not been able to adjust to conditions at the destination also plays a role in bringing this about.

Alternatives to migration. Migration models do not usually encompass variables indicating alternatives to migration. Even so, it is clear that such variables do effect the volume of some migration streams. If the goals sought through migration can also be reached through other means, these alternatives may be chosen by all or some of the potential migrants.

Population control. Where, for instance, emigration is the result of overpopulation in relation to natural resources, population control is an alternative. Historically this has taken the forms of infanticide, late marriage, celibacy, and in modern times birth control.

Economic growth and development. An alternative to economically induced migration is of course economic growth and development. This is relevant for both external emigration and internal migration. In many European countries, regional economic development policies are now in force to combat migration from less developed regions to highly congested urban areas. In Britain, for example, such policies have as an objective the mitigation of congestion in the London area and the Midlands.

Social and economic reform. Social changes may sometimes be needed to curb emigration, especially if the migrants are motivated by wide distinctions between the social classes in their country of origin. Various measures, as for instance redistribution of landed property, may remedy this situation. Potential emigrants may consider "class struggle" or political action resulting in social and economic reform as alternatives to migration. The finding that in Italy before World War I those regions that did not show heavy emigration were characterized by a militant labour organization may be cited as an instance.

Commuting. One alternative to short-distance migration that is becoming increasingly popular is commuting. The decision to commute rather than migrate to a job may be based on various motives, of which vested interests—especially in the sphere of social relations—probably play the largest role.

ADJUSTMENT AFTER MIGRATION

Having migrated, the migrant must adjust to his new environment. In the case of international migration, the process of adjustment is often long, difficult, and painful. Not all migrants succeed in adjusting satisfactorily.

When the region of destination was uninhabited before the migrants arrived, they need only adapt to the physical circumstances. The same is true if the migrants drive out the original inhabitants or if these are relegated to certain limited areas, as in the case of the Indians in North America. There are indications that settlements in uninhabited areas tend to be innovatory, in the sense that new ideas that are latent or dormant in the community of origin are put into practice in the new land.

Assimilation and pluralism

In tribal as well as in individual migrations if the migrants are relatively numerous and from the same cultural background, the immigrants may impose their culture on the original inhabitants. Such a cultural conquest is, however, rare. Usually some elements of the native culture are retained. A cultural fusion then takes place: the native and migrant cultures become mixed. After the Germanic migrations, for instance, there were fusions of Germanic and Roman cultural elements.

A third possibility is that the native and migrant cultures, though affecting each other, retain their independence. In that case one speaks of cultural pluralism. South Africa and Rhodesia are countries in which cultural pluralism subsists as a political ideology.

In most cases nowadays, however, the immigrants in a country are individuals with varying cultural backgrounds. Assimilation is the process whereby these immigrants are absorbed into the culture of the native society. Even in the case of assimilation of individuals, however, the passage of culture elements is not a one-way affair: the immigrants also contribute in varying degrees to the dominant culture. The result of this "melting-pot" is not uniformity but rather the incorporation of a variety of persons into the society.

The success of assimilation depends on several factors. Among them are the migrant's personality, his cultural customs and values, his motives for emigration and expectations of the new land, and, on the other hand, the values and norms of the receiving society, especially the prevalence of prejudice and discrimination. Language is an important intermediary factor. The governments of modern immigration countries such as Australia or Israel actively support assimilation.

BIBLIOGRAPHY. Fairly extensive reviews of various aspects of migration may be found in J.A. JACKSON (ed.), *Migration* (1969); and C.J. JANSEN (ed.), *Readings in the Sociology of Migration* (1970). There are numerous books and articles that treat one or more of these aspects more thoroughly. Some examples are: On international migrations, A.T. BOUSCAREN, *International Migrations Since 1945* (1963); on internal migration in a highly developed country, H.S. SHRYOCK, JR., *Population Mobility Within the United States* (1964); and on migrations in a less developed part of the world, H. KUPER (ed.), *Urbanization and Migration in West Africa* (1965). The important international migrations have mostly found chroniclers. The development of European mass migration to North America is treated by M.L. HANSEN in *The Atlantic Migration, 1607–1860* (1940). The migration from European to Asiatic Russia is dealt with by D.W. TREADGOLD in *The Great Siberian Migration* (1957). Intra-European migrations in the period of the World Wars are analyzed by E.M. KULISCHER in *Europe on the Move* (1948). On immigration in Australia, see R.T. APPLEYARD, *British Emigration to Australia* (1964). Some classics in the field of migration are: On migration and distance, E.G. RAVENSTEIN, two articles entitled "The Laws of Migration," *Journal of the Royal Statistical Society*, 48:167–227 (1885), and 52:241–301 (1889); on differential migration, D.S. THOMAS, *Research Memorandum on Migration Differentials* (1938); on assimilation, S.N. EISENSTADT, *The Absorption of Immigrants* (1954); and for an excellent analysis of free, chain, and mass migration, see J.S. LINDBERG, *The Background of Swedish Emigration to the United States* (1930).

(H.t.H.)

Milan

The destiny of Milan (officially Milano), like that of many of the world's great cities, remains, from several

viewpoints, something of a historical paradox. There are powerful factors supporting the argument that Milan should have become the capital of a unified Italy, and this is the belief of many Milanese, in spite of the fact that Italy's unity was actually born in Turin, rather than in Milan, in 1870. The Milan of today is nevertheless the most industrious and vital city to have achieved prominence since the ancient land of Italy became aware of itself as a modern nation. Contemporary Milan is, without doubt, the richest city of Italy and one of the richest of Europe, so far as money is concerned. When the Milanese assert that Milan is the moral capital of Italy, they not only express the ancient regionalism typical of all Italy, and known as *Campanilismo* (a reference to the church bell of each city), they also refer to something intangible and yet authentic, for they are speaking of quality and values, historical as well as contemporary. And if the rest of Italy, Rome included, accepts this statement, or rather accepts the fact that the statement is made, it is because it is more than a simple claim. It is a claim justified by the contributions in every field—economic, cultural, and ideological—that the city of Milan, in modern times, and particularly since the unification of Italy, has made to the Italian nation. These contributions greatly exceed, even on a statistical basis, those made by all other Italian cities. When one remembers that, in the last century, a writer such as Stendhal, one of the giants of French culture, wished to proclaim himself "Milanese" on his epitaph, one must indeed believe in the fascination Milan exerted then, and still does, and of which the city is fully conscious. The fact, then, that Milan is at a distance from much of the rest of Italy, that it is peripheral in a geographic sense, does not explain its position of second city, a position it has always pathetically and vainly fought. Some of the greatest European capitals are peripheral in this sense.

Competition with Rome

This role was the consequence of the immense historical importance, of the enormous accumulation of myths and symbols, past and present, which conferred on Milan's antagonist, Rome, an inevitable prestige, since it became the heart of a future anticipated in the collective fantasies of the Italian people of yesterday and today. This character is fundamental because a capital is not simply the centre of such and such a government or such and such administrative offices. Milan was, in the 19th century, the most European among Italian cities, but it was not strong enough to become the centre of Europe. On the other hand, Europe was still, during the last century—and perhaps this remains true today—too feeble to seek and find its own centre. European myths, symbols, and values were, and perhaps still are, too weak to let Milan arise as the centre of Europe in the absolute order of things that a capital demands.

It was not by chance that Milan expressed its ideological greatness in the person of a poet, Carlo Porta (1776–1821), who wrote in Milanese—that is to say, in dialect. Yet that poet risked obscurity, both in his own country and abroad, eager as he was to give of his utmost self, aware that this coincided with the finest aspirations of his cocitizens over the preceding century. Rome can absorb the values and language of a renascent Florence and integrate these values throughout the centuries, as the Rome of today demonstrates. In modern Rome, cinematography, which could never take root in Milan, in spite of a thousand attempts, employs the mystery of the physiognomy and of the light of the city to recreate those classic elements, which, in Italy, may be called antique. This Milan cannot do. The majority of its intellectuals, of its writers and artists, at least until the end of the post-World War II era, abandoned the city to rush to Rome. Milan thus remained essentially an economic centre, succeeding, however—alone among Italian cities—in keeping alive an ideological inquisitiveness and a spirit of polemic, which involved not only these two cities but all the others in Italy. One may well hazard the conclusion that Milan's destiny had an unfortunate outcome. In any other country of the world—that is, in any country free from the overwhelming presence of Rome—Milan would have been the capital.

HISTORY

Foundation and early growth. Founded by the Gauls around the year 600 BC, the earliest settlement on the site of Milan became, in ensuing centuries, the capital of a Celtic tribe known as the Insubres. At the time of the Roman conquest, 222 BC, Mediolanum, as it was then called, was already one of the most powerful cities of the region on the Roman side of the Alps known as Cisalpine Gaul. Under the Roman emperor Augustus (63 BC–AD 14), it became a part of the 11th region of Italy, acquiring increasing prestige and economic power until it became the second city of the Western Roman Empire, Rome being the first. In the 3rd century AD, following the partition of the Empire instituted by the emperor Diocletian, it was assigned as residence and main administrative centre for one of the two emperors. The emperor Constantine the Great declared it the seat of the Vicar of Italy. In the year 452, Attila the Hun devastated the city, and, in 539, the Goths destroyed it. The city, however, did not entirely perish as a result of these barbarian incursions, and by the second half of the 10th century city life was surging with renewed vigour. Under the Carolingians (the region was incorporated into the dominions of Charlemagne in 774), life in Milan showed increased vitality, particularly through the late-9th-century efforts of Archbishop Ansperto da Biassono, who rebuilt and strengthened the fallen walls of the city. Under Ariberto da Antimiano (1018–45), the political power of the archbishopric reached its apogee. This assumption of temporal power by the archbishops, dating from around 1000, can be considered as the origin of the subsequent greatness of Milan.

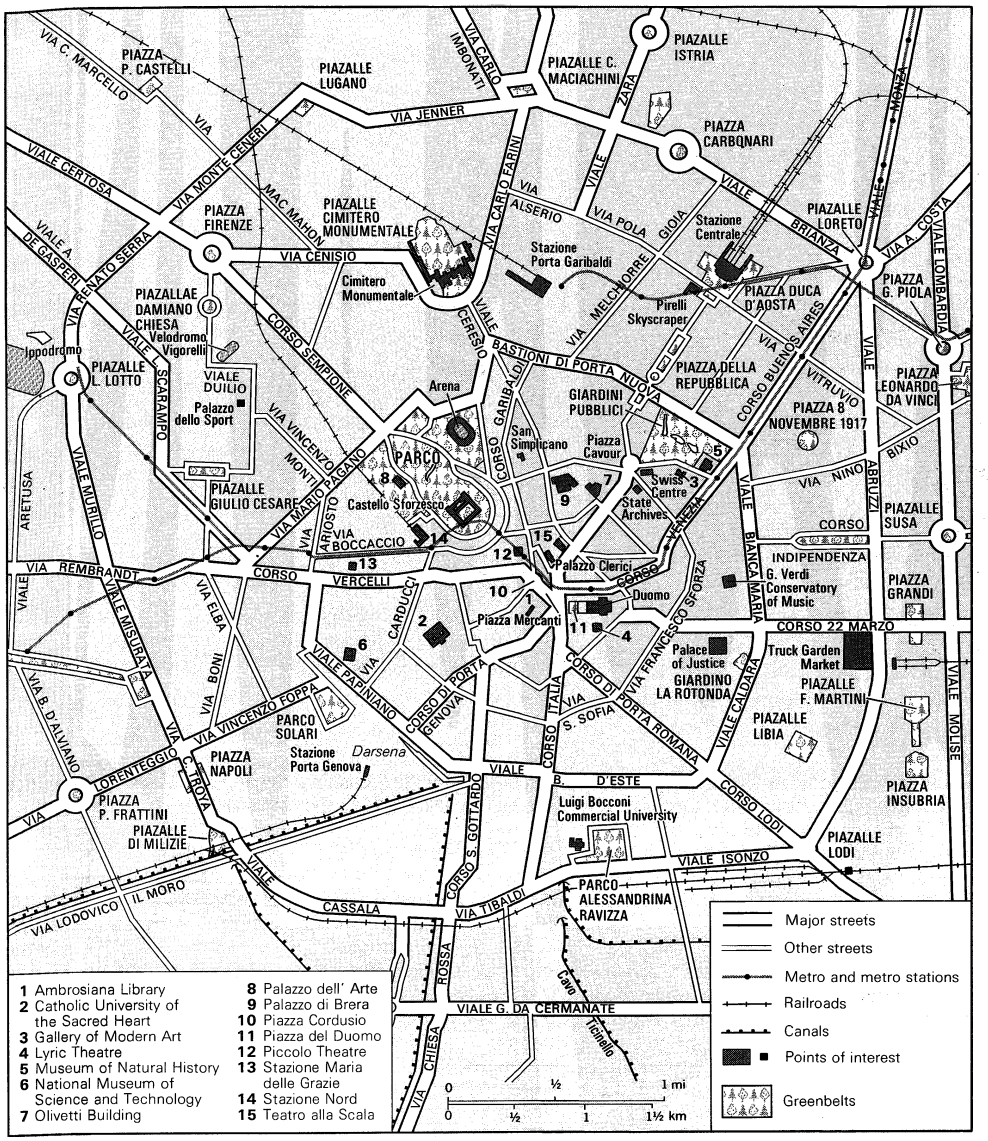
Early settlement

In 1045, however, as a result of tensions engendered by the authority of the archbishops, and because of the increasing growth and stability of the city as a whole, Milan constituted itself as a commune (*comune*), with permanent and autonomous governmental structures. In the resultant struggle for primacy among the cities of Lombardy, Milan became involved in a series of long battles against its less prosperous neighbours—Pavia, Cremona, Como, and Lodi. In 1111 the Milanese razed Lodi, and, after a bitter struggle lasting from 1118–27, Como was destroyed. This was the pretext for the intervention of Frederick I Barbarossa, who decided to bring Milan under the direct authority of the central imperial power of his Holy Roman Empire. The city held out until 1162, when it yielded after a nine-month siege. Its fortifications were then razed, and the destruction of the city was such that the Milanese were forced to seek refuge in the surrounding countryside. The war blazed on until 1183, the year of the Peace of Constance, although Milan, rebuilt in 1167 under the auspices of the newly founded Lombard League, succeeded in playing a major role in the defeat of the German forces of Barbarossa at the Battle of Legnano in 1176. Its privileges rewon, the city attained a splendid economic florescence over the next hundred years.

Establishment of the commune

Feudal conflicts. In the early years of the 12th century, however, the new industrial classes, in particular the guilds of the woollens and armaments workers, increased constantly in power and influence. The feudal nature of the relationship between the archbishop and his allies meant that the archbishop had to make enormous concessions to the emergent social and political forces among the citizenry in order to reinforce his own party, diminishing thereby the financial privileges of the church. Following the worsening of the relationship with Frederick II of Swabia, the Milanese proclaimed Pagano della Torre, a member of a family emerging as leaders of the less feudal of the city's power groupings, as their protector. The city forces were nevertheless defeated by the emperor in the Battle of Cortenuova (1237). In the shadow of the subsequent struggle between the Torriani family and another powerful Milanese family, the Viscontis, the Signorial era was born. The Torrianis, leaders of the new popular forces, took the name of Guelfs; the Viscontis, followed by the aristocracy, headed the Ghibelline faction. In 1277, Ottone Visconti, archbishop of Milan, utterly defeated the enemy in the Battle of Desio. His nephew Matteo succeeded him, and, starting in 1311, Matteo and his heirs

Dynastic struggles



The city of Milan.

reigned as supreme lords of the city and of the surrounding state, replacing the political forms of the commune. Under this lordship, or *signoria*, the industrial and mercantile economy underwent rapid development, giving birth to further powerful coalitions of economic interests. But in 1450, Milan found itself besieged again. Francesco Sforza (1401–66), a ruthless and ambitious general, now occupied the city and founded a new dynasty, basing his claim on his marriage to an illegitimate daughter of one of the Viscontis. A period of great prosperity then began for Milan, based on the power of the Sforzas and the introduction of the silk industry. It was the golden period of the Italian Renaissance, typified by the splendour of the Sforza Court. The dynasty of the Sforzas had but a short-lived enjoyment of power, however. In 1499, the Duchy of Milan fell into the hands of Louis XII, king of France, and also a distant descendant of the Viscontis. In 1500 Ludovico il Moro conquered the state but was defeated at Novara in the same year. The French continued to rule until 1513, when they were overthrown by Massimiliano Sforza, son of Il Moro, who had Swiss assistance. Francis the First, successor to Louis XII, reconquered Milan in his renowned victory of Marignano (now Melegnano), 1515. After a peace treaty signed in 1529, Milan was once more returned to the Sforzas.

The modern period. In 1535 the incumbent duke died unexpectedly, and Milan and the entire Milanese state fell under the domination of the Habsburg emperor, Charles V, who in 1540 invested his son—the future Philip II of Spain—with the duchy. Under the Spanish rule —which was to last until 1706—the political and artistic elite of Milan rapidly succumbed: the dramatic period of dynastic struggle, which was also a period of economic growth, was to be replaced by a long period of economic stagnation and political decline associated with unimaginative foreign rule. In 1630 the city was struck by the great plague. This catastrophe was to be vividly portrayed by the local author Alessandro Manzoni (1785–1873) in his *I Promessi Sposi* ("The Betrothed"), a historical novel that is one of the finest artistic achievements of Italian and indeed European literature. The end of the desolation and squalor of the period of Spanish domination began with the outbreak, in 1701, of the War of the Spanish Succession, following the death of Charles II of Spain. On Sept. 24, 1706, Prince Eugene of Savoy entered Milan as its first Austrian governor, and the city passed thus from Spanish to Austrian rule. Although the first half of the 18th century was marked by neglect and oppression, after the Treaty of Aix-la-Chapelle (1748), the new rulers, in collaboration with the wealthy commercial classes of Milan, were able to foster a half-century of enlightened, if despotic, growth. This was particularly marked in the cultural domain. It is during this period that such figures as Cesare Beccaria (1738–94), the outstanding criminologist and economist, and Pietro Verri (1728–97), the gifted administrator and man of letters, were active. These and other members of a Milanese group known as the Società dei Pugni accepted the innovations of the the-

oreticians of the French Revolution, and this in spite of Austrian censorship. Neoclassical architecture also flourished. When, on May 15, 1796, the republican army of France, with Napoleon Bonaparte at its head, entered Milan, it was greeted enthusiastically, particularly by the middle classes. In 1797, the constitution of a Cisalpine Republic was promulgated. In 1805, Milan became the capital of the Kingdom of Italy, under Napoleon, who was crowned in the city. A true awakening then occurred in the consciousness of the Milanese people, as their city prospered from its domination of most of the Italian peninsula.

The city under Napoleon

These hopes were dashed, however, by the invasion and re-establishment of Austrian authority that followed the collapse of the Napoleonic Empire and the 1815 Congress of Vienna. This alien control of the new Lombardo–Veneto kingdom was to remain for nearly 50 years. Influenced by the new currents of Italian unity and nationalism known as the Risorgimento, and smarting under the oppressive Austrian rule, the citizenry finally rose up in the "Cinque Giornate," the five days of March 18–22, 1848. In one of the most celebrated episodes of the city's history, Milan was liberated from the Austrians for several months until the rebellion was finally smothered. In spite of the fact that by August 6, 1848, the brutal occupation forces of the aging Austrian commander Joseph Radetzky were once more in firm control of Milan, the city decided to continue its resistance to the invaders. Young men crossed the borders of Piedmont and Sardinia to enter its army. It remained for the second War of Italian Independence to finally liberate Milan from foreign control, and a few days after the Battle of Magenta (June 4, 1859), Milan witnessed the triumphant entry of the two allies, Victor Emmanuel II and Napoleon III. The city—by now in the throes of an industrial revolution emphasizing metal products—was henceforth to be linked with the fate of the new Italian state, maintaining itself in a position of prime importance in the national economy. It also shared in the political development of the nation: on March 23, 1919, the formation of militant right-wing groups in the city marked the dawn of Fascism. Intense efforts at reconstruction healed the wounds of World War II, when the city suffered grave damage from intensive Allied bombing. The social and economic conflict that marked much of the city's development found expression in the existence of a strong Communist Party, whose influence continued unabated from the immediate postwar period through the ensuing decades of relative affluence (see ITALY AND SICILY, HISTORY OF).

Restoration and revolution

THE CONTEMPORARY CITY

Physical layout. Milan is set in the heart of the Po Basin of northern Italy, halfway across the immense plain spreading between the Ticino and the Adda rivers. The site is 400 feet (120 metres) above sea level. To the north lies the great sweep of the southern flank of the Alps. Between this semicircle of mountains and the course traced by the Po River to the south, there lies a zone that is arid toward the north, but swampy near the Po, where it turns into an expanse of marshy groves and rice fields. It is at the line of demarcation between these two areas, which are strongly differentiated, that Milan has risen, although these are now only swamplands marking the site of the ancient city. The earliest inhabitants reinforced their defenses by means of the small watercourses of the Seveso, the Nirone, the Lambro, and the Olona.

The physical setting of the city

Each period of historical crisis, advance, and consolidation has been reflected in the organic structure of Milan. For a thousand years the core of the city was located just southwest of the present cathedral, the Duomo (see below, *Cultural life and recreation*), and was made up of the rectangular, four-gated city of Mediolanum, with roads thrusting out from each gate to the surrounding countryside, together with an irregular outer defense consolidated in Carolingian times. This core has influenced the city plan down to the present. The period of dynastic struggle and the imposition of transalpine authority brought further changes. After the city was razed in 1162, an enlarged oval was constructed, the course of its outer walls still traceable in contemporary streets. Spanish domination brought the erection of still another outer ring resulting from their 16th-century reconstructions. This, too, can be traced in contemporary boulevards. Within the city centre, the main focus of activity centred on the Castello Sforzesco, a product of the 15th-century dynastic struggles, reinforced by the Spanish in the following century; the Piazza Mercanti, the centre of medieval economic activity; and the great Piazza del Duomo, laid out before the cathedral in 1489. Castle, cathedral, and a newer commercial area centred on the Piazza Cordusio, appropriate representatives of the motivating forces in Milanese life, have remained to dominate the modern city centre. In 1884, 1912, 1932, and again in 1950, city planners laid

The basic plan

down the basis of a more organic plan, bypassing the radial heritage, in order that new districts might enjoy wide streets and avenues intersecting at right angles. The centres of the newer suburban areas—Bollate, Novate Milanese, Cusano Milanino, Cinisello Balsamo, Sesto San Giovanni, and even Monza (15 kilometres [9 miles] away to the northeast)—are linked to the core of the ancient city by major arteries. Entire industrial districts have developed, particularly in the north and northeast and in the south and southwest. Unfortunately, while the periphery has been amply developed, the central nucleus has not benefitted from a similar transformation and the narrowness of the streets and squares creates great problems for modern traffic. In the urban design of modern Milan practically all industrial growth has been concentrated in peripheral areas. Industrial progress has reached such a level that a third of Milan's population is in some way connected with industrial construction. Heavy industries are concentrated outside the city boundaries, around Sesto San Giovanni. Since 1950 the city centre has fared badly under the influence of industrialization, with many old streets and buildings replaced haphazardly by massive blocks and skyscrapers containing apartments and offices. By the 1970s, the Pirelli Skyscraper, near the Central Station, and the Olivetti Building in Via Clerici were among the few structures of architectural note.

Demography. Milan's population has shown rapid increases over recent decades. In 1931 it had 1,115,841 inhabitants. In 1951 it was 1,274,245. In 1961 the figure rose to 1,599,008, and in 1970 it was 1,713,539. This increase has been due mainly to the flood of immigrants from the impoverished Italian south seeking improved conditions in the factories of the industrial north. During peak years, the annual total of such immigration has exceeded 70,000. Population pressure has resulted in the growth of slums and such shantytowns as Brianza, as well as in an expansion of the city itself. Milan now presses outward into the surrounding countryside with renewed vigour. This is particularly obvious in the northeast, toward Crescenzago, and in the south, toward Rogoredo and Vigentino. Milan's enormous urban expansion has contributed to its economic growth. It is the major economic centre of Italy. With an area of 2,762 square kilometres (1,066 square miles), the province of Milan covers but 0.92 percent of the national territory. The 247 communities that constitute it, however, make it one of the most densely populated provinces of Italy, with a density of 1,377 (1970) people per square kilometre. In addition, its 3,800,000 inhabitants, about half of them concentrated in the capital, represent nearly 7 percent of the population of the entire country and make it the most populous of the Italian provinces. The working population represent more than 50 percent of its inhabitants. Taking into account only the age range between 15 and 65, there is a working population of 75 percent—a very high average for a country such as Italy, which normally offers few work opportunities.

Immigration

Economic life. Milan, the most important economic centre of Italy, owes this fact to its geographical position. Located at the centre of the traffic routes of the Val Padana, it is on the borderline between the advanced agriculture of the fertile irrigated plains to the south and the limited agriculture of the north. In addition, it is backed by an impressive industrial development. Milan's rich and extremely populous surroundings, differing from those of other great Italian manufacturing centres, increase the city's economic importance and potential for expansion. A rich network of road and rail communications spreads toward the outlying areas and particularly toward the north, giving an economic advantage that other Italian cities do not possess.

If the province of Milan represents around 7 percent of the national population, its economic importance is proportionately nearly double; *i.e.*, its economic and financial potential is over 12 percent of that of the whole country. Today the mechanical industries predominate: car production, airplanes, motorcycles, major electric appliances, railroad materials, and other metalworking account for 45 percent of the manpower. Textile manufactures (cotton, hemp, silk, and artificial fibres) are situated in the province, while in the city itself the clothing and custom-made industries predominate. Chemical production is also considerable. Besides producing great quantities of medicinal products, Milan also serves other industries by the manufacture of dyes, soaps, and acids. A noteworthy contribution to the progress of the city economy has also been made by the graphic and publishing industries, as well as by food, wood, paper, and rubber products. Commercial activity is stimulated by industrial development since the manpower involved in commerce has increased from 46,000 in 1911 to 140,000 in 1951 and 190,000 in 1961. The greatest wholesale markets of Italy are also in Milan. Most important among these are the export trades; among them artificial fibres, cotton and wool goods, chemical products, and machinery. Naturally, this enormous economic complex has benefitted from the efficiency of the banks and of the stock market, the latter being the largest in Italy. Milan is the principal centre of exchange in Italy and one of the major economic areas in Europe.

Industrial products

Political and governmental institutions. The city, technically the commune of Milan, capital of the province (*provincia*) of the same name and of the Lombardy Region (*regione*), is under the jurisdiction of the Republic of Italy. The government of the Italian state is composed of a central administration and of a peripheral or local administration system, the first controlling the whole territory, the latter having a limited type of jurisdiction over a limited region. The most important division of the peripheral system is the prefecture (*prefettura*), at the head of which is the prefect, the highest authority of the executive power in the province of Milan. It supervises the activities of public administration. In its own area, the province performs the important functions of regulating health, sanitation, public works, welfare, education, agriculture, and commerce. The province of Milan, as all other Italian provinces, has a vice prefect, a counsellor of prefecture, and an administrative and provincial assembly whose members, as well as its president, are selected by the prefect. The commune of Milan is administered by a council of 18 members, chosen from an assembly of 80 members, and a *sindaco*, or mayor. In the elections of the communal council all electors registered in the province take part in the administrative elections. The assembly and the mayor are elected by the communal council. The *sindaco* is the head of the communal administration and represents the central government of the Republic of Italy. He can perform marriage ceremonies, register births and deaths, and maintain safety and order on behalf of each citizen, etc. The region and regional council, instituted in the early 1970s, are constituted as autonomous entities and have various prerogatives. Among these are the right to promulgate laws on matters relevant to the city so long as they do not infringe upon national interest or the interest of other Italian regions. The regional authorities are the regional council, the assembly, and the president of the assembly. In the commune of Milan, the conciliation judge presides.

Regional innovations

Transportation and services. Rounding off its character as a great centre of production and exchange, Milan is also a major focus of communications. The 26 lines of the state-run railroads are integrated within the city landscape by means of a carefully designed and executed overall design plan. The vast Piazza della Repubblica, for example, which contains the Pirelli Skyscraper and other high buildings, is located on land formerly occupied by a railway station. Trade goods are sent and received at the Lambrate-Ortica Station. Two other stations serve for the transportation of passengers, five more for merchandise. The largest railway loading site is the Central Station. Transalpine tunnels and other mainline connections link Milan with all parts of Europe. The road network converging upon Milan is also important, carrying, as it does, an unceasing flow of foreign and national tourists. Besides being the focus of a number of motorways, Milan is also the starting point for the famous scenic route known as the Autostrada del Sole, which runs down the spine of the Italian peninsula. The metropolitan transportation

service is one of the most active in Europe, having a four-line network and a length of over 18 miles. The central post office functions 24 hours per day. The Urban Streets and Sanitation Department is highly modernized, with a large personnel endeavouring to maintain both the cleanliness of the city and the health of its inhabitants, a task made difficult in some instances by overcrowding and bad housing conditions.

Cultural life and recreation. The most striking of the monuments to be seen in contemporary Milan is the Duomo, a triumph of the architecture of the early Middle Ages, and the third largest church of contemporary Europe, holding more than 20,000 people. Begun in 1386, it took five centuries to complete, and rises over the area occupied at one time by the churches of Santa Tecla and Santa Maria. The most imposing parts of the Duomo are its lateral aspects, its two top crosses, and the apse. In the latter, a powerful impression is made by the three immense Gothic windows of finely carved marble. The casing, of pink-tinged Italian marble, is to be found on all sides of the structure. At the lower level, it lends character to the small trilobate arches, capitals, and flowers; it also appears on the buttresses and, above them, runs along the crowning row of gigantic statues; above these, it covers the decorated water gutters and, finally, enhances the lacelike ornamental crest. The exterior of the cathedral is in fact covered with a remarkable profusion of turrets, pinnacles, and more than 3,000 statues. Within are 52 pillars, each over 80 feet tall and more than 10 feet in diameter and bearing, instead of capitals, a crown of statues within their niches.

The Duomo

The most notable of the city's many palaces is the Brera Palace, the present appearance of which dates from 1615. Its architect, Francesco Maria Richini, infused the whole Milanese Baroque with his severe style. The Pinacoteca di Brera, of international importance, contains a fine collection of north Italian painting. The building also contains the national library, and its beautiful courtyard is dominated by Antonio Canova's statue of Napoleon. On the Corso Garibaldi, or the road to Como, stands San Simpliciano, an extremely ancient church founded, according to tradition, by St. Ambrose, in the first centuries of the Christian era. Its apse contains the famed fresco, the "Coronation of the Virgin," by Ambrogio Bergognone (flourished 1480–1523). In Via Monte Napoleone, there are several handsome palaces, including the Bagatti-Valsecchi palaces. Leonardo da Vinci's fresco the "Last Supper," one of the most famous paintings of the Renaissance, is located in the dining hall of the convent of Sta. Maria delle Grazie. Beyond the Piazza Cavour (which contains a monument to the great Italian statesman after whom it is named as well as the imposing and ultramodern Swiss Centre) lie the public gardens, in which the Museum of Natural History stands. One of its most interesting exhibits is the Turati ornithological collection. The former Villa Reale, now the Galleria d'Arte Moderna, is also nearby. The Biblioteca Ambrosiana (founded 1609 and containing over 600,000 volumes) and the Civic Library with well over 200,000 volumes, and also a stamp collection, are also of significance. Other excellent libraries are found in the universities, the philological clubs of the Lombard Institute of Science and Letters, as well as in the Donati Foundation. The State Archives also contain an imposing collection. Milan is the seat of three universities: the Catholic University of the Sacred Heart, one of the best of its kind in Italy; the State University; and the Luigi Bocconi Commercial University. Other higher educational bodies include the Enrico Fermi Institute for Nuclear Studies and the Giuseppe Verdi Conservatory of Music.

Libraries and universities

Milan's La Scala, constructed 1776–78 by the leading Neoclassicist architect Giuseppe Piermarini, is one of the great theatres of the world. (Piermarini, incidentally, designed the Corso di Porta Romana, the first paved street of modern Europe.) The city also contains the Lyric Theatre, the Odeon, the Piccolo Teatro of the City of Milan, and the Stabile Theatre, home of one of the most important theatrical companies in Italy. There are also a very large number of movie theatres.

Milan is the leading centre of Italy in terms of the equipment, organization, and development of sports. The Sport Palace is a splendid example of modern recreational architecture. At San Siro, the Ippodromo, a large horse-racing arena, is one of the best in Europe. The Mirabello course is also excellent. San Siro has a fine football stadium, a Civic Arena, and numerous other fields for various sports, among which the modern Vigorelli, for cycling races, is well known. The Grand Prix motor-racing circuit at near-by Monza has an international reputation.

BIBLIOGRAPHY. The *Storia di Milano*, published by the Fondazione Treccani degli Alfieri, 16 vol. (1953–62), is the fullest account; but G. GIULINI, *Memorie spettani alla Storia di Milano*, 12 vol. (1760–71, new ed. 1854–57), is still useful for the Middle Ages. E. NOYES, *The Story of Milan* (1908), provides an introductory account in English. For descriptions of the modern city, see F. ELMO, *Milan and its Environs* (1955); ENTE MANIFESTAZIONI (ed.), *Snapshots of Milan* (1961); and A. TIRANTI, *Milan Today* (1958). For architecture, see C. ROMUSSI, *Milano nei suoi monumenti*, 3rd ed., 2 vol. (1912–13). Current information may be found in the monthly survey and statistical bulletin, PALAZZO DEL COMUNE (ed.), *Città di Milano*.

(A.L.)

Military Law

All states require a code of laws and regulations for the raising, maintenance, and administration of their military forces. All this may be considered the field of military law. The term, however, is generally confined to disciplinary military law, that part of the code that aims at and sanctions the maintenance of discipline in the force. In the past this was also known by the name of martial law, a term that now has the meaning of military enforcement of order upon a civil population either in occupied territory or in time of disorder. Members of armed forces do not cease under modern conditions to have duties as citizens and as human beings. All systems of military law must aim to ensure that the soldier is in no way enabled to escape the obligations of his country's ordinary law or of international law as recognized in various conventions.

Historical development. The object of the disciplinary code is to ensure that the will of the commander is put into effect. Military law therefore traces its origins to the prerogative power of rulers. In Rome, just as a sector of civil law developed from the imperium of the magistrates, so did military law derive from the imperium of those same magistrates in their capacity as commanders of the military forces. The Roman historian Tacitus indicates that military justice in the 1st century AD was generally regarded as somewhat rough-and-ready and heavy-handed and varying much with the individual commander. But it became more formalized and received treatment 400 years later in the Digest and Codex of the emperor Justinian. With the rise of the kingdoms of the Middle Ages, the maintenance of discipline was enforced by ordinances or articles of war issued by the sovereign or by a commander authorized by him at the beginning of each campaign. The earliest now extant are those of the English king Richard I in a charter of 1189 AD for the government of those going to the Holy Land.

Articles of war

With mercenary armies drawn from many nations in the wars of the 16th and 17th centuries, each national contingent tended to apply the articles of the supreme commander according to its own rules of procedure. The articles of war of Maurice of Nassau, prince of Orange, and Gustavus Adolphus had a considerable influence on the national commanders who served under them, when they came to command elsewhere. In the English Civil War, the ordinances of the royalist and the parliamentary commanders are thus in the most part literally the same and in the next reign formed the basis of Prince Rupert's code of 1672. The famed discipline of Cromwell's army was not due to any improved code but to the fact that the articles were rigorously enforced. On the continent of Europe, the articles of Gustavus Adolphus continued to be followed until supplanted by the codification of the 19th century, which established throughout those countries a generally similar system that, with revision and amendments, continues to this day.

With the introduction of a standing army in England in 1689, Parliament aimed to prevent this force coming under complete control of the sovereign by a series of mutiny acts, normally passed annually, to which the prerogative articles were subordinate. By a statute of 1717 the power to make articles was embodied in the act. In the United States in 1775 and again in 1806, articles of war were adopted that were modelled upon the mutiny acts and articles then in force in Great Britain. In the British army, the articles of war were replaced in 1881 by an annually renewed Army Act (reformed in 1955), although they continued in the Royal Navy until 1957. In the United States they were replaced by the Uniform Code of Military Justice in 1951.

Persons subject to military law. The jurisdiction of military law is not necessarily confined to offenses injurious to the discipline of the forces committed by members of those forces. It extends in various countries in varying degrees to all offenses committed by members of the forces and to offenses injurious to discipline committed by persons who are not members of those forces. In countries in which an obligation to military service exists, soldiers who fail to answer their initial call-up or report for duty are liable to military jurisdiction for such offenses as desertion or self-mutilation either because the military code makes such offenses applicable to them as a class of civilians (as in Belgium, France, and Italy) or because under the act introducing national service they are deemed to be enlisted on the dispatch of a calling-up notice (as in Great Britain). They continue to be liable for such offenses, even if not otherwise subject to military law, during authorized absence from the conscripted service or temporary reserve service. Reservists are also subject (as in Italy) to military jurisdiction for such offenses as treason, communicating with foreign countries, and revelation of official secrets. In Belgium and France, released soldiers remain liable for rebellion or offenses against superiors committed within one year and six months, respectively, of their release.

Civilian liability to military law

Civilians may become liable to military jurisdiction in a number of ways. In some countries, offenses in the nature of treason, rebellion, impeding military efficiency, or fraud in relation to service property are dealt with under the military code (as in Spain, Italy, and Turkey); in others, such offenses by civilians can only be committed in theatres of operations, in a war zone, or during a state of siege (The Netherlands, Norway). Under such circumstances in other countries nationals may be entirely subjected to the military code (Argentina). In other countries, civilians are liable for instigating and participating in military crimes (Germany, Italy). Austria recognizes no military offenses by civilians.

Among those who fall under military jurisdiction are prisoners of war. Sometimes, as in France, Belgium, and Luxembourg, they are expressly included among those to whom the ordinary military law applies; elsewhere, special regulations concerning their behaviour and trial must be passed. Under the Geneva Prisoners of War Convention of 1949, prisoners of war must be tried by a military court, except where the laws of the belligerent expressly allow a member of the belligerent's armed forces to be tried by a civil court for the same offenses. Prisoners of war must not be sentenced to any penalties other than those which might be inflicted on members of the forces of the detaining power for the same act.

Offenses against military law. The military law of the Anglo-Saxon countries and of countries deriving their military law from them, such as India and other independent members of the British Commonwealth, differs from that of the majority of the continental countries in that the latter divide military offenses into two classes: crimes that are the subject of judicial punishment and, second, breaches of discipline that are subject only to administrative action. The former group of countries (and a few others such as Spain), however, recognize no distinction, regarding all military offenses as crimes. Apart from offenses of a peculiarly military nature, such as mutiny, insubordination, desertion, and misconduct in action or in performance of service duties, when an act committed by a soldier constitutes an offense in the civil code, it will frequently constitute an offense of which military law takes cognizance. In the Soviet Union, Belgium, and The Netherlands, all civil offenses committed by soldiers, except very minor ones, are tried by military court; in France, only those committed on duty and in barracks; and in Italy, none. In Germany, Austria, and Scandinavia, in peacetime, all crimes, military or civil, are dealt with by civil courts. Great Britain, Canada, and other countries include as military crimes all actions committed by soldiers anywhere that would be offenses against the criminal law of their own country, although the most serious of these cannot be tried by a military court unless committed abroad, or in India at specified Frontier Posts. In the United States, because of the differences between the criminal law of different states, certain civil crimes are specifically made offenses against the military code. All countries have rules to prevent the double jeopardy of an offender being punished both by civil and military jurisdiction for the one act. Generally, when civil jurisdiction may be exercised, this takes precedence over military jurisdiction.

Summary punishment. In both Anglo-Saxon and continental systems, soldiers are subjected to penalties imposed summarily as well as to those imposed by courts. In the majority of countries, summary penalties can be inflicted only by officers not lower than the rank of captain, the commanding officer of the military unit being the principal source of discipline. The forms of punishment so inflicted are normally loss of privileges for a specified period, fines, or deprivation of liberty. Higher military commanders usually have power to deal summarily with officers (normally up to the rank of major), though in some countries these will not be liable to loss of liberty.

In Great Britain, the United States, and other common-law countries, there is usually a right of appeal against summary punishment awarded through the military chain of command and extending to the highest authority. In other countries, the appeal will lie to a tribunal. In still others, the soldier may have a choice between appeal through the chain of command or to judicial authority (Norway, Sweden). It is to be noted that in some cases the military superior has the power to increase the punishment (Norway, France).

In the Anglo-Saxon countries, offenses that are beyond a commanding officer's powers are dealt with by a service court (court-martial). In the continental countries, military crimes and similar offenses are also dealt with judicially. In the latter, however, there is an intermediate form of tribunal that deals with the more serious forms of breaches of discipline and may impose punishments affecting a soldier's career, such as loss of rank or appointment, dismissal, or forfeiture of pension rights. In Germany, military courts of service, which also hear soldiers' complaints, may impose career sanctions. Also to be noted are the unit assemblies in the Soviet Union, which are general assemblies of all military members of a unit. All those attending are invited to comment on the behaviour under investigation. An elected tribunal, normally of five, decides whether the public examination is in itself sufficient educational corrective of the aberrant behaviour or whether the offender should be reported to a competent commander for disciplinary measures.

Examination by unit assemblies in the Soviet Union

Courts-martial. Military courts follow a more formal judicial procedure than that observed in summary proceedings. Before trial by court-martial or its equivalents, there is always some formal investigatory procedure. This is normally conducted by a military magistrate and set in motion by a procurator who corresponds to the official responsible for initiating prosecution on behalf of the public in civil trials.

In Great Britain and in countries of the Commonwealth directly deriving their military law from it, the evidence is reduced to writing and considered by the accused's commanding officer, who may then apply for a court-martial to try the accused. In the United States, the preliminary investigation has affinity with civil proceedings before a grand jury.

Pending trial, all countries maintain a presumption of

the accused's innocence. He must be allowed full facilities for preparing his defense, and, where disciplinary requirements necessitate keeping him under arrest, this can only be done under the mandate of a magistrate, normally for limited periods only. When the accused's commanding officer is empowered to order arrest, the progress of the case must be reported at frequent intervals to a higher authority, who will consider whether the arrest should be suspended or modified. Courts-martial are generally composed, depending on the type of case, of not less than three, five, or seven judges. In general they consist of military officers, although in some countries other ranks may be included. In France, for example, underofficers may sit upon a court, and in the United States, if an accused enlisted man so requires, at least one-third of the court must be composed of enlisted men. In Israel, a private soldier may demand one judge of his own rank, and in the Soviet Union, the court includes popular assessors elected for two years by all the soldiers in a unit. Most countries include trained lawyers in their courts. In France, a civilian judge sits with six military members. In The Netherlands, there is a civilian president nominated by the crown for life, in Belgium a civilian judge on a three-year tenure, and in Italy a military magistrate. Each sits with four officers. In the Soviet Union, presidents, vice presidents, and members of military courts are chosen by the Presidium of the Supreme Soviet from citizens on active service aged 25 or over. In courts of first instance, one of these will sit with two popular assessors. In other countries, a court may have a legal adviser who has no vote as a member of the court, as in Great Britain and the United States.

Grades of courts-martial

In some countries there are grades of courts-martial with varying competence as regards persons whom they may try or punishment they may impose. In the United States and Great Britain, general courts-martial composed of not less than five officers with a legal adviser may deal with all persons subject to military law and pass any sentence authorized by the code; special courts-martial (U.S.) or district courts-martial (Britain) consist of at least three officers and have limited powers. In the Soviet Union there are inferior, intermediate, and superior courts. Although under the Anglo-Saxon system, in cases of minor importance, prosecution and defense may be conducted by regimental officers of no legal qualifications, in the majority of countries, the prosecution will normally be in the hands of a legally qualified official, known variously as commissioner, fiscal general, auditor, or military procurator.

A soldier being dealt with summarily, or by disciplinary procedure that is not regarded as judicial action, is not defended. In trials before military courts, all countries allow the accused to be assisted in his defense by an advocate, and in some countries this is compulsory. All countries permit the employment of qualified civilian lawyers. In Greece and the Soviet Union, the defense may be conducted by the family or friends of the accused. In the Soviet Union, additionally, such persons as representatives of syndicates and other social organizations may defend.

The stage at which a defender may operate varies. Normally, he may assist immediately after the first interrogation, when an accused is informed of his rights. He then has rights of intervention during the process of instruction and must be present at such features of it as the interrogation of the accused. In other countries (as in Belgium and Greece), the defender has no part in the instruction and appears only at the trial.

Appeals. Under the Anglo-Saxon system, the findings and sentence of a court-martial are of no effect until they have been confirmed by a military commander, the convening officer, or his superior. Both at this stage and subsequently, the proceedings are subject to review by the service authorities. The service authorities may be moved by a petition on behalf of the convicted soldier, and appeal from a court-martial may also lie to a superior court. In countries in which there is a hierarchy of more or less permanent military courts, appeal will lie to the tribunal next senior to that which tried the accused. In other countries, special courts of military appeal are constituted that may consist of military judges (Israel), mixed military and civilian lawyers (Italy, The Netherlands, Portugal), or purely civilian lawyers (United States and Great Britain). The majority of appeal courts concern themselves only with the legality of conviction rather than with questions of sentence. This is particularly so when there is recourse by way of appeal to the service authorities.

In continental countries, legal questions may be referable to the highest courts. In France, except when judgment has been given in default, the Court of Cassation is the sole court of appeal. In Belgium and Great Britain, final appeal may be made on legal grounds to the Court of Cassation and the House of Lords. Normally, appeal lies only with the defense, but sometimes, as in the Soviet Union, the prosecution has the power to appeal either against the original finding and sentence or on a question of law.

Appeals to ombudsmen

In a few countries, representations about conditions of service and applications for advice and help outside the normal service channels may be made through specific officials. In Norway, a military ombudsman was introduced in 1952. This official sometimes raises questions on disciplinary and penal offenses. The military ombudsman of Sweden, created in 1915, takes note of all sentences of military courts, reports on military prisons, and ensures observation of all regulations by persons concerned in military administration. In other countries in which there is a route of appeal via an ombudsman or similar civilian official (Finland and Germany, for example), there is a marked reluctance on the part of soldiers to take such a course, perhaps because of a general preference for avoiding civilian interference in military affairs. In the United States, there is a reluctance to take grievances to the inspector general of the army rather than going through the normal chain of command, mainly because of a fear of reprisal.

Wartime procedures. In time of war those countries that normally have an exclusively civilian jurisdiction over military offenders will usually introduce courts composed of soldiers. Civilian members of mixed tribunals will normally be replaced by soldiers. Elsewhere, military courts of less senior composition will have extended powers. In addition, the appeal procedure may be superseded or may be liable to be overridden by military commanders in the interests of the immediate imposition of discipline. This applies particularly in the execution of the death sentence.

Current developments. There is a tendency to allow the soldier off duty much greater freedom from discipline than in the past. The German code, for example, places great stress on the soldier's retention of his fundamental rights under the Basic Law, and, generally, the soldier's rights as a citizen are preserved as far as is compatible with the maintenance of discipline and efficiency. In democratic countries, soldiers everywhere retain the right to vote, if necessary by postal ballot, and to support the political party of their choice. Political activity within the service, however, cannot be reconciled with the maintenance of discipline, while the circulation of propaganda or organizing on behalf of political parties whose tenets support a hostile power or are subversive to military discipline must clearly amount to a disciplinary offense as well as a threat to security. The military commander must retain sufficient control over the private lives of his subordinates to ensure that discipline and good order do not suffer. Any orders reasonably calculated to maintain this object are lawful, even when they curtail the private actions of the soldier. Hence, however tolerant the civil legislation of a country might be, the use of drugs, which impair the soldier's efficiency, or the formation of homosexual relationships, which subvert discipline, must be suppressed in any fighting force, just as in all armed forces drunkenness is a specific military offense.

The question of how far a soldier may avail himself of superior orders as a defense to a charge of unlawful action is a topic that has been and continues to be of the greatest importance in relation to war crimes (see WAR,

LAWS OF). The difficulties presented by such cases lend support to the view, at present more ideal than practical, that all such offenses should be tried by some neutral international tribunal. It is perhaps only by the enforcement of such a rule that the soldier who refuses to obey an unlawful order can be protected.

Mill, John Stuart

John Stuart Mill was a British philosopher and economist, prominent as a publicist in the reforming age of the 19th century and of lasting interest as a logician and an ethical theorist.

Early life and career. The eldest son of the British historian, economist, and philosopher James Mill, he was born on May 20, 1806, in his father's house in Pentonville, London. He was educated exclusively by his father, who was a strict disciplinarian. By his eighth year he had read in the original Greek Aesop's *Fables,* Xenophon's *Anabasis,* and the whole of the historian Herodotus. He was acquainted with the satirist Lucian, the historian of philosophy Diogenes Laërtius, the Athenian writer and educational theorist Isocrates, and six dialogues of Plato. He had also read a great deal of history in English. At the age of eight he started Latin, the geometry of Euclid, and algebra and began to teach the younger children of the family. His main reading was still history, but he went through all the Latin and Greek authors commonly read in the schools and universities and, by the age of ten could read Plato and the Athenian statesman Demosthenes with ease. About the age of 12, he began a thorough study of Scholastic logic, at the same time reading Aristotle's logical treatises in the original. In the following year he was introduced to political economy and studied work of the Scottish political economist and philosopher Adam Smith and that of the English economist David Ricardo.

Mill.

While the training the younger Mill received has aroused amazement and criticism, its most important aspect was the close association it fostered with the strenuous character and vigorous intellect of his father. From his earliest days he spent much time in his father's study and habitually accompanied him on his walks. He thus inevitably acquired many of his father's speculative opinions and his father's way of defending them. But he did not receive the impress passively and mechanically. The duty of collecting and weighing evidence for himself was at every turn impressed upon the boy. His childhood was not unhappy, but there is no doubt that it was a strain on his constitution and that he suffered from the lack of natural, unforced development.

Effects of his education

From May 1820 till July 1821, Mill was in France with the family of Sir Samuel Bentham, brother of Jeremy Bentham, the English Utilitarian philosopher, economist, and theoretical jurist. Copious extracts from a diary kept at this time show how methodically he read and wrote, studied chemistry and botany, tackled advanced mathematical problems, and made notes on the scenery and the people and customs of the country. He also gained a thorough acquaintance with the French language. On his return in 1821 he added to his work the study of psychology and of Roman law, which he read with John Austin, his father having half decided on the bar as the best profession open to him. This intention, however, was abandoned, and in 1823, when he had just completed his 17th year, he entered the examiner's office of the India House. After a short probation he was promoted in 1828 to assistant examiner. For 20 years, from 1836 (when his father died) to 1856, Mill had charge of the British East India Company's relations with the Indian states, and in 1856 he became chief of the examiner's office.

In 1822 Mill had read P.E.L. Dumont's exposition of Bentham's doctrines in the *Traités de législation,* which made a lasting impression upon him. The impression was confirmed by the study of the English psychologists and also of two 18th-century French philosophers—Étienne Bonnot de Condillac, who was also a psychologist, and Claude Adrien Helvétius, who was noted for his emphasis on physical sensations. Soon after, in 1822–23, Mill established among a few friends the Utilitarian Society, taking the word, as he tells us, from *Annals of the Parish,* a novel of Scottish country life by John Galt.

Two newspapers welcomed his contributions—*The Traveller,* edited by a friend of Bentham's, and *The Morning Chronicle,* edited by his father's friend John Black. One of his first efforts was a solid argument for freedom of discussion in a series of letters to the *Chronicle* on the prosecution of Richard Carlile, a 19th-century English radical and freethinker. Mill seized every chance for exposing departures from sound principle in Parliament and courts of justice. Another outlet was opened up for him (April 1824) with the founding of the *Westminster Review*, which was the organ of the philosophical radicals. In 1825 he began work on an edition of Bentham's *Rationale of Judicial Evidence* (5 vol., 1827). He took part eagerly in discussions with the many men of distinction who came to his father's house and engaged in set discussions at a reading society formed at the home of English historian George Grote in 1825 and in debates at the London Debating Society, formed in the same year.

Public life and writing. The *Autobiography* tells how in 1826 Mill's enthusiasm was checked by a misgiving as to the value of the ends that he had set before him. At the London Debating Society, where he first measured his strength in public conflict, he found himself looked upon with curiosity as a precocious phenomenon, a "made man," an intellectual machine set to grind certain tunes. The elder Mill, like Plato, would have put poets under ban as enemies of truth; he subordinated private to public affections; and Landor's maxims of "few acquaintances, fewer friends, no familiarities" had his cordial approval.

Beginning of his mature thought

The younger Mill now felt himself forced to abandon these doctrines. Too much in awe of his father to make him a confidant, he wrestled with his doubts in gloomy solitude. He emerged from the struggle with a more catholic view of human happiness, a delight in poetry for its own sake, a more placable attitude in controversy, a hatred of sectarianism, and an ambition no less noble and disinterested but moderated to practical possibilities. Gradually, the debates in the Debating Society attracted men with whom contact was invigorating and inspiring. Mill ceased to attend the society in 1829, but he carried away from it the conviction that a true system of political philosophy was

> something much more complex and many-sided than he had previously had any idea of, and that its office was to supply, not a set of model institutions but principles from which the institutions suitable to any given circumstances might be deduced.

Mill's letters in *The Examiner* in the autumn of 1830, after a visit to Paris, where he made the acquaintance of the younger liberals, may be taken as marking his return to hopeful activity; and a series of articles on "The Spirit of the Age" appeared in the same paper in 1831. During the years 1832 and 1833 he contributed many essays to *Tait's Magazine, The Jurist,* and *The Monthly Repository*. In 1835 Sir William Molesworth founded *The London Review*, with Mill as editor. It was amalgamated with *The Westminster* (as *The London and Westminster Review*) in 1836, and Mill continued as editor (latterly as proprietor, also) till 1840. In and after 1840 he published several important articles in *The Edinburgh Review*. Some of the essays written for these journals were reprinted in the first two volumes (1859) of Mill's *Dissertations and Discussions* and give evidence of the increasing width of his interests. Among the more important are "Thoughts on Poetry and Its Varieties" (1833), "Writings of Alfred de Vigny" (1838), "Bentham" (1838), "Coleridge" (1840), "M. De Tocqueville on Democracy in America" (1840), "Michelet's History of France" (1844), and "Guizot's Essays and Lectures on History" (1845). The twin essays on Bentham and Coleridge show Mill's powers at their splendid best and indicate very clearly the new spirit that he tried to breathe into English radicalism.

Works on logic and political economy

During these years Mill also wrote his great systematic works on logic and on political economy. His reawakened enthusiasm for humanity had taken shape as an aspiration to supply an unimpeachable method of proof for conclusions in moral and social science; the French positivist philosopher Auguste Comte had some influence here, but the main inspiration undoubtedly came from the English scientist and mathematician Sir Isaac Newton, whose physics had already been accepted as a model of scientific exposition by such earlier British philosophers as John Locke, David Hume, Jeremy Bentham, and James Mill. But he was determined that the new logic should not simply oppose the old logic. In his *Westminster* review (of 1828) of Richard Whately's *Elements of Logic*, he was already defending the syllogism against the Scottish philosophers who had talked of superseding it by a supposed system of inductive logic. He required his inductive logic to "supplement and not supersede." For several years he searched in vain for the means of concatenation. Finally, in 1837, on reading William Whewell's *Philosophy of the Inductive Sciences* and rereading John F.W. Herschel's *Preliminary Discourse on the Study of Natural Philosophy*, Mill at last saw his way clear both to formulating the methods of scientific investigation and to joining the new logic onto the old as a supplement. *A System of Logic*, in two volumes, was published in 1843 (3rd–8th editions, introducing many changes, 1851–72). Book VI comprises his valiant attempt to formulate a logic of the human sciences—including history, psychology, and sociology—based on causal explanation conceived in Humean terms, a formulation that has lately come in for radical criticism.

Mill distinguished three stages in his development as a political economist. In 1844 he published the *Essays on Some Unsettled Questions of Political Economy*, which he had written several years earlier, and four out of five of these essays are solutions of perplexing technical problems—the distribution of the gains of international commerce, the influence of consumption on production, the definition of productive and unproductive labour, and the precise relations between profits and wages. Here for the most part Mill appears as the disciple of David Ricardo, striving after more precise statements and reaching forward to further consequences. In his second stage, originality and independence become more conspicuous as he struggles toward the standpoint from which he wrote his *Principles of Political Economy*. This was published in 1848 (2 vol.; 2nd and 3rd eds., with significant differences, 1849, 1852), and, at about the same time, Mill was advocating the creation of peasant proprietorships as a remedy for the distresses and disorder in Ireland. Thereafter, he made a more thorough study of Socialist writers. He was convinced that the social question was as important as the political question. He declined to accept property, devised originally to secure peace in a primitive society, as necessarily sacred in its existing developments in a quite different stage of society. He separated questions of production and distribution and could not rest satisfied with the distribution that condemned the labouring classes to a cramped and wretched existence, in many cases to starvation. He did not come to a Socialist solution, but he had the great merit of having considered afresh the foundations of society. This he called his third stage as a political economist, and he says that he was helped toward it by Mrs. Taylor (Harriet Hardy), who became his wife in 1851.

Activities during his married life

It is generally supposed that Mill writes with a lover's extravagance about Harriet's powers. He expressly says, indeed, that he owed none of his technical doctrine to her, that she influenced only his ideals of life for the individual and for society, and that the only work directly inspired by her is the essay on the "Enfranchisement of Women" (*Dissertations*, vol. 2). Nevertheless, Mill's relations with her have always been something of a puzzle.

During the seven years of his marriage Mill became increasingly absorbed in the work of the British East India Company and in consequence published less than at any other period of his life. In 1856 he became head of the examiner's office in the India House, and for two years, till the dissolution of the company in 1858, his official work kept him fully occupied. It fell to him as head of the office to write the defense of the company's government of India when the transfer of its powers was proposed. Mill opposed the transfer, and the documents in which he defended the company's administration are models of trenchant and dignified pleading. On the dissolution of the company, Mill was offered a seat in the new council but declined it and retired with a pension of £1,500. His retirement from official life was followed almost immediately by his wife's death at Avignon, France. He spent most of the rest of his life at a villa at Saint-Véran, near Avignon, returning to his house at Blackheath only for a short period in each year.

The later years. Mill sought relief by publishing a series of books on ethics and politics that he had meditated upon and partly written in collaboration with his wife. The essay *On Liberty* appeared in 1859 with a touching dedication to her and the *Thoughts on Parliamentary Reform* in the same year. In his *Considerations on Representative Government* (1861) he systematized opinions already put forward in many casual articles and essays. It has been remarked how Mill combined enthusiasm for democratic government with pessimism as to what democracy was likely to do; practically every discussion in

these books exemplifies this. His *Utilitarianism* (in *Fraser's Magazine*, 1861; separate publication, 1863) was a closely reasoned attempt to answer objections to his ethical theory and to remove misconceptions about it. He was especially anxious to make it clear that he included in "utility" the pleasures of the imagination and the gratification of the higher emotions; and to make a place in his system for settled rules of conduct.

Mill also began to write again on the wider philosophical questions that had occupied him in the *Logic*. In 1865 he published both his *Examination of Sir William Hamilton's Philosophy* and his *Auguste Comte and Positivism*, but in both writings his motives were largely political. It was because he regarded the writings and sayings of Sir William Hamilton as the great fortress of intuitional philosophy in Great Britain that Mill undertook to counter his pretensions. In dealing with Comte, Mill distinguished sharply between Comte's earlier philosophical doctrine of Positivism and his later religion of humanity. The doctrine he commended (as he had frequently done previously) because he regarded it as a natural development of the outlook of George Berkeley and Hume; the religion he attacked because he saw in it merely another attempt to foist a priestly hierarchy upon suffering humanity. It is noticeable that Mill's language in these books is much closer to the language of Bentham and James Mill than it had been since his boyhood, and it was as an act of piety that in 1869 he republished his father's *Analysis of the Phenomena of the Human Mind* with additional illustrations and explanatory notes.

Mill in Parliament

While engaged in these years mainly with theoretical studies, Mill did not remit his interest in current politics. He supported the North in the U.S. Civil War, using all his strength to explain that the real issue at stake in the struggle was the abolition of slavery. In 1865 he stood as parliamentary candidate for Westminster, on conditions strictly in accordance with his principles. He would not canvass or pay agents to canvass for him, nor would he engage to attend to the local business of the constituency. He was with difficulty persuaded even to address a meeting of the electors but was elected. He took an active part in the debates preceding the passage of the 1867 Reform Bill, and helped to extort from the government several useful modifications of the bill, for the prevention of corrupt practices. The reform of land tenure in Ireland (see his *England and Ireland*, 1868, and his *Chapters and Speeches on the Irish Land Question*, 1870), the representation of women (see below), the reduction of the national debt, the reform of London government, and the abrogation of the Declaration of Paris (1856)—concerning the carriage of property at sea during the Crimean War—were among the topics on which he spoke. He took occasion more than once to enforce what he had often advocated, England's duty to intervene in foreign politics in support of freedom. As a speaker Mill was somewhat hesitating, but he showed great readiness in extemporaneous debate. Elected rector of St. Andrews University, he published his "Inaugural Address" in 1867.

Mill's subscription to the election expenses of the freethinker and radical politician Charles Bradlaugh and his attack on the conduct of Gov. E.J. Eyre in Jamaica were perhaps the main causes of his defeat in the general parliamentary election of 1868. But his studied advocacy of unfamiliar projects of reform had made him unpopular with "moderate Liberals." He retired with a sense of relief to Avignon. His villa was filled with books and newspapers; the country round it furnished him with a variety of walks; he read, wrote, discussed, walked, botanized. He was extremely fond of music and was himself a fair pianist. His stepdaughter, Helen Taylor (died January 1907), was his constant companion after his wife's death. Mill was an enthusiastic botanist all his life and a frequent contributor of notes and short papers to the *Phytologist*. During his last journey to Avignon he was looking forward to seeing the spring flowers and completing a flora of the locality.

Mill did not relax his laborious habits or his ardent outlook on human affairs. The essays in the fourth volume of his *Dissertations* (1875; vol. 3 had appeared in 1867)—on endowments, on land, on labour, and on metaphysical and psychological questions—were written for the *Fortnightly Review* at intervals after his short parliamentary career. In 1867 he had been one of the founders, with Mrs. P.A. Taylor, Emily Davies, and others, of the first women's suffrage society, which developed into the National Union of Women's Suffrage Societies, and in 1869 he published the *Subjection of Women* (written 1861), the classical theoretical statement of the case for women's suffrage. His last public activity was concerned with the starting of the Land Tenure Reform Association, for which he wrote in *The Examiner* and made a public speech a few months before his death; the interception by the state of the unearned increment on land and the promotion of cooperative agriculture were the most striking features in his program, which he regarded as a timely compromise in view of the impending struggle between capital and labour in Europe. His *Autobiography* and *Three Essays on Religion* (1874) were published posthumously.

Mill died at Avignon on May 8, 1873. A bronze statue of him stands on the Thames embankment in London, and G.F. Watts's copy of his original portrait of Mill hangs in the National Gallery there.

Influence and significance. Mill was a man of extreme simplicity in his mode of life. The influence that his works exercised upon contemporary English thought can scarcely be overestimated, nor can there be any doubt about the value of the liberal and inquiring spirit with which he handled the great questions of his time. Beyond that, however, there has been considerable difference of opinion about the enduring merits of his philosophy. At first sight he is the most lucid of philosophers. Many people have spoken of the marvelous intelligibility of his writing. Usually, however, it is not long before doubts begin to creep in. Although the lucidity remains, its span is seen to be somewhat limited, and one sometimes has the uneasy feeling that he is being equally lucid on both sides of a question.

Evaluation of Mill

Oddly enough, however, this judgment has not led to any neglect of Mill. Little attention is now paid to Hamilton or to Whewell, but Mill's name continually crops up in philosophical discussions. This is partly due to the fact that Mill offers a body of doctrine and a set of technical terms on many subjects (notably on induction) that have proved extremely useful in the classroom. But a more important reason is that he has come to be regarded as a sort of personification of certain tendencies in philosophy that it is regarded as continually necessary to expound or expose because they make such a powerful appeal to serious minds. Thus he is or says he is a Utilitarian; yet nothing, it is pointed out, could tell more strongly against Utilitarianism than certain passages in his writings. Then again, he is said to be an Empiricist (although he says himself that he is not), and his theories of the syllogism and of mathematics are constantly used to demonstrate the fatal consequences of this way of thinking.

It is misleading to speak without qualification of Mill's Utilitarianism. Nor is it sufficient to add that Mill modified the Utilitarianism that he inherited from Bentham and from his father in one way and another in order to meet the criticisms that it encountered in Victorian times. He does, it is true, sometimes give that impression (as in his essay *Utilitarianism*); but elsewhere (as in his essay *On Liberty*) he scarcely attempts to conceal the fact that his premises are completely independent of Bentham's. Thus, contrary to the common belief, it appears to be very hazardous to characterize offhand the precise position of Mill on any major philosophical topic. He sometimes behaved with a reckless disregard of consequences more suitable to a Romantic than to a Utilitarian. He is thoroughly romantic, again, and thoroughly representative of his age in the eagerness with which he seeks out and endeavours to assimilate every last exotic line of thought which shows any signs of vitality. He himself claimed to be superior to most of his contemporaries in "ability and willingness to learn from everybody," and indeed, for all his father's careful schooling, there was never anybody less buttoned up against alien influences

than Mill. In his writings there can be discerned traces of every wind of doctrine of the early 19th century.

MAJOR WORKS

POLITICS AND ECONOMICS: *Essays on Some Unsettled Questions in Political Economy* (1844); *Principles of Political Economy*, 2 vol. (1848; 2nd and 3rd eds. with important differences, 1849, 1852); *On Liberty* (1859); *Considerations on Representative Government* (1861); *Utilitarianism* (1863); *On The Subjection of Women* (1869).

PHILOSOPHY AND RELIGION: *A System of Logic* (1843); *Examination of Sir William Hamilton's Philosophy* (1865); *Auguste Comte and Positivism* (1865); *Three Essays on Religion* (1874).

OTHER WORKS: Essays on "Bentham" (1838) and "Coleridge" (1840) in *Dissertations and Discussions*, 4 vol. (1859–75), also reprinted together with an introduction by F.R. LEAVIS (1950); *Autobiography*, ed. by Helen Taylor (1873).

BIBLIOGRAPHY. Mill's *Collected Works* are currently being published in a definitive edition of 22 vol., ed. by F.E.L. PRIESTLEY and J.M. ROBSON (1963–). The following have appeared: *The Earlier Letters 1812–1848* (vol. 12–13); *Principles of Political Economy* (vol. 2–3, 1965); and *Essays on Ethics, Religion and Society* (vol. 10, 1969). Each volume has full introductions, notes, and indexes. At present, for Mill's later letters it is necessary to refer to *The Letters of John Stuart Mill*, ed. by HUGH ELLIOT, 2 vol. (1910).

Biography: The standard biography is M. ST. J. PACKE, *The Life of John Stuart Mill* (1954), a fascinating and readable book (with bibliography), interpretations sometimes too colourful. Mill's own *Autobiography* has been edited several times, recently by JACK STILLINGER (1969). Stillinger has also edited *The Early Draft of John Stuart Mill's Autobiography* (1961), written in 1853–54, which includes a much more vivid and intimate account of Mill's relations with his father and mother; it suggests a more gloomy picture of his childhood than does the final version. (This is not a work that Mill was himself prepared to publish.) ALEXANDER BAIN, *John Stuart Mill: A Criticism with Personal Recollections* (1882), will never be superseded; an excellent, rambling account by Mill's closest philosophical disciple, it refers to many conversations and quotes from letters now lost. F.A. HAYEK (ed.), *John Stuart Mill and Harriet Taylor* (1951), is full of details about the writing of Mill's works from the 1830s to 1858 (with gaps for times when they were meeting together); the painting of Harriet Taylor should not be missed.

Comment and Criticism: R.P. ANSCHUTZ, *The Philosophy of J. S. Mill* (1953), a subtle and precise study presupposing a wide reading of the texts; K.W. BRITTON, *John Stuart Mill: Life and Philosophy*, 2nd ed. (1969), an introductory book covering Mill's life and work—sympathetic but critical; ELIE HALEVY, *La Formation du radicalisme philosophique*, 3 vol. (1901–04; Eng. trans., *The Growth of Philosophical Radicalism*, 1928; new ed., 1952), the standard comprehensive account of the school in which Mill was brought up, with issues fully analyzed and discussed (with bibliography); J. PLAMENATZ, *The English Utilitarians* (1949), a good account of the background and content of Mill's moral theory; J.M. ROBSON, *The Improvement of Mankind: The Social and Political Thought of John Stuart Mill* (1968), a readable book that offers an account of Mill's life and of his mature views on morals, scientific method, politics, and sociology; M. COWLING, *Mill and Liberalism* (1963), an eccentric account that imputes to Mill a strong strain of authoritarianism; A. RYAN, *John Stuart Mill* (1970), an attempt to show that a single constant theory of inductivism underlies all Mill's writings; PETER WINCH, *The Idea of a Social Science*, ch. 3 (1958), attacks attempts to construct a causal science of human conduct; F.H. BRADLEY, *Ethical Studies*, 2nd ed. (1967), essay 3 is an attack on Mill's hedonism; G.E. MOORE, *Principia Ethica* (1903; paperback edition, 1959), a very lively onslaught on Mill's Utilitarianism, often patently unfair; J.O. URMSON, "The Interpretation of the Moral Philosophy of J.S. Mill," *Philosophical Quarterly*, 3:33–39 (1953), on moral rules; B. MACMINN, J.R. HAINDS, and J. MCCRIMMON (eds.), *Bibliography of the Published Writings of John Stuart Mill* (1945, reprinted 1970).

(R.P.An.)

Millennialism

Millennialism (from the Latin word for 1,000) is a philosophy of history viewed from a Christian theological standpoint and a religious movement now associated with such modern Protestant sects as the Adventists, Jehovah's Witnesses, and certain segments of many Protestant denominations. There have been many millennial groups and individuals throughout church history. The term is derived from the imagery of the New Testament Book of Revelation (Rev. 20), in which the writer describes a vision of Satan being bound and thrown into a bottomless pit and of Christian martyrs being raised from the dead and reigning with Christ for 1,000 years. This 1,000-year period, known as the millennium, is viewed as a time during which man's yearnings for peace, freedom from evil, and the rule of righteousness upon earth are finally realized through the power of God.

NATURE AND SIGNIFICANCE

As a branch of eschatology—that area of theology dealing with last things, such as death, immortality, the Last Judgment, the end of the world, the rewards of the just, and the punishment of the damned—millennialism is concerned with the earthly prospects of the human community. Not limiting itself to the prospects of the individual in this world and the next, millennialism attempts to answer in vivid imagery such questions as: What will be the final end of this world? Will mankind ever fulfill the agelong dream of dwelling in an earthly paradise or will all men be destroyed in a cataclysm of fire brought on by their own folly or God's judgment?

Millennialism is thus the cosmology (study of order) of eschatology, its chronology one of future events, comparable to the historical record of the past.

Millennialism is found within both Christian and other traditions. During the 20th century, anthropologists, historians, and sociologists explored the millennialist aspects of non-Western cultures, finding many striking similarities to the millennialism within the Judeo-Christian tradition (see also TRIBAL RELIGIOUS MOVEMENTS, NEW; MESSIAH AND MESSIANIC MOVEMENTS). The millennial treatises produced by Jewish and Christian believers in the latter part of the Greco-Roman civilization—the Hellenistic period—particularly the books of Daniel and Revelation, provided the building materials from which the successive millennial structures were erected. In constant repetition the motifs, the leading characters, the symbols, and the chronologies of these works have arisen in the teaching of some prophet of the end of the world, each time taking on new significance from associations with contemporaneous events.

Basis in Daniel and Revelation

HISTORICAL AND INTELLECTUAL DEVELOPMENT

The four main periods in the Judeo-Christian millennial tradition are (1) the rise and development of apocalyptic millennial views from about 200 BC until AD 200; (2) the creation of a countervailing allegorical interpretation of the millennium under the Church Fathers Origen and Augustine and the dominance of that theory in Christendom until the 17th century; (3) the re-emergence of a belief in the literal fulfillment of millennial prophecies and the association of those prophecies with a progressive and optimistic philosophy of history from about 1650 to the 20th century; and (4) the recent emergence of sectarian groups that have given new expression to the earliest tradition of apocalyptic and pessimistic millennialism.

Apocalyptic millennialism. Millennialism is dependent on the concept of apocalypticism—the view that God's final intervention in history will be accompanied by dramatic, unusual events.

The Book of Daniel. Western apocalypticism is based upon the archetypal apocalyptic work in the Judeo-Christian tradition, the Book of Daniel. Daniel is the only apocalyptic book to be admitted to the Old Testament canon, just as the Book of Revelation is the only apocalypse included in the canon of the New Testament. There are many noncanonical apocalyptic works from both Jewish and Christian authors, among them the three books of *Enoch*, the *Second Book of Esdras*, the *Ascension of Isaiah*, and the *Apocalypse of Peter*. All of the apocalyptic works written during the first efflorescence of millennialism, including the Book of Revelation, owe much of their shape and style to Daniel. This Old Testament book stands in the succession of the Jewish prophets and was apparently influenced by Iranian religious thought, such as the Zoroastrian concepts of the Last Judgment, the battle between good and evil involving both men and angels, and a punish-

ment of fire for evildoers (see also ZOROASTRIANISM AND PARSIISM).

In the face of a threat to the existence of the Jewish faith and temple worship, a group of zealots revolted in 168 BC against the occupation forces of the Seleucid monarch of Syria, Antiochus IV Epiphanes (*c.* 215–163/164 BC) and against those of their Jewish countrymen who favoured reducing Judaism to the level of a hellenized Oriental (Greek and Syrian) cult. The author of Daniel constructed his work to give aid and comfort to the rebel cause, particularly to assure them that God was aiding them, that the end of their struggles was in sight, and that a new golden age was dawning. In a vision reputed to be seen by King Nebuchadrezzar, he depicted a series of four world monarchies, represented in one passage by parts of a giant statue and in another by mythological beasts, each empire embodying evil to a greater extent than the last. Man's empires will end with the fourth kingdom, which is crushed by a "stone . . . cut out by no human hand,"symbolizing the fact that neither its destruction nor the ensuing order are natural developments from forces latent in history. A figure called the Son of man, however, will institute a fifth, entirely righteous, just, and eternal kingdom.

Visions of the ages of the world

As in the Jewish prophetic tradition that preceded it, Daniel made predictions about the future, but, unlike the predictions of a prophet such as Jeremiah (late 7th to early 6th century BC), the outcome anticipated by the prophet was not the virtually inevitable product of antecedent forces but a total reversal of what might seem to be the likely outcome if God were not to intervene. The reversal of worldly expectations through a violent supernatural intervention in the course of history is one of the most characteristic features of apocalypticism and stands quite in contrast to the older prophetic style. Also essential to Daniel and subsequent apocalypticism is the immediacy of the message and the imminence of the deliverance that is promised—the promise of salvation now. Descriptions of this imminent salvation of cosmic proportions included vivid representations of historical figures who depicted the growth of evil and decline of goodness from past time down to the present, when all wickedness came into terrifying focus.

To these significant emphases in Daniel's apocalypse—the imminent and supernatural intervention of God in man's history and the reversal of the heretofore irresistible progress of evil and declension of good—might be added other characteristics that have proved to be influential. Numerology, mythological figures, and angelology, which have continued to play such a large part in millennial movements, were probably introduced as a result of the influence of Iranian thought. Other characteristics of Daniel, such as its pseudonymous authorship and the emphasis upon the esoteric, mysterious quality of the truths discussed, were probably due to the unique problems faced by the author in presenting these views to a 2nd-century-BC audience.

In the centuries immediately following the writing of Daniel, the apocalyptic world view influenced Jewish culture; the audiences whom Jesus addressed were acquainted with it; and the early Christian Church embraced the apocalyptic world view. The Apostle Paul frequently expressed apocalyptic expectations (I Thess. 4), and Mark 13, a passage often called "the little apocalypse," reflects the apocalyptic expectations of the Roman church at about AD 70.

The Book of Revelation. The Christian Church in the 1st century wrestled with a difficult problem. Jesus had promised the inauguration of a new age, the Kingdom of God, and yet life proceeded after his death in much the same way that it had before his birth, with the exception that Christian believers suffered severe persecution for their faith. The primitive church solved this problem through the paradox of the Second Coming of Christ: Christ has come and is coming again. They believed that the new age had dawned but would not be fully revealed until Christ's Second Coming in glory.

Like the Book of Daniel, the Revelation to John or Revelation was composed during a period of persecution. It was probably written during the last decade of the 1st century AD, and it reflects the persecutions beginning under the emperor Nero (AD 37–68), who seems to be portrayed as the Antichrist—the beast whose symbolic number is 666 (Rev. 13). After addressing letters to churches of Asia Minor, the author depicted his vision of a series of judgments—seven seals opened, seven trumpets blown, seven bowls poured out. The writer directed his attack against the Roman Empire, referred to cryptically as Babylon and as the great harlot. Christ was described as the executor of God's judgment, appearing not as the man Jesus but as an omnipotent king riding upon a white horse with eyes like a flame of fire and a mouth like a sharp sword "with which to smite the nations" (Rev. 19). In the Book of Revelation the assimilation of Jewish apocalypticism to Christianity was completed. Daniel's Son of man was replaced by Christ; many of the numerological formulas were repeated; and the dualistic universe of good and evil, Christ and Antichrist, was provided with a new and unforgettable set of characters. The essence of the apocalypse in Revelation remained what it had been in Daniel: the immediate, direct aid of God was to be momentarily expected, accomplishing the dramatic reversal of history that the believers' present desperate state demanded.

Apocalyptic symbolism

Apocalypticism in the early church. During the first hundred years of Christian history, this form of millenarianism, or chiliasm (from the Greek word for 1,000), was commonly taught and accepted within the church. Persecution of the church was intermittent, however, and apocalyptic zeal flagged without the pressure of opposition. Christian missionaries succeeded in converting large numbers of Roman citizens, and some of the antagonism toward the empire was dissipated. The appeal of millenarian thought was further limited by its association with the heresy of Montanism. In characteristic apocalyptic fashion, Montanus, the founder of the movement, was fascinated with the idea of dividing past and future into units of prophetic calculation. In AD 156, according to the 4th-century Christian antiheretical writer Epiphanius, Montanus declared himself the prophet of a third testament, a new age of the Holy Spirit. Phrygia in Asia Minor became the centre of this ecstatic and ascetic movement whose leaders claimed divine inspiration for their visions and utterances, the main theme of which was the imminent Second Coming of Christ. This concept of the third age, the new day of the spirit of God, has been one of the most consistently repeated features of millenarian history, reappearing, for example, in Joachim of Fiore's philosophy of history during the 12th century, in views of the 17th-century Quakers, and in the apocalyptic speculations of the Seventh-day Adventists of the 19th and 20th centuries. When persecution of Christians was renewed late in the 2nd century, Montanism began to appeal outside Asia Minor and found converts throughout the Roman Empire, including Tertullian, a North African lawyer and theologian. The church survived this persecution, however, and Montanism was stigmatized as a heresy.

The age of the Holy Spirit

The influence of Greek thought upon Christian theology undermined the millenarian world view in another, possibly more significant, manner. In the theology of the great 3rd-century Alexandrian Christian thinker Origen, the focus was not upon the manifestation of the kingdom within this world but within the soul of the believer, a significant shift of interest away from the historical toward the metaphysical, or the spiritual. The association of apocalyptic millenarianism with the Montanist heresy, the growing influence of Greek thought upon Christian theology, and the conversion of Constantine the Great and adoption of Christianity as the favoured religion of the empire—all combined to discredit millenarianism for centuries.

Allegorical millennialism. *Augustinian views.* In the new age of the church triumphant—*i.e.*, when Christianity became the accepted religion of the Roman Empire—Augustine (354–430), bishop of Hippo, gave definitive expression to the view that was to dominate Western civilization through the Reformation. In his

The City of the World and the City of God

City of God, a philosophy of history Augustine viewed the world as eternally divided between the City of the World and the City of God. All men owe allegiance to one or the other of these cities and will ultimately share the fate of that community. The City of the World is ruled by Satan, the prince of this world. He and all who pay homage to his city will suffer eternal punishment. The City of God is represented in the church, and for the church God has ordained salvation from the persecution of the City of the World and eternal bliss in the courts of heaven. Much of this conception is reminiscent of the apocalyptic world view, but the views of Augustine also contained distinct differences.

The dualism represented in apocalypticism is reflected with equal intensity in Augustine's two cities. Furthermore, Augustine remained as pessimistic as any millenarian about the future of the City of the World and the prospect of progress in this world. After his conversion to Christianity, Augustine, a former *bon vivant*, consistently favoured a world-denying and ascetic style of life. In fact, his disillusionment with worldly values was more thorough than that of the millenarians, for he rejected as carnal any expectations of a renewed and purified world that the believers could expect to enjoy. In this respect he differed sharply with the apocalyptic tradition. The millenarian, in contrast to Augustine, had no quarrel with the world as such except that he had found it controlled by his enemies. The millenarian believed that when the imminently expected saviour had defeated these foes, the righteous would share in an earthly paradise, a land of physical, not spiritual, benefits.

The literalistic descriptions of the judgments that were predicted for the wicked and the bliss foretold for the righteous found in such apocalyptic works as the Book of Revelation were interpreted allegorically by Augustine. He expected that ultimately the history of this world would end, but for him the millennium had become a spiritual state into which the church collectively had entered at Pentecost—the time of the reception of the Holy Spirit by Christ's disciples soon after his Resurrection—and which the individual Christian might already enjoy through mystical communion with God. In contrast to the apocalypticist's focus upon the contemporary world, Augustine, though just as influenced by his own cultural milieu, responded with a millennial eschatology that seemed almost oblivious of time. As far as the struggle with evil in this world is concerned, Augustine surrendered and abandoned the field. No imminent supernatural intervention in history was expected, and no dramatic reversal of the tide of battle was anticipated. Augustine

Realized eschatology

taught what has been referred to as "realized" eschatology. For him the battle had already been fought on the spiritual ground that really mattered. God had triumphed. Satan has been reduced to lordship in this world. In the present age the City of the World and the City of God have been forced to coexist. Eventually, even that small patrimony that Satan claimed would be taken from him, and God would become triumphant.

Medieval and Reformation millennialism. Augustine's allegorical millennialism became the official doctrine of the church, and apocalypticism went underground. During the late Middle Ages and the Reformation, millenarian views were frequently voiced, most often by rebels and radicals. Apart from these dissidents, however, the doctrine of Augustine remained unchallenged until the 17th century. The Protestant Reformers of the Lutheran, Calvinist, and Anglican traditions were not apocalypticists but remained firmly attached to the views of Augustine, for whose theology they felt a particular affinity. Many of the allusions of the Book of Revelation were viewed in a distinctly Protestant perspective by the Reformers—the allusions to Rome as the great harlot and as Babylon being transferred to the Roman church, and the pope being identified as the beast. Each of the three main Protestant traditions of 16th-century Europe, however, found support from the secular authorities in Saxony, Switzerland, and England and remained in the same position vis-à-vis the state as had the medieval church. The apocalyptics within medieval Christendom, as well as in the 16th-century Reformation, were those who believed that their only help was the Lord and for whom persecution was a reality and destruction an imminent threat.

Progressive millennialism. The Augustinian millennial world view, though it survived the Reformation, did not survive the intellectual revolution of the 17th century. Behind the development of science lay a profound reorientation of Western thought that involved, in the first place, the rehabilitation of nature. A part of Augustine's rejection of the world stemmed from the frustration felt by his generation in attempting to cope with the natural and social history of its time. By 1600 Europeans had gained confidence in their own abilities. Such philosophers as Francis Bacon announced the dawn of a new day and attacked the Augustinian reluctance to see anything but the work of the devil in attempts to control or understand natural processes. Secondly, European intellectuals were becoming far more interested in measurement and quantification. Allegory fell into disrepute when the medieval interpretation of the nature of the heavenly bodies was proved to be erroneous by the facts discovered by the use of the telescope. A new concern with calculation and literalism spread to biblical scholarship and resulted in the creation of the third type of millennialism found in the Christian tradition—progressive millennialism.

Early progressive millennialism. Joseph Mead (Mede), a 17th-century Anglican biblical scholar, was the pioneer in the movement. Ignoring the allegorical interpretation long associated with the book, Mead took a fresh look at the text of Revelation. He concluded that the Scriptures held the promise of a literal Kingdom of God. The work

Millennialist optimism

of redemption, he concluded, would be completed within human history on the stage of this world. The Book of Revelation itself seemed to contain a historical record of the progress of that Kingdom, and scholars other than Mead soon were speculating where in the prophetic timetable the modern millennialist might locate himself. Thus far, progressive millennialism appeared to be identical with the apocalyptic millenarianism of the early church, but there the similarity ended. The Kingdom would not be brought into being through any dramatic reversal of the historical process, nor did the progressive millennialists believe that the Second Advent of Christ would occur in order to rescue them from destruction. History did not need reversing for these early Enlightenment Christians (those who emphasized reason). They thought of the record of the past as the story of victory over evil and the conquest of Satan. They rejected the fundamental assumptions of the apocalypticist—*i.e.*, that victory would be snatched from the jaws of defeat only by a miraculous deliverance. For them it seemed that the progress of history had been continuously upward, that the Kingdom of God was coming ever closer, and that it would arrive, not without struggle, but on the basis of the same kind of effort that had always triumphed in the past.

In the 18th century the teachings of the progressive millennialists became dominant in many Protestant churches. The Anglican polemicist and commentator Daniel Whitby (1638–1726), in his *Paraphrase and Commentary on the New Testament* (1703), provided such convincing support to the position that he has often been credited with creating it. In America interest in the millennium had not been lacking among Puritan scholars, but it was the great revivalist Jonathan Edwards (1703–58) who first adopted progressive millennialism, giving detailed exposition of his views in his uncompleted *History of the Work of Redemption*. Edwards saw significance for millennialism in the discovery and settlement of the New World, and he anticipated the establishment of Christ's kingdom sometime near the end of the 20th century.

Later progressive millennialism. The association of the millennium with the role of the United States proved to be a volatile 19th-century mixture in the hands of Protestant ministers, and for much of that period millennialism fed the fires of nationalism and Manifest Destiny. In a typical utterance, a leading Presbyterian minister of the 1840s, Samuel H. Cox, told an English audience that, "in America, the state of society is without parallel in

universal history. . . . I really believe that God has got America within anchorage, and that upon that arena, He intends to display his prodigies for the millennium." The late-19th-century movement known as the Social Gospel, dedicated as it was to establishing the Kingdom of God here and now, manifested most clearly the continuing influence of progressive millennialism.

Because the advocates of optimistic millennialism were confident of the ultimate triumph of their cause, it must not be assumed that they took evil lightly. They thought of God's Kingdom as advancing, as Jonathan Edwards argued, but not without destruction. Though they were not apocalyptic, their view of history included the cataclysmic. In the American Civil War, for example, the anti-slavery writer Julia Ward Howe, in "The Battle Hymn of the Republic," described God's truth as "marching on." In Pres. Woodrow Wilson's crusade to make the world "safe for democracy" by the entry of the United States into World War I (1914–18), one can see the same idea barely disguised. According to the progressive millennialists, Christ's Second Advent would occur at the close of the millennium as its crowning event, and, as a result, their position has frequently been called postmillennialism.

Summary of millennial positions

Thus, the three variations of Western millennial thought are: the apocalyptic millenarianism of the early church, especially during its periods of persecution; the allegorical millennialism of Augustine, which dominated the medieval church, was accepted by some of the leading figures of the Protestant Reformation, and continues to receive acceptance among some Roman Catholics; and the progressive millennialism characteristic of Protestantism since 1650 and particularly influential in the United States. These three forms of millennial thought exhaust the catalogue of millennial variations but do not complete the historical survey. The form of apocalyptic millenarianism that achieved acceptance during the formative years of the church has had a history of almost innumerable resurrections, particularly as the expression of the dissident and rebellious.

MILLENARIAN GROUPS

Millennialist pessimism

For apocalyptic millenarianism, as indicated above, no one who is satisfied with his existence, who is wealthy, powerful, or well integrated into his social system will find much appeal in a world view that is focussed upon crisis and pessimistic about the future if God does not bring immediate miraculous deliverance. To many of the desperate men of the later Middle Ages, however, beginning to feel alienation from the simpler pastoral life that was fading away in the face of commercial and urban development, this apocalyptic outlook seemed directly relevant. Beginning as early as the 11th century, especially in those regions most affected by social change, thousands were swept into the camp of self-appointed messiahs, such as Tanchelm, a fiery heretic of the Netherlands. In the 12th century, Joachim of Fiore gave fresh expression to the Montanist millenarian vision of the third age of the spirit. During the Hussite rebellion in Bohemia in the 15th century, one group, the Taborites, gathered massive support around a savage attack upon clerical interests and the proclamation of the imminent return of Christ. These outbursts continued during the Reformation. In the first half of the 16th century, Luther, for example, vigorously opposed enthusiastic prophets of the millennial age and the coming of Christ, such as the radical Reformer Thomas Müntzer. The most famous 16th-century millenarian outburst came at the city of Münster in Westphalia, where refugees from persecution managed to gain control of the city, ejected unbelievers, and, while the community was besieged, attempted to establish a prototype of the New Jerusalem. Again in the 17th century, during the English Civil War, a few apocalyptic Puritans, enthused by the prospect of the millennium, attempted to set up the Fifth Monarchy prophesied in the Book of Daniel.

Other than groups such as the celibate Shakers in England and the United States, the 18th century was relatively free of apocalypticism until the time of the French Revolution; but that great cataclysm and the industrialization of the West encouraged a new wave of millenarian sects, among them the Catholic Apostolic Church, the Seventh-day Adventists, Jehovah's Witnesses, the Latter-day Saints (Mormons), and those premillennialists who contributed directly to the rise of the biblically oriented and conservative movement known as Fundamentalism. The appeal of these groups in the United States increased during times of national crisis or peril—the 1830s, 1870s, and the years surrounding the world wars of the 20th century, which were particularly marked by the prominence and success of apocalyptic appeals. Unlike many of the earlier reawakenings of millenarianism, however, these modern American apocalyptic groups possessed no revolutionary potential. They rather seemed to help their members to sublimate their frustrations in study or proselytizing.

CONCLUSION

Without the influence of the Bible, no connected millennial tradition would exist. The incorporation of Daniel and Revelation in the canon of the Old and New Testaments conferred a timelessness upon books apparently intended only as tracts for their own times. If the authors of Daniel and Revelation had been correct, judgment would have fallen upon the world in their own day. Their literature has survived, however, and become the basis for a whole tradition of expectations. As long as Christians accept the texts of the Bible as the Word of God, the tradition will endure.

Miltiades

Miltiades, famous for his leadership in the Greek victory over the Persians at the Battle of Marathon, was born *c.* 554 BC in Athens. His family must have been extraordinarily wealthy; his father, Cimon, three times won the chariot races at the Olympic games, while his uncle, after whom he was named, was the founder of an Athenian semi-independent principality in the Chersonese. Miltiades the Elder died childless and arranged for his stepbrother's sons to inherit the dominions he had conquered. About 516, Miltiades left for the Chersonese (modern Gallipoli Peninsula), where he strengthened his authority by arresting his potential rivals and by surrounding himself, as tyrants were wont to do, with a heavily armed bodyguard of 500 men. He also married Hegesipyle, the daughter of a Thracian prince. Soon after, nonetheless, his authority was severely limited when Darius I of Persia expanded his power into Europe and reduced Miltiades to the rank of a Persian vassal. He led a contingent in the Scythian expedition of Darius (*c.* 513), and, according to Herodotus, he advised the destruction of the Danube bridge, which would have cut off Darius' retreat. Since Miltiades was not at once expelled by the Persians, the story is doubtful. It is a fact, on the other hand, that when the Ionian revolt against the Persians broke out in 499 BC, Miltiades decided to join the insurgents and to enter into friendly relations with the newly established Athenian democracy. Probably during the revolt Miltiades seized the isles of Lemnos and Imbros, which he eventually ceded to Athens. But the revolt collapsed by 494, and the year after, when Darius' fleet appeared off the Chersonese, Miltiades loaded five boats with his treasures and made for Athens. One of the boats, captained by Miltiades' eldest son, Metiochos, was captured. Metiochos was taken as a lifelong prisoner to

Relations with Darius

Persia, but Darius treated him honourably, married him to a Persian princess, and regarded their children as members of the Persian nobility.

Because of his fabulous wealth, his foreign wife Hegesipyle (who bore him a son, Cimon the younger, in *c.* 510), and his past as a "tyrant," Miltiades was bound to —and did—raise animosities in Athens. Prosecuted for his tyrannical role in the Chersonese, probably at the instigation of the rival clan of the pro-Persian Alcmaeonids, he was triumphantly acquitted as champion of resistance to Persian encroachments upon Greek freedom.

Miltiades, inscribed herm, *c.* 450 BC. In the Museo Nazionale di Ravenna.

The Persians were threatening Athens, which had supported the Ionian revolt with a punitive expedition, and Miltiades, who had first-hand experience of the Persians, was chosen, from 493 onward, as one of the ten generals of the Athenian land forces (unlike Themistocles, he was still thinking in terms of land warfare and of an agreement with Sparta, favoured by the Athenian landowners, the peasantry, and the rural middle class). In the summer of 490 BC the Persians landed at Marathon. The Athenians were faced with the choice of marching out and confronting them there or waiting for them at Athens: the decision was to be made by the Assembly. Miltiades was well aware of the power of the Persian cavalry, which, once out on the open plain, would wreak havoc. He was also anxious for a quick decision, because there were factions within Athens which would have welcomed a Persian victory in order to advance their own political ambitions. His arguments persuaded the Assembly, and the Athenian forces set out. A runner was sent to Sparta, to seek support of the Spartan army, but the Spartans replied that they would participate only at the conclusion of a religious festival six days later. A conflict then arose among the ten Athenian generals over whether to wait or to attack the Persians immediately. The deciding vote was to be cast by the *polemarchos* (supreme military commander) Callimachus, whom Miltiades was able to persuade to immediate action. The operational command of the army was to be held for one day in turn by each of the ten, but the four who had supported Miltiades surrendered their right to command to him.

Battle of Marathon

Occupying the foothills surrounding the bay, Miltiades waited for a favourable moment to attack. He chose a time when the Persian cavalry was nonoperational, either because it was being re-embarked for a possible direct attack on Athens or because of some other circumstance; the reason for its absence is uncertain. Charging a mile across the plain, Miltiades' forces engaged the Persian infantry, killing some 6,400 men (and capturing 7 ships) at a cost of 192 Athenian dead. The rest of the Persian force quickly embarked and put out to sea.

Following the defeat of the Persians at Marathon, Miltiades set out (spring 489 BC) with a fleet of 70 ships on an expedition to conquer those islands that had supposedly sided with Persia. His mission was not a success, and on his return to Athens there was an outcry of indignation, ably exploited by his rivals, the Alcmaeonids. Miltiades, dying of gangrene from a leg wound suffered in a mishap, was fined 50 talents, although the death penalty had been demanded. He probably died soon after in prison.

But the tragic outcome of his life did not cloud the judgment of Miltiades' historical role. His fellow citizens never forgot that it was to his initiative and leadership that they owed their victory over the Persians.

BIBLIOGRAPHY. The best writings on Miltiades in English are in H.T. WADE-GERY, *Essays in Greek History* (1958); E.S. GRUEN, "Stesimbrotus on Miltiades and Themistocles," *California Studies in Classical Antiquity*, 3:91–98 (1970); and the general works by C. HIGNETT, *Xerxes' Invasion of Greece* (1963); and A.R. BURN, *Persia and the Greeks* (1962). The only recent, though highly tendentious, biography of Miltiades is by H. BERVE, *Miltiades: Studien zur Geschichte des Mannes und seiner Zeit* (1937), who eventually qualified and severely modified his theory.

(P.T.)

Milton, John

John Milton stands next to Shakespeare among English poets; his writings and his influence are a very important part of the history of English literature, culture, and libertarian thought. He is best known for his long epic poem *Paradise Lost*, in which his "grand style" is used with superb power; its characterization of Satan is one of the supreme achievements of world literature. Milton's prose works, however, are also important as a valuable interpretation of the Puritan revolution, and they have their place in modern histories of political and religious thought.

Milton, engraving by W. Faithorne, 1670. In the National Portrait Gallery, London.

Milton was born in London on December 9, 1608. His grandfather, an Oxfordshire yeoman, had been a staunch Roman Catholic who had disinherited his son, the poet's father, for turning Protestant. John Milton, Sr., going to London, made his way to prominence and a comfortable fortune as a scrivener, or notary, and through the collateral business of private banking or moneylending. Milton was to pay repeated tributes to his father's generous concern with his education. One debt was in the way of music. The father was a composer of some repute, and the poet's lifelong devotion to music is attested by the warmth of his own allusions and by his early biographers. Of his mother (died 1637) Milton said only that she was well esteemed and known for her charities. He had an older sister, Anne, and a younger brother, Christopher, who became a lawyer.

Education and early poems. Milton was educated at St. Paul's School, London. The conventional date given for his admission is 1620, but it may have been as early as 1615. In addition to his regular schoolwork in Latin, Greek, and—later—Hebrew, the boy had instruction at home, perhaps partly in modern languages, from private tutors. Milton was from childhood a voracious student; he traced the initial cause of his later blindness to his having, from his 12th year, rarely quit his books before midnight. Along with a couple of Latin exercises that have survived, his earliest attempts at verse, made when he was 15, were rhymed paraphrases of Psalms 114 and 136. Milton's closest friend, at school and later, was Charles Diodati, the son of a prominent physician of Italian origin, who went from St. Paul's to Oxford; a less intimate friendship, which also lasted beyond school, was with Alexander Gill, the son of the headmaster.

Years at Cambridge

On April 9, 1625, Milton matriculated at Christ's College, Cambridge; he received his bachelor of arts degree in March 1629 and that of master in July 1632. His experience at Cambridge can be partly gathered from his abundant Latin verse and his seven Latin prolusions (public speeches that were expected to display the speaker's learning and rhetorical and argumentative powers). Apparently in March 1626 he clashed in some way with his tutor and was rusticated. He compared his "exile" at home in London to that of his beloved Ovid and rejoiced in the opportunity to read the books (here Classical plays) "that are my life" and to see beautiful girls while strolling. On his return he was assigned to another tutor and graduated at the normal time.

Milton's nickname at the university, "the Lady," was apparently bestowed because of his handsome and delicate features and a purity of mind and behaviour that disdained the diversions of his coarser fellows. During his seven years at Cambridge he seems to have moved from some unpopularity to general respect and, among dons and cultivated students, to high esteem. He did not love the Scholastic logic that dominated the curriculum; then, as well as later, he denounced it as barren. In his last prolusion (1631–32?) he proclaimed the fervent creed and dream of a young Renaissance Humanist who was at once a Christian, a Platonist, and—whether or not he had yet read Francis Bacon—a Baconian.

Meanwhile, Milton had been learning his craft and sometimes revealing his inner self in writing Latin verse. Neo-Latin poets, such as George Buchanan or the contemporary Hugo Grotius (whom Milton later met in Paris), enjoyed European fame; and students commonly celebrated academic and national events in what was then the normal language of the university world. The young poet's sensuous instincts were revealed in these Latin poems and were further displayed, along with his mastery of Italian, in six Italian pieces (1630?), with which may be linked his first English sonnet, "O Nightingale."

Earliest extant English poems

Early in 1628 Milton wrote the earliest of his extant English poems (apart from the two psalms), "On the Death of a fair Infant," an elegy, in the Elizabethan vein, on his baby niece, Anne Phillips. In part of an academic prolusion in English couplets ("At a Vacation Exercise," July 1628) he declared his devotion to his native language, a style free from eccentricity, and exalted themes concerning nature and man. And in the Latin "Elegy VI," addressed to Diodati in the Christmas season of 1629–30, he praised the light verse kindled by wine and love but turned from that to celebrate the ascetic purity of the heroic poet. The elegy ended with a reference to a poem he had just written, his first great poem in English, "On the Morning of Christ's Nativity." Such a poem, composed shortly after his 21st birthday, may be taken as a kind of announcement of his poetical coming of age and future direction, both in its religious theme and in its mastery of conception and form and image and rhythm. Probably in the long vacation of 1631 Milton wrote the companion poems "L'Allegro" and "Il Penseroso." Less ambitious in theme than the "Nativity," they have their own complexity, concealed beneath a unique grace and charm. They may be said to embody—and excel—the urbane decorum of the lyrical and reflective pieces of Ben Jonson—a quality already manifested in the tiny "Song: On May Morning" (1629–30?) and the "Epitaph on the Marchioness of Winchester" (1631). Milton had lately (1630) also written the lines "On Shakespear," which were printed in the Shakespearean Second Folio, 1632.

Milton's scholarly and literary gifts had from childhood marked him out in the minds of his family and teachers for the ministry; in his later prose he said he had refused to "subscribe slave" in a church governed by prelacy, but the date of his negative decision is not known. As his academic career approached its end, the problem of an occupation would come up, and the poem "Ad Patrem" —though some scholars link it with *Comus* (1634)— may well have been written in 1631–32. In this piece, with a mixture of filial gratitude, firmness, and confidence in poetry and himself, Milton assumes or urges that he should not be pushed into some basely lucrative profession by a father who has fostered his literary pursuits and is himself a devotee of the muses.

Horton period (1632–38). On taking his master of arts degree in July 1632, Milton retired to his father's house —until 1635 at Hammersmith, then at the country estate at Horton, near Windsor—and proceeded to give himself the liberal education Cambridge had not provided. It was in these years that he laid the foundation or set the direction of his liberal thinking. He sought to digest the mass of history, literature, and philosophy, to gain the "insight into all seemly and generous arts and affairs" needed by the citizen-poet who would be a leader and teacher. At times he suspended his labours to visit London in quest of books or something new in mathematics or music.

Self-education

An important landmark in Milton's early development is the sober sonnet "How soon hath Time," written on his 24th birthday. During recent years he had become a figure in the small university world; now he writes this sonnet while his contemporaries are forging ahead, and he has had six months of studious and outwardly unfruitful obscurity at home. But any uneasiness about his present and future is quieted in the earnest dedication of his life to his great Taskmaster's will. What might be called the first pledges toward the fulfillment of this self-consecration were two short religious poems, "On Time" and "At a Solemn Musick" (1632–33?). These are early renderings of the beatific vision that always kindled Milton's imagination. Both, in different sequence, contrast the grossness of temporal life, the jarring discord of sin, with the eternity and harmony of heaven and good.

The same contrast is sounded in the opening lines and carried through the whole of the masque known as *Comus*. During 1630–34, perhaps in 1632, Milton had, at the invitation probably of the musician Henry Lawes, written "Arcades," a miniature masque of Jonsonian courtliness. This presumably led to a request from Lawes for another masque. *Comus* was presented on September 29, 1634, before John Egerton, earl of Bridgewater, at Ludlow Castle, in Shropshire, in honour of his becoming lord president of Wales. *Comus* was Milton's first dramatizing of his great theme, the conflict of good and evil.

If *Comus* was, in a way, a song of innocence, "Lycidas" (written in November 1637) was a song of experience— Milton's first attempt to justify the ways of God to himself and to men. His former fellow collegian, Edward King, was drowned in a shipwreck in the Irish Sea in August 1637, and Milton was asked to contribute to a volume of elegies; "Lycidas," signed "J.M.," appeared at the end of an undistinguished collection of pieces in Latin, Greek, and English (1638). The pastoral convention had, from its Greek beginnings, proved its value as a dramatic vehicle—or mask—for almost anything that a poet wished to say. Milton, working as usual within a venerable tradition, as usual re-created it. He had no reason to feel deep personal sorrow, but the drowning of a virtuous and promising young man, on the threshold of service in God's church, brought home the whole enigma of life and death, of the rightness of things in a world where such events could happen. What if his own talents—which during his years of study he has been nurturing—should be cut off? It is impossible to summarize the complexities and depths of the poem, its reverbera-

Composition of "Lycidas"

ting solidity of reference, its rich variety of pace and tone, the artistic control that dominates turbulent emotions and ends with the high serenity of victory won. "Lycidas" may be the greatest short poem in the language.

Italian tour (1638–39). In May 1638, a year after his mother's death, Milton set off—with one servant—on a visit to Italy. He sojourned chiefly in Florence, Rome, and Naples. Milton and some of his early poems—not those in English—were cordially welcomed among men of letters and patrons and their academies. The experience, which he later described at length in *The Second Defence of the People of England* (1654) and alluded to elsewhere, warmed his heart and nourished his self-confidence. (It may be remembered that at home he had very little literary acquaintance and, outside a small circle, no poetic reputation.) To his host in Naples, Giambattista Manso, marquis of Villa, who had been the patron of Torquato Tasso and Giambattista Marino, Milton wrote a bread-and-butter epistle, "Mansus" (1638–39), which is one of his best Latin poems, a graceful apologia for English culture and a no less graceful statement of his own poetic standing and hopes. He wrote also an epistle to a Roman poet, Giovanni Salzilli, and several epigrams in praise of the singing of the famous Leonora Baroni. Though he mingled happily with Catholics and was a guest at a grand entertainment given by Cardinal Francesco Barberini, the staunch Protestant did not remain silent on matters of religion. He made a call—later recorded in "Areopagitica"—on the astronomer Galileo, who was in semicaptivity because his views on the universe conflicted with the doctrine of the Roman Church. Milton felt obliged to forgo a visit to Sicily and Greece because of news of mounting political tension in England, although, as he says, he lingered some time longer in Italy. In August 1638 Milton's friend Diodati died. Milton had been informed of his loss while in Italy; on his way home he stopped to see Diodati's uncle, Giovanni Diodati, who was professor of theology at Geneva.

Middle period (1641–60). Milton returned to England in July 1639, settled in a house in London, and prepared to take in pupils; the first ones were Edward and John Phillips, the sons of his sister Anne. His elaborate pastoral elegy on Diodati, "Epitaphium Damonis," was written apparently late in 1640 and privately printed. This has commonly been ranked at the head of Milton's Latin poetry, though dissenters may ask if the fact of its commemorating his dearly loved friend has not heightened its intrinsic merits.

Milton had returned to England with plans for an Arthurian epic (plans set forth briefly in "Mansus" and "Epitaphium Damonis"); like other ambitious poets of the Renaissance, he hoped to write the great modern heroic poem. But he was also deeply anxious about the Puritan cause. In his denunciation of hireling clergy in "Lycidas," Milton had virtually declared his Puritan allegiance, and the years 1641–60 he gave almost wholly to pamphleteering in the cause of religious and civil liberty. There is an important personal passage in his fourth tract, "The Reason of Church-government Urg'd against Prelaty" (1642), that shows it was a heavy sacrifice to put aside his craving for poetic immortality and leave off his cherished studies to "embark in a troubled sea of noises and hoarse disputes," but he could not be deaf to God's summons. And, as his work went on, he was sustained by the conviction that in his many and varied defenses of liberty he was, in another way, fulfilling his epic and patriotic aspirations. His first five pamphlets (1641–42) were contributions to the attack made on prelacy in the Anglican Church by a group of Presbyterian divines (called, from their initials, the "Smectymnuus" group). The attack was directed chiefly against its episcopal hierarchy, *The Book of Common Prayer*, and ritual, as being a compromise with Rome. The group urged a return to the democratic simplicity and purity of the apostolic church. Milton's first tract was "Of Reformation Touching Church Discipline in England" (1641). This begins by assailing the Anglican service and ends with a vision of the new and grand Reformation. In the personal passage in "The Reason of Church-government" Milton explains his religious conception of poetry and the deferment of his great epic because of what he feels to be his public duty.

Allegiance to Puritanism

Notoriety came in 1643, with Milton's "Doctrine and Discipline of Divorce" (enlarged edition 1644), followed by three more tracts in 1644 and 1645 on the same theme. His discussion was presumably hastened by his own marital disaster. In June (?) 1642, several months before the outbreak of the Civil War, Milton had married Mary Powell, the daughter of a Royalist squire of Oxfordshire who owed money to his father. Success could hardly be predicted for the marriage of a scholar and poet of 33 to an uneducated girl of half his age from a large, easygoing household. The young wife, visiting her family a little later, declined—doubtless with their backing—to return. The shock must have been especially severe for a man who—as one may infer from the anguished cries that recur in the "Doctrine"—had approached marriage not only with high hopes (and an unblemished past) but with earnest prayers; and there was no release from such a tragic mistake. In the tracts, Milton argued that the sole cause admitted for divorce, adultery, might be less valid than incompatibility, and that the forced yoke of a loveless marriage was a crime against human dignity. Both religious and philosophic tradition and the way of the world (including the usually meagre education given to girls) kept woman inferior to man; Milton, without denying that view, upheld a personal and Puritan ideal of marriage as an active bond of mutual love and mental companionship, an ideal that exalted women far above the level they occupied, say, in Cavalier poetry. He was, however, attacked as a libertine by Royalists and Presbyterians alike. In 1645 friends brought about a reunion between Milton and his wife; and in 1646, when the Powells had been ruined by the war, he took into his house, for nearly a year, the whole noisy family of 10. Three daughters, Anne, Mary, and Deborah, were born in 1646, 1648, and 1652. A son died in infancy. Mrs. Milton died a few days after Deborah's birth.

First marriage

Milton's best known pamphlets (at any rate for modern readers) were published in 1644. "Of Education" is one of the last in a long line of European expositions of Renaissance Humanism. His aim was to mold boys into enlightened, cultivated, responsible citizens and leaders; its basis would be the study of the ancient classics, in due subordination to the Bible and Christian teaching. But he also gave notable emphasis to science. In "Areopagitica," on the freedom of the press, he writes as a scholar and poet and lover of books and reasserts above all his belief in the power of truth to win its way through free inquiry and discussion. The tract seems to have had very little effect in its own time.

On February 13, 1649, two weeks after the execution of Charles I, Milton's first political tract, "The Tenure of Kings and Magistrates," appeared. In it he expounds the doctrine that power resides always in the people, who delegate it to a sovereign but may, if it is abused, resume it and depose or even execute the tyrant. A month later he was invited to become secretary for foreign languages to Cromwell's Council of State. Hitherto a detached observer, Milton, in spite of his private studies, was doubtless eager to have a hand in the workings of government. He was not on the policy-making level, but he had the easy command of Latin needed for foreign correspondence. Also, as a publicist of demonstrated sympathy with the revolution, he was expected to continue his defense of the cause against the multiplying attacks on the regicides.

Secretary for foreign languages in the Council of State

Milton's first effort in this line was "Eikonoklastes" (October 1649), one of a number of answers to *Eikon Basilike*, a book edited from the King's papers by his chaplain, John Gauden; this ostensible self-portrait of the royal saint and martyr, catching the public in its first shock of horror over the execution, was one of the most potent pieces of propaganda in English history, and not even Milton could prevail against it.

During 1651 Milton was censor and supervisory editor of the chief Commonwealth newspaper, *Mercurius Politicus*, edited by Marchamont Needham. In this year he appeared on the European stage, with the publication of

his Latin *Defence of the People of England.* Charles II, in exile, had engaged Claudius Salmasius (Claude Saumaise), the most eminent of classical scholars, to arraign the regicides (*Defensio Regia pro Carolo I,* 1649). Milton was less effective in legal argument than in discrediting Salmasius by personal abuse; like some other crusaders, he tended to see opponents as monstrous enemies of a sacred cause who must be destroyed by any means.

If he was, then and later, uplifted by the vanquishing of a renowned antagonist, he was inevitably and profoundly depressed by the loss of his eyesight; it had been failing for years, and blindness became complete in the winter of 1651–52. Milton was only 43, and the great poem was still unwritten. Blindness reduced his strictly secretarial duties, though he continued through 1659 as a translator of state letters.

Onset of blindness

The Second Defence of the People of England—also in Latin, since it was also addressed to Europe at large—was much more worthy of its subject and its author. In it he celebrated the achievements of the Commonwealth leaders (though he was bold enough to warn Cromwell against one-man rule). In 1659 two more tracts on church and state were published. In "A Treatise of Civil Power in Ecclesiastical Causes" Milton argued for religious freedom (except for Roman Catholics, since Catholicism had shown itself a danger to national security). In "Considerations Touching The likeliest means to remove Hirelings out of the church" he reasserted the ideal of a clergy of apostolic simplicity of life.

His last political pamphlet, "The Readie and Easie Way to Establish a Free Commonwealth," was published in March 1660 and again, enlarged, in April. It was an act no less courageous than futile, since machinery was patently moving to bring back Charles II (he made his triumphal entry on May 29). Milton's pamphlet is a cry of incredulity and despair from the last champion of "the good Old Cause." The glories of the Commonwealth, to which he himself had given 20 years and his eyesight, are being swept away by a nation of slaves "now choosing them a captain back for Egypt." The Restoration was the last and heaviest of Milton's many disillusionments.

Estimate of the prose works

The large bulk of Milton's prose—which fills four times as many volumes as his poetry—is read only by scholars, but much of it is important for several reasons. In an age of great prose, Milton's, at its best, has a very individual if often undisciplined greatness, and "Areopagitica" at least is a classic document and possession of the race. Moreover, as the record of Milton's growth (a leftward growth, in religion and politics) and of his dreams and disillusionments, his prose works are the essential introduction to *Paradise Lost, Paradise Regained,* and *Samson Agonistes,* providing a bridge between the radiant idealism of his youth and the much-tried faith and fortitude of his later years. In particular, his treatise *On Christian Doctrine* held a central place in his thoughts and labours. He seems to have finished it by *c.* 1658–60 (it was first printed and translated by Charles Sumner in 1825). Its importance is that it expounds, with differences, the theological frame of *Paradise Lost.* Viewed in perspective, most of Milton's essential beliefs are those of traditional Christianity, but—always on authority he finds in the Bible—he departs from orthodoxy on some points: God created the world not out of nothing but out of his own substance; God the Father, the Son, and the Holy Spirit are not a coequal Trinity but a descending order; man's soul dies with his body, until revived at the resurrection (this "mortalist" heresy, which is put into the mouth of the despairing Adam, had other adherents in England). Milton's conception of the Trinity, which is too complex for summary, is apparent to alert readers of *Paradise Lost,* though the poem did not disturb generations of the orthodox. More basic for the poem is Milton's denial of predestination (which, of course, is not a heresy). Brought up, like most Anglicans of his time, as a Calvinist, he regarded himself as one at least until 1644, but his final belief was in the Arminian doctrine—the salvation not of a predestined few but of all believers, who constitute the true elect. Milton above all insisted on man's rational freedom and responsible power of choice.

Sonnets and other poems (1642–58). Milton's early poems, in English, Latin, Greek, and Italian, were published at the beginning of 1646 (dated 1645). During the 20 years given to public affairs he was mostly cut off from poetry but did write 17 occasional sonnets, versified a number of Psalms, and began the composition of *Paradise Lost.* Some of the sonnets are deeply personal: two on his blindness (1651?–55) and one on the death in 1658, some months after childbirth, of his second wife, Katherine Woodcock, whom he had married in 1656. The major sonnets have much poetical as well as autobiographical interest, and as a group they illustrate (with "Lycidas") both in texture and rhythm the beginnings of the grand style (which Milton may have learned partly from the 16th-century Italian poets Giovanni della Casa and Torquato Tasso) that was to have full scope in the epic. One is less conscious of sonnet structure and of rhymes than of a single massive unit that approaches a paragraph of Milton's blank verse.

Later life. The Restoration government executed the Commonwealth leader Sir Henry Vane the Younger and exhumed and hanged at Tyburn the bodies of Cromwell, Henry Ireton, and John Bradshaw. Milton himself, as a noted defender of the regicides, was in real danger. In the summer of 1660 a warrant was out for his arrest; he was kept in hiding by friends. In August the Act of Oblivion, granting pardon to most Commonwealth supporters, was passed. Milton was safe within its terms but was nevertheless taken into custody (and released on December 15). According to various early stories, his life was spared through the intercession either of the poet Andrew Marvell, who in 1657 had become a fellow secretary and was now a member of Parliament, or of the Royalist playwright Sir William Davenant, whose life Milton had earlier been the means of saving. It may have been decided that the blind writer was now harmless and that token proceedings against him would be enough.

Milton had given up the idea of composing a British epic. Instead he chose the most momentous event, next to the life and death of Christ, in the world's history—man's Fall from grace. It is not known when *Paradise Lost* was actually begun. Guesses have centred on 1655–58. Clearly, the lines on the poet's having fallen on evil days, in the prelude to book vii, were composed after the Restoration, and the whole may have been done pretty much in the order in which it stands. It was finished by 1665. The first edition of 1667 was in 10 books; this was reissued in 1668 and 1669, and in some of these issues Milton added the prefatory note on his use of blank verse and "The Argument." In the second edition (1674), along with some small revisions, books vii and x were each split into two; and the arguments, formerly grouped together, were placed at the head of the respective books. The main motives and events of *Paradise Lost* had precedent to a greater or lesser degree, though Milton handled them with powerful originality; like a Greek dramatist, he was reworking a story familiar in outline to his audience. His story, moreover, was one of unique truth, sacredness, and universal and eternal import, and it gave the poet the advantage of immemorial belief and association in the minds of his earlier readers. This advantage no longer operates in the same way—although, for modern readers, the fable still possesses at least the immemorial and universal import of archetypal myth.

Composition of *Paradise Lost*

As artist, Milton links himself, both proudly and humbly, with the ancients—especially Homer and the blind bards of Greek myth—but he regularly ranks his Christian theme above the themes of the pagan poets. As he had said long before, in explaining why he must postpone his epic, it was a work

> not to be obtained by the invocation of Dame Memory and her Siren daughters, but by devout prayer to that eternal Spirit who can enrich with all utterance and knowledge, and sends out his seraphim, with the hallowed fire of his altar, to touch and purify the lips of whom he pleases.

Milton's preface stressed the novelty and rightness of blank verse for a heroic poem. His manipulation of rhythm and sound is of course one of his supreme achievements. The continuous flow of his long sentences

and paragraphs is naturally unlike the dramatic blank verse of Shakespearean dialogue, and it builds up a continuous onward pressure. As a modern master of rhythm, T.S. Eliot, has said, Milton's blank verse is never monotonous. The pattern of sound is so wedded to the pattern of sense that each is essential to the other.

Paradise Regained and *Samson Agonistes*

In *Paradise Lost* (ix) Milton had spoken of "patience and heroic martyrdom" as themes unsung, though nobler than martial prowess, and this "better fortitude" was celebrated in *Paradise Regained* and *Samson Agonistes* (1671). *Paradise Regained* is a natural sequel to the long poem: Christ, the second Adam, wins back for man what the first Adam had lost. But Milton did not, as might have been expected, deal with the Crucifixion; instead, he showed Christ in the wilderness overcoming Satan the tempter, thereby proving his fitness for his ultimate trial and, in his human role, showing what man in general might achieve through strong integrity and humble obedience to the divine will. Although the poem has been found cold by the mass of readers and critics, it nevertheless has all the fire of Milton's religious and moral passion and his reverence for true heroism.

For some readers, the drama of *Samson Agonistes* (published in the same volume with *Paradise Regained*) is the most powerful and completely satisfying of Milton's major works. It is by far the greatest English drama on the Greek model. The action, up to the reported catastrophe, is wholly psychological; it is the process by which Samson, "Eyeless in Gaza at the mill with slaves," moves from preoccupation with his misery and disgrace to selfless humility and renewed spiritual strength, so that he can once more feel himself God's chosen champion. The drama must owe a great deal of its power to Milton's sense of kinship with his hero; he has been eyeless in London among a nation of slaves. But the restraint of Milton's art shows itself very clearly: there is nothing in the drama that does not belong to the story of Samson.

Altogether, if *Samson* was his last work, it was a grand testament. Like Samson, Milton was able to conquer despair or to sublimate it in his last three great poems. These expressed, not his earlier revolutionary faith in men and movements, but a purified faith in God and the regenerative strength of the individual soul.

Last years

The poet's final 16 years of life, during which these three works were finished or composed, were—outwardly and in part inwardly—peaceful, although, along with sombre or uplifting thoughts of past and present, there were concrete troubles: a frugal domestic economy necessitated by greatly diminished resources; blindness and what was sometimes a more severe affliction, the pains of gout; and a degree of friction with his daughters, due probably to faults on both sides.

Apart from the publication of books, the chief events of these years were Milton's marriage (1663) to a third wife, the young and amiable Elizabeth Minshull, who survived him, and the removal, during the plague of 1665, to a house at Chalfont St. Giles, Buckinghamshire (now a Milton museum).

Early biographers give pictures of a quiet daily routine. Milton got up at 4:00 AM and had the Hebrew Bible read to him. Meditation, reading, and dictation filled the time until midday dinner. His late and long poems were, of course, composed in his head, especially at night, as famous allusions in *Paradise Lost* indicate; when he was ready "to be milked," he would dictate, often with one leg flung over the arm of his chair. The taking of dictation, the correcting of copy, and reading aloud in various languages were services performed by paid assistants, his two nephews, his younger daughters, and friends and disciples. After dinner, says the 17th-century English antiquary John Aubrey, "he used to walk 3 or 4 hours at a time (he always had a garden where he lived)." In the evening there was reading of poetry, and he went to bed about 9:00, after a pipe and a glass of water. One refreshment was music, playing on the organ or viol and singing; "he would be cheerful even in his gout fits, and sing." And there were many, sometimes too many, callers—foreigners (who came to see the conqueror of Salmasius, not the poet) and English friends, old and young, such as men already mentioned, and the young Quaker Thomas Elwood, whom Milton helped with his Latin. In religion Milton had moved from the low-church Anglicanism of his parents to Presbyterianism to Independency to independence. In the latter part of his life, according to his early biographer John Toland, "he was not a professed member of any particular sect among Christians, he frequented none of their assemblies, nor made use of their peculiar rites in his family." But, as Dr. Johnson observed, suspending his Anglican hostility, "his studies and meditations were an habitual prayer." Milton died on November 8, 1674, "of the gout struck in," just before his 66th birthday. His burial in St. Giles', Cripplegate, was attended by "all his learned and great friends in London, not without a friendly concourse of the vulgar."

Reputation. Milton's reputation grew steadily after 1667 and was well established before Joseph Addison's papers on *Paradise Lost* appeared in *The Spectator* (1712); these were instrumental in extending the poet's fame to the Continent. His influence on 18th-century verse was immense. In the 19th century, two main streams of critical opinion are evident. On the one hand, the revolutionary Romantic poets Blake and Shelley launched the "Satanist" misinterpretation of *Paradise Lost* and made its author, like themselves, a rebel—their attitude is summed up in Blake's saying that Milton was of the devil's party without knowing it (in other words, that he had projected himself into Satan, who was the poem's real hero). On the other hand, other critics—also concentrating on the epic—threw overboard Milton's beliefs and ideas as long-dead fundamentalism and listened only to the organ voice.

The poet's influence waned during the Victorian age, and in the 20th century the new poetry and criticism launched by Ezra Pound and T.S. Eliot were strongly anti-Milton and pro-John Donne. But during the 1940s and 1950s a shift in critical attitudes took place, and dozens of books and hundreds of articles have been given to ideas and beliefs of the thinker, the publicist, and the poet, and have brought a new refinement of perception and analysis to the aesthetic study of Milton's poetry.

MAJOR WORKS

POEMS: *A Maske Presented at Ludlow Castle, 1634* [*Comus*], in an enlarged text, and "Lycidas" (1638) were both reprinted in *Poems* (1645), which included nearly all the other early pieces, "L'Allegro," "Il Penseroso," etc. The second edition (1673) reprinted the 1645 *Poems,* adding two early pieces and later sonnets; political reasons excluded four sonnets, addressed to Sir Thomas Fairfax, Cromwell, Sir Henry Vane, and the one to Skinner beginning "Cyriack, this three years' day." *Paradise Lost,* in 10 books, appeared in 1667 (revised in 12 books, 1674); *Paradise Regained* and *Samson Agonistes* were printed together in 1671.

PROSE: "Of Reformation Touching Church Discipline in England" (1641); "The Reason of Church-government Urg'd against Prelaty" (1642); "An Apology for Smectymnuus" (1642), three of Milton's five tracts against prelacy; "The Doctrine and Discipline of Divorce" (1643, enlarged 1644); "Of Education" (1644); "Areopagitica" (1644); "The Tenure of Kings and Magistrates" (1649); "Eikonoklastes" (1649), reply to John Gauden's *Eikon Basilike;* "A Treatise of Civil Power in Ecclesiastical Causes" (1659); "Considerations Touching The likeliest means to remove Hirelings out of the church" (1659); "The Readie and Easie Way to Establish a Free Commonwealth" (1660); *The History of Britain* (1670); "Of True Religion, Haeresie, Schism, Toleration, And . . . the growth of Popery" (1673); *A Brief History of Moscovia* (1682).

WORKS IN LATIN, GREEK, AND ITALIAN: (POEMS): *Poems* (1645) contained three Greek pieces and five Italian sonnets and a canzone. Most of the notable Latin poems are mentioned above; one other, "Elegy V" ("On the Coming of Spring"), was a fervently "pagan" celebration of awakening life and sexuality.

(PROSE): The seven Latin speeches delivered at Cambridge and Latin letters to friends (published 1674); *Pro Populo Anglicano Defensio* (1651); *Pro Populo Anglicano Defensio Secunda* (1654); *Pro Se Defensio* (1655); *De Doctrina Christiana* (published 1825).

BIBLIOGRAPHY

Editions: The complete works (with translations) were edited by Columbia University scholars, 18 vol. and a useful

2-vol. index (1931–40). H.F. FLETCHER edited a facsimile edition of the complete poems and manuscripts, 4 vol. (1943–48). The complete prose, with translations of the Latin works and elaborate commentaries, is being edited by D.M. WOLFE *et al.*, in 8 vol. (vol. 1–6, 1953–73). *The Student's Milton*, ed. by F.A. PATTERSON (rev. ed., 1933), has almost all the works in one volume, with some apparatus. The most comprehensive one-volume annotated edition is *Complete Poems and Major Prose*, ed. by M.Y. HUGHES (1957). Annotated editions of the complete poems are those of HELEN DARBISHIRE, 2 vol. (1952–55), with mainly textual notes; DOUGLAS BUSH (1965); JOHN CAREY and ALASTAIR FOWLER (1968); and J.T. SHAWCROSS (1963; rev. ed., 1971). There are countless editions of seleected poems. Selected *Prose* is edited by J. MAX PATRICK *et al.* (1967).

Bibliographies: D.H. STEVENS, *Reference Guide to Milton: From 1800 to the Present Day* (1930, reprinted 1967); J.H. HANFORD and C.W. CRUPI, *Milton* (1966); a full annotated reading list in *Milton's Epic Poetry*, ed. by C.A. PATRIDES (1967); CALVIN HUCKABAY, *John Milton: An Annotated Bibliography, 1929–1968* (1969); a descriptive survey in *English Poetry: Select Bibliographical Guides*, ed. by A.E. DYSON (1971). Current writings are recorded in the annual bibliographies of the Modern Humanities Research Association (1920 *et seq.*), in the *Publications of the Modern Language Association of America* (1922 *et seq.*), and in *The Milton Quarterly* (1967 *et seq.*).

Biography and criticism: Milton's utterances on himself and his work are collected in J.S. DIEKHOFF, *Milton on Himself* (1939; 2nd ed., 1965). The six early biographies, by JOHN AUBREY and others, are in *Early Lives of Milton*, ed. by HELEN DARBISHIRE (1932, reprinted 1971); some of them are in *The Student's Milton* (see above). DAVID MASSON's all-inclusive *Life* (6 vol., partly rev., 1881–96) still has its uses. The standard modern biography is WILLIAM RILEY PARKER, *Milton*, 2 vol. (1968). Four small critical biographies are those of J.H. HANFORD (1949), KENNETH MUIR (2nd ed., 1960), EMILE SAILLENS (1959; Eng. trans., 1964), and DOUGLAS BUSH (1964). *The Life Records of John Milton*, 5 vol. (1949–58), is an exhaustive compilation by J.M. FRENCH of documents and references. A compendious account of the life and work is *A Milton Handbook* (5th ed., 1970) by J.H. HANFORD and J.G. TAAFFE.

Early criticism is collected in *Milton: The Critical Heritage*, ed. by J.T. SHAWCROSS (1970), covering 1628–1731; the same editor's sequel (1972) covering 1732–1801; and *The Romantics on Milton*, ed. by J.A. WITTREICH (1970). Milton's Victorian repute is the subject of J.G. NELSON, *The Sublime Puritan* (1963). Twentieth-century criticism is surveyed in books by PATRICK MURRAY (1967) and K.L. SHARMA (1971).

The huge proliferation of criticism and scholarship since *c.* 1917 severely limits references. Some general surveys of the poetry and prose are: E.M.W. TILLYARD, *Milton* (1930; rev. ed., 1966); DAVID DAICHES, *Milton* (1957); DOUGLAS BUSH, *English Literature in the Earlier Seventeenth Century* (1945; 2nd ed. rev., 1962), ch. 12; and the modern biographies cited above. Collected studies by three eminent Miltonists are: M.Y. HUGHES, *Ten Perspectives on Milton* (1965); J.H. HANFORD, *John Milton: Poet and Humanist* (1966); and A.S.P. WOODHOUSE, *The Heavenly Muse: A Preface to Milton*, ed. by HUGH MACCALLUM (1972). Miscellaneous papers appear in the continuing *Milton Studies*, ed. by J.D. SIMMONDS (vol. 1–5, 1969–73).

Studies of major poems, early and late, are D.C. ALLEN, *The Harmonious Vision* (1954); M.H. NICOLSON, *John Milton* (1963); J.H. SUMMERS (ed.), *The Lyric and Dramatic Milton* (1965); JOHN REESING, *Milton's Poetic Art* (1968); BALACHANDRA RAJAN, *The Lofty Rhyme* (1970).

Early poems: The Latin, Greek, and Italian poems are treated by DOUGLAS BUSH and A.B. GIAMATTI in *A Variorum Commentary on the Poems of John Milton*, vol. 1 (1970). A.S.P. WOODHOUSE, DOUGLAS BUSH, and E.R. WEISMILLER deal with all the early English poems (and all the sonnets and psalms) in vol. 2 (3 pt.) of the same *Commentary* (1972). Three useful anthologies of essays are *John Milton: L'Allegro and Il Penseroso*, ed. by E.B. SAFER and T.L. ERSKINE (1970); *A Maske at Ludlow: Essays on Milton's Comus*, ed. by J.S. DIEKHOFF (1968); and *Milton's Lycidas*, ed. by C.A. PATRIDES (1961). CLEANTH BROOKS and J.E. HARDY, *Poems of Mr. John Milton* (1951), discusses the poems of the 1645 volume. Distinctive studies of major early poems are given in ROSEMOND TUVE, *Images and Themes in Five Poems by Milton* (1957). ALAN RUDRUM, *Milton: Comus and Shorter Poems* (1967), is more popular. A recent study of *Comus* is ANGUS FLETCHER, *The Transcendental Masque* (1971). The sonnets have been edited with commentaries by J.S. SMART (1921, reprinted 1966) and E.A.J. HONIGMANN (1966); see also the *Variorum Commentary* above.

Paradise Lost: Modern criticism is analyzed by IRENE SAMUEL in *Critical Approaches to Six Major English Works*, ed. by R.M. LUMIANSKY and HERSCHEL BAKER (1968). Among the scores of modern books, some are focussed on the theological and ethical "argument": J.S. DIEKHOFF, *Milton's Paradise Lost* (1946); D.H. BURDEN, *The Logical Epic* (1967); S.E. FISH, *Surprised by Sin* (1967). Some more general studies are: C.S. LEWIS, *A Preface to Paradise Lost* (1942); BALACHANDRA RAJAN, *Paradise Lost and the Seventeenth Century Reader* (1947); A.J.A. WALDOCK, *Paradise Lost and Its Critics* (1947), an attack that stimulated illuminating responses; ARNOLD STEIN, *Answerable Style* (1953); I.G. MACCAFFREY, *Paradise Lost as "Myth"* (1959); J.H. SUMMERS, *The Muse's Method: An Introduction to Paradise Lost* (1962); ANNE FERRY, *Milton's Epic Voice* (1963); L.L. MARTZ, *The Paradise Within* (1964); NORTHROP FRYE, *The Return of Eden* (1965); HELEN GARDNER, *A Reading of Paradise Lost* (1965); ALAN RUDRUM, *Milton: Paradise Lost* (1966); J.M. STEADMAN, *Milton and the Renaissance Hero* (1967) and *Milton's Epic Characters* (1968). Some special related works are: WATSON KIRKCONNELL (ed.), *The Celestial Cycle: The Theme of Paradise Lost in World Literature* (1952); J.H. SIMS, *The Bible in Milton's Epics* (1962); J.M. EVANS, *Paradise Lost and the Genesis Tradition* (1968); J.E. DUNCAN, *Milton's Earthly Paradise: A Historical Study of Eden* (1972); and the volume by J.M. STEADMAN forthcoming in the *Variorum Commentary* (see above, under *Early poems*).

Paradise Regained and Samson Agonistes: Paradise Regained and *Samson Agonistes* are treated in some books cited above. Others are ARNOLD STEIN, *Heroic Knowledge* (1957); B.K. LEWALSKI, *Milton's Brief Epic* (1966); G.M. CRUMP (ed.), *Twentieth Century Interpretations of Samson Agonistes* (1968); ALAN RUDRUM, *Milton: Samson Agonistes* (1969); *Calm of Mind*, ed. by J.A. WITTREICH (1971); *The Prison and the Pinnacle*, ed. by B. RAJAN (1973); and W. MACKELLAR's *Paradise Regained* and J.M. STEADMAN's *Samson* forthcoming in the *Variorum Commentary* (see above, under *Early poems*).

Other studies: Studies of metrics and style include ROBERT BRIDGES, *Milton's Prosody* (1921); S.E. SPROTT, *Milton's Art of Prosody* (1953); F.T. PRINCE, *The Italian Element in Milton's Verse* (1954); CHRISTOPHER RICKS, *Milton's Grand Style* (1963); E.R. WEISMILLER, in vol. 2 and later volumes of the *Variorum Commentary*.

Milton's political and religious thought is examined in some books already named (*e.g.*, A.S.P. WOODHOUSE, *The Heavenly Muse*, and *Prose Works*, ed. by D.M. WOLFE); in ARTHUR BARKER, *Milton and the Puritan Dilemma, 1641–1660* (1942); in volumes by WILLIAM HALLER (1938, 1955); and in MICHAEL FIXLER, *Milton and the Kingdoms of God* (1964).

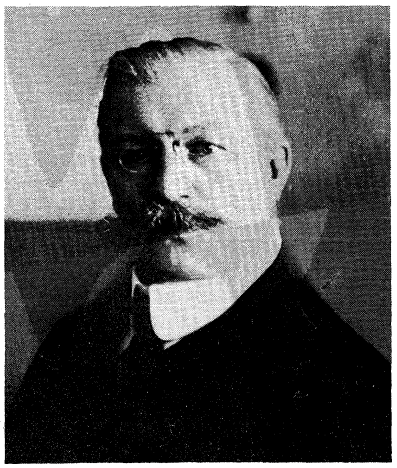
The nature and degrees of Milton's theological orthodoxy and "heresy" have caused controversy: see MAURICE KELLEY, *This Great Argument* (1941), and vol. 6 of the *Prose Works* (cited above); C.A. PATRIDES, *Milton and the Christian Tradition* (1966); and W.B. HUNTER, C.A. PATRIDES, and J.H. ADAMSON, *Bright Essence* (1971).

Some books on special subjects are: IRENE SAMUEL, *Plato and Milton* (1947) and *Dante and Milton* (1966); KESTER SVENDSEN, *Milton and Science* (1956); THOMAS KRANIDAS, *The Fierce Equation: A Study of Milton's Decorum* (1965); and MARCIA R. POINTON, *Milton and English Art* (1970). E.S. LE COMTE compiled *A Milton Dictionary* (1961), containing much precise information. A Milton encyclopaedia is being edited by P.E. BOYETTE *et al.* (D.B.)

Milyukov, Pavel Nikolayevich

The statesman and historian Pavel Nikolayevich Milyukov, after playing a significant role in the events leading to the Russian Revolution of March 1917, served as foreign minister in the Provisional government. His advocacy of constitutional monarchy and his insistence upon continuing the war with Germany proved unpopular. After two months in office he resigned and later went into exile. He remains one of the greatest of Russia's liberal historians.

Milyukov was born in Moscow on January 27 (January 15, old style), 1859. He entered Moscow University in 1877 and soon attained academic distinction as a specialist in Russian history. His three-volume *Ocherk: po istorii russkoy kultury* (1896–1903; Eng. trans. *Outlines of Russian Culture*, 1942) brought him nationwide renown. He was, however, to become even better known as a spokesman for imperial Russia's nascent liberal movement. His concern with contemporary political issues



Milyukov.
EB Inc.

led in 1895 to the loss of his teaching post, whereupon he went abroad, travelling widely and developing a deep admiration for the political values of more advanced democratic countries. On two occasions, in 1903 and 1904–05, he visited the United States, where he gave public lectures on Russian history and politics. As a convinced "westernizer," Milyukov saw tsarist absolutism as the main obstacle to Russia's progress. He strove to make Russian liberalism a more broadly based movement committed to a radical (but not Socialist) transformation of the empire's political and social structure. In particular, he stood for the rule of law, parliamentary government, universal suffrage, a broad range of civil freedoms, the expansion of popular education, and land reform. He was perhaps a better judge of abstract ideas than of human nature and was too inflexible to succeed in practical politics.

Political journalism

As a contributor to a clandestinely circulated journal, *Osvobòzhdeniye* ("Liberation"), founded in 1902, Milyukov did much to swing the moderate members of the zemstvos (local government bodies) to the left. During the revolutionary year 1905, he was active in forming the Union of Unions, a broad alliance of professional associations, and subsequently the Constitutional Democratic, or Kadet, Party. As editor of the Kadet daily newspaper *Rech* ("Speech") and a member of the party's Central Committee, he directed its tactics in Russia's first nation-wide election, which brought the Kadets success at the polls. The gulf between the newly created Duma, or national assembly, and the government could not be bridged, however, and in July 1906 the assembly was prematurely dissolved. Milyukov helped to draft the Vyborg Manifesto, appealing for a campaign of passive resistance to the government; this, technically speaking, was an illegal act. Many moderates thought that his tactics, which involved a measure of cooperation with the revolutionary Socialists, were too radical.

Subsequently Milyukov moved to the right. In the third and fourth Dumas (1907–17), he led the Kadets' depleted parliamentary faction in condemning bureaucratic abuses and championing progressive causes, notably the claims to cultural or political autonomy of national minority groups within the empire. In foreign policy Milyukov stood for cautious support to the Slav peoples of the Balkans, an area he knew well from personal observation. His attitude on this issue and on Russia's claims to the Turkish straits hardened after the outbreak of World War I. Milyukov adopted a patriotic "defensist" policy, which in 1915 led him to criticize the imperial regime for its inefficiency in organizing Russia's resources for the war effort, measured by the standards of its democratic Western allies. He helped to form a Progressive Bloc of moderate Duma leaders, who sought by gentle pressure from public opinion to secure a ministry enjoying the nation's confidence. When these overcautious tactics proved unavailing, Milyukov swung sharply to the left and, on November 14, 1916, delivered a powerful speech in the chamber implying that the government was guilty of treason. His charges had no real substance, but they greatly stimulated revolutionary sentiment, which soon exceeded the bounds Milyukov had expected or desired.

When Tsar Nicholas II abdicated under this pressure on March 15, 1917, Milyukov wanted to preserve the monarchy as a stabilizing force but found little support. The revolutionary tide was now running strongly against him. In the liberal Provisional government under Prince Georgy Lvov, which Milyukov helped to constitute, he towered intellectually over his colleagues but was soon outmanoeuvred by the Socialist leader Aleksandr Kerensky, who favoured a policy of concessions to popular demands, notably on the question of taking immediate steps toward a negotiated peace. As foreign minister, Milyukov clung to the wartime alliances and the demand for Russian possession of the Turkish straits. He resisted heavy pressure from inside and outside the government to send a note to the Allies redefining war aims, and when, on May 1, he yielded, the note was phrased ambiguously. Disturbances broke out in the streets of Petrograd, and Milyukov was obliged to resign (May 15).

Foreign minister

Thereafter he endeavoured to counter the new coalition government's leftward swing by rallying the moderates, but with little success. The Bolshevik seizure of power in November 1917 forced him to leave Petrograd for southern Russia, where he became political counsellor to the leaders of the White Volunteer Army. Subsequently he emigrated to Paris. In 1923, reverting to his earlier radicalism, he sought to unite the various currents of émigré opinion on a common republican democratic platform. This, too, proved a failure: he found that his compatriots preferred more extreme political doctrines. Undismayed, Milyukov held fast to his liberal principles and remained active in politics and scholarship until his death at Aix-les-Bains, France, on March 31, 1943.

BIBLIOGRAPHY. THOMAS RIHA, *A Russian European: Paul Miliukov in Russian Politics* (1969), is a thorough study that emphasizes the period 1905–17. Milyukov's works include *История второй русской революции*, 3 vol. (1921–24), a history of the Russian Revolution of 1917; *Россия на переломе; большевистский период русской революции*, 2 vol. (1927), Russia at the turning point; and *Outlines of Russian Culture* (abridged Eng. trans., 3 vol., 1942; orig. pub. in Russian, 3 vol., 1896–1903). His "Reminiscences," 2 vol. (1955), have in part been translated into English as *Political Memoirs, 1905–1917*, ed. by A.P. MENDEL (1967).

Mime and Pantomime

The words mime and pantomime in the 20th century have often been used interchangeably and are associated mainly with forms of silent comedic acting. They are classic terms originally descriptive of two acting forms. The mime was the Greek comedic actor who spoke with the enactment of his role; the pantomimist was the Roman actor who performed his role with dance and song, or chant. As representation of emotions and actions by bodily movements and gestures in the telling of a story, pantomime has occurred in all primitive cultures, as in war dances, in animal mimicry, and in sacrificial rites. The stylized artificialities in Restoration comedy, the conventionalized symbolic acting of the Chinese opera or Japanese Nō drama, and the acting of comedic performers in the silent films, such as Charlie Chaplin and Buster Keaton, were in the realm of pantomime, as are any dance forms concerned with mood or story portrayals. Musical comedy and opera are pantomimic forms. Actors who speak their roles are also mimes.

In the dramatic theatre it is through mime that the player projects to the audience a visual understanding of his role and the nuances of his words. Not a literal imitator, the mime enlarges and emphasizes the character he performs, revealing his point of view of that character and all its meaning. His gestures are symbols that are a crystallization of human experience—a kind of visual code made up of gestures, smiles, glances, reactions to reflective thought, along with physical action the meanings of which are instantly understood by the audience.

ous kinds of theatre representative of mime or pantomime during the course of theatrical history.

EARLY FORMS

Scraps of manuscripts and vase paintings of Greece from *c.* 600 BC, and fragments of the latter dating back two centuries earlier, attest to the early origins of mime as a theatrical form.

Greek forms. The earliest recorded form of the mime theatre was the *phlyake,* a farcical play on a theme of real life and mythology developed in Sparta, Megara, and other nearby Dorian centres of Peloponnesus. The *phlyakes* were played by stock figures clad in tights or short chitons, grotesquely padded front and back, and most wearing an exaggerated phallus. Like the tragic actors, they wore masks with enormous open mouths that amplified their words. It is believed that most of their dialogue was improvised, although by the 5th century BC their performances may have become more professional. The Athenian playwrights, including Aristophanes, looked down on these rustic plays much as the burlesque theatre was later regarded. The Athenians did not hesitate to make use of such techniques, however, analogies being obvious in the satyr plays that closed the tragic trilogies.

Dorian mimes

The earliest and most famous writer of Dorian mime plays was Epicharmus (*c.* 530–*c.* 400 BC). From 485 to 467 he won fame as a writer of mime in Syracuse, and Aristotle seems to suggest that he was the first dramatic poet of merit to write comic plots and to give literary refinements to the earlier, rude, improvised forms of mime. The few extant fragments and records show that his plays were adaptations of classical legends of the gods and mortal heroes, and political satire and debate played a large part in them. In one episode Odysseus rehearses to himself the story he will tell his comrades on his return home, not unlike Parolles in Shakespeare's *All's Well That Ends Well.* Since the mimes were comic, it must be assumed that the heroic characters were burlesqued. The plays contained not only proverbs but many puns designed to amuse the public. The carefully structured short verse mimes of Herodas (3rd century BC), much more of whose work survived, afford a clearer picture of the form. His mimes, scenes of contemporary life rather than mythological burlesques, were nonetheless broadly comic and often ribald in theme. Theocritus (*c.* 310–250 BC), a Syracusan and the first writer of pastoral poetry, is the most literary of them all. He and Sophron (fl. *c.* 430 BC), also a Syracusan, presented more lifelike mimes, with sharp topical comments and much proverbial wisdom.

The theatre of the Dorian mime comprised much that, by imitation or by coincidence, was to be characteristic of mime and pantomime well into the modern period. It was presumably a combination of words and actions with acrobatics and some dance, and it was comedic. Such stock characters as the thievish slave, the comic doctor, and others who represented aspects of contemporary life appeared repeatedly in the mimes. This theatre had no hesitancy in employing its gods and heroes as human, comedic characters. The mimes and mountebanks of Peloponnesus performed on crude platforms in public squares or outlying fields. The stage was reached by a short flight of steps, and a backdrop often had an opening with a painted window frame surrounding it. A minimum of furniture seems to have been used—a chair or throne, an altar, or a table.

The Dorian mimes were satiric social commentators aware of the temper of their audience. Their farce contained demonic figures and witches; animal masks sometimes appeared in the many licentious dances; and jugglers and acrobats were a part of this theatre. The "literary playwrights" of Athens could not ignore the influence of the mimes: the slave Xanthias tells the audience at the opening of Aristophanes' *Wasps,* "Do not expect anything great and wonderful from us. Do not look for merriment filched from Megara. We do not have a couple of slaves here to scatter nuts from a basket among the spectators nor have we Herakles defrauded of his dinner." Other writers mention the derision of Athenian audiences for the unbecoming jests of the Megarian comedy, and it seems apparent that they considered its stock characters "low comedy."

Indeed, the mime actor was much like the later burlesque and vaudeville comedian and knew what would delight his audience—lasciviousness, sentimentality, poking fun at authority. Throughout the entire history of mime there is a link between its form and the ethics of the day. The mimes appear to have symbolized the moral and religious codes of their period in reverse, and they performed to delight the popular mind.

Mime in Rome. Dorians from Sicilian Syracuse had been of the greatest importance in the form of the Greek mime, and, like the main body of Greek tragedy and comedy, this form was readily accepted on the Italian peninsula, encouraged as well by the ability of the wordless dancer or the broadly descriptive performances of the mimes to circumvent easily all language barriers. It becomes difficult, during the several centuries of cultural mixing about the Mediterranean, to separate pure mime from the main body of Roman comedy—*e.g.,* that of Terence and Plautus—so many elements did they share

with one another and with the Greek mime. The genre that arose apparently in the Campanian town of Atella, known as the *fabula Atellana,* which was a major force on the Roman comedy, bears striking resemblances in themes, character types, costuming, and staging to the Dorian mimes, and its relation to the sophisticated *fabulae* (*fabula,* a generic word for a play) of the Roman stage was similar to that of Megara to Athens.

Mimi and pantomimi

Roman mime, in the early centuries, was bound up with crude stage performances that included improvised farcical scenes, acrobatics, juggling, and the like, acted out by persons of low social status. The companies included women as well as men, and in playing, sex roles were not uncommonly reversed. About the time of Caesar a certain literary element was introduced and mimes were written for enactment by the *mimi*; still, they remained burlesques often so licentious that adultery was encouraged on the public stage. Another similar Roman institution was that of the *pantomimi,* masked dancers who executed their stories by extraordinarily skilled gesture, posture, and rhythmic movement alone. Pylades, a *pantomimus* of tragedy, and Bathyllus, a lighter performer, won acclaim in 22 BC; both played all roles in their dumb shows by changes of masks. A large chorus and orchestra accompanied these solo dancers, and their performances and those of others not only became popular events but also were welcomed into fashionable homes and were patronized by later emperors. The *pantomimi* played on themes from mythology and history rather than the everyday scenes enacted by the *mimi.*

Both the Roman mime and pantomime, the former largely on a low order of literacy despite finer writers like Lucan (AD 39–65) and Statius (*c.* AD 45–96), were so widely favoured that they virtually drove the more noted writers from the stage. Among the causes of this popularity may have been their appeal to the Germanic invaders, who found in them a pleasure not blunted by language barriers. The theatre historian Allardyce Nicoll believes that pantomime may have assumed the form of operatic dance associated in the 20th century with the Russian ballet. Despite the defense by Lucian (*c.* AD 125–*c.* 190)—whose dithyrambic praise of dumb shows, the dialogue *De saltatione* ("Concerning Dance-Acrobatics"), had great influence on dancing masters a millennium and more later and inspired the English pantomime—and by others, these forms continued several centuries into the Christian era in an aura of popularity and disrepute. Perhaps more than any other factor, they were responsible for the church's opposition to theatre, its excommunication of *mimi* in the 5th century and closing of theatres in the 6th.

Oriental dance-dramas. In the East the art of pantomime was developed long before it achieved definite form in the Western world. In India the union of music, song, and dance with character portrayals took place many centuries before Christ. Out of such native drama, with added dialogue, grew the *bhārata-nāṭya,* one of the traditional Hindu dance-dramas, first described by the sage Bhārata (*c.* 6th century BC), on the command of the god Brahmā to introduce dramatic entertainments. The two-hour performances feature a solo dancer backed by musicians and a singer; the dancer neither leaves the stage nor changes costumes. Sections of dance alternate with pantomime, the latter using conventionalized gesture-language. Pantomimic scenes derived from the mythology of Viṣṇu (Vishnu) are still sometimes enacted by the Bengali *jātrās,* folk pageants combining words and conventionalized mime, and the *rasas,* folk dance-dramas. In the 20th century, authentic classical dancing of India was introduced in the United States by Uday Shankar to the accompaniment of Indian music played on native instruments (see SOUTH ASIAN PEOPLES, ARTS OF: *The performing arts*).

Hindu mime

In the theatre of China and Japan pantomime acquired a role unknown in the West, becoming an integral part of the major dramatic genres. The conventions of gesture and movement, as well as the symbolism of the stage properties, in Chinese drama are immense in scope and mystifying to those unfamiliar with the traditional forms. On the Japanese stage dramatic narrative is inseparable from dance and pantomimic conventions, both in the popular Kabuki form and in the more esoteric Nō theatre (see DANCE AND THEATRE, EAST ASIAN; KABUKI THEATRE; NO THEATRE).

Medieval forms. Almost all of the theatre of the Middle Ages can be likened to a kind of travelling circus. Despite the opposition of the church, which instructed bishops to have no players at their tables and frowned on men playing women's roles, the Middle Ages saw the advent at the courts of those malformed figures, the jesters, whose twin-peaked caps with bells became symbols of their profession, and who later became figures in puppet shows and Shakespearean plays both comic and tragic.

The traditions of the *mimi,* together with the many other acts of the skilled clowns, dancers, improvisers of robust scenarios, and others who entertained both the rowdy public and the courts, kept alive the rough spirit of the Roman popular theatre. In the later Middle Ages those itinerant groups spawned such institutions as that of the troubadours, who were the earliest dancing masters at the European courts, and the public entertainments that led eventually to the Italian commedia dell'arte and provided the bases for the popular comedic theatre of Elizabethan England and other countries.

Major plays of the Elizabethan repertory contain evidence of the continuing popularity of "dumb shows," as they were called. Perhaps the most famous Shakespearean example is the dumb-show murder in *Hamlet,* and the clowning of Bottom and his fellows in *A Midsummer Night's Dream* is a delightful spoof of the melodrama of these shows. Pantomime persisted, too, alongside many other theatrical ingredients in the formal masques that became fashionable in the courts of the 17th century.

COMMEDIA DELL'ARTE AND ITS DESCENDANTS

The players who by the 18th century were calling their form commedia dell'arte (*i.e.,* professional comedy), to distinguish themselves from the free-wheeling styles of the amateur mimes and pantomimes and from the actors of literary comedy, employed a style that dated at least from the mid-16th century, when the "Italian comedians," the *teatro dell'improviso,* became popular in both the streets and the courts of Europe. At first improvising around scenarios containing a few key lines and later with fuller scripts, these actors had a large repertory of conventionalized, usually comic, pantomimic movements, called *lazzi.* They sought to rid such improvisatory theatre of free-for-all playing and to establish a more orderly form in which the actors could listen more closely so they might react more properly. In his (1727) history of Italian theatre, Luigi Riccoboni remarked that "the curse of improvisation is that the skill of the good actor is at the mercy of the person with whom he is conversing." By this he meant to scourge the mime-actor who thought of himself as a solo performer. The stock characters who appeared in the situation farces of the *commedia* were widely adapted, by Shakespeare and Molière among others, outside Italy for several centuries: Arlecchino (Harlequin), with his suit of many-coloured patches; Colombina his love; Pantalone, the graybeard with red fez, doublet-and-tights, and black robe; Dottore (Doctor), often bespectacled; the picaresque Scaramuccia (Scaramouche); the flamboyant Capitano; and the *zanni,* a half-mad but clever comic servant. For a fuller discussion of this form, see the article COMMEDIA DELL'ARTE.

The descendants of the *commedia,* which lost its own creative energies late in the 18th century, are numerous, and its characters held European stage into the 20th century. Prohibitions on spoken dialogue in all but royal-patent theatres in Paris and London led to the silent comic dancing and miming of Arlequin in Parisian fairs and to the English pantomimic tradition begun by the dancing master John Weaver at Drury Lane Theatre, London, in 1702. Within 15 years Weaver and John Rich of Lincoln's Inn Fields Theatre were competing in their so-called pantomimes, which became increasingly elaborate with their popularity. Weaver's shows were dramatic ballets with

Harlequin and his fellows

several performers (a form that France knew as *ballet d'action*), whereas Rich introduced grotesque scenes of Harlequin and Columbine, often pursued relentlessly by her father, Pantaloon; neither was the art of the solo *pantomimus* of Rome save in name. Audiences came to demand such pieces before or after (or both) even serious plays: Garrick was to remark, "If you won't come to hear Lear and Hamlet, I must give you Harlequin," and he did. Gradually Harlequin, with his magic wand, was replaced in eminence by the clown, an adaptation of the *zanni*. In the 19th century the "greatest" of the clowns, Joseph Grimaldi, with his clown in *Mother Goose*, helped bring to this pantomime the wealth of folklore, a repertory that was also tapped by others for "Red Riding Hood," "Cinderella," "Blue Beard," "Aladdin," and similar tales. This tradition evolved into the Christmas pantomine, still one of the most popular of English holiday entertainments. Among its continuing conventions is the role of "principal boy," which has been played by many of England's leading comediennes.

In Germany, too, Harlequin proved a threat to "serious" drama, and in France Harlequin's course roughly paralleled that in England. The French rejected the clown, however, developing in his stead the pale-faced, moonstruck Pierrot, a figure made popular first by Jean-Gaspard Deburau and carried through six subsequent generations of his descendants. Many other managers specialized in dumb-show melodramas and acrobatic spectacles under the term "pantomime."

MODERN TRENDS

Among the most significant developments in mime and pantomime since the late 19th century have been the strong impact made by persons experimenting with theories of body movement on the art dance (ballet and so-called modern dance as distinct from popular stage dancing and acrobatics), the re-emergence of mime and pantomime as silent theatrical performances by one or more mimes (as they refer to themselves), and an increased awareness of the value of absolute bodily control by actors in all dramatic media.

Mime in modern dance

Perhaps the major characteristic of the modern dance since its emergence as a recognizable trend around 1900 is its constant search for new methods of expression and communication through movement alone. Its pioneer theorists, including François Delsarte, Émile Jaques-Dalcroze, and Rudolf Laban, were no less theorists and experimenters with new forms and styles than were its practitioners, Isadora Duncan, Ruth St. Denis, Mary Wigman, Martha Graham, Doris Humphrey, Katherine Dunham, Merce Cunningham, Alvin Ailey, and Alwin Nikolais. Ballet, which had reached a nadir around the turn of the century, was itself given fresh artistic vigour in good part through its interactions with this new dance and through the influences of choreographers like George Balanchine and Jerome Robbins, who were willing to borrow or could move easily between the two forms. For more detailed information on this movement in dance, see the article MODERN DANCE.

In a constant teaching-learning relation with the modern dancers were others whose interest lay not only in dance but in pure mime as well. The theories and teachings of Étienne Decroux (1898–), a student of Dalcroze in Paris, were brought to the U.S. by Alvin Epstein. The leading figure in American mime was Angna Enters, who had studied with another Dalcroze pupil, Itō Michio, but had pursued her own belief in an eclectic approach: that each performer must evolve his own mode of expression, be it realistic and mimetically descriptive or totally abstract. In France, important work, in addition to that of Decroux, was done by Jean-Louis Barrault and by Marcel Marceau, who invented the white-faced character Bip, for whom he became famous. Bip is his translation into his own individual style of pantomime of the classic Pierrot of the commedia dell'arte. Marceau defines his work as the art of expressing feelings by attitudes and expressing words through gestures. Pierrot has been a subject for pantomimists ever since his invention, appearing in many versions. Deburau was noted for his pale-faced version, and Charlie Chaplin's little man is another classic example. The Russian play *He Who Gets Slapped* (1914) by Leonid Andreyev presents another form of Pierrot as a tragic circus clown.

The art of silent but precise communication of feeling was especially visible, indeed necessary, on the motion-picture screen, particularly in the "silent era" before the advent of sound pictures in 1927. Among many film actors who made silent pantomime an aesthetic delight were Chaplin and Ben Turpin, both of whom, interestingly, combined the broad comedy and the pathos of character inherent in the centuries-old traditions of the mime and pantomime.

Mime in modern acting

The realistic drama of Ibsen, Chekhov, and Shaw that came into vogue early in the century demanded from its performers an attention to fine detail in movement to replace the broad gesture of melodrama and the bravura acting of the romantic theatre. Following the pioneer theories and training of Konstantin Stanislavsky in Russia, schools and academies of acting began to include pantomime in their curricula, using it as a means both of communication and of achieving maximum control by the actor of all parts of his body. Playwriting itself shows an awareness of the dramatic effectiveness of wordless action. Samuel Beckett's plays depend at times as much on movement prescribed by the playwright as on his dialogue, and of note is the appearance of the mime Alvin Epstein in the New York productions of Beckett's *Waiting for Godot* and *Endgame*. Indeed, the whole "theatre of the absurd" movement after World War II showed in part a rejection of a literary theatre—as in Eugène Ionesco's *The Bald Soprano* ridiculing language as a means of communication—and looked to the rougher side of theatrical tradition for its inspiration.

Many reasons may be offered for the persistence of mime and pantomime as an inherent part of theatrical action. High among the reasons, however, is the fact that these words seem to describe, whatever the forms they connote at any given place or time in history, a theatre that is easily understood and enjoyed by all classes of society, from the least to the most literate and sophisticated. They both deal with the enacting, with or without words, spoken or sung, of aspects of human behaviour that are at once universal and yet related to the manners and modes of contemporary life. The forms may be of the commonplace or vulgar, but the spirit is of the human essence that all art seeks to discover.

BIBLIOGRAPHY. Books covering mime and pantomime within a larger context of drama and dance include: A. NICOLL, *Masks, Mimes and Miracles: Studies in the Popular Theatre* (1931, reprinted 1964); W. BEARE, "The Mime," in *The Roman Stage: A Short History of Latin Drama in the Time of the Republic*, 3rd ed., ch. 18 (1965); JEAN-LOUIS BARRAULT, *The Theatre of Jean-Louis Barrault* (Eng. trans., 1961); and W. SORELL (ed.), *The Dance Has Many Faces*, 2nd ed. (1966). A more exclusive focus on the history of these forms may be found in R.J. BROADBENT, *A History of Pantomime* (1901, reprinted 1965); A.E. WILSON, *The Story of Pantomime* (1949), *King Panto: The Story of Pantomime* (1935); and A. EPSTEIN, "The Mime Theatre of Etienne Decroux," *Chrysalis*, 11:3–13 (1958). The interaction between mime and the commedia dell'arte is among the subjects covered in M. SAND, *History of the Harlequinade* (1915, reprinted 1968); C.W. BEAUMONT, *History of Harlequin* (1926, reprinted 1967); and A. NICOLL, *World of Harlequin* (1963). The nature of mime and analyses of mime and dance movements are in RUDOLF VON LABAN, *Mastery of Movement* (Eng. trans., 1950; 2nd rev. ed., 1960); A. MORGAN, *An Hour with Delsarte: A Study of Expression* (1892); E. JAQUES-DALCROZE, *Eurhythmics, Art and Education* (Eng. trans., 1930); and A. ENTERS, *On Mime* (1965).

(A.E.)

Mimicry

Mimicry is a biological phenomenon in which two or more organisms, usually biologically unrelated, or only distantly related, resemble each other closely, the resemblance itself conferring advantage upon one or both of them. The type of natural selection and the basis of the selective advantage distinguish mimicry from other types of resemblance, especially convergence. In mimicry the

animate agent of selection (*e.g.*, a predator, a symbiont, the host of a parasite, depending on the type of mimicry encountered) interacts directly with at least two of the similar forms and is deceived by their similarity. The participants in the mimicry situation, therefore, normally must occupy the same geographical area. A convergent resemblance, on the other hand, results from the action of similar forces of natural selection (*e.g.*, temperature, food habits, predation) on unrelated organisms, which may be geographically or temporally isolated from each other.

In the most studied mimetic relationships the advantage is one-sided, one species (the mimic) gaining advantage from a resemblance to the other (the model). Since the discovery of mimicry in butterflies in the mid-19th century, a great many plants and animals have been found to be mimetic. In many cases the organisms involved belong to the same class, order, or even family, but numerous instances are known of plants mimicking animals and of animals mimicking plants. Although the best known examples of mimicry involve similarity of appearance, investigations have disclosed fascinating cases in which the resemblance involves sound, smell, light production (bioluminescence), behaviour, and even biochemistry.

A key element in virtually every mimetic situation is deception by the mimic, perpetrated upon a third party (sometimes called the receiver), which mistakes the mimic for the model. This third party, which exerts the selective pressure that makes mimicry advantageous, may be the collective potential predators upon the mimic, potential prey animals of a predacious mimic, or even one sex of the mimic's own species. In some cases, such as host mimicry by parasites, the organism deceived is the model.

Definition of mimicry

Because of the variety of situations in which mimicry occurs, a formal definition must rest upon the effect of certain key communicative signals upon the appropriate receiver and the resultant evolutionary effect upon the emitters of the signals. Mimicry may be defined as a situation in which virtually identical signals, emitted by two different organisms, have in common at least one receiver that reacts in the same manner to both signals because it is advantageous to react in that manner to one of them (that of the model), although it may be disadvantageous to react thus to the other.

The distinction between camouflage and mimicry is not always clear when only the model and the mimic are at hand. When the signal receiver is known and its reactions understood, however, the distinction is quite clear: in mimicry the signals have a special significance for the receiver, hence also for the sender, which has evolved the signals in order to be perceived by the receiver; in camouflage the sender seeks to avoid detection by the receiver through the imitation of the background or substrate or of a particular element of the environment. For further information on camouflage, see COLORATION, BIOLOGICAL.

BASIC TYPES OF MIMICRY

Batesian mimicry. In 1862 the English naturalist Henry W. Bates published an explanation for unexpected similarities in appearance between certain Brazilian forest butterflies of two distinct families. Members of one family, the Heliconiidae, are unpalatable to birds and are conspicuously coloured; members of the other family, the Pieridae, are edible to predators. Bates concluded that the conspicuous coloration of the inedible species must serve as a warning for predators that had learned of their inedibility through experience. The deceptively similar colour patterns of the edible species would provide protection from the same predators. This form of mimicry, in which a defenseless organism bears a close resemblance to a noxious and conspicuous one, is called Batesian, in honour of its discoverer.

Müllerian mimicry. Bates observed, but could not explain, a resemblance among several unrelated butterflies, all of which were known to be inedible. There seemed to be no reason for these species, each of which had an ample defense with which to back up the warning coloration, to be similar. In 1878 a German zoologist, Fritz Müller, suggested that an explanation for this so-called Bates' paradox might lie in the advantage to one inedible species in having a predator learn from another. Once the predator has learned to avoid the particular colour pattern with which it had its initial contact, it would then avoid all other similarly patterned species, edible and inedible. The initial learning experience of the predator often results in death or damage to the inedible individual that provided the lesson; there is thus some cost to the species that teaches the predator of its inedibility. Evidence indicates that there is little or no inherited recognition by predators; each individual learns of noxious or inedible species by sampling them. Other inedible species resembling the first, however, do not have to sacrifice individuals to teach this same predator, and the number of individuals sacrificed in educating the entire predator population is spread over all of the species sharing the same warning pattern. The tendency of inedible or noxious species to resemble each other is called Müllerian mimicry.

The value of similarity between models

Aggressive mimicry. In some situations, it is of advantage to a predator to resemble its prey, or a parasite its host. Aggressive mimicry, for which the phrase a wolf in sheep's clothing is an apt description, does not involve warning mechanisms. The mimic adopts certain of the recognition marks of its model, in order to secure advantage over the model itself or over a third species that interacts with the model. The model may be only a single stage of the life cycle, as in the case of parasitic cuckoos, the eggs of which resemble those of their hosts (see below *The occurrence of mimicry among plants and animals*), or it may be a prey of the mimic's victim, as in the case of angler fishes, which possess wormlike lures that bring other fishes within reach.

Automimicry. The phenomenon of automimicry involves the advantage gained by some members of a species from its resemblance to others of the same species. Males of many bees and wasps, although defenseless, are protected from predators by their resemblance to females that are equipped with stingers. Some butterflies are able to gain protection against predators through the ability to absorb, tolerate, and retain in the immature (larval) stage, poisons from the plants on which they feed. Individuals or even whole populations of such butterflies may fail to acquire such protection, as a result of feeding on nonpoisonous plants, but they are avoided by predators that have sampled protected individuals of the same species.

Other forms of mimicry. Many forms of mimicry do not fit neatly into any of the above categories. The roles of mimic, model, and receiver may be juxtaposed and multiplied to provide intricate and remarkable relationships, the unravelling of which may take years of study. One such case, studied in detail by a German zoologist, Robert Mertens, involves several species of poisonous and nonpoisonous South American snakes. The coral snakes (*Micrurus*), long recognized as dangerously poisonous, possess a brilliant red, black, and yellow ringed pattern generally believed to serve as warning coloration. Nearly identical colour patterns are found in several genera of nonpoisonous and mildly poisonous snakes, usually called false coral snakes or coral mimics. It was long assumed that the false coral snakes gained protection from their resemblance to the virulently poisonous ones, but Mertens has pointed out that the predator that samples a true coral snake will probably not survive to act as a selective force on the less dangerous species. It is quite likely that the role of receiver in this mimicry situation is played by the predator that has survived a painful but educational encounter with the moderately poisonous forms and therefore avoids both the highly poisonous true coral snakes and the nonpoisonous false corals. This form of mimicry, in which a mimic is more strongly protected than the model, has been called Mertensian mimicry.

Coral snake mimicry

WARNING SYSTEMS

The chemical basis for repulsion. Many plants are characterized by the production of unusually large num-

The origin of repellant chemicals

bers of metabolic waste products, often called secondary metabolites, that do not play a part in growth. Because plants do not have the excretory systems that would make it possible to eliminate such substances entirely, secondary metabolites—complex chemicals that include alkaloids, terpenes, phenylpropanes, resins, lignins, saponins, flavonols, and anthocyanins—are stored in the plant tissues. Many such substances are also found in animals that feed upon such plants, usually as a result of the inability of the animal's excretory system to get rid of the plant substances. Many animals produce substances similar to the plant secondary metabolites and store them in glandular pockets (*e.g.*, as in toads, salamanders, and some insects) or in musk glands (beaver, muskrat). Arthropods, particularly insects, are notable for the production of excretory substances that serve as means of defense. Millipedes of the family Glomeridae, for example, secrete a bitter substance (a quinazoline) that repels birds; similar substances, differing only slightly in molecular structure, are found in palms. The fact that a certain chemical substance is restricted to a specific function, such as sex attraction, does not necessarily mean that it was evolved from scratch for that purpose. It seems rather that natural selection follows the easiest course and makes use of substances already present, and sometimes widely distributed. If so, the appearance of such substances in other organisms is not too surprising.

Cardiac glycosides in milkweeds

Among the chemical compounds that protect certain plants from insects or other animals that might feed on them are the cardenolides, or cardiac glycosides. These substances have a highly specific toxic effect on the vertebrate heart and also activate the nerve centre in the brain that causes vomiting. Because the amount necessary to cause vomiting is about half the amount necessary to cause death through heart failure, an animal that samples a plant containing cardenolides is not killed but survives with the knowledge that the plant is inedible. Certain milkweeds (*Asclepias*) that contain cardenolides are the primary food of the larvae of danaine butterflies, including the familiar monarch and queen butterflies (*Danaus plexippus* and *D. gilippus*). The larvae consume the poison without ill effects and retain it through the pupal stage to adulthood. As adult butterflies, they enjoy protection from vertebrate predators.

There is, of course, no such thing as complete protection. Just as danaine larvae are able to eat the protected milkweeds, some predators are able to prey upon the protected butterflies. Birds of the Old World bee-eater family (Meropidae) specialize on bees, which are protected by their stings from many predators. Bee-eaters and a few other birds are able to eat bees because the horny beak protects them from being stung while the insect is being killed and because they have evolved behavioral mechanisms for removing the stinger (usually by wiping the insect on a perch) before swallowing the prey. Rabbits are able to eat the extremely poisonous mushrooms of the genus *Amanita* without ill effects. The larvae of the Florida feather moth (*Trichoptilus parvulus*) consume the insect-trapping glands on the leaves of the sundew (*Drosera*).

The evolution of warning systems. *The selective advantage of warning.* When an organism possesses a mechanism that provides protection from predators, there is a further advantage in preventing the potential predator from even sampling the protected organism. By the act of learning of the danger, the predator may well kill or maim the individual if, for instance, the protected species must be tasted for its inedibility to become known. Many protected insects are provided with tougher skins than their unprotected relatives, but the sampling by a vertebrate predator is almost sure to do some damage. Many noxious organisms have evolved warning (aposematic) mechanisms that serve to identify them clearly to a predator who has had prior experience with the same or similar species.

The value of not being tested

Warning systems often rely primarily on bright colours, but these may be supplemented by olfactory, acoustic, or behavioral means. The New World skunks, for example, have a prominent black and white pattern that renders them clearly recognizable to potential nocturnal predators. When threatened, skunks perform a highly stylized display dance, thus ensuring that the predator will see and recognize the warning coloration.

Acoustic warning signals are often favoured over visual ones because they allow the animal the option of remaining hidden. The rattlesnakes (*Crotalus* and relatives), which need protective coloration to avoid alerting their prey, are able to provide acoustic warning to large animals that threaten them. Many moths of the families Arctiidae and Ctenuchidae are bad tasting, but would be vulnerable to nocturnal predation by bats were it not for the emission of series of high-pitched clicks, audible to bats, made when the moths hear the bats' own ultrasonic navigational pulses. That the moth clicks actually do serve as warnings is borne out by the fact that captive bats ignore thrown mealworms (which they normally relish) when the mealworms are accompanied by recorded moth clicks. Several species of edible moths also produce clicks and may be regarded as Batesian mimics of the unpalatable species.

The role of the receiver. In some cases, the animal who serves as the receiver of the warning signal reacts by means of an innate system that exists independently of experience. Generally, however, a predator must learn the significance of the warning signal through experience. If the predator is a slow learner, or if the warning signal is not sufficiently distinct to avoid confusion with beneficial sensory impressions that the predator receives, several experiences may be necessary. Natural selection, therefore, will favour warning systems that are devoid of ambiguity. Experimentation has shown that certain birds and mammals, at least, are capable of acquiring and retaining knowledge of some aposematic mechanisms from a single experience.

Combination of warning systems with concealing coloration. It is of obvious advantage for an aposematic organism to be able to control the display of the warning system, partly to minimize the amount of sampling, with its concomitant liability of injury, by naïve receivers. Acoustic and chemical warning systems allow this. Many protected animals are coloured to match their backgrounds but provided with flash areas of warning coloration. Examples of these organisms are the tiger moths (certain of the Arctiidae), in which the hind wings are yellow or orange but are kept under the streaked brown fore wings until the moth is molested.

THE OCCURRENCE OF MIMICRY AMONG PLANTS AND ANIMALS

Batesian mimicry. The stinging Hymenoptera (particularly the bees, wasps, and hornets), well protected from most predators and usually equipped with conspicuous warning coloration, are mimicked by insects of many other orders. Ladybird beetles (Coccinellidae) and leaf beetles (Chrysomelidae) are inedible and are provided with prominent colours and usually with contrasting spots. A whole group of Philippine roaches of the genus *Prosoplecta* mimics these beetles, having undergone profound modification in accomplishing the similarity. To simulate the short, rounded form of the ladybirds, the large hind wings of the roaches are rolled and folded in a manner unparalleled in other insects.

Mimicry in the swallowtail butterfly

The order Lepidoptera abounds with Batesian mimics, the best known of which is a swallowtail butterfly, *Papilio dardanus*, a widespread African species. In many populations of this species the females are polymorphic; *i.e.*, a number of different types (morphs) of coloration are found, with each morph a mimic of a species of inedible butterfly of another genus (either *Danaus* or *Amauris*). In all populations, the males are nonmimetic, retaining the same yellow and black pattern throughout. The presence of polymorphism, coupled with the ability of the lepidopterist to breed and rear this species in the laboratory, makes this an apt species for the study of colour inheritance. Investigators have found that mimicry in *Papilio dardanus* depends upon the action of certain primary genes, the expression of which is switched on or off by modifier genes. The modifier genes reduce the number

of possible morphs to the restricted number of mimetic forms. The effects of modifier genes are not carried to the offspring when members of different geographical races are crossed. This finding suggests that each set of modifier genes is adapted to the gene complex in which it normally occurs and in which it probably evolved.

Müllerian mimicry. Müllerian mimicry often occurs in groups of unrelated species, all noxious or inedible and all possessing the same conspicuous warning coloration. Such groups, called mimicry rings, often have associated Batesian mimics. It is not always easy to evaluate the palatability of members of such rings, and thus to distinguish Müllerian from Batesian mimics. Parallel Müllerian mimicry rings are known from South Africa, Borneo, and the tropical Americas; each contains such unrelated insects as malacodermoid and longicorn beetles, butterflies, true bugs, and spider wasps. In South America inedible butterflies of many distinct nymphalid subfamilies (Danainae, Ithomiinae, Acraeinae, and Heliconiinae) share the same warning coloration. Certain species show a highly perplexing divergence from the usual mimicry principles, however. It is axiomatic that maximum protection is gained by Müllerian mimics when all individuals employ the same signal, a principle known as signal standardization. Two species of *Heliconius* (*H. melpomene* and *H. erato*) are polymorphic, however, with each morph in one species duplicated by one in the other and with the morphs of each pair having virtually contiguous geographical ranges. The Müllerian principle appears to be working here between species but not within them.

Mimicry rings

Aggressive mimicry. Examples of aggressive mimicry are abundant and varied; each has its own particular ramifications of basic mimicry principles. The examples cited below illustrate a few of the remarkable extremes in the evolution of mimicry.

Parasitic worms. The flukes (Trematoda) are a class of parasitic worms belonging to the phylum Platyhelminthes. One species, *Leucochloridium macrostomum*, resides principally in the intestine of songbirds. The eggs of the parasite pass to the outside in the feces of the birds, and are readily ingested by a terrestrial snail, *Succinea*, an inhabitant of waterlogged meadows and riverbanks. The parasite eggs hatch into the first larval form within the snail. The next stage, called the sporocyst, is strikingly green in colour and bears yellow-brown rings. The sporocyst develops in the snail tissues and carries several sacs of "spores," one of which is placed into each of the snail's tentacles, or eyestalks. The sac then begins to pulsate violently, at about 40 to 70 beats per minute. The tentacle of the snail becomes greatly enlarged and eventually is transformed into a transparent covering over the pulsating sporocyst. *Succinea* usually avoids light, but specimens with this parasite do not. When the snail appears with its conspicuous, pulsing eyestalks, birds mistake the eyestalks for insect larvae, bite them off, and eat them. Within the bird, the sporocyst then hatches into the final larval stage, which grows into an adult worm. In the meantime the snail's eyestalk regenerates, and the cycle is repeated when another sac passes into the new eyestalks. Because the sporocysts of other trematodes are neither brightly coloured nor mobile, it can be concluded that the colour and pulsation of *Leucochloridium* are adaptations for arousing the interest of the insectivorous birds. Under normal circumstances the host birds do not eat snails, so the sporocyst must imitate the bird's proper food, in order to be eaten and to complete its life cycle in the bird host. The process represents an unusual case of aggressive mimicry, for the sporocyst within the snail eyestalk deceives the bird into infecting itself with the parasite.

Alteration of the snail host

Another trematode, *Cercaria mirabilis*, is notable in that a different larvae form, called a cercaria, is particularly large. The appearance of this cercaria and its hopping mode of locomotion cause it to resemble a small, swimming crustacean or mosquito larva, with the result that fish mistake it for food and swallow it. Research on parasites of this kind is much easier when it is recognized that the larval stages often mimic the food of their respective hosts. Examination of the parasite often provides a suggestion as to the probable host.

Insect-luring plants. Newly hatched flesh flies (*Sarcophaga*), blow flies (*Calliphora*) and greenbottle flies (*Lucilia*) are attracted to glistening droplets or imitations of droplets. The grass of parnassus (*Parnassia palustris*) has flowers with five nectar petals, which bear glistening buttons, but no nectar. They attract flies, nevertheless, and reward them with nectar in two depressions on the upper surfaces of the petals. The insectivorous sundew (*Drosera*), on the other hand, presents a deceptive lure, consisting of glistening secretory droplets on the glandular leaves, which trap insects that are then dissolved with digestive juices. The pitcher plants (*Nepenthes, Darlingtonia, Sarracenia, Cephalotus*) have jug-like leaves, which may bear flowerlike markings near their openings. Some have a flap or hood that enhances the resemblance to a flower and prevents filling with rainwater. One form, *Nepenthes*, secretes nectar at the lip of the pitcher. A foraging insect landing on this apparent flower slips on the edge and falls in. A band of gland cells below the slippery region secretes an enzyme that digests protein. The lower part of the pitcher contains a watery mixture containing digestive fluid and insect remains.

Pitcher plants

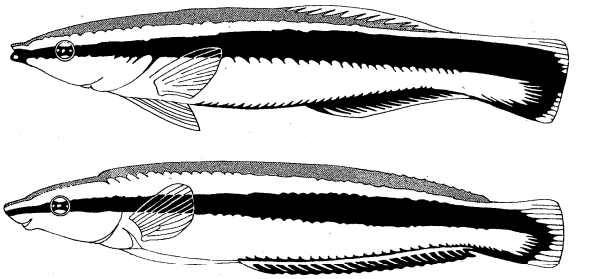

Figure 1: Differences and similarities between (top) the cleaner wrasse (*Labroides dimidiatus*) and (bottom) its mimic, the sabre-toothed blenny (*Aspidontus taeniatus*).

The cleaner mimic. One of the few cases of mimicry reported among vertebrates is that of a so-called cleaner fish. This example involves a particularly close imitation of a model involving shape, coloration, and behaviour. The model, a wrasse *Labroides dimidiatus*, of the Indo-Pacific Ocean, is known as a cleaner fish because it removes and eats externally attached parasites and, occasionally, damaged skin fragments from other marine fish. It occupies specific sites, or territories, on coral reefs, where, within a six-hour period, the individual cleaner may be visited by up to 300 other fish seeking its services. The other fish are attracted by the conspicuous black and white coloration of the cleaner and by its dancelike swimming pattern, in which the tail fin is spread and the posterior part of the fish oscillates up and down. The fish undergoing cleaning acts as though it were in a trance, while the cleaner fish cleans its body, including the inside of the mouth and gills. Even large predatory fish allow themselves to be cleaned, and the much smaller cleaner almost invariably emerges uninjured from their throats. It is quite apparent that the cleaners are protected from these predators although neither inedible nor capable of self-defense.

At the cleaning stations of the cleaner fish, there is often found quite another fish, the sabre-toothed blenny, *Aspidontus taeniatus*. It is similar to the cleaner fish in size, coloration, and swimming behaviour, and it even exhibits the same dance as the cleaner. Fish that have had experience with the cleaner position themselves unsuspectingly in front of this mimic, which approaches carefully and bites off a semicircular piece of fin from the victim and eats it. After having been repeatedly bitten in this way, fish become distrustful even toward genuine cleaners. Observations in the wild indicate that younger fish are the principal victims of the mimic, whereas older fish avoid it whenever possible. It is unlikely that the ability to discriminate between the mimic and the model develops automatically with age and is independent of experience; and this is borne out by the finding that adult fish kept in an aquarium and not previously exposed to the mimic

Mimicry by the sabre-toothed blenny

confuse cleaner and mimic just as younger fish do. If such adult fish are kept with the mimics for a certain length of time, however, they eventually avoid these and the genuine cleaners. The obvious conclusion from these experiments is that other fish cannot distinguish between the model and the mimic without having had experience with both. Evidently victims of the mimic seek out and learn characteristics that enable them to distinguish between reliable and unreliable cleaners—that is, between the model and mimic, respectively. The most successful individuals among the mimics, therefore, are those that most confuse their victims. As a result, the further development of the mimic is steered in the direction determined by the characteristics of the cleaner; for example, the model occurs as a number of local races within its area of distribution, each of which shows its own peculiarities in coloration, such as a small or large black vertical stripe at the base of the pectoral fins or an orange-red spot on the flanks. In every case, the local population of the mimic shows the same special coloration as does the model in that particular area.

One of the interesting and highly unusual aspects of the cleaner-mimic relationship is that the individual characters of the mimicry pattern, especially the behavioral ones, have been traced to their origins. Certain chance similarities include body size and shape, as well as swimming pattern. The drive in the mimic to approach other fish, for example, is a specialization of a more general pattern, observable in nonmimicking relatives of the blenny, involving searching for food on suitable surfaces. The basic colour pattern of light and dark horizontal stripes is characteristic of fish that swim in open water, but the actual coloration of the mimicking blenny has been selected for closer resemblance to the cleaner wrasse. Interestingly enough, the blenny alters its coloration with its motivational state and adopts the appearance of the cleaner only under the specific conditions of self-confidence and intent to attack. As a group, blennies tend to wriggle while swimming, to counteract a strong tendency to sink at the tail. The sabre-toothed blenny, however, when confronted with danger holds the body stiffly without wriggling, allowing the hindquarters to sink somewhat, and advances solely by the use of the pectoral fins, in the manner common to wrasses. Superimposed on this motion is a nodding of the blenny's head, typical of approach-retreat conflict behaviour in blennies, but resulting in a stimulation of the swaying dance of the cleaner. The combination of coloration and behavioral signals has a particular significance for the experienced visitor to the cleaner's station, and causes it to adopt the posture that invites cleaning. In so doing, the visitor gives the mimic an opportunity to take a bite from a fin.

Fireflies. A form of aggressive mimicry that relies entirely on behaviour occurs in certain North American fireflies (Lampyridae). Males of these familiar night-flying beetles emit light bursts in flight according to highly specific patterns. The females, usually stationary, respond to the flash patterns of males of their own species with specific patterns of their own. The flying male responds to the appropriate female signal by approaching, landing, and courting. Most adult fireflies are short-lived and do not feed at all, but females of the genus *Photuris* have been found to feed on other beetles, including males of the genus *Photinus.* Upon perceiving a flashing male *Photinus,* the female *Photuris* responds with a flash that mimics the female *Photinus.* As the male *Photinus* approaches, the female *Photuris* even reduces the intensity of her flashes, to resemble more closely the weaker signals of the smaller female *Photinus.* The hapless male, after landing, is seized and eaten by the *Photuris.* In response to males of her own species, of course, the female *Photuris* gives a flash response quite different from that of *Photinus.*

Host mimicry by parasites. Another form of mimicry, sometimes considered an extension of aggressive mimicry, is mimicry of a host by its parasite. Most of the best known examples occur among birds and represent some of the few known instances of mimicry in that class of animals.

Cuckoos. The European cuckoo (*Cuculus canorus*) is a brood parasite—*i.e.,* it lays its eggs in the nests of other birds, which act as foster parents for the young cuckoos. The most frequent foster parents are various species of small songbirds. Although the eggs of the various host species span a great range of colours and spotting, there is a striking correspondence in appearance between the eggs of the cuckoo and those of the host. A female cuckoo normally deposits only one egg in each host nest and removes one of the hosts' eggs, leaving the same number of eggs as were previously there. Most small birds react unfavourably if they perceive a foreign egg in the nest and either abandon the nest, build another nest right over the first, or eject the strange egg. It is known that each female cuckoo consistently lays eggs of one colour pattern and must therefore parasitize only a few host species. Some cuckoos do lay in the nests of the wrong hosts occasionally, because of inability to find the correct nest, and most of such eggs are probably removed by the hosts, providing strong selection tending to eliminate the defects. One survey has shown that of 1,642 cuckoo eggs laid in the nests of the correct (matching) hosts, only 8 percent were lost, whereas of 298 in the nests of the wrong hosts, 24 percent were lost. It is logical to conclude, therefore, that a cuckoo that lays its egg randomly, leaving the survival of the eggs to chance, would produce fewer offspring than one that selects hosts whose eggs match her own. Although the control of egg coloration is probably genetically determined, the choice of correct hosts is believed to be the result of a learning process that takes place when the female cuckoo is a nestling and learns to recognize its own foster parents.

Egg matching by cuckoos

Parasitic weaverbirds. Brood parasitism is also found in African whydahs, or widow birds, the subfamily Viduinae of the weaverbird family, Ploceidae. Each species of whydah parasitizes a single species of estrildid finch (Estrildidae). In this case, egg colour does not seem to be a factor in acceptance of the parasite's egg, because both groups have pure white eggs. It has been argued that the whydah, many relatives of which have spotted eggs, have evolved white eggs to match those of their estrildid hosts. More significant, however, is the highly specific pattern of spots and protuberances at the corners of the mouth (gape) and on the palate, tongue, and lower mandible of the nestling. This pattern, which varies from one species of finch to another, serves as a releaser for feeding behaviour on the part of the parents, which ignore any nestling that does not display the proper pattern for the particular

Mimicry of mouth patterns

species. In every species of parasitic weaver studied, the nestling has been found to match perfectly the mouth pattern of the estrildid host. In addition to mimicking the mouth patterns of their hosts, whydah nestlings also duplicate the specific begging calls and peculiar head movements of their hosts. The coloration of the juvenile plumage of the young whydah is identical to that of the host species, ensuring that the whydah will be fed after fledging. The digestive system of the young whydah is closely adapted to the particular type of food utilized by its host species, unlike that of the young cuckoo, which seems to be able to accept a variety of foods, from insects to mouse meat.

With each species of parasitic weaver closely committed to a single species of estrildid finch, it is obviously important that whydah species not hybridize, for the hybrid offspring would certainly not match either possible host in all of the important features. It is surprising to find seven forms of the paradise whydah (*Steganura*) so similar in appearance that they were once considered races of one species. Each of the seven, however, has its own estrildid host species, indicating that seven species of paradise whydah are represented. As is frequently the case with closely similar bird species, hybridization is effectively prevented through the use of species-specific vocalizations by the males. An unusual feature of this situation is that each widow bird species uses the same vocal pattern as its estrildine host. The young parasitic weavers apparently learn the songs of their host species during the critical learning period common to songbirds generally. As adults, the male whydahs use these estrildid vocalizations and gain response only from females that have been reared by the same foster species. This example is the only known one of a species-isolating mechanism consisting of vocalizations learned from another species.

Mimicry to effect pollination and dispersal. In some instances, plants have been found to rely on mimicry to attract insects as aids in pollination or in the dissemination of seeds or spores.

Orchids. Many flowering plants lure insects through the use of bright colours that indicate the presence of nectar. Some orchids mimic other flowering plants without offering any nectar, relying on those that do provide nectar to reward the nectar seekers.

Flowers resembling female insects

A group of orchids, often known by descriptive names such as fly orchid, bee orchid, and spider orchid, carry the deception further, actually mimicking the insects themselves. The best known orchids of this type are members of the genus *Ophrys*, the flowers of which have interested man for centuries. The labellum of the *Ophrys* flower is a specialized median petal that acts as a dummy female of a species of bee or wasp (depending on the species of *Ophrys*), the resemblance being so close that males visit the flower in an attempt to copulate with the dummy female. In the course of precopulatory and copulatory movements, the visiting insect acquires the pollen sacs (pollinia) of the orchid and subsequently transmits them to other blossoms. A similar situation occurs in an Australian orchid, *Cryptostylis leptochila*, which bears a sufficient resemblance to the female of the ichneumon wasp *Lissopimpla semipunctata* to induce copulation by the male wasp.

An important feature in the mimicry of female insects by orchids is flower size. Too small flowers do not provide adequate stimulus for the copulatory attempts necessary to plant the pollinia on the insect. If the flower is too large for the insect, the insect's head does not reach the stigma of the flower (the female receptor site for pollen), and the pollinia are not deposited.

The colour of the labellum is also important in attracting and properly orienting the male insect. The males are more attracted to dark than to light colours and to a contrasting dark spot on a light background. A velvety surface is a more effective attractant than a shiny one. The centre of the labellum of *Ophrys insectifera* bears a dark red spot, almost black, whereas the lateral lobes of the labellum are a somewhat lighter purple-red. Female wasps of the genus *Gorytes*, males of which are highly attentive to this orchid, are black dorsally with dark purple wings. Where the folded wings overlap over the female's body, there is a glistening area closely resembling the shiny central spot on the flower. The overall effect is further enhanced by movements of the flower in the wind.

Odour plays a particularly strong role in attracting male insects to the mimicking orchids. Some female Hymenoptera secrete odoriferous substances (pheromones) that initiate search behaviour in the males and guide them to the stationary females. Such attractant chemicals are usually limited in effectiveness to the producing species or a few close relatives. *Ophrys* flowers give off odours similar to, if not identical with, those produced by females of their associated insects. In a few cases the odour of the flower is a more potent attractant for the male than that of the appropriate female; the orchid not only mimics the sex attractant, but improves upon it.

Carrion flowers, stinkhorn mushrooms, and mosses. A group of flowers are able to attract dung beetles (certain of the Scarabaeidae) and carrion flies (Calliphoridae) by mimicking the odours of dung or rotting flesh used by these insects as guides to sites for egg deposition. The deception is so complete in some carrion flowers (*e.g.*, *Stapelia*) that blow flies actually lay their eggs in the flowers. The cuckoopint (*Arum maculatum*), by a metabolic level unequalled among plants, spreads its odour over a wide area by an elevation of temperature that increases the vaporization rate of the volatile odour substance. An elaborate mechanism in the cuckoopint ensures that a pollen-laden visitor remains long enough to deposit the pollen. The sheath of the floral structure, upon which the insect lands, is made slippery by oil droplets with the result that the insect slides down into a cup equipped with a ring of spines to prevent escape. In trying to climb out, the insect deposits pollen on the tiny female flowers, from which the insect receives nectar. During the night, the male flowers mature and cover the resting insect with pollen. Then the spines shrink, and the insect is released. The production of the attractant odour occurs at midday, when many carrion-seeking insects are active, on the day before the male flowers mature; the timing of odour production is controlled by a substance produced by the male flowers six to 18 hours before maturity.

The insect trap of the cuckoopint

A similar situation is found in stinkhorn mushrooms of the genus *Phallus*, found in woodlands and meadows of the Northern Hemisphere. The cap of the young stinkhorn is covered with a thick, greenish-black, shiny layer of gelatinous spore slime (gleba), which is eaten by blowflies and other insects attracted by the carrion-like odour. The spores pass through the digestive tracts of the insects and are voided with the feces, thus ensuring the dispersal of the mushroom.

Some mosses (*e.g.*, some members of the genus *Splanchnum*) have flowerlike structures that attract flies to aid in spore dispersal. Insects are attracted by the mimic of a nectar-bearing true flower and by a carrion-like odour.

Mimicry within species. The three essential participants in mimicry, model, mimic, and receiver, need not always be members of different species. In mimicry of the host by a parasite, for instance, the host species provides both model and receiver. In another type of mimicry the mimic and receiver are members of the same species. An example of this type is found in the small South American characoid fish *Corynopoma riisei*, in which the gill cover of the male is elongated into a thin whitish stalk that terminates in a small blackish plate. During courtship, the male raises the stalk and waves it jerkily in view of the female, who mistakes the tip for an edible object, such as a tiny crustacean. As she nears the male in her attempts to grasp this supposed prey, mating takes place.

Egg mimicry in cichlid fishes

Another remarkable form of mimicry within the same species occurs in the African mouthbrooding cichlid fish of the genus *Haplochromis*. The female takes the eggs into her mouth immediately after they are laid, even before the male can fertilize them. The male, however, carries conspicuous yellow or orange spots near the base of the anal fin, which closely resemble the eggs of the particular species. Although the female is inhibited from eating while carrying eggs, she is strongly motivated to

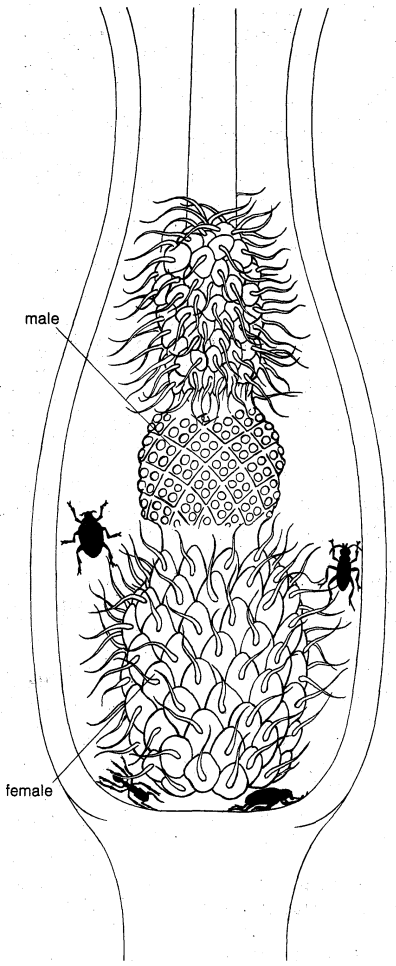

Figure 3: Flowers of the cuckoopint (*Arum maculatum*). The odour emitted by the flowers attracts insects that deposit pollen (see text).
From W. Wickler, *Mimicry in Plants and Animals* (© 1968); used by permission of McGraw-Hill Book Co., Inc.

pick up loose eggs in her mouth. The male displays the fin spots to the female while releasing sperm; the female, as she attempts to pick up the false eggs, takes in sperm that fertilize the eggs in her mouth. In this case the model (real eggs), mimic (false eggs), and receiver (adult female) are all of the same species.

THE EVOLUTION OF MIMICRY

The effectiveness of warning systems. There is considerable experimental evidence to illustrate how effectively predators learn to avoid certain adverse stimuli. Chickens conditioned by electric shock to avoid drinking dark-green water drank progressively more from paler solutions in proportion to the intensity of the colour. This experiment suggests that even an incomplete warning system provides a modicum of protection. The degree of protection provided is also affected by the strength of the punishment; after strong shocks the chickens drank only from very light coloured solutions. In the presence of severe punishment, an improved warning system made little additional effect once a threshold level was reached.

In other experiments, starlings (*Sturnus vulgaris*) were fed normal meal worms, two segments of which had been painted orange. To provide aposematic "models" the experimenter made other meal worms distasteful and painted the same segments green. "Mimics" were marked with green but not rendered unpalatable. There is no known instance in nature in which animals employ green for warning; there was therefore no possibility that the birds had already learned to avoid the experimental colour pattern. Before long the green marked worms were completely avoided, regardless of palatability, even when the ratio of edible to distasteful was 60:40. This indicates that the number of mimics can exceed that of the model, when the resemblance is close, without loss of protection. When the ratio was increased to 90:10, 17 percent of the mimics were avoided, probably sufficient to a selective advantage in nature. Although a test bird would occasionally peck at a model, then reject it, the same action was sometimes shown to a mimic that it had picked up, suggesting that a premature response had been altered by subsequent consideration.

The reconstruction of evolutionary pathways. Analysis and understanding of a given mimicry system require a rather comprehensive knowledge of morphology, behaviour, ecology, and mutual relationships of animals usually in different classes—for example, wasps (Hymenoptera), flies (Diptera), insect-eating amphibians, reptiles, birds, and small mammals. Tracing the evolution of such a complicated system requires a detailed acquaintance with a large group of forms related to each of the animals involved. Such data, in fact, are seldom available.

Reconstructing the evolution of a case of mimicry within the same species, however, is relatively simple, requiring detailed knowledge of but one rather narrow taxonomic unit. Such a reconstruction is valuable, because mimicry is an indispensable tool in the study of the evolution of animal communication, and usually starts from conspicuously elaborated signals, which postulate a signal receiver interested in them. The receiver practically always has undergone a special molding toward optimal receiving of the signal. The mutual adaptations of the sender and the receiver must be examined separately. This examination is easily made, so far as the evolution of a reaction or of a receiving mechanism is concerned, in all predators trying to find their prey and in all prey animals attemping to escape an approaching predator. The suppression of signals may be studied in predators trying to sneak up on a prey unnoticed. The elaboration of a signal, which must, of course, be important to the receiver, can only be studied after consideration of compensatory adaptations in the receiver and in situations where the sender has a one-sided interest in the signal. The deceiving signal can be derived only from one of two types: a signal developed by the receiver and another signal sender in their common interest or a signal emitted by another signal sender and only made use of by the receiver in its own interest. Both cases, by the definition given above, are called mimicry. An additional advantage is that the model is known to be the final stage toward which the mimic will evolve (so far as the signal characters are concerned), thus indicating a trend in evolution that is still operating and that probably will further elaborate the mimetic signals.

Elaboration of the warning system

If a *Haplochromis* female fish were to discriminate between real eggs and the egg dummies of the male and were to stop reacting toward the latter, her eggs would remain unfertilized. In such cases of deceptive signals developed within the same species natural selection operates against better signal discrimination on the part of the signal receiver.

The importance of the signal receiver. Fundamental characteristics of mimicry are determined mainly by behavioral properties of the signal receiver. A precise knowledge of the identity of the receiver and a thorough study of its behaviour are therefore indispensable for the understanding of mimicry. Moreover, mimicry is not sharply distinct from, but gradually merges into, other sender-receiver communication systems. Palatability is a matter of degree; whole ranges of increasing distastefulness therefore exist, even in the mimics, model and mimic in the extreme case being equally unpalatable and sharing the same warning coloration. This system, called Müllerian mimicry, could be considered not to be true mimicry, after all, because no one is deceived, and it is impossible to designate one as model and the other as mimic.

Although all individuals of a given wasp species look alike and are all equally protected, this phenomenon is not usually called Müllerian mimicry, simply because the signals were not independently, convergently evolved. Because, however, the male wasps have no protective properties but retain their group-specific warning color-

ation, this is Batesian mimicry, although model and mimic are of the same species and their signals homologous (evolved from the same source). Convergence of the signal characters, therefore, is essential only for the so-called Müllerian mimicry, and thus Müllerian mimicry is distinguished from other cases of signal standardization. The typical (Batesian) mimicry merges into Müllerian mimicry if the difference between the consequences for the receiver of reacting similarity to model and mimic diminishes; and by homology of the signal characters it further merges into general signal standardization.

Insects may be protectively coloured to resemble a wasp or a twig, the first case being called mimicry, the latter mimesis, or protective coloration. The difference again lies within the signal receiver. If the mimetic signal does not release any reaction in the receiver, it falls under mimesis. This distinction is illustrated by the Dutch biologist L. de Ruiter's experiments with stick caterpillars, which, by virtue of their close resemblance to twigs, are protected against insect-eating birds. As soon as the number of caterpillars becomes too large, however, the bird develops an interest in them, attacks real twigs, and also finds some caterpillars. If one positive experience with the caterpillar has the same weight as a negative one with the twig (the signal remaining unchanged), the relative abundance of caterpillars and twigs determines whether all twigs are mistakenly exterminated or whether the feeding reaction toward twiglike objects disappears, thus protecting the caterpillars.

This study again illustrates the importance of the bird's ability to decide correctly which is the model and further shows how easily an object (the twig) may quite involuntarily become a "mimic." Another example illustrating the importance of a correct model is found in the common farming relationship between ants and aphids. The protuberances, called the siphones and cauda, on the abdomens of aphids resemble respectively the bases of the antennae and labium of the ant's head. The aphid's abdomen is thus mistaken by the ant for the head of a fellow ant, thereby eliciting the food-begging response, which is identical with milking. Saturated ants in turn even try to feed the abdomens of the aphids. Aphid species with reduced abdominal siphones use their hind legs as antennae dummies, the movements elicited being originally defensive movements. This situation is exactly the way in which mimicry arises. Mimetic characters need not have evolved under the selection pressure of mimicking; in fact, their earliest evolutionary stages could not even have been brought about in this way. All cases studied thus far can be traced back to an incipient stage of deceptive resemblance, initiated as a preadaptive, nondirected by-product of pre-existing species-specific features, thus providing a point of attack for new selective pressure.

The effects of selective pressure. The selective consequences for the signal receiver of responding to the model are always positive (the reaction would disappear if, on balance, it were unfavourable to the receiver). The mimic always has a selective advantage in releasing the reaction from the receiver. An unfavourable signal by the mimic would also disappear by natural selection.

The selective consequences of signalling by the model

The selective consequence for the model eliciting and obtaining the reaction from the receiver may be of several types. Consequences may be absent, if the model is an inanimate object, on which natural selection does not act. They may be negative, if the model is nonaposematic (nonwarning), such as the tiny crustacean, usually eaten by the signal receiver and mimicked by the male *Corynopoma* characin in order to attract the female. They may instead be positive, as in the wasp, which remains alive if it is avoided by the predator; in the cleaner, which feeds on parasites harmful to other fish; or in those hymenopteran females whose male-attracting signals are mimicked by certain orchids. Mutual interest is present between model and receiver in cases of aggressive mimicry where both belong to the same species and in typical Batesian mimicry.

Constant learning by the signal receiver results in a strong selective pressure on the mimic against detectable differences from the model, but it also exerts a strong pressure on the model to develop new differences from the mimic. Typically, it is the group of songbirds parasitized by cuckoos that has developed the most divergent egg colour patterns; the group of estrildine finches, parasitized by widow birds, that has developed particular gape patterns; and among the cleaner wrasses the species *Labroides dimidiatus*, mimicked by the blenny *Aspidontus*, that develops into many different local races.

There is a boomerang effect, characteristic of parasite-host relationship—the more successfully a bird rears young cuckoos, the more certain it is that it will lose its own young, because they are killed off by the young cuckoo. Parasites that are too successful, therefore, harm themselves, for each female cuckoo needs several nests of the same host species for her eggs. In an area containing particularly successful cuckoos, the number of reed warbler nests has been found to decrease from year to year, while the percentage of nests parasitized by cuckoos increases from year to year. This ratio means that a cuckoo too well adapted reduces the availability of its own hosts, while one insufficiently adapted kills off its own offspring. Presumably, selection in both directions produces a continual oscillation in the densities of hosts and cuckoos. A similar dilemma is inflicted on man, who acts as a predator against weeds in crop fields and by winnowing selects the wanted seeds from the usually smaller weed seeds. The flax dodder (*Cuscuta epilinum*), growing as a creeper around flax and linseed plants and damaging them, originally had small seeds that could be easily separated from the larger flax seeds. A special mutant of the flax dodder is now cultivated and spread by man, despite being against his interests. By a mutation that produced twin seeds, the dodder has evolved the capability of being separated out and planted with the desirable flax seeds. In this case, the parasite mimics the protected plant, receiving the same protection.

The effects of geographical distribution and population density. It has been postulated that the model and mimic should occur in the same area—*i.e.*, be sympatric. They need not always be sympatric, however, but must only have a signal receiver in common: a model might be in Africa and its mimic in Europe (or vice versa), functionally connected by a migratory bird. Another postulate, that mimics must be less numerous than their models, means, correctly stated, that the receiver has to meet the mimic less often than the model; this postulate is based on the assumption that one experience with the model has the same aftereffect, the same weight, as has one with the mimic. This assumption, however, has been proven not always to be so; in fact, the negative experience seems usually to be the stronger one. This negative experience may result from an encounter with the model (a wasp) or with the mimic (for example, the *Aspidontus*). There might very well be more wasp mimics than wasps, but, in the case of the cleaner mimic, it is probable that the mimic in fact has to be less numerous than the model. The protective power of the model, of course, which provides the advantage of being its mimic, is reduced with an increasing number of mimics, because the predator will eat larger numbers of them before his first encounter with the model.

Relative populations of model and mimic

The importance of mimicry to evolutionary theory. The mimicry hypothesis emerged in the middle of the Darwinian controversy and provided an ideal test case for the views of Darwin and his contemporary Alfred Russel Wallace on the operation of natural selection in the evolutionary change of living organisms. It is now quite evident that the basic theory of natural selection is correct, and that the theory is strengthened by many detailed studies of the process by which a mimetic resemblance is brought about and selected for. Investigating suitable cases of mimicry provides important insight into the evolution of signals and the process by which signals get their meaning.

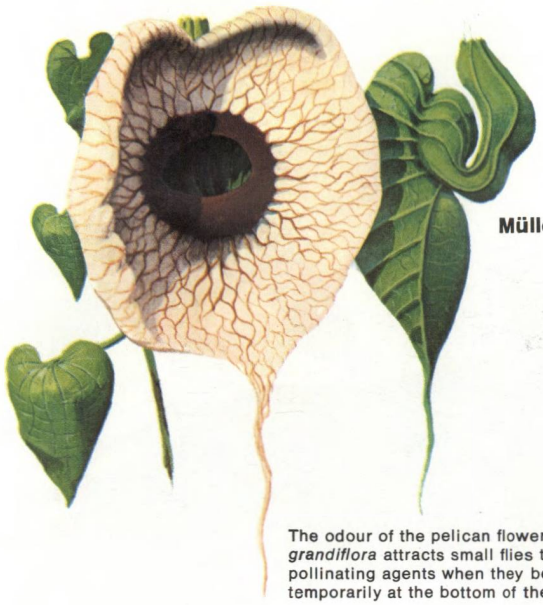
Müllerian and other forms of mimicry



The odour of the pelican flower *Aristolochia grandiflora* attracts small flies that act as pollinating agents when they become trapped temporarily at the bottom of the flower.

The labellum (lip) of the flower of the orchid *Ophrys apifera* imitates a female bee; males attempting to copulate with the flower act as pollinators.

Mimicry in coral snakes and similar forms. (Left) venomous Eastern coral snake *Micrurus fulvius*; (centre) harmless king snake *Lampropeltis polyzona*; (right) moderately venomous rear-fanged false coral snake *Erythrolamprus aesculapii*.

Müllerian mimicry in unpalatable New World tropical butterflies.

Melinaea ethra (family Ithomiidae)

Mechanitis lysimnia (family Ithomiidae)

Lycorea halia (family Danaidae)

Heliconius narcaea (family Heliconiidae)

Painting by C. Olsen

The zone-tailed hawk is able to surprise its prey because of its resemblance in appearance and flight pattern to the carrion-feeding turkey vulture.

Aggressive mimicry in birds

Superficial resemblances of cuckoos to the sparrowhawk and shikra frighten other birds from their nests, allowing the cuckoos to deposit their eggs in them.

The parasitic whydah deposits its eggs in the host finch's nest. The young whydah mimics the mouth pattern of the young estrildid finch, thereby triggering feeding behaviour by the estrildid host.

Minamoto Yoritomo

Minamoto Yoritomo was the founder, in the 12th century AD, of the shogunate, or *bakufu* (military administration), and of the line of feudal lords, which, through the shogunate, ruled Japan for 700 years. He was of noble and, as a descendant of the emperor Seiwa (reigned 858–876 AD), even royal lineage. His family name, Minamoto, is Genji in Chinese (Gen being the Chinese reading of the symbol for Minamoto), and it is immortalized as the embodiment of ancient courtly ways in *The Tale of Genji* (*Genji monogatari*), one of the world's earliest and greatest novels. But the family's immediate past was military as well as aristocratic, and Yoritomo's personality was impatient with the court's cultured and precious subtleties. He wanted power and was jealous, suspicious, and cold-hearted, even in his own circle. He went as far, in fact, as to liquidate several near relations. But once in power, he proved an excellent administrator.

Aristocratic and military background

Minamoto Yoritomo, colour on silk cloth attributed to Fujiwara Takanobu (1142–1205). In the collection of Jingō-ji, Kyōto.

Yoritomo was born in 1147, the third son of Minamoto Yoshitomo, who, in 1159, attempted to destroy Taira Kiyomori (scion of another dominant military family, the Taira clan) in the Heiji War, in Kyōto Province. He was defeated, however, and his son Yoritomo was captured and banished to Izu Province (a peninsula southwest of Tokyo), where he lived for 20 years under Taira surveillance.

Yoritomo enlivened his rustication by seducing the daughter of his jailer, Itō Sukechika. The latter's rage forced Yoritomo's flight to the protection of Itō's superior and neighbour, Hōjō Tokimasa, a Taira vassal whose hostile attitude to the Taira clan typified the contemporary split between court and country. Hōjō's daughter also succumbed to Yorimoto's blandishment but had to postpone marriage until 1180, when her official fiancé, the pro-Taira acting governor, had been eliminated. The essential feature, however—an understanding between Tokimasa and Yoritomo—was swiftly completed; and Yoritomo's political pretensions now enjoyed support.

Meanwhile Taira Kiyomori, the head of the Taira clan, exercised his power over the Imperial court, thus alienating Shirakawa II, the retired Emperor. (At this period of Japanese history the emperor often lived in "retirement" away from court so he could rule without the hindrance of the highly detailed court ceremonials. This practice was known as *insei*.) Most of the aristocracy and the heads of the great temples and shrines were also resentful of the Taira clan's hold over the Emperor.

In 1180 Minamoto Yorimasa, another member of the Minamoto clan, joined in a rebellion with an Imperial prince, Mochihito-ō, who summoned the Minamoto clan to arms in various provinces. Yoritomo now used this princely mandate as a justification for his own uprising. Despite Mochihito-ō's death, which occurred shortly before Yoritomo's men were led into battle, he succeeded in gaining much support from the feudal lords in the eastern provinces. Many members of the Taira family also enrolled under Yoritomo's banner, for they were disappointed with their meagre rewards from cousins at court. Yoritomo immediately advanced to Kamakura (about ten miles south of Tokyo) and established his headquarters there. As well as consolidating a hold over his own vassals in the Kantō area (west of Tokyo), Yoritomo tried to organize the Minamoto followers under his direct control. He was loath to relinquish control to any of his various relatives, and to this end he established the Samurai-dokoro (Board of Retainers).

In 1183 Minamoto Yoshinaka, a cousin of Yoritomo, occupied the Hokuriku district and invaded Kyōto, the seat of the court. The emperor Shirakawa II, who always hoped to play off supporters, as well as enemies, against each other to regain some of the substance of Imperial power, invited Yoritomo to put an end to Yoshinaka's dangerously successful career; and Yoritomo accordingly crushed Yoshinaka at Kyōto. Yoritomo now established the Kumonjo (Board of Public Papers) and Monchūjo (Board of Questioning), setting up not only a military but also an independent political government in the east, yet one that was recognized by the central Imperial court in Kyōto. In 1184 Yoritomo's considerable armies, commanded by his two younger brothers, Minamoto and Yoshitsune, a brilliant commander of whom Yoritomo was jealous, were ranged against the Taira forces for what was hoped would be a climactic campaign, but decisive victory was not gained until the following year. After Minamoto's next victory, the Emperor supported Yoshitsune in efforts to restrain Yoritomo's power. But Yoritomo immediately expelled Yoshitsune and imposed on the Emperor the establishment of *shugo* ("constables" or "guardians") and *jitō* ("district stewards") throughout Japan, avowedly to capture Yoshitsune, though such arrangements were instrumental in making Yoritomo's ascendancy nationwide. Soon after, Yoritomo succeeded in having his brother Yoshitsune put to death.

Yoritomo gave his *shugo*, each placed in a province, the function of administering and policing the Minamoto vassals locally. The *shugo* also administered the judicial proceedings in cases of rebellion and murder, and they thus acquired something of a military hold over each province. To supervise individual estates, the more pacific office of *jitō* was created, which levied taxes and undertook the management of the estates. And, not surprisingly, both the *shugo* and the *jitō* became feudal lords. Through these institutions, Yoritomo was thus able to undermine the central government's local administrative power, and subsequently he even made efforts to rule

remote districts, such as Kyushu, Japan's southernmost island.

Supremacist ambitions

In 1185 he destroyed Fujiwara Yasuhira, an independent noble of the Tohoku area, demonstrating his ambition to create a power structure independent of the capital, at Kyōto. In 1192, a few months after his old rival Shirakawa II's death, Yoritomo, now with no one to balk him of his ultimate ambition, titled himself Sei-i Taishogun (meaning "Barbarian-Quelling Generalissimo"), becoming the supreme commander over the feudal lords. The Kamakura shogunate was now formally complete.

After 1192 Yoritomo's policies were designed to relieve the strain between the military lords and the court aristocrats, and the powerful temples and shrines. Thanks to the institutions of the *shugo* and *jitō*, relations between the court of Kyōto and Yoritomo's government at Kamakura were fairly stable. Yoritomo died in 1199.

Yoritomo is often charged with cruelty, particularly in the killing of his cousin and brothers, but political circumstances of his time were difficult. He had above all to prevent discord among his vassals and the whole military class if his work was to attain the permanence that it did. (K.N.)

Minas Gerais

Minas Gerais, an inland state (*estado*) of Brazil, is the storehouse of the mineral riches of that country, as is indicated by its name, which means "general mines." The state is bounded on the north by the states of Goiás and Bahia; on the east by Bahia, Espírito Santo, and Rio de Janeiro; on the south by Rio de Janeiro and São Paulo; and on the west by São Paulo, Mato Grosso, and Goiás. Its area is 226,708 square miles (587,172 square kilometres). Its population (1970) was 11,600,000, being exceeded among Brazilian states only by that of São Paulo. The state capital is Belo Horizonte.

History. Minas Gerais was first explored by Fernão Dias Pais Leme between 1664 and 1677, though he was not the first European to penetrate it. The discovery of gold in 1692 to 1695 by bands of adventurers from the São Paulo settlements led to every occupation and profession being abandoned in the mad rush for the new mines. Minas Gerais at first formed part of the captaincy of São Paulo, but in 1720 it was established as a separate captaincy general and was brought more directly under the Portuguese crown. The arbitrary restrictions imposed upon the colonists aroused dissatisfaction among them and eventually led to a conspiracy in 1789, inspired by a fear that the Portuguese government was about to enforce the collection of its "royal fifth" of the mining output, which had largely fallen into arrears. Among the conspirators was one José Alves Maciel, who had just returned from France, where he had met Thomas Jefferson and had become infected with French revolutionary ideas. A number of residents became involved, and reckless talk in public places led to the arrest of the conspirators. Only one was executed, a poor, uneducated subaltern militia officer, Joaquim José da Silva Xavier, nicknamed O Tiradentes (the Tooth Puller), the others being imprisoned or banished. Tiradentes has since been glorified as a national hero of Brazilian independence. Minas Gerais has traditionally played an important role in Brazilian politics, in part because of its central position but also because of the dense population in its southeast. In 1822 it became a province in the Brazilian Empire, and in 1891 a state in the federal republic. In 1897 the old colonial capital of Ouro Prêto was deprived of its administrative function. The new capital was placed at Belo Horizonte, where a new city, laid out on previously almost unoccupied land, was planned and built. Ouro Prêto became a national monument, and Belo Horizonte has become a city with a population of more than 1,100,000.

The Minas Gerais gold rush

The natural environment. *Relief and drainage.* Minas Gerais lies almost wholly within the geologically ancient, mineral-rich uplands known as the Brazilian Highlands. Only small sections of the southern and eastern parts are within the zone of the Great Escarpment which forms the eastern margin of the highlands. In the southwest, along the border of São Paulo, is the commanding range of mountains known as the Serra da Mantiqueira, whose highest summit, Pico das Agulhas Negras (also known as Pico do Itatiaia), reaches 9,144 feet (2,787 metres). This range ends near the easternmost border of São Paulo. The other principal mountain range is the Serra do Espinhaço, which begins a little south of Belo Horizonte and extends northward into Bahia. It forms the divide between the rivers draining to the São Francisco River and those draining eastward directly to the Atlantic (the Doce, Mucuri, Jequitinhonha). The greater part of the state consists of a much dissected hilly upland reaching an elevation of about 2,600 feet (790 metres) above sea level. In the west, on the border of Goiás, Minas Gerais consists of a plateau, part of an ancient erosion surface still untouched by stream erosion over wide areas and standing about 4,000 feet (1,200 metres) above sea level. The watershed divides, often erroneously described as mountain ranges, are in fact remnants of this old erosion surface. Minas Gerais is drained to the east and south of the Serra do Espinhaço by the smaller streams named above and by tributaries of the Paraíba. In the southwest it is drained by the Rio Grande, one of the major headwaters of the Paraná River, which reaches the sea at Buenos Aires. The whole northwestern part of the state is drained by the São Francisco, which flows northward through a rift valley to the west of the Serra do Espinhaço. Along the western border is a triangular projection (Triângulo Mineiro) lying between the Rio Grande on the south (border of São Paulo) and the Paranaíba on the north (border of Goiás).

Drainage

Climate. The climate is characteristic of an upland region in the low latitudes. Temperatures are not so high as they are along the coast. At Belo Horizonte, 2,800 feet (852 metres) above sea level, the average of the warmest month (February) is 72° F (22° C); and the average of the coldest month (July) is 62° F (about 17° C). The rainfall throughout most parts of the state averages between 40 and 60 inches (1,000 and 1,500 millimetres) but is concentrated in a rainy season between November and March. The period between May and September is very dry, and lack of moisture is a major factor in agriculture along the stream divides.

Natural vegetation. Reflecting these climatic conditions, the southern and eastern part of the state was originally covered with a dense tropical forest, consisting of many species of trees that retained their leaves throughout the year but with a few that shed their leaves in the dry season. Semideciduous forest was called *mata de primeira classe* ("first-class forest") by Brazilians.

On the upper slopes of the Serra da Mantiqueira and of the Serra do Espinhaço, the forest gives way to upland meadows or to a scrubby growth of deciduous woodland. All of southwestern and western Minas Gerais is covered by a woodland savanna, consisting of stretches of grassland mingled in complex fashion with stands of woodland. The latter (*campo cerrado*, literally "closed grassland") is made up of low broadleaf trees with gnarled trunks. Even in the midst of the woodland savanna, however, semideciduous forests extend along the deeply cut river valleys.

Population. The population of Minas Gerais is chiefly of Portuguese origin, with a considerable admixture from other European countries. Persons of African and mixed (African and European or European and Indian) ancestry constitute other important elements, although their numbers are proportionately less than in some of the other states. As in the nation as a whole, the population is young, with a high proportion in the younger age groups and a very small proportion in the group aged 65 and over. The language is Portuguese, and the predominant religion is Roman Catholic.

The cities and towns

Belo Horizonte, not only the state capital but also a leading industrial centre, is by far the largest city. The second city is Juiz de Fora (population 220,000) in the south, noted for its textiles. Other important cities and towns are Barbacena (58,000), Governador Valadares (125,000), Venda Nova (120,000), Uberlândia (110,000), and Uberaba (108,000). Outside of the cities there

is a dense rural population in the south and east, but the whole northern and western part of the state is still very thinly occupied so that the population density as a whole is only about 51 persons per square mile.

Administration and social conditions. The state government and its principal agencies and offices are located at Belo Horizonte, the capital. The state has its own constitution and laws, in conformance with the national constitution. The governor and the members of the legislature are elected. Minas Gerais has been one of the few states of Brazil able to sustain an economically viable state government, most of the others having to rely on aid from the central government.

Living conditions in general are higher in the urban areas, and health services are more accessible in the cities. Primary, or elementary, education through the first four years is free and compulsory, as in the rest of Brazil. Although shortages of schoolrooms and teachers throughout the nation have prevented the achievement of universal literacy, Minas Gerais has been one of the leading states in providing for education. About half of all Brazilian primary pupils and even higher proportions of secondary and university students live in Minas Gerais and three other states, Guanabara, São Paulo, and Rio Grande do Sul. The Universidade Federal de Minas Gerais, one of the country's 24 official universities, was founded in 1927, and the Universidade Católica de Minas Gerais was established in 1958; both are in Belo Horizonte. The Escola Nacional de Minas e Metalurgia (founded 1876) is at Ouro Prêto.

Economy. The largest source of wealth in Minas Gerais is mining. Of major importance are iron ore and ferroalloys. Large steel plants make use of the ores. But the largest source of employment is agriculture, and the greater part of the area is used for pasture of cattle.

Minerals. Minas Gerais has long been known for its wealth of minerals and its mining activities, supplying half the mineral production of Brazil. Gold was discovered in 1698. At first the many prospectors who rushed into Minas Gerais only looked for gold in the stream gravels, and there are many marks of abandoned placer mines at the valley bottoms and on hillsides. Gold was found in various streams draining away from the Serra do Espinhaço.

In 1729 diamonds were discovered, also in stream gravels, near Tejuco (now called Diamantina). These precious commodities created great wealth in the 18th century, and Ouro Prêto, the administrative centre of Minas Gerais, became a city of great splendour, with numerous beautifully decorated churches. But by 1800 the richest gold sources had been used up, and the miners turned their attention elsewhere. It is interesting, however, that at Morro Velho, a few miles south of Belo Horizonte, a British mining company has been mining gold continuously since 1834. This mine is now one of the world's deepest. Minas Gerais is also widely known for its semiprecious gems, such as aquamarine, amethyst, tourmaline, and topaz, and it is an important source of industrial diamonds. From the high country in the western part of the state come large quartz crystals, used in radios and other electronic communications equipment.

Iron and manganese deposits

Of greater importance in modern times, however, are the vast deposits of high-grade iron ore and manganese. In the southern part of the Serra do Espinhaço there is a large reserve of iron ore, containing few impurities and so located that it can be mined with mechanical shovels. By the late 1960s there were three large-scale steel plants using this ore. Iron and manganese from Conselheiro Lafaiete, near the southern end of the Serra do Espinhaço, are used to supply the steel plant at Volta Redonda and also a newer plant located near Santos. Ores from Itabira, on the headwaters of the Rio Doce, supply a new plant nearby. These ores are also used in several large plants and hundreds of smaller ones that use charcoal as fuel. Moreover, Brazil now exports its iron ore. Brazil has contracted to send some 50,000,000 tons (45,000,000 metric tons) of iron ore to Japan before 1977. This ore moves down the Rio Doce to the new ore port of Tubarão, just north of Vitória in Espírito Santo.

Another iron-ore shipping arrangement was made with a combined Brazilian–U.S. firm to send ores from Minas Gerais to a new ore port on the Baía de Sepetiba near Angra dos Reis, west of Rio de Janeiro.

In addition to iron and manganese, industrial diamonds, and gem stones, Minas Gerais supplies bauxite, zirconium, iron pyrite, rutile, graphite, chromite, molybdenum, nickel, tungsten, titanium, beryl, and mica.

Manufacturing. Manufacturing and processing industries have developed in and around the cities, especially around Belo Horizonte, where industrial air pollution has become a problem. In addition to iron and steel, principal industries include food processing, textiles, chemicals, and furniture and other consumer and capital goods.

Agriculture. The agricultural area of Minas Gerais is almost exclusively a region once occupied by semideciduous forest, which has been cleared by centuries of slash-and-burn agriculture, or land rotation. In this system of agriculture, a tenant farmer clears the forest by cutting and burning it at the end of the dry season. He then plants maize (corn), rice, beans, and cassava (manioc) and is able to reap fair harvests for a period of two or three years before the essential infertility of the soil becomes apparent. He then plants pasture grass, chiefly for cattle grazing, and moves to a new part of the forest. This area is the chief source of beef for Rio de Janeiro, São Paulo, and other cities. Dairy farming is important in southern Minas Gerais. In only a few spots is the land used for sugarcane or coffee, which were formerly of greater importance. On the hillsides, used for poor pasture, are traces of coffee plantations. The state is still a leading producer of rice, beans, maize, and cheese.

Tourism. Another aspect of the economy of Minas Gerais is tourism. In the Serra da Mantiqueira and in the southwestern uplands of the state, to the north of these mountains, are a number of resort towns, most of them possessing various hot and curative baths. The mineral waters are bottled and widely dispensed in Brazil. The more important centres are Araxá, Caxambu, Lambari, Poços de Caldas, and São Laurenço. Health resorts have also been established at the higher elevations.

Roads and railroads

Transportation. Minas Gerais is served by railroads, all-weather highways, airports, and by river steamers that descend the São Francisco from Pirapora to Juàzeiro in Bahia. The main railroad, Estrada de Ferro Central do Brasil, runs from Rio de Janeiro to Belo Horizonte, with a narrow-gauge extension to Pirapora. To the west of this line is the narrow-gauge Viação Ferrea Centro-Oeste; east of it is the Estrada de Ferro Leopoldina, also narrow gauge. A railroad also ascends the valley of the Rio Doce from Vitória to Itabira and continues to Belo Horizonte.

Since World War II all-weather motor highways provide easy access to Rio de Janeiro, São Paulo, and the capital, Brasília. Most of these roads parallel the earlier railroads rather than providing feeder service. Away from the main highways and the railroads the roads are passable for motor traffic only in dry weather.

Cultural life. As is to be expected, the cultural life of the state is concentrated in its cities and especially in the capital, Belo Horizonte. The city plan was based on that of Washington, D.C., with broad, tree-lined avenues and a main concourse, Avenida Afonso Pena, leading from a large central square, Praça da Liberdade. There are many impressive government and other buildings. Its university library is one of the nation's 10 regional centres of bibliography and documentation for scientific information. The city's plan included the large recreational area at the artificial lake Pampulha. The half-dozen or more newspapers in the state are published in the capital.

The state's chief historical attraction is Ouro Prêto, the old colonial capital. It was decreed a national monument in 1933 and the surrounding area a biological preserve in 1967. Public buildings, churches, and private homes, mostly from colonial times, have been preserved or restored. The Escola Nacional de Minas e Metalurgia and a museum of minerals are located in the colonial governor's palace and a historical museum in the old penitentiary. A national park system was established in 1937.

Mind, Philosophy of

One thing that sharply distinguishes man from the rest of nature is his highly developed capacity for thought, feeling, and deliberate action. Here and there in other animals, rudiments, approximations, and limited elements of this capacity may occasionally be found; but the full-blown development that is called a mind is unmatched elsewhere in nature. The existence of a mind in some sense is reflected in an extremely diverse class of occurrences: sensations such as tickles and aches, mental images, sense perceptions, emotions, memory and expectations, desires, believing, inferring and other types of reasoning, dreams, motives, choices, actions, traits of character and personality, and the unconscious.

PHILOSOPHY OF MIND AS A DISCIPLINE

Task and scope of the field

The task of the philosophy of mind is to examine and analyze those concepts that involve the mind (including the very concept of the mind itself) in an attempt to discover the nature of each of these concepts, the relations between them, how they are to be classified, and how they are to be related to certain other concepts—especially to the concepts of matter and energy, the human body, and, in particular, the central nervous system.

It should be clear that the range of topics in the philosophy of mind goes far beyond what is intended in everyday discourse by "mind." When, for example, the layman speaks of someone as having "a good mind" or as pursuing "the pleasures of the mind," he is thinking of those particular activities that have to do with abstract reasoning, intellectual pursuits, and the exercise of intelligence. The "mind," as the term is used more technically in this article and in the philosophy of mind in general today, encompasses sense perception, feeling and emotion, traits of character and personality, and the volitional aspects of human life, as well as the more narrowly intellectual phenomena.

In this article, the following topics are examined: the relation of the philosophy of mind to other areas of investigation, both inside and outside philosophy; various philosophical theories of what is peculiar to the mind and mental phenomena; various philosophical theories of the nature of the mind and its relation to the nonmental; philosophical issues concerning particular mental phenomena; and some implications of the philosophy of mind for metaphysics and epistemology.

Relation to other disciplines

In distinguishing the field of philosophy of mind from other sorts of investigation, one immediately obvious feature is its subject matter, the nature of mind and its various manifestations. This serves to distinguish it from empirical sciences like astronomy and physics, which study matter in motion; from formal disciplines like geometry and algebra, which study mathematical relationships; and from other fields of philosophy like the philosophy of art and the philosophy of law. But subject matter alone does not serve to distinguish the philosophy of mind, since the mind is the subject of investigation of other disciplines as well—especially of psychology and of certain phases of biology, physiology, sociology, and anthropology. In comparison with these fields, it is by its method that the philosophy of mind is to be distinguished; for it proceeds not by the methods of empirical investigation—detailed sense observation, the formulation of predictions, the construction of experiments, inductive confirmation, the inventing and testing of contingent generalizations, theories, and laws—but by the method of philosophical reflection. That method consists of the examination of meanings, the analysis and clarification of concepts, the search for necessary truths, the use of deductive inference, *reductio ad absurdum*, and arguments with infinitely repeating terms and other forms of a priori reasoning, and the attempt to arrive at and evaluate the fundamental principles that underlie and justify the basic forms of human thought and endeavour.

Although the philosophy of mind is a distinct field of investigation, it has many important relations with other fields. First, its methods, being those of philosophy in general, are to be tested by the fruits that they have yielded in other areas: if a method has been successful in other areas, it is reasonable to try it here; if unsuccessful in other areas, it is suspect here. Second, the conclusions achieved in such fields as theory of knowledge, metaphysics, logic, ethics, and the philosophy of religion are quite relevant to the philosophy of mind; and its conclusions, in turn, have important implications for those fields. Moreover, this reciprocity applies as well to its relations to such empirical disciplines as neurology, psychology, sociology, and history. Thus, the philosopher of mind must keep himself informed of developments in all related fields of investigation.

THE SEARCH FOR A CRITERION OF THE MENTAL

The bewildering variety of phenomena that fall under the heading of the mind or the mental was listed earlier. The question arises, however, whether there is something that all these mental phenomena have in common, something that characterizes them or can serve as a criterion of the mental. More specifically, are there features that are necessary or sufficient for mental phenomena?

Family resemblances among phenomena

It should be pointed out at the very start that, according to some contemporary philosophers, it is a basic mistake to lump all these phenomena together under a single heading. An Analytical philosopher, Gilbert Ryle, in his *Concept of Mind* (1949), maintained that it is only through a series of confusions that one comes to think that there exists here a natural class of kindred phenomena. Even if, contrary to Ryle, it is held that it is reasonable to group these phenomena together, it still might well be that they have nothing in common; and even if they have, that something could turn out to be either peripheral and inessential or comparatively minor and thus might not go very far toward explaining why they all had come under that heading. The remarkable pioneer of 20th-century Analytical philosophy Ludwig Wittgenstein showed that a number of things could come under a particular heading not by virtue of having certain features in common but by virtue of having a "family resemblance," just as members of a family might have a typical appearance even though there was no set of features possessed by all of the members; and the possibility must be left open that this is the case with the various instances of mental phenomena.

Many philosophers, nevertheless, have searched for something that could serve as the criterion of the mental, something that distinguishes what is mental from what is not. Some of the more promising candidates are examined below.

Purposeful behaviour. Whenever a man watches a hungry animal using stealth and cunning in searching out, attacking, and killing its prey, he cannot but believe that the animal has a purpose and uses intelligence in achieving his goal. Whether it be a team of scientists designing a way of launching a man to the moon, an ape figuring out how to screw two pieces of pipe together to get a banana that is out of reach, or—at a much lower level—a lobster trying to get out of a pot of boiling water, there seems to be a mind at work. Somewhere, as the phenomenon is traced farther down the ladder in the scheme of things toward inanimate matter, a line must be drawn; but there is no agreement about where it should be drawn. It would be widely agreed that an ovum that has just been fertilized does not have a mind and that a normal adult does—but it is impossible to say exactly where in human development the change occurs. On the other hand, it would be just as wrong to conclude that because there is no sharp dividing line there is no change as it would be to conclude that red and orange are the same colour because no sharp line divides them. In both instances there will be a range, as with all vague terms, within which the picking out of a dividing line will be arbitrary; but at either end beyond that range a clear and definite difference will be evident.

The question may then be raised of how adequate purposeful activity is as a criterion of the mental. A major issue arises from the fact that a mechanical device can be built that exhibits the kind of activity ordinarily called purposeful—a surface-to-air missile, for example, so designed that it will hunt for a jet aircraft by searching for,

Teleological mechanisms versus mental activity

and zeroing in on, the heat exhaust, thereby finding and destroying the aircraft. Such devices, known as "servomechanisms" (of which a thermostat is a simple example), achieve an end state by systematically diminishing any deviation from that predetermined end state. There are, in addition, the modern computers, capable of receiving, storing, and retrieving information, of making inferences, and of communicating information. Near the height of modern sophistication in machine technology are those machines, combining servomechanisms and computers, designed to roam the surface of the moon, gathering, processing, and sending back data and thus providing what would seem to be paradigms of purposeful behaviour and raising the question whether such systems are examples of minds at work. There are three possibilities worth considering: (1) one might continue to hold that purposeful behaviour is the criterion of the mental but argue that these devices do not really meet the criterion of exhibiting purposeful behaviour; (2) one might hold that the more complex of these devices do indeed have minds—simple and rudimentary, to be sure, but still minds—"artificial intelligences" that in a very literal sense have beliefs, think thoughts, solve problems, and achieve goals; or (3) one might give up the criterion of purposeful behaviour, or at least give it up as a *sufficient* condition of the mental.

Someone defending possibility (1) would attempt to find some feature of purposeful behaviour that could not be found in any mechanical device. He might hold, for instance, that the alleged purposes of mechanical devices are built in by their designers and that it is not up to the devices to choose their purposes. Against this line of argument, however, others might assert that for a large number of organisms the basic purposes are also built in through the genetic mechanisms of heredity: basic biological drives for food, sex, and safety govern most of their purposeful behaviour. People who accept this point of view argue that, in most cases, the organism is not really free to choose its purposes. On this argument, even human beings seem to display such built-in purposes; and it would be specious, at least in this instance, to deny them minds on this account.

Machines, man, and inventiveness

Conceding that organisms have some built-in controls, the defender of the first possibility might then argue that the higher organisms have a flexibility that allows for the development of purposive methods that are novel. Machines, he would allege, solve problems only by the methods designed into them, whereas creatures with minds can invent new methods. Against this line of argument others might argue that machines have been developed to use trial and error, analyze the outcomes of trends, and come up with new approaches that are more successful than earlier ones, and that, in an important sense, such machines might be called creative, since they "learn from experience" and use "ingenuity." Many observers assume that this trend in machine technology will continue and that machines will be developed with much, if not all, of the flexibility of many of the creatures that would unhesitatingly be acknowledged to have minds.

The basic issue, then, is whether a philosopher would want to say that a machine has a mind if it exhibits the flexibility in purposeful activity of, say, a normal seven-year-old child, who undoubtedly has a mind. In accepting possibility (2), he would maintain that such a machine does have a mind and exhibits a wide range of the phenomena called mental. Many contemporary philosophers, however, would reject that thesis, considering it a needless flaunting of common sense and an affront to ordinary language to speak of a heat-seeking missile, or even a lunar robot, as having a mind. Because something essential still appears to be omitted, further attempts are made below to get at the essence of the mind.

Intentionality. Another characteristic of the mental is sometimes thought to be found in certain ways in which a man may be said to have something as his object. Thus, thinking, believing, desiring, and other such attitudes are thought to resemble one another in that they may be said to take an object, or to be directed upon an object, in a way quite unlike anything to be found in what is purely physical. "Intentionality" is the term for this way of being directed upon an object. The concept had been emphasized by some of the Scholastics and was introduced to modern philosophy in 1874 by a German philosopher and psychologist, Franz Brentano, and more recently has been clarified and defended by a United States philosopher, Roderick M. Chisholm.

The nature of intentionality. The idea of intentionality can be explicated in the following way: If one imagines three objects arranged as in Figure 1 and then supposes

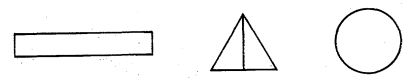

Figure 1: Three arbitrary physical objects in meaningless configuration (see text).

that the wind blows them so that they are arranged as in Figure 2, there results, from the physical point of view, simply a new arrangement. From a psychological point

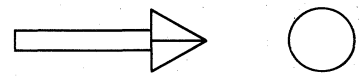

Figure 2: Physical objects with intentionality.

of view, however, something radically new also has appeared: one object is now pointing to another—aimed at or directed toward it. It would seem that such pointing cannot be accounted for if the observer confines himself to the purely physical facts of the new configuration and that his mind has to be brought in to account for the feature of pointing to. Thus, intentionality is a prima facie reasonable candidate for the criterion of the mental.

Added characteristic of aim or direction

Intentionality is exhibited in a variety of phenomena. Thus, if a person has an emotion toward an object—*e.g.*, loves, fears, pities, envies, or reveres it—he has an intentional attitude toward it. Other examples of intentional attitudes toward an object are: looking for or expecting, believing in, doubting or conjecturing about, daydreaming, reminiscing, imagining, favouring or disapproving—a list that seems to go on endlessly. Because it clearly comprises so many of the things that one thinks of as typically mental, intentionality, being of broader scope than purposefulness, would seem to be a better choice than purposeful behaviour for the criterion of the mental.

One of the characteristics of intentionality is what the Scholastics called "inexistence": a man may be intentionally related to an object that does not exist or to an event that does not occur. Thus, what a man looks for may not exist, and an event that he believes to occur may not occur at all. In contrast with such a nonintentional phenomenon as bumping into something, in which the object bumped into must be real, looking for something (an intentional act) does not necessarily imply that the object looked for exists. Similarly, in contrast with an explosion's resulting in the fact that many were hurt, a witness's believing that many were hurt (again an intentional act) does not imply the fact that many were hurt. Thus, existence and truth are irrelevant to intentionality.

Though this possible relationship to nonexistent objects as opposed to existences is a necessary feature of intentionality, it is not sufficient to define it, for there are phenomena that are equally concerned with nonexistent essences that are nonetheless nonintentional. "That lady resembles a mermaid," to use an example of Chisholm's, may be a true sentence even if mermaids, though having an essence, do not exist. Similarly, "That metal will ignite at temperatures above 1,000,000°" may be true whether or not such temperatures exist. Thus, intentionality requires further characterization if its scope is to be narrowed to exclude such examples as these.

Another characteristic of the intentional state is that not every description of its object will be appropriate. Assuming that his pen is the millionth pen produced this year, for example, a man may be in the intentional state of searching for it as his pen but not in a state of searching for the millionth pen produced this year; similarly, he may believe this is his pen and yet not believe that this is

the millionth pen produced this year. This second feature of intentionality, often called "referential opacity," is such that a true sentence asserting an intentional state will become false when some alternative description of the object of that state is substituted for it (it is false that he is searching for the millionth pen).

There is no general agreement on the best way of conceiving of intentional phenomena. Brentano, at one point, thought of intentionality as being a relation between a subject and an entity, in which the entity is something that might or might not exist; but, grave difficulties arise in the effort to characterize the ontological status of such an entity—*i.e.*, its kind of reality. More popular today are certain linguistic approaches: intentionality may be viewed, for example, as it was by Rudolf Carnap, a philosopher of science, and others, as a relation between a subject and a piece of language or, as it has been explained by others, as a relation between a subject and a linguistic practice or linguistic role. Under this view, the intentionality consists not in the relation of a subject to an *essence* (that of a millionth pen) but in its relation to a *sentence* ("This is the millionth pen . . .") that has that alleged essence as its meaning. It remains to be seen whether such approaches will succeed in dealing with all intentional phenomena. It would seem to pose particular difficulty in those cases in which the intentional state is overtly directed toward some existent entity, with language playing a minor or null role, as in situations when one feels anger, pity, or love toward someone; or when an animal is stalking its prey (which involves an intentional state). In such instances, an analysis in terms of linguistic attitudes would seem wide of the mark.

Application of intentionality to nonliving systems

The scope of application of intentionality. The question of whether intentionality can apply to nonliving physical systems has become a controversial issue. If it can apply, then either intentionality would have to be given up as a criterion of the mental or else one would have to say that such systems have some mental characteristics.

It will be useful to consider a system designed for some purpose, taking the example again of the surface-to-air missile that searches for jet aircraft, and to ask whether it has intentionality. It does satisfy the first characteristic mentioned above: that it can be truly said to be a jet searcher regardless of whether there are or have been any jet aircraft (one could similarly design a unicorn searcher built to detect unicorns by their special horn). The question next arises whether some descriptions of the object are inappropriate. On the supposition that all and only jet aircraft have a component made of compound *X*, one can ask whether it would be true of the missile that it searches for things with a component made of compound *X*. It would seem that—unless this compound chances to be what the search system was sensitized to—the foregoing statement is a false, and thus an inappropriate, description of the device; and if so, it is plausible to regard the missile as a physical system with intentionality as that notion has been here characterized. An intentional physical system, however, would have to be of considerable complexity. One would not want to say that the left-hand complex in Figure 2 was pointed to the right-hand figure unless he had in mind that, if the right-hand figure were to shift its location, the left-hand complex would shift appropriately. If it did keep shifting appropriately, however, it would seem proper to say that it points to the right-hand figure, for a compass clearly points to magnetic north. The question remains, however, whether *all* intentional phenomena are capable of appearing as instances in nonliving physical systems—whether such a physical system could have, for example, an emotion toward something, daydream about something, or be amused by something. Here it is very difficult to cite a plausible case; it would appear that one would have to strain such concepts considerably to apply them to nonliving systems.

The thesis that intentional phenomena are the essence of the mental thus seems problematic. Its suggestion that the jet-searching missile has a mind or partakes of the mental, as appeared in the discussion of the criterion of purposeful behaviour, would, to many scholars, appear to be quite implausible. Nor does it seem that the trouble lies in the limited number of intentional phenomena found in the missile. Even the lunar-exploration machines, with all of their flexibility and multiplicity of functions, would not be said by most analysts to have minds.

It might be possible to save intentionality as the criterion of the mental by insisting on the presence of such highly sophisticated intentional phenomena as emotions, daydreams, or amusement, but then one would have to deny minds to those human beings who lack a sense of humour, never daydream, or are coldbloodedly unemotional, which does not seem correct either. Some progress can be made here if the question is asked whether intentionality is a necessary condition of all mental phenomena —whether there are any phenomena that are mental but nonintentional. Examples of a mental phenomenon that can most plausibly be said to be nonintentional are sensations, such as feeling pain, which lack both of the aforementioned characteristics of intentionality—inexistence and referential opacity. A man cannot feel a pain that, unbeknown to him, does not exist; if he feels pain, there must be something he feels. Moreover, if a man feels pain, and the pain is identified with the effect of a tumour, then he does feel the effect of the tumour.

Sensations, which thus lack both of the characteristics of intentional phenomena, are not just an odd counterexample; not only do sensations comprise a large and central group of mental phenomena, but they also call attention to an important aspect of many other mental phenomena, viz., subjective experience. The arrow in Figure 2 may point to the circle, but it does not have the subjective experience of pointing, it does not feel itself pointing; and the jet-searching missile does not experience how it feels to be searching for jets. But when a person is in an intentional state, directed toward an object, he—at least sometimes—experiences, feels, or is aware of that directedness.

Clearly, this usage of "intentionality" differs somewhat from that of medieval philosophy; and there are other features of the concept, not covered here, that are stressed by Phenomenologists and Existentialists.

Subjective experience. It is often maintained that the essence of the mental consists of states of consciousness taken as subjective experiences. When a person wakes up or regains consciousness after a general anesthetic, a host of experiences of colour and light, sounds, feelings, thoughts, and memories flood in on him. As far as his objective, observable behaviour is concerned, he may be lying unmoved and unmoving; but as far as his state of consciousness is concerned, he may be undergoing a series of subjective experiences.

Consciousness, "raw feels", discrimination

To take an example, when a person sees a scarlet patch, he experiences the homogeneous, spread-out, distinctive scarletness present before him. A blind or colour-blind person who has never experienced scarlet would not have the awareness of scarlet that the normally-sighted person has. He might have some vague idea, as did the hero of the story told by John Locke, a 17th-century British Empiricist:

> A studious blind man, who had mightily beat his head about visible objects, and made use of the explication of his books and friends, to understand those names of light and colours which often came in his way, bragged one day, that he now understood what scarlet signified. Upon which his friend demanding, what scarlet was? the blind man answered, It was like the sound of a trumpet.

This reply is not totally wide of the mark; but any sighted person will have a far more precise idea of scarlet than that. What he has and what the blind person lacks is something that philosophers have called the "raw feel" of scarlet, that peculiar and special way scarlet looks.

The subjective experience of scarlet is to be contrasted with the discrimination of scarlet things. One could imagine a blind person who was able to discriminate scarlet from other colours by the use of optical instruments (*e.g.*, spectroscopes with Braille printouts). But he would lack the subjective experience of scarlet; he would not know the look of scarlet. A blind person might even be

imagined with, say, a totally severed optic nerve, who was so equipped with instruments that his behaviour was indistinguishable from that of a sighted person; but he would still lack the subjective experiences of sight.

Defenders of this view would claim that there is a great variety of subjective experiences and that the experience of colours is only one of them. Sensations (*e.g.*, the experiences of pain, tickles, throbbings, pangs, nausea, and tiredness) provide another such example. Still other subjective experiences include: the experiencing of images (afterimages, memory images, and others); feelings of exultation, depression, pride, anger, fear, and love; and thoughts (imaginings, surmisings, doubtings, and recollectings). All of these are episodes, occurring at a particular time and place, in which the subject is in a state of awareness that has a particular content.

Adequacy as a criterion of the mental. The question now arises of how adequate subjective experience is as a criterion of the mental—whether, though it is obviously a sufficient condition for something to be mental, it is a sufficient condition for something to have a mind. The Scotsman David Hume, an 18th-century philosophical Skeptic and historian, once asked whether a creature that had but one state of consciousness could be said to have a mind and concluded that it could not. In his view, it takes, at the very least, a number of states of consciousness linked by memory before one would say that the creature has a mind; and it may be that there has to be a certain level of complexity in the nature and relation of the conscious states for there to be a mind.

The unconscious, dispositional, behavioral

It is doubtful, however, whether consciousness is a necessary condition for the mental. Before Sigmund Freud, it would have been widely agreed that the notion of unconscious mental phenomena was logically impossible—a contradiction in the very terms. That view had one important exception, however: Gottfried Wilhelm Leibniz, a 17th-century Rationalist and mathematician, held that there are *petites perceptions* of which the subject is unconscious. They are so slight, so similar to others, so familiar, or in such a crowd of other perceptions, that the subject is unaware of them at the time. One of the examples that Leibniz cited is the person who is unaware of the roar of the waterfall or the rumble of the mill if he has lived nearby for some time. Leibniz seemed to have had in mind what modern psychologists call "subliminal" perceptions, viz., those below the threshold of awareness but still capable of leaving some effects on the mind. But Leibniz confined unconscious states to perceptions; he would not have allowed unconscious beliefs, desires, emotions, or judgments.

It was Freud's great contribution to have discovered a range of phenomena of which the patient was unconscious but which was very much like typically mental phenomena, especially in their behavioral manifestations. In the light of such similarities, it was plausible to extend the concept of the mental to include these unconscious phenomena—especially since they were such that the patient could become conscious of them through hypnosis or psychotherapy. Freud postulated a mechanism that he called "repression" to explain why the patient is unconscious of them.

In addition to the subliminal and the unconscious, there are more familiar characteristically mental phenomena that do not consist of states of consciousness. When a man falls into a dreamless sleep, he does not lose all his beliefs or abandon all his goals, he does not cease wanting a better world or being artistic or imaginative or lazy, nor does he forget how to do arithmetic or speak French. A person is not jealous of someone only when thinking of him, nor does a businessman have confidence in the dollar only when concentrating on business. Obviously, these mentalistic characteristics can apply in a dispositional way to people who are not at that moment expressing or exhibiting the disposition.

Furthermore, as Ryle has pointed out in great detail, a person may use his mind on many occasions without the feeling of subjective experiences. As he says,

> When we describe people as exercising qualities of mind, we are not referring to occult episodes of which their overt acts and utterances are effects; we are referring to those overt acts and utterances themselves. (This and the following quotations attributed to Ryle are from *The Concept of Mind* by Gilbert Ryle. Copyright © 1949 by Gilbert Ryle. Reprinted by permission of Barnes & Noble, Publishers, New York, Hutchinson Publishing Group Ltd., London.)

To be responsive to one's surroundings, to act intelligently, deliberately, with wit or good grace, to do arithmetic or logic, to be sympathetic or coldhearted, to drive alertly or absentmindedly—none of these requires the occurrence of subjective experiences or inner states of consciousness, the immediacy of feelings or sensations. In such activity, there may be nothing going on except performances of a particular kind, and there may be nothing more required except that under further circumstances other performances of a particular kind will be forthcoming. It is, thus, reasonable to conclude that subjective experience is not a necessary condition for the mental.

Ryle's charge of a category-mistake

Those who have put the private events of subjective experience at the center of the mental have committed what Ryle calls a "category-mistake . . . represent[ing] the facts of mental life as if they belonged to one logical type or category, . . . when they actually belong to another." The mistake consists of taking talk about a person's mind as talk of events in a world parallel to the ordinary world but occult and mysterious. The truth, according to Ryle, is that

> to talk of a person's mind . . . is to talk of the person's abilities, liabilities and inclinations to do and undergo certain sorts of things, and of the doing and undergoing of these things in the ordinary world.

It would be rash, however, to draw the further conclusion that subjective experiences are in no way involved in whatever is mental. Returning to the case of Leibniz' *petites perceptions* that are not experienced, a person can be conscious of them in various ways, either before getting used to them or when they are alone or when their intensity or his own sensitivity is increased; and Freud's unconscious phenomena can become conscious phenomena under favourable conditions. The beliefs that a man is not aware of in sleep are sometimes the objects of his consciousness, as are his moments of laziness and imaginativeness, his knowledge of arithmetic, and his goals. It is dubious that something that has no connection with states of consciousness could qualify as mental.

Core characteristics of subjectivity. Philosophers are still in deep disagreement on how to characterize what is peculiar to subjective experiences. Some hold that the existence of subjective experience indicates that there are peculiar events that do not occur in the public space–time world that everyone shares and has equal access to but occur only in a private world that each person has exclusively to himself, which he cannot share with others, and to which no one else has access. One man's sensations, for example, are private events that occur in his private world, and another man's sensations occur in a second private world, so that each person has a private world with its own private events.

The role of privacy

Ryle has called this view, with what he admits to be "deliberate abusiveness," "the dogma of the Ghost in the Machine." He characterizes the dogma as follows:

> Minds are not in space, nor are their operations subject to mechanical laws. The workings of one mind are not witnessable by other observers; its career is private. Only I can take direct cognisance of the states and processes of my own mind. A person therefore lives through two collateral histories, one consisting of what happens in and to his body, the other consisting of what happens in and to his mind. The first is public, the second private. The events in the first history are events in the physical world, those in the second are events in the mental world.

Are there private events? Even so adamant a critic of privacy as Ryle admits the existence of some private phenomena, chiefly dreams and daydreams, sensations, thoughts, and imaginings. He insists, however, that

> the sequence of your sensations and imaginings is not the sole field in which your wits and character are shown; perhaps only for lunatics is it more than a small corner of that field.

In Ryle's view, private events occupy a small and in-

essential place in the total range of mental phenomena; but they do occur.

The notion of privacy is really the conflation of two ideas: the metaphysical idea that mental events do not occur in space and the epistemological idea that mental events are objects of awareness solely to the person who is subject to them. Each of these may be considered in turn.

Nonspatiality of mental events

The Rationalist René Descartes, the earliest major philosopher of modern times, held that the essence of all that is nonmental consists in being extended in space. Turning this around and broadening it, one could say that the essence of the mental consists in the lack of spatiality; *i.e.*, the lack of shape, size, and, above all, location. If the philosopher confined himself to events, he would say that necessarily a physical event occurs in some place or other, but, necessarily, a mental event does not. It would be conceded that the person who experiences the mental event does typically have a location, and this leads to the question of why the event is not located where the person is located.

A defender of the nonspatiality criterion would argue that such ascriptions of location to mental events are very different from ascriptions of location for physical events. For a physical event, it is always possible to ask whether it occurred at some point, in some part, or throughout the location. Thus, if the temperature of a body of water rises, one can ask precisely where the rise occurred—at certain points, in certain parts, or throughout the volume. But if a thought occurs, it is senseless to ask whether it occurred throughout the area or only in some part of it. Furthermore, if the water undergoing the rise in temperature is in a box, it is reasonable to say that a rise in temperature occurred in the box; but if the person having a thought is in a box, it is senseless to say that a thought occurred in the box. So the sort of ascription of location is quite different for mental events, and the criterion can still be used to mark off the mental from the physical.

The question remains whether the sort of nonspatiality that is allegedly appropriate to the mental is peculiar to it. If such a physical event as recovering from an illness or changing shape is considered, it would appear also that it does not make sense to ask whether the event occurred throughout the whole volume, in some part, or at some point. Thus, it would seem that even this modified notion of spatiality does not uniquely distinguish the mental.

Privileged status of subjectivity. Other philosophers would interpret subjective experiences not as private events but as a special way of knowing certain events, specifically by introspection. This is called the "privileged access" view. John Locke, contrasting this way of knowing with sensation, called it "reflection," defining it as "that notice which the mind takes of its own operations and the manner of them." It is a way of being aware of one's own present states without the intervention or use of the senses. The emphasis here is on the nature of the way of knowing rather than on the nature of the events known. Someone who holds the privacy view will have to hold that there is some special way of knowing these special events, but someone who holds the privileged access view is not necessarily committed to holding that the events so known are in any way special. A person could hold that one and the same event can be known both by sense perception and in some other way. Being knowable by introspection would then be the characteristic that defines events as mental. Such an account, however, would not rule out that they may also be knowable by sense perception or by inference.

Objections and rejoinders

Some contemporary philosophers deny that there is any such special way of knowing. Ryle offers three objections: first, it would require that there be simultaneously multiple attentions—in the mental event itself and in the attending to that event; though it is not denied that such divisions of attention are possible, he suggests that they are more unusual and difficult to achieve than the proponent of introspection would have the reader believe; second, because there is obviously some upper limit to the number of simultaneous attendings that a person is capable of, there will have to be some mental acts of which a person is unaware, and if it is admitted that some mental events occur without being known in this special way, it is fair to ask whether one must assume that any of them are known that way. Finally, for many states of mind—*e.g.*, extreme panic or fury—the person is so involved that he is incapable of taking note of them; yet such states are not, in consequence, suspect—the person involved is as sure that they occur as he is of any so-called mental events. There is thus no need to postulate this special way of knowing to account for man's knowledge of any such events.

It is not clear how compelling Ryle's objections are. It is admitted that attention can be divided, though it may be contended that it is unusual and difficult to achieve this division. Others would reply that it is a lot more common and easier than might be thought, that it occurs whenever a man takes note of his mental states. And from the fact that he cannot take note at the same time of very many of his mental states, it hardly follows that he never does; each could still be introspectable even if it was not actually introspected on that occasion. As for Ryle's third objection, it might be that some states of mind cannot be introspected, but it does not follow that none can be introspected; they might still be private for all that. Ryle, for instance, while denying introspection, admits retrospection, a capacity to recall one's states just after they occur. It would seem, however, that there is no important difference between a concurrent "introspection" and a prompt "retrospection." One advantage of retrospection is that it would explain a man's self-knowledge of those events that are difficult to explain in terms of introspection; *e.g.*, extreme panic or fury.

Whether a person introspects or retrospects (the truth appears to be that sometimes he does the one, sometimes the other), he would still seem to have a kind of knowledge about his own present and recently past mental states that he does not have of the mental states of others and that others do not have of his. It is not possible either to introspect or retrospect the mental states of others; the knowledge that a man has of the present and immediately past mental states of others must be based upon perceptions or inferences from perceptions, whereas the knowledge that he has of his own present and immediately past mental states need not be, and usually is not, so based.

Introspection as defining the mental

It is possible that the notion of introspection can thus be used to define the mental. Such a definition would be of the form: a mental event is an inner event that can be introspected. The difficulty remains, however, of how "introspected" is to be defined. If it is defined merely as "known without inference or sense perception," then it would seem to apply equally to the knowledge of certain bodily events that no one would want to call mental. A man can know without sense perception, for example, that his heart is beating rapidly or that his fingers are crossed. To rule such cases out, one can include among the senses the kinesthetic sense that utilizes nerve endings within the body—those, for instance, that register the conditions of one's own muscles. But then it might appear that one must say that sensations are not mental phenomena, since the awareness of them typically involves such nerve endings. Such an admission, however, would be fatal for the privileged access view because sensations are precisely the sort of thing to which a person is supposed to have privileged access. If, on the other hand, the philosopher makes it a matter of definition that introspection applies only to the mental, then he cannot define the mental in terms of introspection. Thus, philosophers are at the present time faced with serious and unsolved difficulties in using the notion of introspection to define the mental.

Finally, it is significant here, as it was in the discussion of subjective experience, that to much of man's mental life and to many of the exercises of his mind—*e.g.*, employments of intelligence—he has no special privileged access; there are, in addition, the unconscious phenomena that are not introspectable. So introspection cannot be a necessary condition of the mental.

There is a clue to a more satisfactory criterion of the mental that can be found in the attack on introspection

cited above. There the difficulty was noted that there does not seem to be a way of distinguishing how a man knows his mental state from how he knows such inner physical states as the rapid beating of his heart. But it may be argued that there does seem to be a difference between these two ways of knowing: specifically, it is clear how a person could be shown that he was mistaken in believing that his heart was beating rapidly; but it is by no means clear what would show a person that he was mistaken in believing himself to be feeling a particular throbbing, pounding sensation. For mental events, the subject's own beliefs are peculiarly authoritative. This authority only holds, of course, for present mental events; it is clear that many things could show that a person's belief about a past mental event of his was mistaken. It is sometimes claimed that what distinguishes mental events is their so-called indubitability—the fact that a belief by the subject that the event is occurring cannot be false and is in no way subject to error. In recent times, however, the view that first-person, present-tense reports of mental events are indubitable has come under serious attack; to make such a report is to classify, and it is argued that it is always possible to err in classification.

Indubitability; incorrigibility; presumption

Instead of holding that such beliefs are indubitable, it is often more modestly maintained merely that such beliefs are "incorrigible," meaning that nothing will count as overthrowing (or correcting) such beliefs. A person who believes that he is experiencing a throbbing sensation may be mistaken; but there is nothing that will show an observer or him that he is mistaken, nothing that will entitle either of them to believe that he is mistaken. He may be experiencing a throbbing sensation even when no part of his body is actually throbbing, though the explanation for this curious fact might not be known.

It might be objected against the incorrigibility thesis that the same difficulty that arises for the alleged indubitability of first-person, present-tense beliefs about mental events also arises for their alleged incorrigibility. For if misclassification is possible, it would also seem possible to gather evidence that someone is misclassifying. If one could confuse a throbbing sensation with a different but somewhat similar sensation, it is reasonable to believe that this confusion could be known by others to have occurred. Perhaps the best that can be said for the incorrigibility thesis is that there is always a strong presumption that such beliefs are true, though this presumption can sometimes prove to be unwarranted. But then it is by no means clear that privileged authority is a unique criterion that distinguishes mental events, for such a presumption would also hold for many nonmental events as well (*e.g.*, the belief that one's heart is beating rapidly). Yet if the degree of presumptive force is taken into account, it is reasonable to say that it would be *comparatively* harder to overthrow beliefs about one's present mental events; and perhaps this is all that one needs to give the criterion force.

THE EXISTENCE AND STATUS OF THE MIND

The basic metaphysical issues in the philosophy of mind concern whether the mind exists and, if it does, what kind of existence it has and what its relation is to the rest of what exists. Materialists hold that only physical matter (and physical energy) exists. For those who hold, on the other hand, that the mind exists as an immaterial entity, there are dualistic theories for which both immaterial minds and material bodies exist, and immaterialistic theories for which only minds exist but not bodies. There are, finally, the so-called neutral monist theories for which the fundamental existents in nature are neither mental nor physical but some neutral stuff out of which both the mental and the material are formed.

History of Materialism

The mind as material. The basic contention of Materialism is that nothing exists but matter and its purely material properties, so that the concepts that are necessary and sufficient for describing and explaining matter will be necessary and sufficient for describing everything that exists. This view can be found in the early Greek philosophers. Thales of Miletus, who lived some 2,500 years ago (6th century BC) and who is generally regarded as the first philosopher in the Western tradition, is supposed to have held that all things are composed of water in some form or other; later thinkers added air, fire, and earth to the list of fundamental elements. The philosopher Anaxagoras of Clazomenae, born about 500 BC, introduced a new factor, *Nous* (Mind), which arranged all other things in their proper order, started them in motion, and continues to control them. There is still controversy as to how his concept of Mind is to be understood, but since he spoke of Mind as being "the finest and purest of all things" and as occupying space, it is likely that he did not think of it, as some later thinkers did, as nonmaterial stuff but rather as a very special kind of material stuff.

It was with the Atomists, Leucippus of Miletus and his disciple Democritus of Abdera, in the 5th and early 4th centuries BC, that Materialism was given its most developed statement. According to them, nature consists solely of an infinite number of indivisible particles, having shape, size, and impenetrability, and no further properties, and moving through an otherwise empty space. The shape, size, location, and movement of these particles make up literally all of the qualities, relations, and other features of the natural world. Such phenomena as sensations, images, sense perceptions, and thought—of particular interest to the philosophy of mind—are explicitly held to consist in the various qualities and relations of the particles.

Contemporary Materialists would, no doubt, wish to incorporate into their theory the latest findings of the physical sciences—the convertibility of matter and energy, the wave–particle duality, and the various subatomic particles and antiparticles with their peculiar properties, including the conservation of charge, direction of spin, and direction of time—but these would represent mere changes in detail. In broad outline, the theory would be the same.

Given the theory of Materialism in such broad outline, however, a serious question remains concerning the actual account to be given of such phenomena as sensations, images, perceptions, emotions, memories and expectations, desires, beliefs, thoughts, imaginings, and intentions. Among the possible views are those called eliminative Materialism, Behaviourism, and the central-state theory.

Eliminative Materialism. A philosopher might hold that there are no such things as sensations, images, perceptions, or emotions and that there never have been such. From this view, those who have believed in the existence of such things have simply been mistaken. A person might hold this view, called eliminative Materialism, on the grounds that all such talk is (1) meaningless noises, gibberish, or (2) part of a set of theories that are outmoded, scientifically fruitless, and to be discarded, like theories about witches or the Homeric gods. On either account, it is implied that all such terms should be eliminated from the philosopher's vocabulary. There is a further doctrine, however, to the effect that all such talk is (3) meaningful but nondescriptive and without truth value. On this account, the proper function of such language is not to state facts but might be to prescribe or evaluate.

Two kinds of reductive Materialism

Among Materialistic views, the alternative to eliminative Materialism is some kind of reductive Materialism. According to this view, there are indeed such things as sensations, images, perceptions, and emotions, but they are only complicated forms of matter in motion. The philosopher may thus continue to use terms referring to such things (in contrast with eliminative Materialism), but he should keep in mind that no extra entities or features are being postulated over and above the physical entities with their physical features.

Behaviourism. If one asks reductive Materialists what sensations, images, and the like are, he will find that two alternatives have been proposed. The first is Behaviourism, the view that all such terms refer to the behaviour or movements of certain bodies, particularly of the higher animals. Thus, the Behaviourist would claim that to feel pain is to groan, writhe, blanch, moan, and so on, or at

least to be disposed or tend toward such behaviour; to desire food is to engage in eating in the presence of food, in hunting in the absence if food, and so on, or at least to be disposed or tend toward such behaviour; and so also with all of the states and activities that one thinks of as mental.

Usually, Behaviourism is intended as a logical doctrine to the effect that the very meanings of the words referring to the mind, its mental states and activities, are to be analyzed in behavioral terms, that every mentalistic term is synonymous in meaning with some behavioral term. It is important to distinguish this view, logical Behaviourism, from the view of many psychologists that the most fruitful way to study psychological phenomena is to study human and animal behaviour. Such a view might be called methodological Behaviourism because it is actually the proposal that the science of psychology restrict itself to certain methods. It does not entail logical Behaviourism. Logical Behaviourism might also be distinguished from the view that psychological and behavioral terms, though not synonymous in meaning, have, as a matter of fact, the same denotation or reference, a view that might be called de facto Behaviourism.

Central-state theory. The second type of reductive Materialism is the central-state theory. In this view, mental states and activities are identical with states and activities within the body (hence this theory is sometimes called the identity thesis). In particular, they are identical with states and activities of the central nervous system or brain. Thus, to feel pain is for the brain to be in a particular state; to desire food is for the brain to be in another state.

Distinctions parallel to those for Behaviourism can be made for the central-state theory. A psychologist might hold that the only useful way of studying psychological phenomena is to study the central nervous system; this view might then be called methodological central-statism. A philosopher might hold that the very terms referring to the mind, its mental states and activities, are synonymous with neurological terms (or, more plausibly, that they *should* be taken to be synonymous—they obviously are not synonymous as language now stands). This position, which could be called logical central-statism, would differ from the eliminative Materialism mentioned above in that it would retain mentalistic terms rather than eliminate them, but would redefine them neurologically. If this came to pass, such terms might eventually disappear, a result that eliminative Materialism would strive to achieve more directly.

Plato's *psychē*; Descartes's substances

The mind as immaterial. Plato was the first important figure in the Western tradition explicitly to defend the doctrine that the mind is an entirely nonmaterial entity —without such defining material properties as size, shape, or impenetrability—separate and distinct from the human body and able to exist apart from it. Plato used the Greek word *psychē* (traditionally translated as "soul") to refer to this entity.

Plato held that the mind (*psychē*) was in charge of the body and directed its movements. In his dialogue the *Phaedrus*, Plato spoke of the mind as having both appetitive desires and the higher desires and as having, in addition, a rational capacity to control, direct, and adjudicate between these two types of desires. This rational capacity of mind is the most valuable aspect of man, the part most worthy to be nurtured and developed, and the aspect of man most likely to be immortal (much of the dialogue concerning the last hours of Socrates, the *Phaedo*, is about these topics).

Dualism. Plato was a dualist; he believed in the existence of both material entities and immaterial ones. The most explicit statement of dualism, however, is found in the writing of René Descartes, who argued that mind and matter are two separate and distinct sorts of substances, absolutely opposed in their natures, each capable of existing entirely independently of the other.

The dualist is faced with the question of how, if at all, mind and matter are related to each other. Most dualists would agree that in rocks, tables, and other material things, matter exists alone and unrelated to mind; and that at what is called death (since for Descartes the soul is immortal), immaterial minds exist unrelated to matter. In the case of a living human being, however, there are two substances: a mind and a body. Thus, the question arises of how the relation between them is to be conceived. Any dualistic theory would have to account for certain obvious facts about human beings. When people's bodies are affected in certain ways—when subjected, for example, to bright lights, loud noises, rises in temperature —people often experience colours, sounds, or sensations of warmth or of pain. Again, when people experience certain things, their bodies undergo certain changes—they shut their eyes, they put their hands to their ears, they perspire, or their faces become pale.

There are various ways that dualists have proposed to account for these facts. The most straightforward position is interactionism, the view (held by Descartes) that mind and body are capable of affecting each other causally, so that what happens in the body can produce effects in the mind and vice versa. Descartes decided that somewhere within the nerve tissues of the brain was the place where the interactions occurred and chose the pineal gland as the precise point because of its central location. (It is now known that the pineal gland cannot perform the functions that Descartes attributed to it, though its precise functions are still unknown.)

Interactionism; epiphenomenalism; parallelism

It is an implication of interactionism that there cannot be a complete explanation of brain functioning exclusively in terms of the laws of neurology because of the intervention at crucial moments of the influences of the mind. This limitation has struck many scholars as an important difficulty. One way around it is epiphenomenalism, the view that the body can affect the mind but that the mind cannot affect the body. Mental events are mere by-products of brain activity, like the exhaust from an engine or the shadows cast by moving figures. When the mind would appear to be affecting the body, as when the experience of pain seems to cause one to grimace, the epiphenomenalist hypothesizes that the very brain state that produces the experience of pain also produces the grimace.

Dualists of either the interactionist or epiphenomenalist persuasion are committed to the existence of causal relations between body and mind. Some philosophers, struck by how entirely different mind and matter are supposed to be on the dualist hypothesis, have held it to be impossible that they could affect each other. Psychophysical parallelism avoids this difficulty by postulating that mind and body are like two perfect clocks, each with its own mechanism but in constant and uniform correlation with the other. Unfortunately, the analogy does not hold very well, for the mind does not seem to have the kind of internal mechanism that would account for any precise sequence of its successive states, and without such a mechanism it would be implausible to expect a constant but noncausal correlation between those states and states of the body.

Immaterialism. Some philosophers have held the doctrine of immaterialism, so named by Bishop George Berkeley, one of the classic British Empiricists, in whose view everything that exists is mental, "of the stuff that dreams are made of," and there is no such thing as the material. There are two major alternatives here: that reality consists of one vast, all-encompassing mind, or that it consists of a plurality of minds. The former position is sometimes called absolute Idealism; the latter, which Berkeley himself held, is sometimes called subjective Idealism. (The term Idealism is often used with wider connotations to include any view that attributes greater value or importance to the mental than to the material aspect of things, or emphasizes the role of the mind in determining the nature of things.)

Berkeley's mentalism

The philosophy of Berkeley represents a highly developed and energetically defended statement of the position that reality consists wholly of minds, the divine Mind and the multiplicity of finite minds that includes all men. Whatever exists does so either because it is a mind or because it is dependent upon a mind; nothing material exists. Berkeley argued that the notion of the material should play no role in one's thinking, for its existence is

unverifiable, its postulation unnecessary, and, at bottom, the very notion is self-contradictory. How does Berkeley view the status of tables and chairs, rocks, the moon, and all of the other apparently material things that everyone accepts as existing? Berkeley agreed that they do indeed exist but only as collections of ideas that exist in the mind of God and that are often caused by God to exist in the minds of men as well.

There are well-known difficulties in Berkeley's view. His account of the nature of tables and other objects cannot be accepted as an account of the meanings of these terms because it is implausible to think that the concept of a divine Mind is somehow part of their meaning. Nor does it seem a plausible scientific theory about such objects because of its ad hoc character and its lack of predictive value. If the notion of God is dropped, however, the philosopher is left with the phenomenalistic theory that such objects are collections of appearances. But phenomenalism also has serious difficulties; in particular, it cannot in the end account for the difference between real objects and illusions because it cannot provide an account of the difference between circumstances in which perceptions are veridical and those in which they are not.

The other variety of immaterialism, called absolute Idealism, derives from certain doctrines of Immanuel Kant and of the classical German Idealists who followed him—Johann Fichte, Friedrich Schelling, and G.W.F. Hegel—concerning the fundamental dependence of reality on mind or spirit in general. Among the several philosophers who have defended this view, there was, at the turn of the 20th century, F.H. Bradley, whose *Appearance and Reality* (1893; 2nd edition 1897) comprises its most systematic exposition and defense. Bradley denied that a plurality of minds exists and insisted that there is only one infinite Mind, Idea, or Experience that comprehends all of existence within it.

Neutral theories. Another important view has been that neither the mental nor the physical is really fundamental; each is an aspect of some underlying reality that is neither mental nor physical but neutral between them. There are many variants of such a view. Spinoza, a 17th-century Rationalist, held that the underlying substance, which encompassed all of reality and which he called God or Nature, had both thinking (the mental) and extension (the material) as attributes. A modern version of this position is that of Peter Strawson, a leading philosopher of the Oxford "ordinary language" school, who differs from Spinoza in holding that there is a multiplicity of substances, some of which are purely material and some of which are persons (thus he is not really a monist). Strawson conceives of persons as substances whose nature is to have both mental and physical attributes. Thus, one and the same substance can have both qualities, and the difference between the mental and the physical is conceived as a basic difference between the qualities.

Spinoza's substance and attributes

A different approach was suggested in some of Hume's writings and diversely stated by the Pragmatist William James and by various Positivists (Ernst Mach, Rudolf Carnap, and A.J. Ayer). They postulate a number of particular entities, experiences, that go to make up minds when they are related in certain ways, as by the laws of association and memory, and that go to make up bodies when the entities are related in other ways, as by the laws of perspective. Thus, a person's mind is conceived to be just the collection of his experiences, whereas a physical object is conceived to be just the collection of experiences that people can have of it. Here the difference between the mental and physical consists in the different kinds of relations obtaining between the neutral particulars, experiences.

Recently, it has been suggested by certain Linguistic philosophers that the difference between mind and body lies in two different kinds of language or conceptual systems: the physicalistic-conceptual language, on the one hand, with its spatiotemporal terms, and person-talk, on the other, with its reference to norms for assessing the rationality, moral responsibility, and ethical value of human actions.

Existentialist and Phenomenological philosophers have expressed similar conclusions, supported not so much by linguistic considerations as by general observations of man's condition as a being in the world, with a body, which he experiences and which, by its nature, affects his experience. Man can be viewed as a spatiotemporal aggregate, an object for observation, study, and manipulation, an instance of the laws of nature. But man can also be viewed as a self-moved mover, a being who alters himself and the world through the decisions he makes, who determines values and invests things with those values, who can make his life and his world according to the values that he determines, and who, in the end, can negate his values and even terminate his life by choice. Here, on the mind–body problem, the philosopher finds surprising similarities between some Analytic philosophers of the English-speaking world and the more speculative continental philosophers.

Existentialist and Phenomenological views

THE ANALYSIS OF MENTAL PHENOMENA

When the specific phenomena that go to make up the mental are considered, one finds that they all raise philosophical issues, only some of which can be sketched here. Mental phenomena are traditionally divided into three areas: the cognitive, which is concerned with knowledge; the affective, with feeling; and the volitional, with action. It is no longer believed that this division reflects the three so-called basic faculties that comprise the mind; nevertheless, as a very rough classification, it provides a convenient approach to the variety of mental phenomena.

The cognitive. Many philosophers from Plato on have taken man's ability to know as the characteristic distinguishing him from all other animals. The very name of his species, *Homo sapiens*, means "man the knower."

If one asks what knowledge is, he has raised the central problem of a major field of philosophy, epistemology. But there is also a very important psychological aspect to knowledge, and that is where the philosophy of mind becomes relevant. It is often claimed, for example, that knowing that something is so entails believing that it is so; and the nature of belief lies clearly within the province of the philosophy of mind. Since a person does not lose a belief when he is not consciously attending to it (for example, when he is asleep), the approach to belief most in favour today is to treat it as a disposition, which, like all such, comes to open expression only sporadically. Other psychological phenomena falling within the area of the cognitive are attention, sense perception, understanding, memory, inferring, and doubting. The view that each of these requires a subjective experience has been effectively refuted in the writings of Ludwig Wittgenstein, one of the seminal thinkers of modern Linguistic Analysis. Remembering that the oven is still turned on may consist in nothing but getting up in the middle of a conversation, going over to the oven, and turning it off, all the while animatedly continuing the conversation. But exactly why this is called "remembering that the oven is still on" is not clear. Perhaps the best that can be said is that there are analogies between such instances of remembering and other, more self-conscious instances. It is the task of the philosophy of mind to examine, classify, and analyze the relations among such phenomena.

Psychological aspect and phenomena

The affective. Man has not only the capacity to know but also the capacity to respond emotionally to what he knows. A man may not only believe that some event will occur, but he may also dread it or welcome it. Concerning the things that a person knows, he may approve or disapprove, love or hate, pity or envy, enjoy or abhor them. Here, although the subjective experience often plays an important role, it clearly is not the whole story. To enjoy doing something, as has been pointed out, is not to do the thing *and also* undergo a series of experiences of enjoyment; it may simply be to do the thing when circumstances permit and make efforts to avoid its cessation or interruption. But a disposition-to-behave approach will be less successful for other affective phenomena. For example, people have feelings about the past—regret, nostalgia, pride—feelings in which future behaviour plays a relatively minor role.

All of the affective phenomena so far considered have

the property of intentionality, of being directed toward an object. It is clear, however, that this is not a sufficient condition for defining the affective, since it marks out too broad a scope—including, for example, believing, which, though intentional, falls not within the affective but within the cognitive. But neither does intentionality seem to be a necessary condition of the affective. Moods like depression, anxiety, or joviality may not have any specific object, though it is sometimes replied that such emotions take as objects anything the person happens to think of. Sensations also do not seem to be intentional, even though they are usually classified as affects. One view is that sensations are really cognitions—the awareness of some bodily disturbance. The difficulty in trying to decide whether a sensation is an affect or a cognition further illustrates the inadequacy of the classification of mental phenomena into the cognitive, affective, and volitional.

The volitional. Intellect and emotion often come to expression in volition and action, important topics in the philosophy of mind—topics that comprise such concepts as motive, desire and purpose, deliberation, deciding, intention, trying, and action, both voluntary and involuntary.

There is a rough distinction to be made between the things that happen to a person and the things he does or makes to happen. If a person slips on the ice, it is something that happens to him; if he walks on the ice, it is something that he does. "Henry slid on the ice" is ambiguous: it may report something that happened to Henry or something that Henry did, depending upon the meaning. In this example, the observable event may be the same: from a photograph of Henry sliding on the ice one may not be able to tell which it is. The problem of action is primarily to understand this distinction and its ramifications. Wittgenstein once put the question this way: "And the problem arises: what is left over if I subtract the fact that my arm goes up from the fact that I raise my arm?"

Wittgenstein's question on action

There are a number of different answers: (1) Actions are events produced by causes of certain sorts—volitions or acts of will according to some theories; beliefs and desires under other theories; and simply persons or agents in yet another theory. (2) Actions are events that are "caused" in a special sense; they have a teleological rather than an efficient or mechanical cause, or an immanent (or originating) cause rather than one that is merely a reaction to, or modification of, an action coming from some other source. (3) Actions are events that are properly characterized and assessed in terms of rules of conduct, or principles of rational and ethical behaviour, and for which the agent is held responsible, liable, accountable, to be praised or blamed, rewarded or punished.

Any theory of action is expected to throw light on the issue of free will, a matter of great importance for ethical theory. If the philosopher holds that free will is compatible with determinism, any of the views above will allow for free will. Even if he holds that an action is not free if it has causes that eventually lie outside the agent, his view will be compatible with the various views of action unless he holds the version of (1)—that an action is an event produced by volitions or beliefs and desires—and also holds the additional thesis (2)—that volitions or beliefs and desires themselves have causes that lie outside the agent. Only then will there be no freedom of the will.

SOME METAPHYSICAL AND EPISTEMOLOGICAL ISSUES

Personal identity through time. A person, as he goes through life, changes in many ways; but he remains the person that he was. He is that person who was born on a certain day, that person who graduated 23rd in a particular high school class, who married on a certain date in a certain place; he has a particular identity through time. It is difficult to state what exactly it is that makes a person one and the same self through time.

Bodily versus psychological criteria

An obvious starting point is the fact that throughout a person's natural life he has the same body and that this is what makes him one and the same person throughout a particular period of time. But there are difficulties in this view. First, since the body cells are constantly being replaced and in some instances whole organs are transplanted, it is not clear what makes a particular body identical with a body that existed, say, 20 years earlier. A second difficulty arises through the possibility of brain transplants; if two brains were interchanged, in all likelihood there would be a systematic interchange of memory, beliefs, personality and character traits, skills, and habits of thought and action. Such a transplant would incline one to say that not merely a small portion of each body had been interchanged but two people as well; for one also takes as a criterion of personal identity similarities through time of memory, personality, skills, and habits. After all, a man is often willing to say that this is the same person who did something in the past, not on the basis of knowing that it is the same body but on a quite different basis—that the person recounts the past situation with great accuracy, exhibits similar personal reactions, and displays the same skills.

Because two different kinds of criteria, bodily and psychological, are used for determining personal identity, it is possible to imagine instances of conflict in which the criterion of bodily identity would indicate that it is a different person but the psychological criteria would indicate that it is the same person and vice versa. The Bohemian novelist Franz Kafka, known for his nightmarish works, in his short story *Die Verwandlung* (1915; Eng. trans., *The Metamorphosis*, 1937) tells of a person who awoke one morning to find, to his horror, that he had the body of a large insect. Although his family accepted his conclusion that he was the same person even though he had an entirely different body, others would have disagreed. There is still, in fact, considerable disagreement among scholars on this whole issue—on how to state precisely the bodily criterion; on whether there is a psychological criterion as well and, if so, how it is to be formulated; on what is the basic criterion of personal identity; and on what to say about instances in which criteria conflict.

Personal immortality. Many people believe that when the human body ceases to be a living system, there is not total annihilation of the person but that in some respect the person continues to exist. The philosopher of mind can put aside the various watered-down versions of immortality in which the person continues to exist in the remote sense that people still remember him or his works or that his influence continues through history. The philosopher does look with interest, however, on the claim that there is an immortality in which a person, in his survival, meets the psychological criteria of personal identity, of inheritance of memory, beliefs, habits, and personality characteristics.

Problems of meaning and fact

It is clear that a person's view of immortality will be affected by opinions that he holds about the relation of mind to matter. Given the versions of Materialism that urge the elimination of mental terms or their definition in bodily terms or that take bodily identity to be the basic criterion of personal identity, the very notion of survival after death is completely unintelligible. Many philosophers, however, reason that, since the notion of survival is intelligible, such versions of Materialism cannot be accepted. Central-state or identity theorists would admit survival to be an intelligible notion but would view it, like lightning without electricity, as something that never happens; they would thus be in agreement with many dualists, in particular epiphenomenalists and psychophysical parallelists. Even an interactionist would be free to accept or reject survival, as would a neutral monist.

If a philosopher holds that survival is an intelligible notion, he is still left with the further question of whether it ever happens. In the past there have been various a priori arguments for survival after death. Arguments based upon the nature of the self, such as its indivisibility, can be found in Plato's *Phaedo*. Kant argued that man's moral principles require survival as a postulate. But among those today who hold that survival is intelligible, it is widely agreed that a priori arguments will not do. If there is survival, they say, it is a contingent fact and not a necessity; one must thus look to empirical data for guidance. A survey of the evidence shows that the case against survival, though strong, is by no means conclusive. One

thing is clear: if there is survival, the survivors can theoretically give firsthand testimony to it, whereas if there is no survival, there will be no one to give such testimony.

Knowledge of other minds. An important problem in the theory of knowledge has been the status of the belief in other minds, the belief that one's own consciousness is not the only consciousness in existence. Though few, if any, sane persons have seriously accepted solipsism (the view that one's own is the only consciousness), the grounds for rejecting it are not at all clear.

Again, as with the problems of personal identity and personal survival, one's view of the relation of mind to matter is relevant. On various Materialistic views, the problem reduces itself to that of justifying the belief in an external world that contains other bodies of the appropriate sort and with the appropriate behaviour. But for dualists and immaterialists, who hold that mental phenomena are something irreducibly different from the physical, there is the further question of whether that something is unique to oneself or whether there are other instances of it in the world.

Direct, transcendental, analogical approaches

Some scholars claim that men sometimes have direct awareness of the conscious states of others, either in telepathic experiences, moments of empathy, or even in everyday social intercourse. There is, moreover, a transcendental argument, found in Kant and recently defended by Strawson, holding that, unless a person could be confident of the existence of other minds, he could not be confident of the existence of his own mind. A quite different line of reasoning, the so-called argument from analogy, is based upon the similarities between one's own body and its behaviour, on the one hand, and other human bodies and their behaviour on the other. To pursue the argument, since a mind is known to be associated with one's own body, it is reasonable to conclude (by analogy) that another mind is also associated with the body of another person. Finally, there is the view that the best way to explain the complex behaviour of other bodies, especially their ability to behave rationally, and in particular to speak and communicate information, is to postulate other minds at work.

None of these arguments compels strong conviction, certainly not the degree of conviction that all men feel concerning the existence of other minds. Whether stronger arguments will be found, whether philosophers must admit that there is a considerable amount of faith required here, or whether they will reformulate their concepts of the mind in a more Materialistic way to bring them in closer accord with observable data remains to be seen.

BIBLIOGRAPHY. Although the philosophy of mind has only recently emerged as a special field, many of its topics have long been discussed. Various formulations of Materialism can be found in the writings of the pre-Socratic philosophers, especially LEUCIPPUS and DEMOCRITUS. PLATO'S dualism and his views on the nature of the soul appear in the *Phaedo, Timaeus, Phaedrus,* and books iv and x of the *Republic.* ARISTOTLE devoted a whole treatise, *De Anima* (*On the Soul*), to the subject, expressing a qualified Materialism. THOMAS HOBBES, *Leviathan* (1651), was radically Materialistic; whereas RENE DESCARTES, *Meditationes de prima philosophia,* 2nd ed. (1642), and other writings, present a classic interactionist dualism. Dualism of the parallelist variety can be found in the writings of GOTTFRIED LEIBNIZ. BENEDICT DE SPINOZA, in his *Ethica* (1677), rejected both Materialism and dualism, expounding a double aspect theory. GEORGE BERKELEY, *Treatise Concerning the Principles of Human Knowledge* (1710), provides the classic statement and defense of Idealism (in his word, Immaterialism).

The contemporary interest in the philosophy of mind is largely a result of GILBERT RYLE'S brilliant and polemical *Concept of Mind* (1949). Also of great importance was the wholly new approach to all of philosophy taken by LUDWIG WITTGENSTEIN in his *Philosophical Investigations* (1953), which contains many specific applications to the philosophy of mind. There followed a spate of journal articles, some of the best of which are in the following anthologies: ALAN ROSS ANDERSON (ed.), *Minds and Machines* (1964); MYLES BRAND (ed.), *The Nature of Human Action* (1970); VERE C. CHAPPELL (ed.), *The Philosophy of Mind* (1962); ANTONY FLEW (ed.), *Body, Mind, and Death* (1964); DONALD F. GUSTAFSON (ed.), *Essays in Philosophical Psychology* (1964); STUART HAMPSHIRE (ed.), *Philosophy of Mind* (1966); SIDNEY HOOK (ed.), *Dimensions of Mind* (1961); HAROLD MORICK (ed.), *Introduction to the Philosophy of Mind* (1970); GEORGE PITCHER (ed.), *Wittgenstein* (1966); G.N.A. VESEY (ed.), *Body and Mind* (1964); ALAN R. WHITE (ed.), *The Philosophy of Action* (1968); and OSCAR P. WOOD and GEORGE PITCHER (eds.), *Ryle* (1970). Selections written from Existentialist and Phenomenological perspectives are in STUART F. SPICKER (ed.), *The Philosophy of the Body* (1970). Introductory writings that include original contributions as well as balanced assessments are GERALD E. MYERS, *Self* (1969); ALAN R. WHITE, *The Philosophy of Mind* (1967); and JEROME A. SHAFFER, *Philosophy of Mind* (1968). For analyses of particular mental phenomena, see G.E.M. ANSCOMBE, *Intention* (1957); D.M. ARMSTRONG, *Bodily Sensations* (1962); P.T. GEACH, *Mental Acts* (1957); STUART HAMPSHIRE, *Thought and Action* (1959); ANTHONY KENNY, *Action, Emotion and Will* (1963); A.C. MACINTYRE, *The Unconscious* (1958); NORMAN MALCOLM, *Dreaming* (1959); A.I. MELDEN, *Free Action* (1961); R.S. PETERS, *The Concept of Motivation,* 2nd ed. (1969); H.H. PRICE, *Thinking and Experience,* 2nd ed. (1969); CHARLES TAYLOR, *The Explanation of Behaviour* (1964); RICHARD TAYLOR, *Action and Purpose* (1966); and A.R. WHITE, *Attention* (1964). Concerning some of the metaphysical and epistemological issues, A.J. AYER, *The Concept of a Person,* (1963); and SYDNEY SHOEMAKER, *Self-Knowledge and Self-Identity* (1963), deal with the problem of personal identity. Issues concerning the possibility of an afterlife are discussed in C.J. DUCASSE, *Nature, Mind and Death* (1951) and *The Belief in a Life After Death* (1961); and by C.D. BROAD in *Religion, Philosophy and Psychical Research* (1953) and *Lectures on Psychical Research* (1962). The problem of one's knowledge of other minds is explored in HAROLD MORICK (ed.), *Wittgenstein and the Problem of Other Minds* (1967); ALVIN PLANTINGA, *God and Other Minds* (1967); and JOHN WISDOM, *Other Minds* (1952).

Minerals

A mineral is a solid formed by natural processes; generally it is crystalline and inorganic. Approximately 50 new species are added each year to the presently known 3,000 types. Minerals of recognizable shape, colour, and other properties are collected in museums and by private collectors; particularly beautiful rare minerals are prized as gems. These specimens are very atypical, however, and most minerals in nature occur inconspicuously as the components of rocks and soil.

The fundamental nature of minerals is revealed by complex chemical and physical techniques. The internal crystal structure and the chemical composition are characteristic properties of each mineral, and they permit definitive characterization and an understanding of the processes controlling the growth and subsequent history of minerals. The obvious surface properties of minerals such as shape and colour tend to depend on the fundamental properties but are often confused by accidental features, such as those produced by exposure to weathering, that hinder or prohibit identification. The classification of minerals historically began from consideration of surface properties, but it is now based on internal properties.

Synthetic equivalents of some minerals are produced industrially (*e.g.*, rubies and diamonds), and certain biological products also consist of minerals (*e.g.*, apatite in bones and teeth; phosphate and oxalate minerals in biological stones and certain tumours). Many industrial processes depend directly on mineralogical reactions (*e.g.*, crystallization of slag in blast furnaces, and of concrete and cement), and all metallic processes depend ultimately on minerals as a source. Mineralogy plays a role in all the geological sciences and in many of the other physical sciences. For example, agriculture depends on the maintenance of appropriate minerals in soils, and the distribution of ice is critical to meteorological phenomena. In fact the condensation of gases into minerals is proposed as a major accretion process in the universe—the ultimate origin of the Earth would be the condensation of solar matter.

This article provides a summary of the nature, properties, and occurrence of minerals and of mineral associations and origins. For more specific information on rock-forming minerals and other important mineral groups, see the separate articles: AMPHIBOLES; CARBONATE MIN-

ERALS; CLAY MINERALS; FELDSPARS; FELDSPATHOIDS; MICAS; NATIVE ELEMENTS; OLIVINES; PHOSPHORITES; PYROXENES; SILICA MINERALS; SILICATE MINERALS; SULFIDE MINERALS; and ZEOLITES. The crystal structure of minerals is presented in greater detail in CRYSTALLOGRAPHY, and the occurrence of minerals on and within the Earth is further treated in ORE DEPOSITS; IGNEOUS ROCKS; SEDIMENTARY ROCKS; METAMORPHIC ROCKS; and EARTH, STRUCTURE AND COMPOSITION OF. See GEMSTONES for additional information on precious minerals; for discussions of the conditions surrounding mineral formation in nature, see the articles GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES; and GEOCHEMICAL EQUILIBRIA AT LOW TEMPERATURES AND PRESSURES.

THE NATURE OF MINERALS

Crystal structure and chemistry. All minerals have regular arrangements (lattices) of atoms that have some geometrical symmetry. For each repeating unit cell, the smallest unit of a mineral that retains its basic structure and composition, there are sets of sites occupied by atoms at distances determined by the chemical bonding of the constituents involved. In quartz, for example, each silicon atom is surrounded by four oxygen atoms lying at the corners of a tetrahedron at a distance of 1.6 angstroms (one angstrom unit equals 10^{-8} centimetre). Each oxygen atom is close to two silicon atoms, and the whole atomic assemblage can be considered as an infinite framework of silicon–oxygen bonds. The crystal structure can be determined by X-ray-diffraction methods—*i.e.*, subjecting a crystal to radiation and employing Bragg's law, which relates the wavelength of radiation and the angle of diffraction of the radiation to the internal spacing of crystallographic planes. The cell dimensions, symmetry, and diffraction intensities provide unique identification.

From the geometrical distribution of atoms in the unit cell, and from the general principles of chemical bonding, the type of chemical bonding can be envisaged and used in the interpretation of mineralogic properties.

This topic is treated more fully in the article CHEMICAL BONDING, and the four principal types that are of mineralogical concern will be but briefly described here. The first of these is ionic bonding, the permanent transfer of electrons from atoms to form ions, which undergo electrical attraction and repulsion. A second type is covalent bonding, in which clouds (groups) of electrons are shared between atoms. Metallic bonding involves the formation of an electron "gas" throughout an entire crystal. Van der Waals bonding, the fourth type, is a weak attractive force resulting from temporarily induced distortions of electron clouds. Most bonds are a mixture of more than one type.

Copper and gold typify metallic bonding and have atoms lying at the faces and corners of the cubic unit cell, so that each atom has 12 neighbours. Arsenic is only semimetallic; its structure is similar to that of copper or gold but is distorted so that it has three nearest neighbours to which it is partly bonded covalently.

Halite (common salt) typifies ionic bonding. The sodium and chlorine atoms lie in interpenetrating lattices, and the symmetry is such that each atom has six near neighbours.

Diamond is a prime example of covalent bonding. Carbon atoms lie in a tetrahedral arrangement with covalent bonds linking all atoms into a single edifice. In graphite, however, which also consists solely of carbon, the carbon atoms lie in layers or planes of hexagonal symmetry; they are bonded by covalent forces within the layer but by weak van der Waals forces between the layers.

Irrespective of the type of bonding, the crystal structure is based on fascinating geometrical considerations. Even the most complex mineral structure has a simple underlying pattern that can be analyzed by using the principles of symmetry and topology (the study of geometric properties that are unchanged by continuous transformation). Complex structures are always distorted in response to subtle chemical forces not completely understood.

The condensed nature of crystalline minerals results in close packing of near-spherical units in most ionic and metallic forms. Covalent forces require special bond angles that are inconsistent with simple concepts of close packing. On Earth, oxygen (O^{2-}) is the dominant anion (negatively charged ion), and it is larger than most of the cations (positively charged ions). The outer part of the Earth may be said roughly to consist of close-packed oxygen ions with the interstices occupied by cations.

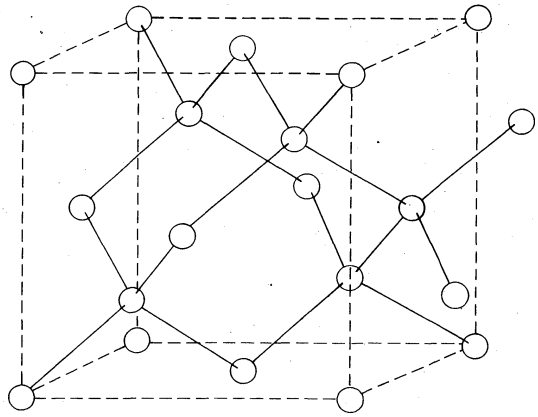

Figure 1: Structure of diamond. Positions of carbon atoms are shown by circles, direction of strong covalent bonds by the solid lines; dashed lines show the unit cell.

Close packing in mineral structures

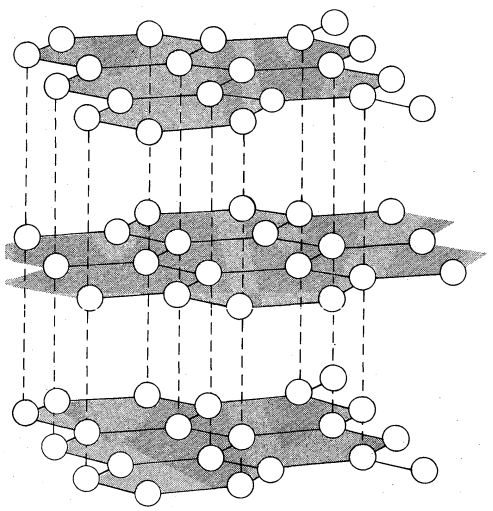

Figure 2: Structure of graphite. Each atom is bound triangularly to three neighbours, producing layers.

The two simplest close-packed arrangements are cubic close packing and hexagonal close packing. The former is illustrated by the structure of copper and gold. There are two types of interstices, one type between six atoms (*i.e.*, six-coordinated) and one type between four. The halite structure, for example, consists of small sodium cations (Na^+) that occupy the six-coordinated holes between the large chlorine anions (Cl^-). The substance magnesium oxide (MgO) may exist deep in the Earth with the

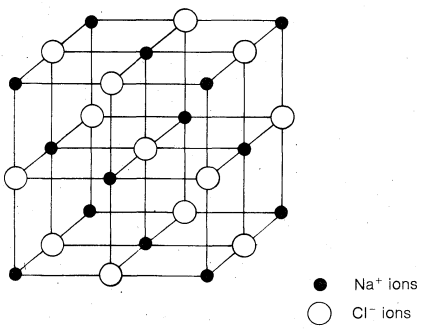

Figure 3: Structure of halite, NaCl.

halite-type structure composed of large oxygen anions (O^{2-}) and small magnesium cations (Mg^{2+}). The second type of interstice can be envisaged from the diamond structure. If every alternate atom grows while the other half diminishes in size, the large ones ultimately will come into contact, and the small ones will just fill half the holes, leaving the other half empty.

Effect of ionic size

Ions have different inherent sizes, and the actual crystal structures result from minimizing the electrical potential.

Ward's Natural Science Establishment, Inc.

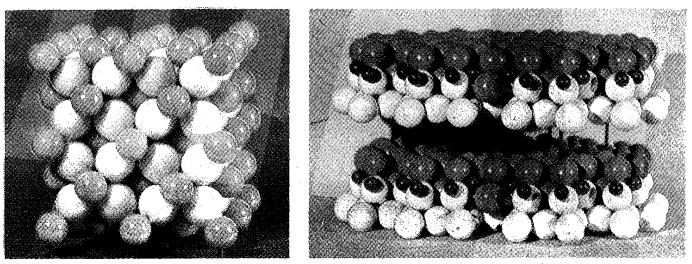

Figure 4: *Models of two types of crystal structures of minerals.* (Left) Crystal structure of fluorite, CaF_2, an example of strong ionic bonding. Red balls represent calcium and yellow balls fluorine ions. (Right) The structure of kaolinite, $Al_4Si_4O_{10}(OH)_8$; closely packed atoms in the composite slabs are held together by strong covalent and ionic forces. The slabs, however, are electrically neutral and only weakly held to one another by van der Waals bonding. Yellow balls represent oxygen atoms arranged in tetrahedra; silicon atoms occur within the tetrahedral pores and are not visible. Small brown balls are aluminum and blue are hydroxyl ions.

The complex structure of kaolinite, a clay mineral and aluminum silicate of composition $Al_2Si_2O_5(OH)_4$, serves as an example. Tiny silicon ions (Si^{4+}) lie between four large oxygen ions (O^{2-}) linked to form a hexagonal sheet. Large hydroxyl ions (OH^-) form another hexagonal sheet and also occur enmeshed with the oxygen sheet. Small aluminum ions (Al^{3+}) bond to four OH^- and two O^{2-}. The $Al_4Si_4O_{10}(OH)_8$ "sandwich" is electrically neutral and is bonded to adjacent sandwiches by weak and ionic van der Waals forces.

Many groups of minerals have the same topology in their crystal structure even though the actual cell dimensions are slightly different. This arises when the ratio of the ionic radii is within the tolerance for that particular structure type and when the ions have the appropriate charges. Examples of such isostructural minerals are calcite ($CaCO_3$), siderite ($FeCO_3$) and rhodochrosite ($MnCO_3$); halite (NaCl), sylvite (KCl) and periclase (MgO); diopside ($CaMgSi_2O_6$) and aegirine ($NaFeSi_2O_6$).

Polymorphic changes

Many chemical compositions yield more than one structural type, and these are known as polymorphs. Thus SiO_2 yields a host of polymorphs, including quartz, tridymite, cristobalite, coesite, and stishovite. The $CaCO_3$ composition occurs as calcite and aragonite. Under thermodynamic equilibrium, each polymorph would occur only for a specific range of temperature, pressure, and composition; however, a polymorph may grow metastably, or persist metastably—*i.e.*, resist change in response to small disturbances despite the fact that some other phase would be wholly stable under the same conditions —as a result of energy barriers to atomic movement. Other polymorphs are related merely by change of interatomic angles culminating in a symmetry change: the so-called high quartz changes to low quartz at 573° C (1,063° F), accompanied by a symmetry change from hexagonal to trigonal (see SILICA MINERALS). Other polymorphic changes involve the atomic distribution between sites. Sanidine and microcline, two of the feldspars *(q.v.)*, are polymorphs of potash feldspar ($KAlSi_3O_8$) and differ in that microcline has the Al and Si atoms segregated each into its own sites, whereas sanidine has a random distribution.

An ideal crystal structure would yield a chemical formula with exact ratios: $CaMgSi_2O_6$, for example. Packing tolerance exists in most structures, however, and extensive atomic substitution (often called solid solution) is permitted. Solid solution is essentially the compositional

Solid-solution series

variation of a single crystalline phase between finite limits without the appearance of a second phase. If the atomic substitution causes only minor structural distortions, which is the case for the common substitutions of silica (Si) and alumina (Al), then atomic substitution at temperatures above absolute zero is favoured on theoretical grounds. The extent of solid solution normally increases with temperature and may be complete. With falling temperature, dissolution or exsolution into two intergrown mineral phases may occur, or ordered structures may form.

Some minerals have unoccupied sites. Sulfides provide the best examples: pyrrhotite (iron sulfide) has a range of composition in which iron may be present in quantities equal to or down to eight tenths the amount of sulfur present. The formula is: $F_{1-x}S$, in which x varies up to 0.2; only in meteorites and in lunar samples is the end-member troilite (FeS) typical.

In general, rock-forming minerals contain a bit of everything ranging from major constituents (over 1 percent), minor constituents (below 1 percent), and trace elements (parts per million or less). Only by combination of subtle analytical methods can the complete chemical analysis be obtained. The principles underlying the distribution of chemical elements in and between minerals are covered in ELEMENTS, GEOCHEMICAL DISTRIBUTION OF.

Morphology. The shape of minerals obeys the rules of crystallography, which developed historically from the study of minerals. Museum collections naturally emphasize well-shaped crystals grown in cavities, but most minerals interfere with each other's growth in rocks. In analogous fashion, snowflakes contrast with block ice. Well-shaped crystals have characteristic angles between faces that are related to the dimensions and symmetry of the internal structure. Ideally, each group of faces related by the symmetry would be equally developed, thus providing the form; a set of six faces on a cube of galena or the prism faces on quartz are examples. Most minerals show

Gerard—EB Inc., (top right) Floyd R. Getsinger, (bottom right) Benjamin M. Shaub

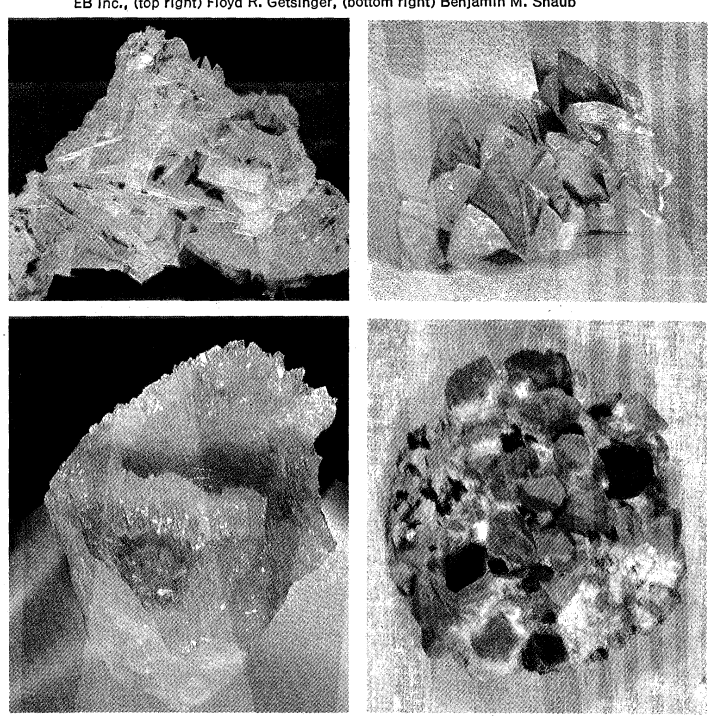

Figure 5: *Representative minerals that sometimes occur as euhedral crystals.* Although in the minority, they receive the most attention because of their beauty and because they reflect the basic crystal form and structure of a particular mineral. (Top left) Wulfenite, $PbMoO_4$, from Mexico. (Top right) Calcite, $CaCO_3$, from Chihuahua, Mexico. (Bottom left) Rose quartz from Minas Gerais state, Brazil. (Bottom right) Microcline feldspar, $KAlSi_3O_8$, variety amazon stone, with smoky quartz, from Colorado.

several types of faces, and the relative development of each form yields the habit. Quartz from volcanic rocks usually grows as a hexagonal pyramid, whereas quartz from low-temperature veins is dominated by a hexagonal prism. Some minerals almost always show the same habit (*e.g.*, the icosahedral habit of garnet), but others (*e.g.*, feldspar) show major variations from one locality to another that are only partly correlative with the temperature and other obvious physical and chemical factors.

Certain crystals have pseudo-symmetry and during their growth incoming atoms may adopt a new configuration rather than adopting the old one. Such multiple crystals are called twins, even though many twins consist of more than two units. Easily recognized twinned minerals are staurolite, pyrite (the "iron cross"), sanidine (Carlsbad twin), aragonite, and spinel; in thin section, the twinning of microcline and plagioclase is often characteristic. Twinning also results from deformation and symmetry inversion as a consequence of changed pressure and temperature conditions.

Classification in terms of structure and composition. Historically, mineral names were assigned haphazardly, with many errors and much redundancy. In spite of attempts to develop rational systems, the present conglomeration of proper names is useful, reasonably consistent, and fascinating from the etymological viewpoint. Since the 19th century, better understanding of crystal structure and chemical composition has led to slow refinement of mineral nomenclature. Since 1960, an international committee of nomenclature has reviewed new proposals for mineral names and attempted to remove redundancies. Generally speaking, a new mineral name is adopted only upon satisfactory evidence of (1) a significant change of chemical composition in a known structure type or (2) a completely new structure type of any composition. The discoverer has the right to propose a proper name (ending in "-ite") consistent with absence of confusion with an existing name. In complete solid solution (atomic substitution) series, a name is usually accepted for each of the constituents present. Gold and silver are such a pair, for example, and, if gold dominates, then gold is the name assigned for (Au, Ag); the name silver would be used for (Ag,Au). Minor constituents are represented by adjectival modifiers—*e.g.*, argentian tetrahedrite for minor Ag in $Cu_{12}Sb_4S_{13}$. Exceptions arise from such special features as changes of symmetry (*e.g.*, sanidine and anorthoclase in the feldspar group) and from historical precedent (*e.g.*, many subdivisions of olivine, plagioclase, and pyroxene). Names should be useful, reflecting the principal properties, and particularly complex mineral groups need many names even if they break some desired artificial system. Several thousand names are in common use, modified slightly from one language to another.

Mineral nomenclature

The first recorded classification was by the Greek philosopher Theophrastus. Subsequent schemes utilized mostly physical properties, but increasing chemical knowledge led to classifications based on chemical composition, such as that by a Swedish chemist, Axel Fredrik Cronstedt, in 1758. Major advances in both chemistry and mineralogy permitted James Dwight Dana, an American mineralogist, to develop his *System of Mineralogy* in 1837; the later editions of this work served as a primary reference source. Although ignorant of crystal structure, Dana proposed a system that correlates well with present knowledge. In this article, minerals are classified into 13 groups; those marked by an asterisk (*) are covered or partly covered in separate articles: *(1) native elements; *(2) sulfides, arsenides, and antimonides; (3) sulfosalts; (4) oxides and hydroxides; (5) halides; *(6) carbonates; (7) nitrates and iodates; (8) borates; (9) sulfates; (10) chromates; *(11) phosphates, vanadates, and arsenates; (12) tungstates and molybdates; and *(13) silicates. In this classification, the first group concerns single-element minerals with metallic or covalent bonding; the second two groups are principally metallic; the next two groups are principally minerals with ionic bonds, generally of equal strength; and the remaining groups have complex structures in which tightly bonded groups (*e.g.*, carbonate) are joined to ions by weaker bonds. The mineral groups are dominated by oxygen, which accords with its great geochemical abundance. In each group, isostructural minerals (*i.e.*, those with similar crystallographic structures) are placed together, and minerals are arranged on the basis of structural properties.

Dana's classification system

In the discussions that follow it is important to bear in mind that the Earth consists of three concentric shells—the crust, mantle, and core—which differ in chemical composition and in the conditions of pressure and temperature that prevail. Certain minerals that are known to form only under conditions of high temperature and pressure (*e.g.*, diamond) cannot form at the Earth's surface; others, which do form under surface conditions (*e.g.*, evaporites), cannot be expected to occur at depth in the mantle. For a detailed exposition of conditions in the Earth's crust, mantle, and core, see EARTH, STRUCTURE AND COMPOSITION OF.

Native elements. These are rare at the Earth's surface because most chemical elements combine rapidly with oxygen, sulfur, and halogens. A few metallic elements are highly resistant and form stable native metals (platinum, gold), and a few survive in special environments, although they are unstable in the presence of atmospheric gases or solutions (copper, mercury, arsenic, antimony, iron). Sulfur and carbon (as diamond and graphite) are metastable with respect to oxygen but persist in special environments. Diamond is truly stable only at pressures that are equivalent to depths of several hundred kilometres in the Earth, and its persistence testifies to the difficulty of the transformation to graphite at the Earth's surface. Iron characteristically occurs in reducing environments (where oxygen is lacking), as typified in certain meteorites and in the Moon. The crystal structures of the native elements are simple. Carbides, nitrides, and phosphides are normally classified with native elements, since the carbon (C), nitrogen (N), and phosphorus (P) atoms merely fill the interstices between the metal atoms. See further NATIVE ELEMENTS.

Sulfides, arsenides, and antimonides. During melting of planetary material, sulfur combines with metals such as iron to form a liquid that is immiscible, or will not mix, with a silicate liquid. The sulfide–metal melt produces the native iron and troilite (FeS) that are seen in meteorites and in volcanic rocks from the Moon and are inferred to occur in the Earth's core. During the complex chemical processes of chemical differentiation near the Earth's surface, much of the sulfide is oxidized and hydrolyzed to form sulfates or gases, and some is converted to sulfur. Surviving sulfides, especially those in veins and hydrothermal deposits (those resulting from high-temperature solutions derived from magma), represent important ores of copper, zinc, silver, lead, mercury, and other metals. Arsenic and antimony tend to be associated with sulfur, though their semimetallic nature results in somewhat different properties. For convenience, the complex sulfosalt minerals (treated below) are separated from the sulfides, arsenides, and antimonides, most of which have simple binary (two-element) compositions.

Importance of sulfides as ore minerals

The sulfides, arsenides, and antimonides mostly have semimetallic properties and structures based on packing of small metal atoms between close-packed, large sulfur, arsenic, and antimony atoms. Molybdenite (MoS_2) has a layer structure in which SMoS sandwiches are weakly bonded together, however. Understanding of the chemical bonding in sulfides is still primitive, and most mineralogists believe that the bonding includes metallic, covalent, and ionic components (see further SULFIDE MINERALS).

Sulfosalts. The general chemical formula of the sulfosalts is $X_aY_bS_c$, in which X is silver, copper, or lead; Y is arsenic, antimony, or bismuth; and S is sulfur. All of the 100 or so mineral species are rare and difficult to identify correctly without advanced techniques. The best known species are tetrahedrite-tennantite $[Cu_{12}(Sb,As)_4S_{13}]$; the ruby-silver group pyrargyrite-proustite $[Ag_3(Sb,As)S_3]$; enargite (Cu_3AsS_4); bournonite ($PbCuSbS_3$); and boulangerite ($Pb_5Sb_4S_{11}$). The crystal structures are related to those of simple sulfides

such as galena (PbS) but are modified severely to take account of the chemical differences between sulfur and the semimetallic arsenic, antimony, and bismuth. All have low thermal stability and occur typically in low- to moderate-temperature ore deposits. All occur as exploitable ores, often in association with other economic minerals, and solid solution is common.

Oxides and hydroxides. Ice and quartz are the principal oxides on the Earth's surface. Cuprite (Cu_2O) occurs in oxidized copper deposits, and periclase (MgO) occurs rarely in marble but may be a major constituent of the deep mantle of the Earth.

The spinel group

The spinel group of minerals, with the general formula AB_2O_4 (representing two constituents, *A* and *B*, combined with oxygen, O) contains a wide range of natural minerals and artificial products. The structure consists of cubic close-packed oxygen atoms with *A* and *B* atoms in 4-fold and 6-fold interstices, respectively, giving a structural formula AB_2O_4. To balance the electrical charges (eight negative charges are given by O_4), one divalent cation (II) and two trivalent ones (III) are needed. Normal spinels have II in *A* and two III in *B*, whereas inverse spinels have III in *A* and II + III in *B*; disordered spinels also occur. The distribution of atoms depends on subtle chemical factors and on temperature. Natural spinels contain principally divalent magnesium, iron, manganese, and zinc; trivalent aluminum, iron, and chromium; and quadrivalent titanium, but spinels can be synthesized from many more elements. Spinel of any colour can be synthesized; natural gem spinel (typically ruby colour) mostly comes from gravels in southeastern Asia formed by weathering of metamorphosed aluminous limestone. Spinels occur as octahedral crystals, often exhibit twinning, and may be magnetic, depending upon the properties of the ions in the *A* and *B* sites.

Magnetite and chromite (the only ore of chromium) occur as accessories in basic and ultrabasic rocks (igneous rocks rich in iron and magnesium). Gravity settling produces rich ore bodies. Magnetite weathers and concentrates in beach sands; it also occurs in veins and metamorphosed rocks. The zinc spinels occur as ores in limestones and schists.

Oxides with the general formula R_2O_3 have cations coordinated 6-fold in hexagonally close-packed oxygens. Corundum (Al_2O_3) and hematite (Fe_2O_3) are isostructures. Ilmenite ($FeTiO_3$) has divalent iron and tetravalent titanium atoms alternating in the aluminum sites of corundum.

Corundum tends to occur naturally as hexagonal barrels or plates in high-temperature rocks rich in alumina and low in silica. Its hardness (9 on the Mohs' scale, which ranges from 1 to 10; see below *Hardness*) results in corundum-rich rocks (*e.g.*, emery) being used as abrasives. Most commercial corundum is made synthetically in high-temperature furnaces by fusing bauxite, however. Clear, coloured crystals of natural corundum are prized gems, especially those showing asterism (a starlike effect visible in transmitted or reflected light). Gem-quality synthetic corundum is used in jewelry, clock and instrument bearings, and in crystal lasers. Coloured varieties result from substitution of metals for aluminum: chromium in red ruby and iron or titanium in blue or black sapphire. Asterism results from exsolution into oriented shapes obeying 6-fold symmetry.

Hematite, the most important iron ore, occurs in beds resulting from precipitation of colloidal (very finely dispersed) iron weathered from iron-bearing rocks. Complex chemical and biological reactions occur involving other iron minerals. Massive or powdered hematite is reddish, but museum specimens often occur as metallic flakes or as kidney-shaped masses. Powdered hematite is used in red paint and for polishing (jeweller's rouge).

Ilmenite is an accessory mineral of iron- and magnesium-rich rocks on Earth and in lunar maria. Its high specific gravity (4.7) results in gravity concentrations in igneous rocks and in beach sands; these are exploited as titanium ores.

Rutile and uraninite

The rutile group comprises rutile (TiO_2), cassiterite (SnO_2), pyrolusite (MnO_2), and stishovite (SiO_2). The tetragonal structure—consisting of three mutually perpendicular crystallographic axes, two of which are of equal length and longer or shorter than the third—has six-coordinated cations and three-coordinated oxygens. Rutile and cassiterite occur as stout dark prisms with a Mohs' hardness of about 6½. Rutile is an accessory in high-temperature rocks, and cassiterite occurs in hydrothermal veins. The high densities (4.2 and 7) and resistance to weathering result in concentration in beach sands and alluvium, forming principal ores of titanium and tin. Anatase and brookite are rare polymorphs of rutile. Synthetic rutile is used in jewelry.

Pyrolusite, braunite [$(Mn,Si)_2O_3$], manganite [(MnO(OH)], and psilomelane (hydrated barium manganese oxide) are principal manganese minerals of variable composition and crystal structure composing fine-grained ores of manganese. Such ores form typically in bogs from colloidal solutions derived from weathered rocks or in veins.

Uraninite has an imperfect crystal structure (similar to that of fluorite), and the composition ranges from UO_2 to U_3O_8. It occurs in pegmatites (very coarse-grained igneous bodies) and in veins. Alteration to other uranium minerals (uranyl hydroxides and silicates) and redistribution by sedimentary and solution processes lead to complex chemical variations and geographic distribution of uranium ores. Minor occurrences of rich pitchblende ore are now supplemented by low-grade sources of uranium minerals. Thorium and rare earths are major constituents of uranium minerals.

The hydroxide minerals

All hydroxides are low-temperature minerals typically formed from products of aqueous alteration or from hydrothermal veins. The crystal structures consist of hexagonal layers of cations bonded to six hydroxyls or oxygens. Interlayer bonds are weak, and this results in soft crystals. Brucite [$Mg(OH)_2$] typically occurs in magnesium-rich rocks subjected to low-temperature hydrothermal action or metamorphism (*e.g.*, serpentinite and magnesian marbles). Hydrated iron and aluminum oxides occur everywhere on the Earth's surface and represent the stable forms, with respect to which other iron and aluminum minerals are metastable.

The aluminum ore, bauxite, consists of boehmite [AlO(OH)], diaspore [AlO(OH)], and gibbsite [$Al(OH)_3$] plus iron oxides. Clay and laterite soil consist principally of aluminum hydroxides. Alumina is resistant to leaching and may precipitate as hydroxides that render the soil incapable of sustaining agriculture.

Limonite is an iron ore containing goethite [FeO(OH)] and other hydrated iron oxides of complex structure. The hydrated iron oxides result from weathering of iron minerals in aqueous oxidizing environments. Most deposits are sedimentary, but some specimens occur in veins as crystals or stalactites (deposits suspended from the roofs of caverns).

Halides. Fluorine substitutes in silicates of high-temperature rocks and occurs as fluorite (CaF_2) in veins. Fluorite occurs in cubes, often beautifully coloured (but rarely red) from various trace substituents or lattice defects (the two most common defects in crystals are partial slippage along a crystallographic plane and a void or missing lattice element). The variety Blue John from Derbyshire, England, is used for ornamental vases, but the softness (hardness of 4 on Mohs' scale) precludes its use as a gem. Fluorite is the principal fluorine mineral, and increasing demand as an industrial flux and for fluorinated organic materials of high stability has led to reworking of many old galena deposits, with which fluorite is typically associated. Fluorite and fluorine glasses are valuable for their high optical refringence (refraction of light).

Chlorine, bromine, and iodine tend to end up in solutions, and form a major part of seawater. Evaporation of aqueous bodies leads to sequential precipitation of halide minerals as each successive solubility limit is reached (see further EVAPORITES). The resulting sedimentary deposits are structurally weak and are squeezed into salt domes. Halides also occur in volcanic sublimates.

Halite, or common table salt (NaCl), and sylvite (KCl)

are isostructural minerals that occur as cubes or in massive deposits. Sylvite is more bitter than halite. Although transparent when pure, many specimens are coloured by impurities. Carnallite, a hydrous potassium magnesium chloride, is a deliquescent mineral that occurs at the top of many salt deposits.

Cerargyrite (AgCl) occurs in the oxidized zone of silver deposits as waxlike, ductile masses. Atacamite [$Cu_2(OH)_3Cl$] is a green secondary mineral in the oxidized zone of copper deposits in arid regions. Cryolite, a sodium fluoride (Na_3AlF_6), is a very rare mineral used as an electrolyte for industrial electrolysis of aluminum ores and now mostly synthesized from fluorite.

Calcite, aragonite, and dolomite

Carbonates. At low temperatures under oxidizing conditions, carbon combines with oxygen to form the triangular CO_3 group. Bonding to metal ions such as Ca, Mg, and Zn leads to about 100 carbonate minerals, of which calcite ($CaCO_3$) and dolomite [$CaMg(CO_3)_2$] are the dominant constituents of limestones and dolomites. Calcite and the polymorph aragonite form the skeleton of many organic creatures, particularly marine invertebrates. Many carbonate minerals contain water of hydration. Carbonates are typical weathering products of ores, resulting from reaction with carbonic acid: the copper mineral malachite [$Cu_2CO_3(OH)_2$] is an example (see further CARBONATE MINERALS; and LIMESTONES AND DOLOMITES).

Nitrates and iodates. In the geochemical cycle, nitrogen becomes present in water as nitrate ions—as an end product of volcanic emissions and the breakdown of organic matter. In very arid climates, nitrate is deposited as soda-nitre ($NaNO_3$) and nitre (KNO_3). Because of the very high solubility, other evaporite minerals such as halite are precipitated first. Alkali nitrates are also produced by bacteria and by reaction of organic matter with salts. Only the Chile deposits are really significant commercially. Most nitrate for fertilizer results from synthesis using atmospheric nitrogen.

Some rare iodates (*e.g.*, lautarite [$Ca(IO_3)_2$]) occur together with nitrates.

Borates. The boron ion is very small and exists in both triangular BO_3 and tetrahedral BO_4 groups. Furthermore, the groups condense into clusters, rings, and chains.

Borate minerals occur principally in dried-up basins (playas) fed by waters rich in volcanic emanations; many complexities result from resolution, reprecipitation, and burial of deposits. The principal commercial borates are kernite [$Na_2B_4O_7 \cdot 4H_2O$], borax [$Na_2B_4O_7 \cdot 10H_2O$] of mule-train fame, and colemanite [$Ca_2B_6O_{11} \cdot 5H_2O$]. All are white and have complex crystal structures. Thermal stability is low. Molten borax dissolves many substances, the metallic elements of which can be identified from the colour of the resulting glass bead.

A group of rare borates containing beryllium, aluminum, or magnesium occurs in contact metamorphic deposits (where various rocks are heated at the contact with an igneous rock body intruded at high temperature) and hydrothermal veins. All but one are free of water, but many contain hydroxyl. The rare gem sinhalite ($MgAlBO_4$) has an olivine-like structure with B in fourfold coordination. The ludwigite group occurs in contact-metamorphosed limestones.

Boracite ($Mg_3B_7O_{13}Cl$) occurs in evaporite beds with halides and sulfates, along with a complex group of hydrated magnesium and calcium borates.

Sulfates. Approximately 130 minerals contain sulfate ions. In the geochemical cycle, sulfides and volcanic emissions of sulfurous gases tend to become oxidized. Some sulfates result from local oxidation of ore sulfides, but large sulfate bodies result from evaporation of sulfatic solutions. Barite, celestite, and anglesite are isostructural minerals in which tetrahedral SO_4 groups provide 12 oxygen atoms around the large cations to yield the compositions $BaSO_4$, $SrSO_4$, and $PbSO_4$, respectively. Barite typically occurs in veins associated with lead ores as dirty, massive deposits. Its low solubility leads to sedimentary deposits from limestone weathering. Barite is readily identified from its heaviness (specific gravity of 4.5). Barite can participate in major solid solution with celestite, but the latter is usually pure. Celestite is a relatively rare mineral that may occur in a variety of sediments, probably as a precipitate from solutions; it also occurs in hydrothermal veins. Anglesite is a rare mineral formed in the oxidized zone of galena ores.

Anhydrite and gypsum

Anhydrite ($CaSO_4$) has a different structure because the smaller Ca cation is bonded to only eight oxygens of the SO_4 groups. The symmetry is orthorhombic (three mutually perpendicular crystal axes of unequal length), and three mutually perpendicular cleavages are characteristic. Anhydrite occurs in massive deposits interstratified with beds of gypsum, carbonates, and halides. Seawater precipitates anhydrite above 42° C (108° F), or at lower temperature upon evaporation. Gypsum is deposited at lower temperature or lower salinity. Some deposits of gypsum and anhydrite probably were derived by alteration of the other mineral; that is, by hydration or dehydration.

Gypsum ($CaSO_4 \cdot 2H_2O$) is an important economic mineral, being used extensively in wallboard and cements for the construction industry, as fillers in paper and paints, and as a soil dressing. Its softness (hardness of 2 on Mohs' scale) and the waxy surface of the massive variety alabaster permit use in statues and ornamental carvings. Most gypsum is massive and stained. Rare, transparent, well-developed crystals are called selenite. Fibrous forms are called satin spar. The weakly bonded structure contains water molecules and SO_4 groups in a monoclinic cell (three crystallographic axes of unequal length, two of which are perpendicular and the third inclined). Swallow-tailed twins are displayed commonly in mineral collections. Dehydration near 100° C (212° F) produces the hemihydrate used commercially as plaster of paris because it rehydrates to a solid aggregate of gypsum. Heating to 200° C (about 400° F) produces anhydrite. Gypsum occurs not only in evaporite deposits, as noted above, but also in low-temperature hydrothermal veins and as products of volcanic gases.

Epsomite ($MgSO_4 \cdot 7H_2O$) and kieserite ($MgSO_4 \cdot H_2O$) are just two of the six hydrates of magnesium sulfate deposited by appropriate solutions at characteristic temperatures and subject to hydration and dehydration reactions as conditions change.

Chalcanthite ($CuSO_4 \cdot 5H_2O$), antlerite [$Cu_3(SO_4)(OH)_4$] and brochantite [$Cu_4(SO_4)(OH)_6$] are the three common sulfates formed as alteration products of copper ores in arid regions. The copper ions cause rich blue (chalcanthite) and green colours (antlerite and brochantite).

Glauberite [$Na_2Ca(SO_4)_2$] and

polyhalite [$K_2Ca_2Mg(SO_4)_4 \cdot 2H_2O$]

are important minerals in salt deposits. Other notable sulfates include mirabilite ($Na_2SO_4 \cdot 10H_2O$), which occurs as an evaporation product of saline lakes and as a soil efflorescence, melanterite ($FeSO_4 \cdot 7H_2O$), a greenish-blue weathering product of iron sulfides, and alunite [$KAl_3(SO_4)_2(OH)_6$] and jarosite [$KFe_3(SO_4)_2(OH)_6$], which are isostructural. Alunite results from alteration by sulfatic gases in volcanic regions, whereas jarosite is formed by alteration of iron ores.

Chromates. Chromium mostly substitutes in iron and aluminum minerals. Under oxidizing conditions, crocoite ($PbCrO_4$), an orange-red monoclinic mineral, occurs as a secondary product of lead minerals.

Phosphates, vanadates, and arsenates. Although quantitatively insignificant except for apatite, there are more than 250 minerals in this group—resulting from an incredible variety of crystal structures. The complex ions condense into clusters and link with cations, hydroxyls, and water molecules into families of fascinating chemical and topologic interest (see further PHOSPHATE MINERALS). Here only the vanadates and arsenates are briefly considered.

Important arsenates include adamite [$Zn_2AsO_4(OH)$], erythrite [$Co_3(AsO_4)_2 \cdot 8H_2O$], and

annabergite [$Ni_8(AsO_4)_2 \cdot 8H_2O$]

which are oxidation and hydration products of zinc, co-

balt, and nickel ores. Mimetite [$Pb_5(AsO_4)_3Cl$] and vanadinite [$Pb_5(VO_4)_3Cl$] belong to the pyromorphite structural group. These minerals form by alteration of lead sulfides using components brought in from breakdown of arsenides and vanadium-bearing minerals.

Carnotite [$K_2(UO_2)_2(VO_4)_2 \cdot 3H_2O$] and tyuyamunite [$Ca_2(UO_2)_2(VO_4)_2 \cdot nH_2O$] are rare but widespread alteration products of vanadium and uranium ores; their yellow colour is quite distinctive.

Tungstates and molybdates. Wolframite [$(Fe,Mn)WO_4$] and scheelite ($CaWO_4$) are the principal ores of tungsten. Wolframite occurs in high-temperature hydrothermal veins and altered rocks, and scheelite occurs by contact metasomatism of carbonate rocks. Both minerals contain tetrahedral WO_4 groups bonded to metal cations.

Wulfenite ($PbMoO_4$) is a minor ore of molybdenum and occurs frequently in weathered lead ores. Spectacular orange-yellow square plates are familiar to mineral collectors. The crystal structure is similar to that of scheelite.

Occurrence of silicate minerals

Silicates. The high abundance of oxygen and silicon in the solar system, plus the separation of much of the iron metal and sulfide as an immiscible phase, leads to the dominance of silicates in the terrestrial planets. On Earth, the crust and mantle essentially consist of silicates with only trivial amounts of other minerals. There are approximately 600 silicate minerals, but the major rock-forming minerals at the Earth's surface fall into the principal families of olivine, pyroxene, amphibole, mica, feldspar, quartz, aluminosilicates, feldspathoids, clay minerals, and zeolites. Each of these families is represented by separate articles that describe the principal properties; a few general relationships are described here to provide a framework within the overall subject of minerals (see further SILICATE MINERALS).

At low pressures, silicon enters the tetrahedral "hole," or site, between four oxygen atoms to form the basic silicate building block. This tetrahedral unit can yield Si_2O_7 groups; rings and chains of SiO_3; and sheets and frameworks of SiO_2. The silicate units combine with metal cations, water molecules, carbonate ions, etc., to yield a great variety of structures. Most structures have an elegant geometric pattern of fundamental topologic significance.

With falling temperature, natural silicates tend to be more polymerized or occur in more forms. At high temperature, olivine is stable. Silicon and magnesium or iron atoms enter the interstices of oxygen atoms in a hexagonal close-packed pattern to form isolated SiO_4 groups, linked by magnesium atoms in 6-fold coordination. Zircon ($ZrSiO_4$) also has isolated SiO_4 groups, but zirconium (Zr) is in 8-fold coordination. Pyroxene, *e.g.*, diopside ($CaMgSi_2O_6$), has SiO_3 chains that are cross-linked by cations. Amphiboles such as tremolite [$Ca_2Mg_5Si_8O_{22}(OH)_2$] have Si_8O_{22} bands. The mica mineral muscovite [$KAl_2Si_3AlO_{10}(OH)_2$] has triple sandwiches of aluminosilicate sheets surrounding aluminate sheets. Feldspars, feldspathoids, and zeolites consist of an aluminosilicate framework into whose holes cations and water molecules enter.

Wide ranges of chemical substitution occur, governed by ionic sizes and charges. Aluminum commonly substitutes for silicon, and divalent cations such as calcium, magnesium, and iron show extensive or complete substitution. Coupled substitutions occur: thus albite ($NaAlSi_3O_8$) and anorthite ($CaAl_2SiO_8$) form the end members of the plagioclase feldspars.

Aluminum is a common constituent of silicates, substituting for silicon in tetrahedral coordination with oxygen or occurring in sites that are surrounded by six oxygens. The AlO_6 octahedron can form column or sheet structures. In the aluminosilicate polymorphs of Al_2SiO_5 (sillimanite, andalusite, and kyanite), columns of shared AlO_6 octahedrons are cross-linked by tetrahedrons and octahedrons. In mica and clay minerals, sheets of aluminate octahedrons are combined with silicate sheets plus hydroxyls and water molecules.

Water molecules enter silicates only at low temperature, as in the zeolites. With increasing temperature, hydrous silicates give way to hydroxylates or anhydrous silicates.

High-pressure assemblages

At high pressures, silicates invert to denser polymorphs or assemblages. Thus the feldspar albite ($NaAlSi_3O_8$) gives way to quartz and jadeite, the pyroxene structure of which has a tighter packing. Some hydroxylate minerals are stable at high pressure. In the Earth, increasing depth results in a greater pressure and temperature. In addition, there is a change of bulk chemical composition, first to a composition rich in magnesium silicate and, ultimately, to iron plus sulfide. Laboratory studies plus observations on rocks erupted from great depths and on meteorites suggest that garnet, pyroxene, olivine, and spinel structures are important in the upper mantle of the Earth. These structures have different chemical compositions from those found on the Earth's surface because there exists the tendency of metal ions to move toward a higher coordination as the pressure increases.

From the economic viewpoint, silicates form the major part of many inorganic building materials from granite to concrete. Kaolin and nepheline are used for ceramics; olivine, beryl, zircon, feldspar, and other silicates are used as gems. Silicates are generally unsuitable as ores for metals because of the difficulty of separating the oxygen from the metal.

THE PHYSICAL PROPERTIES OF MINERALS

Increasingly simple visual and tactile estimations of mineral properties are augmented by complex techniques from the domain of solid-state physics (See *Bibliography* for tabulation of data).

Mohs' scale of hardness

Hardness. The simplest estimate of hardness involves scratching by reference minerals arbitrarily chosen for the Mohs' scale in 1882 and placed in numerical order of increasing hardness: 1 talc, 2 gypsum, 3 calcite, 4 fluorite, 5 apatite, 6 orthoclase, 7 quartz, 8 topaz, 9 corundum, and 10 diamond. The scratch test must be made carefully because many minerals contain surface impurities. Quantitative estimates utilize the magnitude of indentation made by a known load applied to a known point (*e.g.*, the Vickers hardness test often applied to ore minerals). Each step on Mohs' scale corresponds approximately to a doubling of the indentation. Hardness is a directional property, especially of kyanite, for which it varies on the cleavage face from 4 to 5 when scratched parallel to the long, or *c*, axis, and 6 to 7 in a direction that is perpendicular to it. The octahedral surface of diamond is the hardest of all minerals. The hardness tends to correlate with the weakest of the bonds in the crystal structure, ranging from the van der Waals bonds of talc to the covalent bonds of diamond.

Cleavage, fracture, and parting. Strain beyond the elastic and plastic limit causes either irregular fracturing or cleavage along one or more planar surfaces. Fractures result from accidental irregularities, but cleavages are controlled by unequal (anisotropic) bonding strengths in different directions in the crystal structure; they always occur parallel to potential faces. The lubricating properties of graphite, talc, and molybdenite result from cleavage into tiny slippery flakes. Mica cleaves into thin, insulating plates that are useful in the electrical industry. In many minerals, chemical bonding is only weakly anisotropic, leading to imperfect cleavage. Parting resembles cleavage but is not an inherent property of the mineral; it results from various defects such as chemical changes and twinning.

Specific gravity. The specific gravity of a mineral is the ratio of the mineral density to that of water at 4° C (39° F), and it varies from 0.92 for ordinary ice to 21 for platinum. Direct measurements of the ratio of weight to volume are affected by voids and impurities. Suspension in heavy liquids of mineral powder followed by determination of the heavy liquid provides higher accuracy. The density can be calculated from the unit cell volume (determined by X-ray diffraction) and the chemical composition, assuming full atomic-site occupancy. Minerals are commonly separated in laboratories and industrial plants by suspension, or sinking, in liquids. Many monomineralic igneous rocks and economic-mineral deposits form by density separation.

Mineral deformation

Elasticity and strength. Under low stresses minerals are elastic, but under higher stresses some kind of permanent deformation occurs. In the Earth, velocity of seismic waves is related to these stresses (see EARTHQUAKES). The rigidity coefficients decrease with temperature and correlate with the type of chemical bonding and atomic packing. Metallic minerals are ductile (*e.g.*, will flow under high stress), and empirical relations for oxides and silicates are very useful.

The onset of permanent deformation occurs at lower stresses as the temperature rises. Controlled laboratory experiments, especially of carbonates and silicates, delineated the failure mechanism in terms of fracturing, twinning, and structural inversion. Particularly important are deformations induced by shock, produced naturally by meteorite impact and experimentally by explosions. The pressure and temperature rise very rapidly as the shock front passes, resulting in deformation, inversion to dense polymorphs, and finally melting as the peak pressure rises (see further METEORITE CRATERS). Intensity of meteorite impact and nuclear explosions is calibrated by the deformation: for most natural silicates, melting occurs by about 0.5 megabar. Occurrence of coesite and stishovite, the high-pressure forms of SiO_2, is used as a criterion for meteoritic origin of circular features.

Magnetic and electrical properties. Minerals may be ferromagnetic, or attracted by a magnet (iron), anti-ferromagnetic (magnetite; used in primitive compasses), paramagnetic (all iron-bearing silicates), or diamagnetic —that is, repelled by a magnet (many iron-free silicates). The position of the magnetic field at the time of rock consolidation can often be determined from the magnetic direction of the constituent minerals (see ROCK MAGNETISM). Minerals are separated in the laboratory and commercially by passing them down an inclined chute between the jaws of an electromagnet. Certain ore bodies are located from their magnetic field, and subtle features of chemical forces and site distribution of atoms also are determined from techniques based upon magnetic properties.

Mineral conductivity

Minerals range from electrical conductors (metals), to semiconductors, to nonconductors (mica and graphite). Minerals with good conductivity have metallic lustre, whereas most transparent ones have low conductivity. Natural and synthetic mica is widely used as an insulator. Nonconducting crystals with polar directions become electrically charged under compression (piezoelectricity) or upon heating (pyroelectricity). Quartz piezoelectric oscillators are used for generation of ultrasonic waves (militarily exploited for submarine detection) and provide highly stable frequency standards. Tourmaline pyroelectric crystals are used in pressure gauges.

Optical properties. Light incident on the surface of a mineral is partly reflected, partly transmitted, and partly absorbed. Minerals with a high reflectivity have metallic bonding, whereas those with a high transmissivity have ionic or covalent bonding. The optical properties vary with direction (except for isometric minerals—those in which properties are the same in all directions) and depend on the atomic nature of the crystal structure.

Colour of minerals

The colour of a mineral as seen by the naked eye or at low magnification is a broad property that often depends on elusive factors. The colour of a metallic mineral is governed by the interaction of light with the surface. Some metallic minerals such as gold are chemically stable, yielding an intrinsic colour. Most are unstable, yielding a coating of a different colour (silver, copper, and many sulfide minerals). The intrinsic colour is yielded by rubbing the mineral on a porcelain plate to obtain a streak. The colour of a transparent mineral may be intrinsic (*e.g.*, green of the birthstone peridot), arising from interaction of the electromagnetic radiation with electrons, or it may be extrinsic, arising from inclusions (*e.g.*, reddish or whitish orthoclase). Intrinsic colours can arise from major constituents (divalent iron in peridot and copper in chalcanthite) or from minor constituents substituting into the crystal structure (chromium in ruby), or even from lattice defects. The colour may vary with the direction of light propagation (pleochroism), as in cordierite and alkali amphibole. Some minerals show a wide range of intrinsic colours (diamond, corundum, fluorite, beryl). The causes of some typical colours (blue and green of kyanite, green of the amazonite variety of microcline) are highly controversial despite extensive research. Sub-microscopic inclusions causing complex diffraction yield the remarkable light scattering of moonstone and labradorite. Flakes of iron oxide cause the light scattering of aventurine. Star gems (rubies, sapphires, garnets) contain sub-microscopic inclusions oriented in crystallographic planes. Colour thus is often a poor guide to mineral identification.

The reflected light from polished surfaces permits ready distinction between many opaque minerals on the basis of brightness, colour, and anisotropy (variation of properties with crystallographic direction) and is mandatory for study of ore minerals and host rocks.

Transparent minerals (especially in rocks) are commonly identified by transmitted light, using polarized light passing through thin sections or through fragments mounted in oil.

Most minerals have anisotropic optical properties, and incident light splits up into two polarized waves with different velocities. The plane of polarization and velocity vary with direction, and the principal indices of refraction, orientation of the optic axes, and variation of indices with wavelength (dispersion) and absorption of light serve to identify most transparent minerals, but the procedures are highly technical.

Advanced studies utilize a microscope fitted with a multi-axis stage for orienting the mineral; this permits the measurement of all optical properties. Routine studies of thin sections of rocks rely on the skill of the microscopist, who mentally correlates the properties seen in different grains. The degree of relief, polarization colour, position of optical extinction, shape, twinning, nature of inclusions, and other factors are all used to yield a probable identification.

Thermal properties. The thermodynamic properties are a function of pressure, temperature, chemical composition, and distribution of atoms in the crystal structure. Measurements are made of the specific heat, melting point, latent heats for change of state, thermal conductiv-

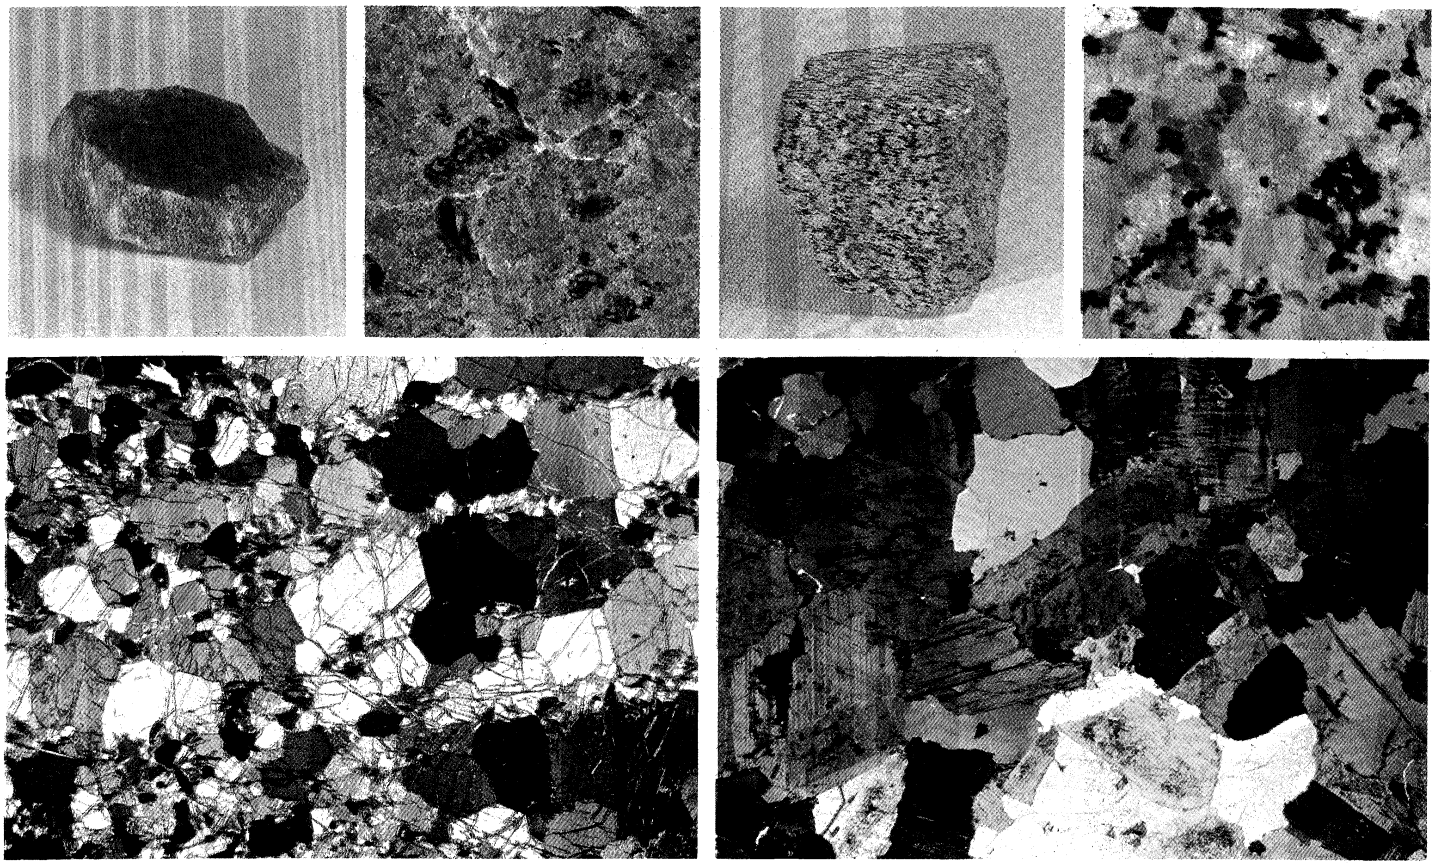

Figure 7: *Two types of crystalline aggregates at three levels of magnification.*
Most mineral crystals occur without faces (anhedral crystals) and as crystalline aggregates in the form of rocks. (Top left) Olivine crystals forming the monomineralic rock dunite, in which the individual crystals can scarcely be distinguished. (Centre left) Polished surface of the specimen (magnified 2×). Light green grains are olivine, dark spots are magnetite and serpentine. (Bottom left) Photomicrograph of the specimen in polarized light (magnified 12×). The different colours are due to the optical effect of the different orientations of the olivine crystals on the polarized light; most of the grains are olivine. (Centre right) Quartz, feldspar, biotite, and hornblende crystals forming the rock granite, a polymineralic aggregate. (Top right) Cut and polished surface of the rock (magnified 1½×). Large pink crystals are microcline feldspar, white ones are sodic plagioclase feldspar, small smoky ones are quartz, and black spots are biotite and hornblende. (Bottom right) Photomicrograph of the rock in polarized light (magnified 12×). White and gray crystals are quartz, light to dark bluish-gray ones are feldspar, those with irregular cross-hatching are microcline perthite, and those with finely ruled parallel lines are sodic plagioclase. Most of the green and brown crystals are biotite; the brown one in the centre is hornblende.
D.L. Weide

ity, and similar thermal properties. Differential thermal analysis involves detection of temperature discontinuities as heat is supplied at a constant rate: the discontinuities reveal structural changes that are diagnostic of some minerals (dehydration and structural readjustment in clays; bond-bending inversion in quartz; oxidation; structural breakdown).

Radioactivity. Minerals containing uranium and thorium provide commercial sources for nuclear energy and can be detected by radiation counters. The crystal structures of minerals containing thorium (zircon, allanite, thorite) commonly undergo a change of state by internal movement of recoiling atoms. Inclusions of these minerals in some other minerals are revealed in thin section by pleochroic halos; thus biotite is bleached.

Deliberate etching reveals the track of radioactive particles in minerals. The size of the track provides a measure of the energy of the particle. Study of minerals from the lunar surface is providing estimates of their exposure time to, and mass distribution of, cosmic rays.

Determining the ages of minerals

Several rock-forming minerals contain enough radioactive material to permit determination of the time since the radioactive material was incorporated in the mineral. The techniques involve accurate mass spectrometry and careful consideration of the thermal history of the mineral. The isotope potassium-40 decays to argon-40, but argon may be either lost or gained by diffusion, and thus misleading ages may be obtained. The uranium isotopes decay to lead isotopes, permitting a check on the concordance of the ages implied by the different decay series. The rubidium isotope, rubidium-87, decays to strontium-87, augmenting the abundance of the latter. Measurement of coexisting minerals with different amounts of rubidium and strontium permits estimation of the age at which the minerals formed together and the original isotopic ratio of the mineral system. Careful study permits selection of genuine ages from misleading ages, and the principal mineral-forming events on the Earth are dated (see DATING, RELATIVE AND ABSOLUTE). Isotope studies of meteorites and of terrestrial and lunar minerals yield crucial information on the chemical evolution of the solar system.

The distribution of stable isotopes between minerals, or between minerals and solution, depends on the temperature. The distribution of the isotopes oxygen-16 and oxygen-18 between silicates and oxides of rocks and the distribution of isotopes in biological carbonates yield estimates of their equilibrium temperatures.

Luminescence. The emission of light from a relatively cool mineral results from extremely complex electronic processes and from various energy sources. The luminescent colour bears no relation to the natural colour. Fluorescence excited by ultraviolet radiation permits rapid detection of certain minerals, including some uranium ores. Cathodoluminescence (excitation by accelerated electrons) is routinely used to identify some rock-form-

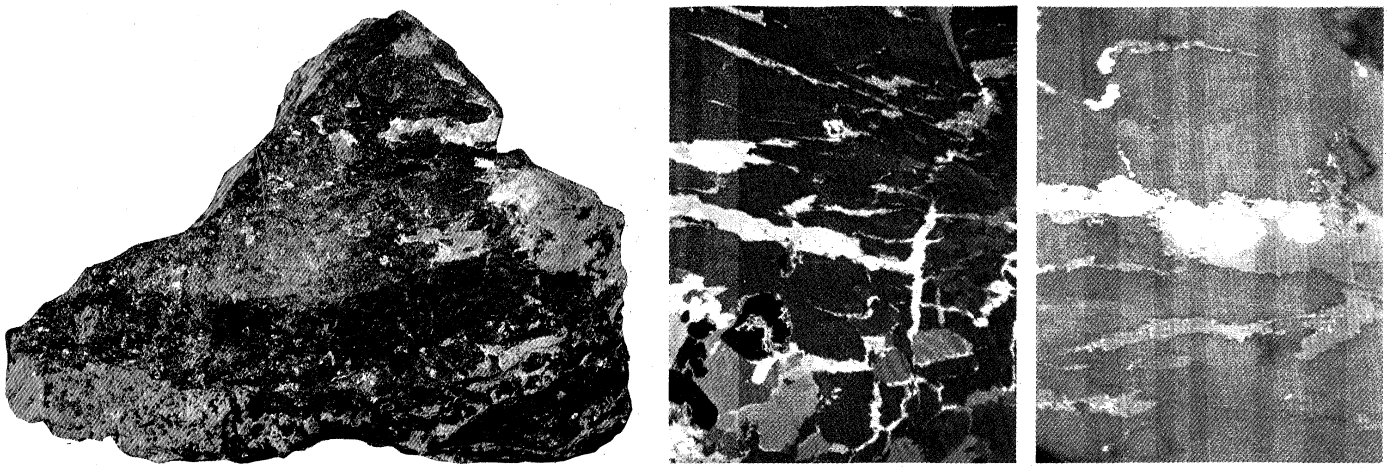

Figure 8: *Aggregation and intergrowth of ore minerals at megascopic and microscopic levels.*
(Left) Aggregate of copper ore minerals (from Arizona) including bornite, Cu_5FeS_4 (reddish purple to iridescent blue where tarnished); covellite, CuS (dark blue); chalcopyrite, $CuFeS_2$ (yellow); and quartz and altered rock (white and light gray). (Centre) Photomicrograph of polished surface of what appears megascopically to be covellite (magnified 200 ×). The specimen is actually bornite that has been partly replaced by extremely fine-grained covellite (greenish-gray). (Right) Photomicrograph of central portion of polished surface to left, showing covellitized bornite (pink to red) more clearly (magnified 400 ×). Much more bornite is present than is apparent at lower magnifications. Also present are chalcocite, Cu_2S (gray), chalcopyrite (yellow), and tiny crystals of pyrite, FeS_2 (pale yellow), in the chalcocite veins.

ing minerals and to map variations of chemical composition as in carbonates and feldspars. Thermoluminescence is the emission of light released from stored energy levels

Benjamin M. Shaub

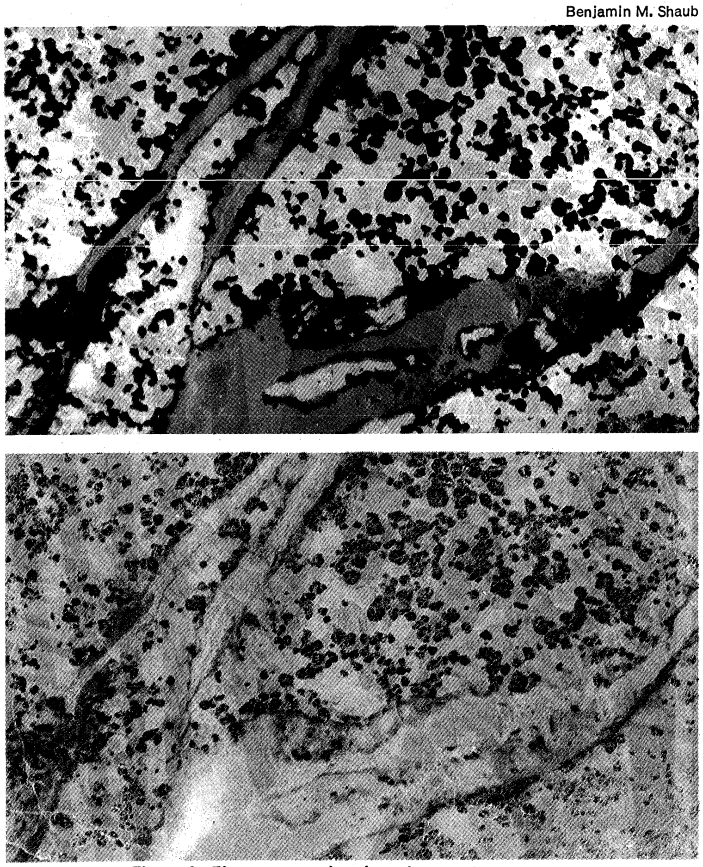

Figure 9: *Fluorescence in minerals.*
(Top) Specimen, in ordinary light, of calcite (calcium carbonate) with grains of black franklinite (a zinc, manganese, and iron oxide) and veins and grains of brownish-gold willemite (a zinc silicate), from Franklin, New Jersey. (Bottom) Fluorescent colours due to excitation by ultraviolet light. Red is calcite, green is willemite, black is nonfluorescent franklinite.

by heating: it provides a crude estimate of the radiation and thermal history of certain minerals and rocks. Triboluminescence is the emission of light induced by mechanical deformation, as in sphalerite and fluorite. The electronic processes are known for very few luminescent minerals (*e.g.*, manganese substitution in red luminescing calcite). The phenomenon is erratically developed for most minerals, and for each mineral species there are several causes, including chemical substitutions and physical defects.

THE OCCURRENCE OF MINERALS IN NATURE

General geochemical considerations

Minerals result from a sequence of complex processes that began with chemical differentiation of the solar system to form planets and that ended, in many cases, with crystallization in rocks or ore bodies controlled by trivial local factors. The occurrence of minerals, therefore, involves a general understanding of geochemistry, geophysics, and petrology (the study of rocks), as well as special factors involved in the formation of ore deposits. Although spectacular advances have been made in these subjects during the 20th century, and particularly since 1950, the factors controlling mineral genesis are often controversial, and ideas can be expected to undergo revision.

The continuing changes on Earth and in the solar system result in mineralogic changes such that mineral genesis must be considered in terms of kinetic rather than static factors; most minerals become transformed to other minerals by reaction with air and water when they reach the Earth's surface, for example.

The presence of water is extremely important because it permits concentration of elements to form valuable ore bodies. The extreme dryness of the Moon inhibits formation of such types of ores, and it appears likely that the number of mineral types found on the Moon will be small. Under dry conditions, mineral concentrations arise principally from the processes of liquid immiscibility and from gravity settling of crystals from liquid. Under aqueous conditions, these processes are supplemented by incongruent solubility, by differential resistance to weathering, and by fluid transport and deposition. Furthermore, biological processes profoundly affect weathering and deposition on Earth.

In the magmatic domain, the classification of elements into lithophile, chalcophile, siderophile, and atmophile groups for those elements with an affinity for silicate, sulfur, iron, and oxygen, respectively, is extremely important in providing a guide to whether an element enters a mineral containing oxygen or sulfide or whether it occurs as a native element or enters the atmosphere. In the low-temperature aqueous domain, the relation between ionic charge and ionic radius controls whether an element is transported as a soluble complex anion (for example, the

sulfate anion SO_4^{2-}) or a soluble cation (sodium, Na^+, for example) or whether it forms a hydrolysate, such as $Fe(OH)_3$, which is insoluble. The first two types may react to form a precipitate (*i.e.*, sodium sulfate [Na_2SO_4]). Finally, the availability of oxidizing material is important in determining the valence state of iron and manganese and in determining the extent and nature of alteration.

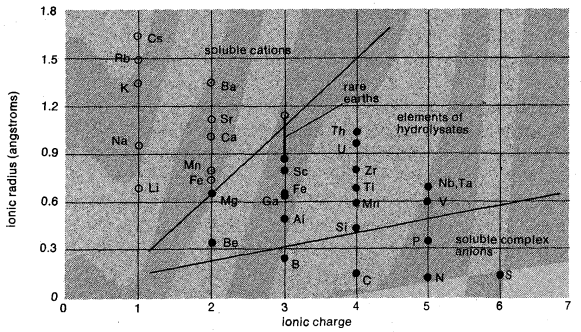

Figure 10: Consequences of ionic radius and ionic charge in geochemical processes (see text).

Derivation from silicate magma

Mineral associations in igneous and metamorphic rocks. Volcanic rocks on Earth are extruded igneous rocks and are readily proved to have crystallized from a liquid silicate magma containing some water and volatile gases. Rocks of similar composition but of coarser grain size are recognized to have crystallized at some depth within the Earth. There is considerable controversy about the origin of such deep (plutonic) rocks, however, and about the origin of the magmas responsible for volcanic rocks. Almost certainly many processes including melting, crystallization, annealing, remelting, and metasomatism (process of rock replacement), are involved. Particularly spectacular are kimberlite pipes (relatively narrow igneous bodies that extend downward into the Earth's crust) containing diamonds that probably were derived from depths of several hundreds of kilometres.

Igneous rocks are dominated by the silicate minerals (olivine, pyroxene, feldspar, quartz, feldspathoid, mica, amphibole); their differing proportions yield the various rock types. Accessory minerals (magnetite, ilmenite, sphene, zircon, apatite, allanite, fluorite, xenotime) occur in small quantities, but occasionally they are concentrated into ore bodies either by gravity separation or by later weathering.

During the crystallization of igneous rocks from silicate melts, the small amounts of water and volatile gases tend to concentrate, particularly in granites. This leads to the crystallization of especially large crystals. The concentrations may be small in volume (vugs) or may become large pegmatite bodies, commonly known as veins or dikes. Most pegmatites contain essentially the same minerals as the host rock, but a few pegmatites of great economic importance contain spectacular minerals of rare elements (*e.g.*, beryl, lepidolite, pollucite, cassiterite).

Metamorphic processes are commonly described as being either of contact or regional type. In the contact type, an intrusive magma heats an existing rock, producing a narrow zone of recrystallized minerals. Volatile gases from the magma may cause extensive alteration of the chemical composition (especially typical for magmatic intrusion of limestone), producing skarns. Such skarns may prove exploitable as ores.

Regional metamorphism involves burial (often of a sediment) followed by release to the surface after erosion. The pressure and temperature rise to a maximum and then fall. During the rise, the rock normally contains water, which acts as a catalyst for recrystallization. The water is essentially lost in the process, resulting in metastable persistence of minerals during cooling. Many sediments are rich in alumina and silica, resulting in the formation of aluminosilicates, cordierite, staurolite, and others, each of which forms at a specific range of temperature and pressure. Any type of rock may undergo metamorphism, however, resulting in extraordinary complexities that have been only partly resolved. Nevertheless, considerable progress has been made in estimation of pressure–temperature–time–composition relations for the great metamorphic cycles associated with sedimentation and mountain building (see further ROCK METAMORPHISM, PRINCIPLES OF; and METAMORPHIC ROCKS).

Typical metamorphic minerals in mineral collections are garnet, kyanite, staurolite, tremolite, idocrase, and wollastonite. Almost all silicates, and many other minerals, may occur in metamorphosed rocks; calcite in marble is a good example.

Veins, replacements, and secondary deposits

Mineral associations in ore deposits. The crust of the Earth is unstable, and this condition results in extensive deformation and fracturing associated with igneous and other activity. The fractures form channels for aqueous solutions that deposit minerals; many are of economic value and are called ore deposits. The mineral deposits are loosely classified by the supposed temperature of deposition: hypothermal (300°–500° C [600°–900° F]); mesothermal (200°–300° C [400°–600° F]); and epithermal (up to 200° C). Pressure is also an important parameter. Typical minerals in this classification scheme are as follows: hypothermal—cassiterite, wolframite, scheelite; mesothermal—sulfides of copper, zinc, iron, and lead; epithermal—sulfides of antimony, mercury, silver, lead, zinc, and silver and gold as native metals. Gangue minerals (those associated minerals that are not of economic value) commonly include quartz and carbonates, among others; a few, such as fluorite and barite, may be of commercial value, however.

Solutions may percolate through porous rock, resulting in the precipitation of new minerals and alteration of old ones. Some of these replacement deposits, such as those of copper sulfides, have economic value.

Primary sulfides are unstable in the presence of air and water. A vein of primary sulfides becomes leached at the surface, producing a gossan (*e.g.*, decomposed rock) of quartz and iron oxides. Above the water table, oxidized and carbonate minerals such as malachite, azurite, and cuprite are formed. Below the water table, secondary sulfides such as chalcocite and covellite are precipitated.

In volcanic regions, escaping aqueous solutions mix with surface water to produce hot springs and fumaroles. Most of the deposited material is silica, but some deposits contain sulfur, sal ammoniac, sulfides, or oxides.

Mineral associations in sedimentary rocks and precipitates. Upon exposure to water and air, most minerals break down to yield a residue and an aqueous solution. A few minerals such as quartz are highly resistant to alteration but are released by breakdown of other minerals to be concentrated into mechanical sediments. The products of breakdown proceed in several directions, depending on several chemical and mechanical factors. The hydrolysates form clays (mostly hydrated aluminosilicates), chert (silica), bauxite (alumina), and sedimentary iron silicates (glauconite, chamosite). Under oxidizing conditions, some iron and manganese become oxides. Under reducing (anaerobic) conditions, as in swamps, in the presence of sulfur-bearing material, iron sulfides and carbonates may be precipitated. Bacteria are increasingly recognized as important agents in both weathering and precipitation of such sediments.

Biological factors and the role of organisms

The soluble cations plus complex anions enter oceans and lakes, where they react with each other and with volcanic emanations plus the atmosphere. Biological organisms produce carbonates that yield limestone. Calcite and aragonite react with magnesium from seawater to form dolomite. Silica is incorporated by some organisms, such as the single-celled Radiolaria. Parts of the ocean floor and some lake beds are covered by nodules rich in manganese oxides containing other valuable elements. A host of complex organic and inorganic reactions occur in seawater, resulting in relatively small changes of composition. In lakes, the composition may change drastically as a result of variation of rainfall and of incoming and outgoing flows. Drying up of a basin leads to sequential precipitation of evaporite minerals as the successive solubility products are reached. The resulting layered beds of salt (*e.g.*, gypsum, halite, sylvite, carnallite) are of

great economic value, especially as they are often associated with deposits of sulfur and petroleum.

Beach sands are commonly dominated by quartz grains sorted by prolonged mechanical processes. Heavy minerals may be concentrated into deposits of economic value (*e.g.*, gold, cassiterite, ilmenite, diamond).

Knowledge of marine and lake sediments is rapidly increasing as a result of deep drilling, dredging, and seismic studies. Marine sediments are composed of minerals derived from: rock fragments transported by rivers and ocean currents; windblown debris, such as desert sand and volcanic ash; chemical deposition, as in the case of carbonates, zeolites, and manganese nodules; death of biological organisms; and volcanic intrusions. The resulting minerals are slowly yielding evidence on the time of their deposition and the nature of the chemical environment. Ultimately the history of the ocean basins and continents will be derived from the mineral properties. For example, the recurrent beds of evaporite minerals in the Mediterranean Sea indicate cyclic sedimentation and dehydration associated with the differential movement of Africa and Europe. The concepts of sea-floor spreading and plate tectonics will be checked by the isotopic ratios of the minerals in these areas.

Mineral associations in the Moon, planets, and meteorites. Study of the lunar rock samples returned by the Apollo and Luna missions suggests that the most important factors controlling the formation of minerals on the Moon are: (1) crystal–liquid differentiation of material rich in basaltic components and low in volatile material, (2) an absence of biological processes, (3) absence of hydrothermal processes and water transport, (4) a high degree of reduction of transition metals and europium to low-valence states, and (5) liquid immiscibility.

Minerals of the lunar surface

The lunar maria (surface depressions) contain surface lava flows consisting of dominant pyroxene, plagioclase, olivine, and ilmenite plus about 30 other minerals. Troilite and native iron separated from a liquid immiscible with the silicate liquid. Spinel and armalcolite (an acronym from the American astronauts Armstrong, Aldrin, and Collins) are early minerals. The final products of crystallization contain an immiscible rhyolitic (equivalent to granite in composition) liquid associated with small amounts of apatite, whitlockite, pyroxferroite (a new mineral), zircon, and various other rare minerals, some of which are not yet identified.

The lunar surface is covered by fragmented minerals and rocks, some deformed by meteorite impact and others thermally sintered into breccia (rock consisting of coarse, angular fragments). Fragments rich in one mineral (either plagioclase or pyroxene or olivine) suggest mechanical processes for concentrating minerals by density fractionation in magma. Satellite photography and other remote studies of the surface indicate complex mineralogic variations over the surface that will be resolvable only by detailed exploration. Information available by 1971 indicated highland regions dominated by pyroxene and plagioclase, but most mineralogists and petrologists expect to discover many complex rocks in future lunar exploration. Occurrence of ice in shaded regions and of valuable mineral deposits could not be ruled out in 1971, though the low content of hydrogen and of noble metals in Apollo rocks definitely indicates less favourable economic prospects than on Earth.

Martian and meteorite mineralogy

The mineralogy of Mars is highly speculative. Remote studies indicate polar caps composed principally of solid carbon dioxide (Dry Ice). The surface is heavily cratered in places but shows curious chaotic features elsewhere. The origin of the reddish colour is speculative; it may be due to iron oxide or to biological causes. Direct mineralogic studies may begin in 1975 with unmanned landings and continue around 1980–2000, at which time samples will be returned to Earth. The high density of the planet Mercury suggests a mineralogy dominated by iron. The high surface temperature (near 500° C [900° F]) and high pressure (100 atmospheres, mostly CO_2) of Venus should cause an unusual mineralogy. Asteroids are prime targets for mineralogic study.

The origin of meteorites is controversial (see METEORITE). Their mineralogical and chemical properties are being pursued vigorously in an attempt to determine the development of the solar system. Important concepts governing the genesis of their minerals are: (1) condensation from a solar nebula falling in temperature, (2) mechanical accretion, (3) crystal–liquid fractionation plus metal–silicate immiscibility, (4) mechanical disruption, and (5) shock metamorphism upon collison of meteorites with the Earth. The high state of reduction results in minerals not occurring naturally on Earth.

The iron meteorites typically contain kamacite and taenite, iron and nickel alloys, troilite (FeS), cohenite (Fe_3C), schreibersite (Fe_3P), and similar mineral species. The stony meteorites are dominated by olivine, pyroxene, and plagioclase. Carbonaceous chondrites contain low-temperature minerals, including layer silicates and water-soluble salts (hydrated sulfates). Application of advanced techniques has resulted in discovery of many new minerals, including ringwoodite and majorite, high-pressure polymorphs of olivine and pyroxene. Some of the minerals not found on Earth are: osbornite (TiN); sinoite (SiON); oldhamite (CaS); lawrencite ($FeCl_2$); farringtonite [$Mg_3(PO_4)_2$]; and kosmochlor ($NaCrSi_2O_6$). Rare diamond apparently results from shock upon Earth impact.

The studies of meteorites and planets are changing the old parochial concept of mineralogy as a study of material from the Earth's surface. New concepts of solar mineralogy are developing rapidly as a result of exploration of the solar system, and studies of light from intergalactic regions suggest the presence of graphite and silicate grains.

EXPERIMENTAL SYNTHESES OF MINERALS

Purposes and utility of synthetic minerals

Minerals are synthesized under controlled conditions to obtain information about how they form naturally and to produce commercially valuable products. Growth may occur under conditions of thermodynamic equilibrium, but commonly the first products of synthesis are metastable and only give way slowly to the stable materials. Even when the equilibrium conditions of mineral growth are known, care must be taken in the application to natural minerals. Kinetic factors are extremely important: indeed, if all mineralogic reactions achieved equilibrium, it would be impossible to obtain information about the mineralogic history of the solar system.

Processes and products of mineral synthesis. Essentially all minerals have been synthesized, or can be expected to be synthesized, if the appropriate conditions are used. Some minerals that require complex atomic ordering have not been synthesized, however, presumably because of extreme sluggishness of atomic movement at low temperature. The most important examples are microcline and low-temperature varieties of plagioclase; their high-temperature equivalents with disordered atoms can be synthesized easily.

Several gem minerals are synthesized commercially, and the first synthesis of diamond (by the General Electric Company about 1950) resulted from technical advances of high-pressure research. Probably the most important synthetic minerals from an economic viewpoint are zeolite molecular sieves, which have revolutionized industrial catalytic processes. The synthetic relatives of the extremely rare mineral faujasite (from the hilly area of Kaiserstuhl, near Sasbach, West Germany) and other synthetic zeolites are used for a variety of processes utilizing petroleum. The industrial zeolites are metastable products produced by rapid reaction of alkaline material with aluminosilicate gels at temperatures around 100° C (212° F). Other important industrial minerals are crystals such as ruby used in lasers or in electronic equipment. Synthetic alumina minerals are used for industrial bearings and in clock movements. Synthetic quartz is used in optical equipment and piezoelectric oscillators. Synthetic diamond is a better abrasive than natural diamond.

Synthesis of individual minerals

Individual minerals are synthesized by choosing conditions of pressure, temperature, and bulk composition for which only one mineral phase crystallizes. Sulfide minerals can be synthesized easily by heating the appropriate

source material in sealed silica tubes. Salts can be obtained by concentrating brine until the solubility product is exceeded. Refractory minerals such as corundum are synthesized by fusing alumina in a furnace using the Verneuil process, in which material melted by an oxyhydrogen torch crystallizes onto a seed forming a boule. Minerals stable only at elevated pressure, such as diamond, can be synthesized only in special high-pressure equipment.

Crystallization of some minerals proceeds rapidly only in the presence of a catalyst or flux. Fluxes may operate by producing a low-melting liquid from which the mineral crystallizes. The synthesis of diamond is promoted by catalyst or fluxes. Water is often an extremely effective flux; for silicates it increases crystallization velocities by many orders of magnitude.

Some minerals can crystallize only when the atmosphere is inert or controlled. Thus, ferrous minerals will grow only in the absence or near absence of oxygen gas: otherwise minerals like magnetite or hematite will form.

Phase equilibria of mineral systems. The equilibrium assemblages of coexisting minerals are governed by thermodynamic principles that are covered, according to the equilibrium temperatures and pressures involved, in the articles GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES; GEOCHEMICAL EQUILIBRIA AT LOW TEMPERATURES AND PRESSURES. Mineral assemblages up to depths of several hundreds of kilometres in the Earth (and for the entire Moon) can be simulated by high-pressure–high-temperature apparatus working under static conditions; the existing limits are several hundreds of kilobars (the bar is a unit of pressure equal to a barometric reading of 750 millimetres at 0° C [32° F]) and any necessary temperature. Experiments using explosives and other means of generating shock waves permit transient attainment of pressures up to one or two megabars and correspondingly high temperatures.

Mineral reactions at the Earth's surface generally occur in the presence of aqueous solutions and are governed by the oxidation–reduction conditions as well as the concentrations of cations and anions in the solution. Difficulty of obtaining equilibrium at low temperatures has led to a major attempt to calculate the stability of mineral assemblages from the measurable thermodynamic properties of the individual minerals. Combination of these calculations and careful observations of both synthetic and natural mineral assemblages has produced a fairly good understanding of mineralogic processes at the Earth's surface, but the details are very complex.

Interpretation of natural occurrences. The interpretation of natural occurrences in terms of synthetic data requires careful evaluation of kinetic factors. Fortunately, most minerals appear to retain their bulk composition during falling temperature, and solid-state reactions, including atomic ordering and exsolution, often give evidence about the nature of the cooling history. In general, mineralogists and petrologists find that careful study of coexisting minerals and of rock formations permits estimates of the maximum temperature attained by the minerals to within an accuracy of 100° C (180° F) or so. Pressure estimates are more difficult and tend to be qualitative or semi-quantitative. The inversion of calcite to the high-pressure form aragonite at several kilobars pressure and the supplanting of albite by jadeite plus quartz provide estimates of the minimum pressure attained in certain metamorphic rocks. The formation of aragonite in certain biological organisms at atmospheric pressure is a warning of the extent of nonequilibrium processes. But in general, the progress of mineral syntheses, especially after 1950, is one of the major advances of science and technology and is leading to a significant quantitative control on models for the formation of the Earth and solar system and major improvements in living conditions for the human race.

Mining and Quarrying

Mining, in a broad sense, is the excavation of valuable mineral materials from the Earth's crust and includes minerals of organic origin, such as coal and petroleum. This article, however, describes only the mining of metallic and nonmetallic nonorganic materials; for coal and petroleum see the articles COAL MINING; PETROLEUM AND GAS EXTRACTION.

This article is divided into the following sections:

I. Development of mining techniques
  Early history
  Development of modern excavating technology
    The Americas
    Australia
    Europe
    Africa
    Soviet Union
II. Underground mining
  Prospecting and exploration
  Choosing a mining method
    Rock mechanics
    Evaluating geologic features
    Engineering-design factors
    Geology, rock structure, and geometry
  Mining operations
    Explosives
    Drilling
    Hoisting
    Loading and haulage
    Ventilation and lighting
  Mining methods
    Intervals between levels
    Underground opening support
    Open stopes
    Supported stopes
    Top slicing and sublevel caving
    Block caving
III. Surface mining
  Basic open-pit mining techniques
  Quarrying
IV. The mining industry
  Organization and management
  Conservation, ecology, and mining

Quarrying is the process of obtaining stone from surface excavations, such rock material being produced either in regular blocks (dimension stone) by cutting methods or in variable-sized fragments (crushed stone) by blasting with explosives. Excavation of gravel is considered by some to be a form of quarrying, and both are types of open-pit, or surface, mining.

The preliminary treatment of minerals, rocks, and ores after they leave a mine varies widely. Rock to be used for aggregate is crushed and screened. Most ores must be crushed before they are treated further. Some low-grade ores, including copper, are concentrated before smelting or further refining. Low-grade taconite (siliceous iron) ores must be ground, concentrated, and pelletized before they can be smelted to recover the iron.

Few minerals can be employed in their raw state, and most must be treated or refined before they are used. Nonmetallic minerals also may require purification. Hence, the development of mining has been necessarily paralleled by the development of treatment processes known collectively as extractive metallurgy. Modern mining has thus been made possible by the development of technology to a high degree both in mining and in the treatment of mined products. Mineral resources have played a dominant role in the political power of nations throughout recorded history, and the current world political situation emphasizes the importance of mineral resources in establishing high standards of living as well as influencing world politics.

I. Development of mining techniques

EARLY HISTORY

Archaeological discoveries indicate that mining was practiced in prehistoric times. Apparently, the first mineral man used was flint, largely for weapons. Certain minerals, such as ochre, black pigments (manganese ore), or chalk, were also mined and used as pigments.

Placer deposits

Gold was one of the first metals utilized, being mined from stream beds of sand and gravel where it occurred as a pure metal (placer deposits) because of its chemical stability. Although chemically less stable, copper occurs in native form and was probably the second metal discovered and used. Silver was also found in a pure state and at one time was valued more highly than gold.

According to historians, the Egyptians were mining copper on the Sinai Peninsula as long ago as 3000 BC, although some bronze (copper alloyed with tin) is dated as early as 3700 BC. Iron is dated as early as 2800 BC; Egyptian records of iron-ore smelting date from 1300 BC. Found in the ancient ruins of Troy, lead was produced as early as 2500 BC.

One of the earliest evidences of building with quarried stone was the construction (2600 BC) of the great pyramids in Egypt, the largest of which (Khufu) is 230 metres (750 feet) on a side and contains approximately 2,300,000 blocks of two types of limestone and red granite. The limestone is believed to have been quarried from across the Nile. Blocks weighing as much as 32,000 pounds (14,500 kilograms) were transported long distances and elevated into place, and showed precise cutting that resulted in fine-fitting masonry.

Agricola's *De re metallica*

One of the most complete early treatments of mining methods in Europe is by the German scholar Georgius Agricola in his *De re metallica* (1556). He describes detailed methods of driving shafts and tunnels. Soft ore and rock were laboriously mined with a pick and harder ore with a pick and hammer, wedges, or heat (fire setting). Fire setting involved piling a heap of logs at the rock face and burning them. The heat weakened or fractured the rock because of thermal expansion or other processes, depending upon the type of rock and ore. Crude ventilation and pumping systems were utilized where necessary. Hoisting up shafts and inclines was done with a windlass; haulage was in "trucks" and wheelbarrows. Timber support systems were employed in tunnels.

DEVELOPMENT OF MODERN EXCAVATING TECHNOLOGY

Great progress in mining was made when the secret of black powder reached the West, probably from China in the late Middle Ages. This was replaced as an explosive in the mid-19th century with dynamite, and since 1956 both ammonium nitrate fuel-blasting agents and slurries (mixtures of water, fuels, and oxidizers) have come into extensive use. A steel drill with a wedge point and a hammer were first used to drill holes for placement of explosives, which were then loaded into the holes and detonated to break the rock. Experience showed that proper placement of holes and firing order are important in obtaining maximum rock breakage in mines.

The pneumatic hammer

The invention of mechanical drills powered by compressed air (pneumatic hammers) increased markedly the capability to mine hard rock, decreasing the cost and time for excavation by several-fold. It is reported that the Englishman Richard Trevitheck invented a rotary, steam-driven drill in 1813. Mechanical piston drills utilizing attached bits on drill rods and moving up and down like a piston in a cylinder date from 1843. In Germany in 1853, a drill that resembled modern air drills (see below) was invented. Early drills required frequent repairs, as many as 200 being required to keep 16 in operation. Piston drills were superseded by hammer drills run by compressed air, and their performance improved with better design and the availability of quality steel.

Developments in drilling were accompanied by improvements in loading methods, from handloading with shovels to various types of mechanical loaders. Haulage likewise evolved from human and animal portage to mine cars drawn by electric locomotives and conveyers and to rubber-tired vehicles of large capacity. Similar developments took place in surface mining, increasing the volume of production and lowering the cost of metallic and nonmetallic products drastically. Large stripping machines with excavating wheels used in surface coal mining are employed in other types of open pit mines.

The Americas. Perhaps the first mining by Europeans in the Americas after Columbus was for copper in Cuba in 1554. Many small deposits of copper and iron were discovered in the 13 colonies that became the United States; all were producing small amounts of iron by the end of the Revolutionary War. Iron was first produced from the extensive Lake Superior deposits in 1846. Though much of the richer iron ore had been exhausted by the early 1970s, lower grade taconite ore is now being mined and concentrated by special processes.

California gold rush

While gold has been found in several places in North America, and the existence of gold in California was previously known, its discovery in 1848 had marked effects upon immigration and economics in the United States. The first gold mined was in placer stream deposits that proved to be extensive; some deposits were later mined by dredges. The gold deposits were traced upstream to the source from whence they had been eroded, which led to the discovery of the Mother Lode, a rich quartz vein of unusual length in the Sierra Nevada Mountains. Gold was later discovered in Alaska in 1880 on the beaches and in streams and in vein deposits in the mountains inland, in both Alaska and British Columbia.

One of the richest silver mines in America was located at the Comstock Lode in 1859, near what is now Virginia City, Nevada, an area that had been worked for placer gold. Several valuable deposits were discovered in Colorado beginning in 1859, yielding gold and silver from districts known as Leadville, Cripple Creek, and others.

Lead mines existed in what is now Missouri as early as 1687. The mines of southeast and southwest Missouri have supplied large amounts of lead and other metals. More recent discoveries in south central Missouri indicate the possibility of a lead belt across the state.

Lead was discovered in Bingham Canyon, Utah, in 1863, leading ultimately to the discovery and development of the great Utah copper open-pit mine. The successful exploitation of massive low-grade copper deposits of the western United States and elsewhere in the world was made possible by the discovery of the process of mineral flotation, which permits the economical concentration of the ore before it is smelted.

Wide-scale development of mining in Canada has been fairly recent. Iron ore was found in Newfoundland and

gypsum in Nova Scotia. Much of the mineral wealth is found in the Canadian Shield (pre-Cambrian rocks, 570,000,000 years old). Large deposits of ilmenite (titanium-iron ore, Tahawus, New York), gold (Kirkland Lake), copper (Sudbury Basin), and iron (Lake Superior) are currently being mined, as well as gold deposits in the West (Yellowknife).

In South America, Chile is noted for its deposits of sodium nitrate (1880–1930) and copper. The economic manufacture of synthetic sodium nitrate has, however, decreased the value of Chilean deposits. Copper was mined by the Spaniards as early as 1601, but most production now comes from massive low-grade deposits. Chile also has several rich iron-ore deposits, as well as some sulfur. Bolivia is the world's second-largest producer of tin. Gold, silver, and other metals and minerals are produced in other Latin American countries.

Australia. Gold was discovered in 1851 in New South Wales and later in Victoria, but after 1857 opportunities for miners to make a living decreased. The Broken Hill, Mount Isa, and Kalgoorlie gold mines have been most productive. Copper, silver, zinc, and tin are also produced in varying amounts. Australia leads the world in production of opals. In the past decade, 1960–70, active exploration led to discovery of extensive new deposits of metallic and nonmetallic mineral deposits.

Europe. France has notable iron deposits, while England's deposits of coal and iron have made it a source of steel. Open-pit operations in western Europe include mining of iron, limestone, granite, and shale. In France the Minette iron deposit, previously exploited by open-pit methods is now mined by underground techniques. Ammonium nitrate fuel oil and slurry blasting agents have been widely adopted in some European countries, though their use is restricted in some. Stripping, mining, loading, and transport are practiced in much the same manner as in the Americas, with some differences due to geography and local conditions.

Africa. The continent of Africa is the source of about 84 percent of the world's diamonds (major producers are South Africa, South West Africa, Angola, Zaire, Ghana, Sierra Leone) and over one-half of the gold (South Africa). Cobalt (65 percent of world supply; Zaire and Morocco), chrome ore (30 percent; South Africa and Rhodesia), and manganese (25 percent; South Africa and Gabon), all important in strengthening steel, are other products of this area. The huge copper-mining operations in the Shaba Province of Zaire became a source of political difficulty following that nation's independence in 1960. In western Africa, high-grade iron deposits, magnetite and hematite, are mined by the open-pit method. Other mining practices generally resemble those employed in Europe.

Soviet Union. Besides extensive reserves of coal, the Soviet Union probably has a greater variety of minerals than any country outside the United States. The Krivoy Rog deposits, similar to the Lake Superior deposits, have produced large tonnages of iron, which is also found in the Ural and Crimea areas. The Soviet Union leads the world in manganese reserves and has deposits of copper, lead, zinc, and aluminum, as well as nickel, gold, and platinum. Nonmetals include potassium and phosphate salts for production of fertilizer, asbestos, talc, magnesite, salt, and gems. See the Table for a listing of leading mineral producers.

II. Underground mining

PROSPECTING AND EXPLORATION

In the past, many deposits of valuable minerals were found by means of outcrops, but few such deposits near the surface remain to be discovered. Currently, most new deposits are located by means of geological techniques,

often supplemented by geophysical and geochemical methods. Prospecting is also being conducted to find deposits under the ocean. An understanding of the processes by which deposits were formed is a valuable aid in prospecting, since geologic controls can furnish information as to the likely position of ore.

The first step in modern prospecting is the compilation of all existing geological information on the area of interest. A detailed study and mapping of surface features follows; these are correlated with known structures that are projected to depth where possible. All evidences of mineralization, favourable structures, or environment for deposits are carefully recorded and employed as indicators of ore. If evidence of the possible presence of valuable deposits is found, a drilling program is carried out to obtain more information about subsurface geology and to intersect ore structures if possible. Data obtained in prospecting may also be employed in the exploration or evaluation stage that follows.

Indicators of ore

Types of geological evidence are both regional (of broad extent) and local (of limited extent). For metallic deposits, the presence of batholiths (large, irregular masses of igneous rock that have melted or forced their way into surrounding strata), certain volcanic and igneous rocks, the age of rock relative to mineralization periods, presence of favourable rocks, and climatic conditions may be important. Local surface features that can provide valuable clues are presence of rock alteration, trace mineralization in surface rocks, and quartz and other gangue (non-ore-bearing) minerals. Rock fractures, particularly fault zones, are important, as well as beds or zones that are favourable for mineralization. Many deposits "bottom out" with depth because pressure or other factors were unfavourable for mineral deposition.

Geochemical prospecting is the chemical analysis of rocks to determine the presence, usually in very small amounts, of possible trace elements. The patterns of dispersion of certain elements have proven to be valuable in conjunction with geologic data in locating and defining the limits of valuable ore bodies.

Geophysical methods employed vary with the local conditions. Seismic techniques, which involve transmission of low-frequency waves through the Earth's crust and recording of their behaviour, are utilized to determine underground structure, particularly in horizontal-bedded deposits. Magnetic methods determine the presence of magnetic bodies. Electrical methods indicate the presence of conductive materials. Gravity methods detect the presence of more dense bodies. Geiger counters ascertain the presence of radioactive minerals.

Obtaining cores

Prospect drilling is often performed with diamond drills to obtain cylindrical specimens of the rock and ore, called cores. The drill bit is a hollow cylinder embedded with commercial-grade diamonds on one end and attached to a core barrel. The drill and core barrel are rotated with the bit against the rock by means of hollow drill rods through which water flows to keep the bit cool and wash out the cuttings. Diamond drilling is of greatest value where the rock can yield intact cores that can then be employed to map underground geology or to give solid samples of valuable rock or ore.

When a valuable deposit is discovered, prospecting phases into exploration, which is planned to yield necessary data concerning size, shape, and value to furnish information to begin development. Careful trenching (digging a trench to obtain samples of ore lying near the surface), drilling, and sampling are carried on to give reliable information before large capital expenditures are made or the necessary plant is purchased.

Modern computers are often employed to calculate possible risks, profits, and other results of further exploration. Sample values obtained for the material to be mined are usually evaluated by use of the theory of probability, with average values weighed by the amount of ore they represent or by a similar method.

A mineral deposit is a "wasting asset," and, hence, its present value is calculated on the basis of the fact that the worth of the mine will be zero at the end of a certain period of time. The cost of capital equipment must be amortized accordingly, and a reliable estimate of the life of the mine is made. Rates of interest and return of investment are calculated to ensure adequate profits before the time a deposit is mined out.

CHOOSING A MINING METHOD

A space in an underground mine from which ore has been removed is called a stope. Depending upon conditions, stopes require varying amounts of support to prevent the earth and rock above (called overburden, or capping) from collapsing. In some mines, ore is extracted from several different underground levels. In this case, intervals must be left between the levels to prevent collapse. Figure 1 is a composite sketch illustrating various terms used in underground mining.

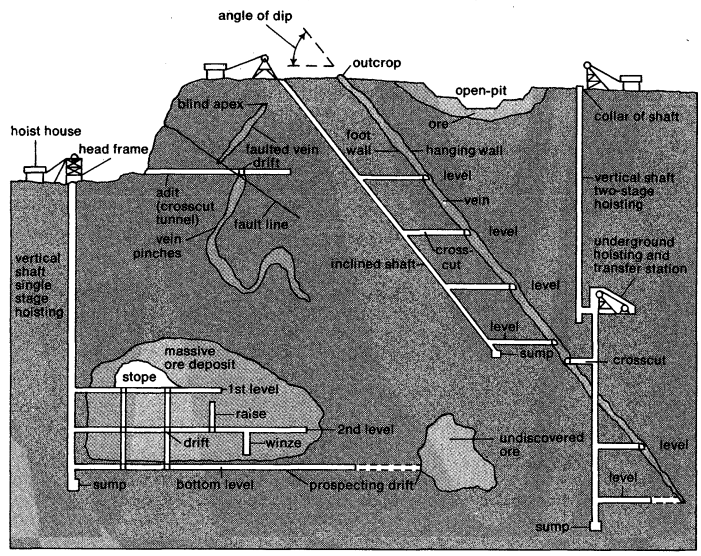

Figure 1: Illustrations of terms used in mining.

Rock mass stability

The stability of rock masses in which ore deposits occur in many cases determines the method of mining employed, although other factors may dictate the method used. Geologic and rock-mechanics data (see below) are the most reliable guides for evaluation of the adaptability of mining methods to a given deposit. Ideally, a method of mining is employed that will yield the largest net financial return consistent with safety and optimum extraction of valuable minerals.

Rock mechanics. The term rock mechanics is used to define the study of the behaviour of rock materials as they relate to man-made engineering projects that involve rock in place. Thus, studies are made of the physical properties of rock specimens that are taken from a rock mass. Many intact rocks behave elastically under load, and the theories of elasticity and the strength of materials are applied. Compressive and tensile strength are measured, as well as the strength under confining pressure (see MATERIALS TESTING).

Dynamic rock mechanics deals largely with waves caused by explosives and their effects in rock breakage, with rock breakage in drilling, with mechanics of rock bursts (sudden collapses), and with effects of large, underground explosions.

Methods have been devised to measure stresses, strains, and displacements in rock, both in open pits and underground. These studies are made to determine the stability of rock structures, support requirements, the behaviour of subsiding (settling) masses in caving and longwall methods of mining, and for increasing the efficiency and safety of mining.

Evaluating geologic features. Geologic details are carefully evaluated so that preliminary openings may be placed to best advantage; permanent openings may be located in stable rock; stopes may be planned for optimum stability and ground control; mine openings may be maintained at minimum cost; underground water may be

avoided; overall mining methods, including caving procedures, may be planned; and safety can be achieved.

Geologic features that influence the choice of mining method include the size and shape of the ore body; the depth and type of overburden; the location, strike (horizontal course), and dip (the angle at which the deposit is inclined from the horizontal) of the deposit; the strength and physical character of the ore; the strength and physical character of the surrounding and overlying rock; the presence or absence of aquifers (water-carrying rocks); and the grade and type of ore.

Engineering-design factors. Important factors in engineering design of underground mines include strength of ore and wall rocks; shape, horizontal area, volume, and boundary regularity of the ore body, and the thickness, dip or pitch or both of the deposit and ore shoots; continuity of the ore; depth below the surface; nature of the overburden; and position of the deposit relative to surface improvements, drainage, and other mine openings. It is usually necessary to minimize those factors of lesser importance in order to satisfy the requirements of the more critical ones.

The strength of both ore and wall rocks fixes the safe size of openings, the length of time they will stand, and the support required. Stability depends not only on the strength of the solid rock but also on the existence of fractures, joints, and other discontinuities and their geometric arrangement.

Ore body shapes

Shapes of ore bodies vary from massive to tabular (having two parallel surfaces) and from bedded deposits to pipes, shoots, dikes (fissures in older rock filled with igneous material), and sills (strata of igneous rock found between beds of other rock), depending on their origin and the character of the host rock structure. The attitude (inclination) of a deposit directly influences the mining method. A tabular deposit dipping at a high angle, for example, may be removed without use of supports if the walls are moderately strong. The roof of a similar deposit dipping at a low angle, however, may need support.

A regularly shaped deposit may require less support. Mining operations in an irregular deposit will produce stopes with uneven walls, overhanging slabs, and projecting columns of wall rock that may require support if the rock is fractured or broken.

A small ore body in firm rock may be mined without support, but larger ones in the same kind of groundmass may require it. There is a limit to the length or width of an unsupported rock arch or span that will possess sufficient strength to stand.

Usually, as depth increases, a method must be changed because openings require more support. Shallow deposits are subject to relatively low lithostatic (weight of overlying rock) pressures. The vertical pressure on mine openings usually increases proportionately with depth. The direction of pressure in walls or roofs of an excavation depends on the attitude of the deposit and local geologic factors and must be considered in stope support. In a steeply dipping tabular deposit, waste (broken-rock) filling will furnish adequate support against side pressure, whereas in a wide deposit, in which the critical pressure acts downward, filling cannot be relied on to prevent all movement. Thus, a cut and fill method can be employed where the pressure is from the sides and the back is strong and self-supporting, but if the critical pressure is vertical, square setting (a heavy square framework of timbers) supplemented by filling or some other method of support is necessary (see below *Underground opening support*).

Geology, rock structure, and geometry. In addition to their value in exploration, geological theories of the genesis of mineral deposits are also valuable guides in mine operation, influencing prospecting, exploration, development, and exploitation. In prospecting, geology is a vital tool in finding new ore bodies and is most effective in the hands of an experienced mining geologist. In exploration and development, the mine engineer should have a knowledge of strength of materials, rock mechanics, and of the structural features of the deposit that will affect the production of ore and the margin of profit. Most of these factors can be treated in only a semiquantitative manner, because the behaviour of rock structures is complex. Design details may also be considered in relation to bedded deposits, veins, and massive deposits.

Bedded and sedimentary deposits that have not been disturbed by faulting, folding, or other action are, like flat-lying beds of coal, simple to mine. Support problems are often easily solved, and a systematic method of pillar support is employed. Poor rock in the immediate roof, however, such as shale, creates hazardous conditions. The most serious problem in this type of mine may be determination of the number, size, and position of pillars required for support.

Dangers of shale roofs

Many commercial mineral deposits are found in or closely associated with veins in fractures, shear, and fault zones. Deposits vary from tabular veins to pipelike bodies and shoots and may be regular or irregular, wide or narrow, continuous or discontinuous. Thus, many different methods are used to mine them.

The large, disseminated copper-ore bodies of the western United States are typical massive deposits; those with enough overburden or capping to prohibit mining by open-pit methods are often mined by block-caving (see below). Deposits of porphyry coppers are usually extensive, flat-lying, and relatively regular in outline; though low-grade, their reserves are usually measured in millions of tons. The concentration of valuable minerals has been the result of geologic changes that left behind a weak, leached overlying rock mass.

MINING OPERATIONS
